Total hip arthroplasty (THA) has been a successful reconstructive procedure to mitigate pain associated with diseases of the hip joint. However, THA procedures require revision due to mechanical or biological failure. The purpose of this study was to synthesize and examine the evidence on the relative risk of revision in men and women following primary THA procedures. We conducted a systematic literature review of cohort studies reporting THA revision risk estimate by gender. Study quality scoring and a random effects meta-analysis were performed to estimate the meta-relative risk (meta-RR) and corresponding 95% confidence interval (95% CI) of revision, comparing men to women. Males had a statistically significant increased risk of revision following primary THA (meta-RR=1.33 (95% CI: 1.13-1.57)), when compared to females. When stratified by cause of revision, males had a statistically significant increased risk of revision due to any-cause (meta-RR=1.16 (95% CI: 1.01-1.33)), aseptic loosening (meta-RR=1.54 (95% CI: 1.05-2.25)), and infection (meta-RR=1.55 (95% CI: 1.11-2.15)). For primary THA operations performed during the 2000s, males in Europe had a statistically significant increased risk of revision (meta-RR=1.42 (95% CI: 1.25-1.61)) while males in the United States had a statistically significant decreased risk of revision (meta-RR 0.80 (95% CI: 0.72-0.89)). These results support evidence of gender-specific risks would help reduce post-surgery complications.
The four-hour canine non-anticoagulated venous implant (NAVI) model is a standard test procedure used to assess acute thrombogenicity of blood-contacting medical devices. The FDA final guidance (2016) on ISO 10993-1 recommends that thrombogenicity be assessed as part of a safety or functional study conducted in a relevant animal model, if such a study is generally conducted for a particular device type. This abstract describes using a porcine model to assess a percutaneous transluminal angioplasty (PTA) balloon catheter with a balloon coated with paclitaxel (drug) and a citrate ester (excipient). Acute thrombogenicity was first evaluated in a non-anticoagulated model using three swine. Test and control (commercially marketed comparator) devices were placed in the L and R femoral veins and exposed to blood for 6 hours. The animals were euthanized, and the veins with the devices in situ were removed. The venous wall of each sample was cut longitudinally, and the luminal surface of the vessel and device were scored for adherent thrombus similar to the scoring scheme used in the NAVI model (ISO 10993-4 2017). Thrombogenicity scores were 3-4 (moderate to extensive thrombus) for the test articles and 2-3 (mild to moderate thrombus) for the control articles. In a subsequent study with clinically relevant levels of heparin as performed per the FDA guidance, results showed non-existent to minimal thrombus for both test and control articles. No thromboembolism was observed in the heart or lungs of any animal. These results support the use of the porcine model for NAVI and AVI testing and demonstrate the hemocompatibility of this device. In addition, these studies conducted on smaller balloon size were successfully used to support a device modification with longer balloon sizes (up to 150% longer). Future considerations for thrombogenicity testing of drug-device combination products should incorporate the topography of drug surfaces and geometrical features (folding patterns) in selecting the appropriate model (NAVI vs. AVI) for favorable outcomes.
that generate nano-sized chromium oxide particles are unlikely to result in cytotoxic or inflammatory responses in periprosthetic tissues, and 2) adverse biological responses likely occur only under suboptimal wear conditions that generate a sufficient dose of larger particles with greater amounts of cobalt.

M. Kovochich1, D. Fung1, K. M. Unice2, S. Mahoney1, D. J. Paustenbach3, and B. L. Finley1. 1Cardno ChemRisk, Aliso Viejo, CA; 2Cardno ChemRisk, Pittsburgh, PA; and 3Cardno ChemRisk, San Francisco, CA.

Shortly after 2010, some cohorts with well-fixed MoM THA devices started to experience elevated revision rates (above 1% per year). These reports coincided with a major shift towards the use of non-traditional revision criteria that consisted of blood metal measurements and non-radiographic soft tissue imaging. The purpose of this analysis was to evaluate the impact of the non-traditional diagnostic testing on the revision rate trends. We reviewed the available published studies that reported revision rates for MoM THA devices and stratified the results by 1) recalled or discontinued MoM THA devices with mechanical challenges, 2) well-fixed MoM THA devices that received traditional patient management (hip scores and radiographs), and 3) well-fixed MoM THA devices that received non-traditional patient management (blood metal testing and soft tissue imaging). Discontinued or recalled devices with design issues had high revision rates, with 75% of studies (21/28) reporting greater than 1% revisions per year. Revision rates for well-fixed MoM THA devices that received traditional patient management consistently showed lower revision rates: 100% of the studies (44/44) reported estimated revision rates of 1% or less per year. In contrast, patients with well-fixed MoM THA devices that were evaluated with blood metal testing and soft tissue imaging consistently had high revision rates, with 79% of studies (15/19) reporting greater than 1% revisions per year. Our review found that some patients with well-fixed implants underwent revision operations even when symptoms (e.g., pain, discomfort, instability) were mild or absent. We conclude that the recent increase in revision rates for well-fixed MoM implants is due to a divergence in revision criteria and does not appear to be related to any actual changes in MoM implant performance (e.g., higher rates of implant loosening due to high wear). The implications of these results are discussed with regards to patient management as well as specificity and sensitivity of diagnostic testing for local tissue responses.

M. Kovochich1, D. Fung1, K. M. Unice2, S. Mahoney1, D. J. Paustenbach3, and B. L. Finley1. 1Cardno ChemRisk, Aliso Viejo, CA; 2Cardno ChemRisk, Pittsburgh, PA; and 3Cardno ChemRisk, San Francisco, CA.

Characterizing Cytotoxic and Inflammatory Responses to Metal-on-Metal Wear Debris from Normal Versus Edge-Loading Conditions

M. Kovochich1, E. S. Fung1, S. Mahoney1, K. M. Unice2, D. Fung1, D. J. Paustenbach3, and B. L. Finley1. 1Cardno ChemRisk, Aliso Viejo, CA; 2Cardno ChemRisk, Pittsburgh, PA; and 3Cardno ChemRisk, San Francisco, CA.

The majority of previous studies that evaluated inflammatory and cytotoxic responses to wear debris from metal-on-metal implants utilized particles with physical and chemical characteristics that differed from clinically relevant particles released in vivo from MoM implants under normal wear conditions. Additionally, no previous study has attempted to understand the potential difference in biological responses to clinically relevant MoM wear debris generated under normal versus abnormal (e.g., edge-loading) conditions. The goal of this study was to understand the potential cytotoxic and inflammatory response to clinically relevant MoM wear debris generated during normal versus edge-loading conditions. Wear debris particles from each condition were isolated from Pinnacle MoM simulator fluid and sterilized prior to biological testing in a murine macrophage cell line (RAW 264.7). Particles generated from edge-loading conditions were larger and contained more cobalt (Co) compared to particles from normal wear conditions. Particles and ions from normal implant conditions up to 1021 cycles per mL (1000 ppb total Co and chromium (Cr)) did not induce significant toxicity or inflammation as detected by MTT assay and TNF-a cytokine release, respectively. In contrast, particles and ions released from edge-loading conditions induced significant cytotoxicity and TNF-a cytokine release when RAW 264.7 cells were exposed to 1021 cycles per mL (61124 ppb total Co and Cr) for 24 hours. The 25% inhibitory concentration (IC50) was approximately 26,000 ppb (Co and Cr) was calculated for the metal concentration which resulted in a 25% decrease in cell viability. The IC50 value for edge loading particles and ions was over 150-fold greater than metal levels observed in synovial fluid in well-functioning implants. These results indicate that 1) normal wear conditions...
antioxidant potential in BEAS-2B cells, pretreatment with a "non-toxic" HEMA dose for 24 hours did not reduce the toxic response to a subsequent HEMA exposure. In summary, the results indicate that HEMA induced the Nrf2 activity in BEAS-2B cells, while the Nrf2 pathway was continuously active in A549 cells. However, the results do not support a hypothesis suggesting that increased Nrf2 activity protects cells against HEMA-induced toxicity. This may point to mechanisms independent of oxidative stress to explain HEMA toxicity.

2163 Extractable Characterization of Critical Components Used in Cartridges of Electronic Nicotine Delivery Systems
W. Xie, RAI Services Company, Winston-Salem, NC.

Electronic Nicotine Delivery Systems (ENDS) contain liquid formulations (e-liquids) that are heated to generate aerosols. The potential of chemicals to leach from the device materials has been an area of interest for this type of consumer product. ENDS cartridges are commonly composed of polymers, elastomers, metals, glass, and electronic components. Characterization of extractables from such materials can be used to establish a repository of potential analytes for leachable testing. In this study, an extractables analysis was conducted on critical components from a "cig-a-like" ENDS product. Critical components are defined as components that are in contact with the e-liquid, aerosol, or surrounding critical components were solvent extracted under exaggerated temperatures and conditions with consideration of the e-liquid formulation in selection of the solvents. Extraction methods included elevated temperature sealed vessel, reflux, and Soxhlet extraction. Extraction solvents included low-pH water (pH = 2.5), high-pH water (pH = 9.5), isopropanol, and methylene chloride for organic extractables. Nitric acid (5%) was used as a solvent for metals/elements. Additionally, the components were placed in sealed vials for headspace analysis of volatile organic substances. The resulting extracts were chemically characterized via spectroscopic and chromatographic methods to establish the metal/elemental and organic extractable profiles. These analyses provided semi-quantitative extractable profiles of the ENDS critical components. Characterization of the extractables from materials of ENDS supports verification of materials selection, manufacturing processes, as well as development of a repository for potential future leachable assessments.

2164 Presence of Particulates and Color in Device Extracts: Do They Really Pose Any Safety Risk to Patients?

For in vitro test systems. The device extract is often found to be colored and/or particulates leading to uncertainties in assessing their biological significance. A polyurethane catheter upon extraction at 50°C for 72h showed visible green color in the sesame oil but not in the saline extract. The colorant was identified by UV-Vis method and not by the conventional GC-MS or FTIR. Since this is a urethral stent, the extractions were repeated in a physiologically relevant solvent—synthetic urine. Results showed no visible color leaching in synthetic urine, indicating that the pigment is not bioavailable and thereby supporting the safety of the device. Wire guides are stainless steel metallic structures, which facilitate the placement of catheters used in cardiology and angiographic procedures usually for a period of 30 minutes. During biocompatibility testing devices that were cut into sections for extraction in saline (70°C for 24h) were found to contain particulates. Chemical analysis by ICP-MS showed the presence of zinc, iron, or silicone, and their amount per device was found to be below the permissible daily exposure levels. It is pertinent to note that during normal clinical use, the device is not cut. Therefore, studies were repeated with intact devices for extraction at 37°C for 6h. The results indicated no visible particulates with passing biocompatibility test results. Further, when the wire guides were analyzed using an in vitro model with flow in a mock blood vessel, the size and number of particulates were within the limits of USP <788>, supporting the safety of the product. Finally, the saline extract (50°C for 72h) of a blood-contacting catheter was found to be orange-brown in color due to the presence of minocycline and rifampicin. In the in vitro assay, the extract was non-hemolytic after the absorbance values were corrected for background interference. In summary, the visible particulates and color in test extracts sometimes come from undue manipulation of test article and/or overly extreme extraction conditions.

2165 In Vitro Assessment of Medical Device Extracts’ Potential to Produce Skin Sensitization
F. Cottrez1, C. Pellevoisin1, K. Coleman1, and H. Groux1.
1 ImmunoSearch, Nice, France; 2 EPSKIN Academy, Lyon, France; and 1 Medtronic, Minneapolis, MN.

The ISO norm 10993 part 10 describes the procedure for the assessment of medical devices and their constituent materials with regard to their potential to produce irritation and skin sensitization. The success of the recent Round Robin Study to assess in vitro skin irritation of medical device extracts, with Reconstructed Human Epidermis (RHE) models, opened the way to in vitro approaches for this endpoint. For skin sensitization of medical devices, polar (physiological saline) and nonpolar (sesame oil), were spiked with different concentrations of sensitizer and successfully detected with SENS-IS assay in the Episkin model and the SkinEthic RHE model. Then, samples of polymers used in medical device industry, MED-2000 silicone, were loaded with 6 known sensizers (10% final concentration): 1-phenyl-1,2-propanedione, 1-Chroro-2,4-dinitrobenzene, Diethyl maleate, p-Benzoquinone, Propyl gallate and Phenyl Benzoate and extracted in polar and nonpolar solvents in accordance with ISO 10993-12:2012. After optimization of the original protocol used for near chemical methods, the SENS-IS method was able to correctly classify the 6 polymers. These preliminary results show that the Episkin model and the SkinEthic®-RHE model could be used in the SENS-IS assay to assess the sensitizing potential of medical devices extracts. Further studies are engaged with a more comprehensive set of molecules. If confirmed, these results would allow toxicologists, familiar with either the Episkin or the SkinEthic-RHE model to assess skin sensitization with the SENS-IS assay.

2166 Fluoropolymers: Biomaterials That Satisfy Global Polymer of Low Concern Criteria

Fluoropolymers, common biomaterials used in medical devices, are high-molecular-weight polymers within the per- and polyfluoroalkyl substances (PFAS) group of fluorinated substances. PFAS are currently in the focus of researchers and regulators due to widespread presence of per- and polyfluorinated sulfonate (PFOS) and perfluorooctanoic acid (PFOA) in the environment and biota, including humans. Fluoropolymers, such as polytetrafluoroethylene (PTFE), have unique properties that constitute a distinct class within the PFAS group. Fluoropolymers have thermal, chemical, phototoxic, hydrolytic, oxidative, and biological stability. They have negligible residual monomer and oligomer content and low to no leachables. Fluoropolymers are practically insoluble in water and not subject to long-range transport. With a molecular weight well over 100,000 Da, fluoropolymers cannot cross the cell membrane. They are not bioavailable or bioaccumulative, as evidenced by biocompatibility studies on PTFE: acute and subchronic systemic toxicity, irritation, sensitization, local toxicity on implantation, cytotoxicity, in vitro and in vivo genotoxicity, hemolysis, complement activation, and thrombogenicity. Clinical studies of patients receiving permanently implanted PTFE cardiovascular medical devices demonstrate no chronic toxicity or carcinogenicity, or reproductive or developmental or endocrine toxicity. This poster includes fluoropolymer biocompatibility, human clinical and physical-chemical-thermal-biological data to show that fluoropolymers satisfy globally recognized assessment criteria to be considered as “polymers of low concern”. Fluoropolymers are distinctly different from other polymeric and non-polymeric PFAS and should be separated from them for hazard assessment or regulatory purposes. Grouping fluoropolymers with all classes of PFAS for read-across or structure-activity relationship assessment is not scientifically appropriate.
As part of a toxicological risk assessment, an analysis of leachable substances was conducted for a ventricular catheter, which is intended for use in patients to drain CNS fluid that contributes to excess intracranial fluid pressure. To capture leachables that may be released during long-term implantation, a chemical characterization was performed using prolonged extractions, along with non-volatile residue (NVR) as a surrogate to monitor the endpoint of exhaustive release of organic chemicals. Separated extractions were conducted with solvents of three different polarities: isopropanol and hexane, which exhibit somewhat nonpolar characteristics, yielded much higher extractable masses of organic analytes—chiefly silicones—than purified water. Based on the results of NVR analysis, concentrations of individual chemical analytes were measured following a single, prolonged solvent extraction of the device. With isopropanol, successive extractions demonstrated exhaustive conditions were achieved (based on NVR levels <10% of the initial extracted amount) after three 72-hour extractions at 50 degrees C, with solvent removal and analysis of NVR after each step. The NVR data exhibited an asymptotic depletion curve, consistent with previous GC/MS analysis results from consecutive extractions. To evaluate whether the prolonged, continuous extraction was exhaustive, the leachable NVR from 3 consecutive 72-hour extractions was compared to NVR measured from a single, prolonged extraction covering the same time frame (216 hrs). A statistical comparison found that leachable NVR was significantly higher with three successive extractions as compared to that observed following a single prolonged extraction, and suggests that solvent replenishment with successive extractions is necessary to overcome the influence of the polymer/liquid partition coefficient. These results will be discussed in the context of the physical-chemical properties that can limit leachability, e.g., analyte solubility, polymer swelling, diffusion rate, and equilibrium partitioning. Based on these findings, the total leachable analyte mass as determined with a single, prolonged extraction was adjusted by a factor of 1.24, equal to leachable NVR measured with multiple, successive extractions divided by that measured with a single prolonged extraction. Use of this adjustment assured that leachability was not underestimated when evaluating risks based on prolonged extraction data.
sure to arsenic. However, the long-term exposure resulted in increased growth of HK-2 cells as compared to control HK-2 cells. Additionally, the arsenic exposed cells also acquired morphological changes of EMT and stemness. These changes were further confirmed by analysis of gene expression in arsenic exposed HK-2 cells. Most importantly, the arsenic exposed cells acquired the pathogenic features of fibrosis as supported by fibrotic morphological changes as well as the changes in expression of pro-fibrotic genes. These changes in growth pattern and EMT properties of arsenic exposed cells were reversed by the treatment with epigenetic reagent, 5-Aza-2’-deoxycytidine. Therefore, the findings of this study suggest that acute exposure to arsenic can cause loss of kidney epithelial cells with potential significance to acute kidney injury (AKI), whereas the chronic exposure to arsenic can increase the risk of chronic kidney diseases specifically the kidney fibrosis. Additionally, our data suggests that the adverse effect of arsenic in kidney epithelial cells is mediated by epigenetic mechanism and therefore potentially can be reversed by epigenetic therapeutics.

**2172 Arsenic Disrupts Muscle Stem Cell Determination through Fibroblast Mitochondrial Maladaptation that Directs a Dysfunctional Extracellular Matrix Memory**

T. Anguiian, A. Sahu, F. Ambrosio, and A. Barchowsky. University of Pittsburgh, Pittsburgh, PA.

Chronic arsenic (As) exposure increases risk of adverse health outcomes that include skeletal muscle dysfunction and mobility decline. We reported that As impairs muscle maintenance and regeneration by inducing maladaptive mitochondrial phenotypes in muscle stem cells (MuSC), connective tissue fibroblasts (CTF), and fibers. We also found that As impairs muscle functional memory in extracellular matrix (ECM) that disrupts the MuSC niche and misdirects differentiation of muscle progenitor cells from myogenesis to fibrogenesis. We asked whether dysfunctional mitochondria in As-exposed CTF direct ECM alteration, and whether restoring CTF mitochondrial function reverts ECM memory. CTF were isolated from mice exposed to 0 or 100 μg/L As(III) in drinking water for 5 weeks. The CTF were cultured to elaborate ECM for 2 days before decellularization. Human muscle progenitor cells (HMPC) were seeded on the decellularized ECM and differentiated for 2 days. Myogenesis was impaired when HMPC were seeded on ECM derived from As-exposed CTF, relative to control CTF. In addition to this, desmin, indicators of myogenic differentiation, were downregulated in As-CTF plated on As-CTF ECM, while PDGFRα and CD34, indicators of fibroblast/adipocyte progenitors, were increased. To demonstrate that As-impaired mitochondrial function in CTF is responsible for a pathological ECM, the MuSC were treated with 500 μM As(III) for 7 days. To verify that As-impaired muscle differentiation and muscle regeneration in vivo. Our data indicate that As impairs muscle maintenance and regenerative capacity by targeting CTF mitochondria, and that therapies restoring muscle mitochondria may effectively treat muscle dysfunction in As-exposed individuals. Supported by NIH grants R01ES023696, R01ES023696.S1, and R01ES022529.

**2173 Selene Restores the Pax6 Gene Expression in Arsenic-Exposed Neuronal Cells of Golden Syrian Hamster, Mesocricetus auratus**

A. Sampayo-Reyes1, A. Aguirre-Velázquez2, M. Bermúdez de León3, R. Tamés-Guerra4, R. Marcos5, and A. Hernández1. 1Universidad Autónoma de Nuevo León, San Nicolás de los Garza, Mexico; 2CIBN, IMSS, Monterrey, N.L., Mexico; 3CIBN, IMSS, Monterrey, N.L., Mexico; 4Universidad Autónoma de Nuevo León, San Nicolás de los Garza, N, L, Mexico; 5Universitat Autònoma de Barcelona, Barcelona, Spain.

Arsenic is an environmental pollutant distributed worldwide that generates public health concern. Various types of cancers and other diseases, including neurologic disorders, have been associated with arsenic consumption in drinking water in human populations. At a molecular level, arsenic and their metabolites have the capacity to provoke genome instability, causing an altered expression of genes. Pax6 gene, which encodes a transcription factor, is a target of arsenic in neuronal cells. The aim of this study was to evaluate the effect of antioxidants, as α-tocopherol succinate (alfa-TOS) and sodium selenite, on gene expression levels of Pax6 in the brain and cerebellus of Golden Syrian hamsters exposed chronically to arsenic in drinking water. Reverse-transcription coupled to quantitative PCR confirmed that arsenic downregulates the Pax6 expression in nervous tissues. Treatment with α-TOS did not modify Pax6 expression in presence of arsenic; however, the combined treatment of sodium selenite with arsenic restored the Pax6 expression in brain and cerebellus of arsenic-exposed hamsters. Although the chronic exposure to arsenic can increase the risk of chronic kidney diseases specifically the kidney fibrosis. Additionally, our data suggests that the adverse effect of arsenic in kidney epithelial cells is mediated by epigenetic mechanism and therefore potentially can be reversed by epigenetic therapeutics.

**2175 Suppression of Erythroid Progenitor Cell Development by Environmentally Relevant Levels of Arsenic**

S. Medina1, H. Xu1, F. T. Lauer1, S. Wang2, K. J. Liu1, and S. W. Burchiel2. 1University of New Mexico, Albuquerque, NM; 2Chinese Academy of Medical Sciences and Peking Union Medical College, Tianjin, China.

A high prevalence of anemia has been reported in human populations chronically exposed to arsenic (As) in drinking water. However, the mechanistic basis for this association has not been fully elucidated. Our recent findings showed that 60 day drinking water exposure of adult male C57BL/6J mice to environmentally relevant levels (500 ppb) of arsenite (As3+) suppressed the development of early bone marrow erythroid progenitor cells and resulted in anemia. Therefore, the purpose of this study was to evaluate the in vitro effects of As3+ in isolated cell culture in suppressing cell proliferation, viability, differentiation and maturation of primary mouse bone marrow erythroblasts. A significant dose-dependent suppression in the colony-forming ability of the earliest stage of committed erythroid differentiation, burst-forming unit erythroid cells (BFU-E), was found at concentrations as low as 100 nM As3+ and monomethyarsonous acid (MMA3+). Additionally, using primary mouse bone marrow cells, we developed an in vitro differentiation model to monitor erythroid maturation based on progressive changes in CD71 and Ter119 surface marker expression utilizing flow cytometry. After 24 h, a significant accumulation of the earliest stages of erythroid differentiation (i.e., BFU-E/colony-forming unit erythroid cells) as well as a subsequent decrease of the immediate down-
Arsenic (+3 Oxidation State) Myelotransferase (AS3MT) Genotype Is Associated with Metabolites That Are Linked to Diabetes Susceptibility in Individuals Exposed to Arsenic in Chihuahua, Mexico

E. M. Martin1, G. González-Hortá1, B. Sánchez-Ramírez2, L. Ballinas-Casarrubias3, D. S. Gutiérrez-Torres2, R. H. Cerón2, D. V. Morales2, F. A. Baera Terrazas1, Z. Drobona2, W. Jia3, G. G. García-Vargas2, L. M. Del Razo4, M. A. Mendez1, M. Styblo1, and R. C. Fry1. 1 University of North Carolina at Chapel Hill, Chapel Hill, NC; 2 Universidad Autónoma de Chihuahua, Chihuahua, Mexico; 3 Colegio de Médicos Cirujanos y Hematópatas del Estado de Chihuahua, Chihuahua, Mexico; 4 Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 5 Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional, Mexico, Mexico.

The enzyme Arsenic-3-Methyltransferase (AS3MT) is responsible for the metabolism of inorganic arsenic (iAs). Polymorphic variants of AS3MT are associated with increased risk of iAs-associated diabetes mellitus (DM). At present, it is unclear what metabolic processes are influenced by AS3MT impacting the risk of DM development in the context of iAs exposure. To investigate the role of AS3MT single nucleotide polymorphisms (SNPs) as a susceptibility factor in the development of DM, we integrated genotype and metabolomics data from DM and non-DM individuals exposed to iAs. The 123 profiled individuals come from the Chihuahua Cohort in Mexico. To characterize metabolite profiles in relation to six SNPs in AS3MT linear regression modeling was used. The results demonstrate that four SNPs, rs17881215, rs3740393, rs3740390 and rs1928353, were associated with 12 urinary and plasma metabolites. Among the identified metabolites, an enrichment for, amino acid metabolism was identified. Interestingly, the enriched metabolites included phenylalanine, arginine and methyl-L-histidine which have been previously linked to blood sugar control in humans and delay of suppression of liver gluconeogenesis. This novel integration elucidates a potential mechanistic basis for the findings that AS3MT polymorphisms are associated with risk of DM development in iAs exposed populations.

2178 Requirement of NADPH Oxidase Activity for Arsenic Inhibition of PARP-1

L. Volk1, K. L. Cooper1, A. Duran2, E. Dashner-Titus1, K. J. Liu1, and L. G. Hudson1. 1 University of New Mexico Health Sciences Center, Albuquerque, NM; and 2 The Ohio State University, Columbus, OH.

Human epidemiological studies show a correlation between arsenic and ultraviolet radiation (UVR) exposure with respect to the development of skin cancer. Previous studies have shown that exposure to environmentally relevant arsenic levels, particularly in conjunction with UVR exposure, results in oxidative damage to DNA and proteins via the generation of reactive oxygen species (ROS). However, arsenic and UVR generate ROS by different mechanisms, with evidence supporting arsenic induced ROS via stimulation of NADPH Oxidase (NOX). Additionally, it has been shown that exposure to arsenic can result in the inhibition of poly(ADP-ribose) polymerase-1 (PARP-1) activity, resulting in retention of DNA damage. Together, the evidence supports the hypothesis that arsenic hinders the function of specific DNA repair proteins, and consequently sustains DNA damage induced by UVR. To further elucidate the mechanism of arsenic co-carcinogenesis, it is necessary to determine the requirements for PARP inhibition and arsenic augmentation of UV-induced DNA damage via NOX. In this study, we used a selective inhibitor of NOX, apocynin, and a ROS scavenger, MnTMPyP, to determine the relative contribution of arsenic exposure on normal human neonatal epidermal keratinocytes (HEK). The PrestoBlue viability assay was performed on HEKn cells to confirm non-cytotoxic concentrations. We found that treatment of HEKn cells with apocynin or MnTMPyP ablated arsenic-stimulated ROS measured by DCF staining, decreased PARP oxidation, and partially restored PARP activity. It is predicted that the partial restoration of PARP activity will decrease retention of UV-induced DNA damage augmented by arsenic with studies underway. Current analysis includes in vivo studies of DNA damage retention in arsenic exposed p91phox/- mice. Due to the prevalence and severity of skin cancer, it is important to elucidate the mechanisms by which arsenic acts as a co-carcinogen in humans.

2179 Low Arsenic Concentrations Are Pro-Atherogenic in the Apolipoprotein E Knockout Mouse Model

D. Plourde, C. Chiavatti, M. Lemaire, C. Lemarie, S. Lehoux, and K. K. Mann. Lady Davis Institute, Montreal, QC, Canada.

In humans, arsenic exposure increases the risk of atherosclerosis, the gradual occlusion of the large arteries with fibro-fatty plaque. Epidemiologic data indicate that this may occur at low arsenic concentrations, near the maximum contaminant level of 10 ppb. We have previously shown that 200 ppb sodium arsenite increased the atherosclerosis in apolipoprotein E knockout (apoE-) mice after 13 weeks, but the effects of lower concentrations was unknown. Therefore, we analyzed the effects of oral exposure to sodium arsenite from 10-200 ppb after 13 weeks. Importantly, we found that even at the lowest concentration of arsenite, there was a significant increase in atherosclerotic plaque size in the aortic arch and in the aortic sinus. In our previous studies, we found that arsenite exposure resulted in decreased smooth muscle cells and collagen within the plaque. This change is indicative of a less stable phenotype that could increase the risk of rupture and subsequently, myocardial infarct or stroke. In addition, we observed that lipid increased within the plaque without concomitant increase in macrophage content, suggesting the macrophages were retaining more lipid intracellularly. We also assessed these plaque components in apoE-/- mice exposed to 10-200 ppb arsenite. Interestingly, we observed the macrophage lipid accumulation occurred at lower concentrations than the decreased smooth muscle cell/collagen content. Together these data suggest that in the apoE-/- model, low concentrations are pro-atherogenic and that macrophage lipid homeostasis is more sensitive to arsenite-induced perturbation than the smooth muscle cells.

2176 Requirement of NADPH Oxidase Activity for Arsenic Inhibition of PARP-1

L. Volk, K. L. Cooper, A. Duran, E. Dashner-Titus, K. J. Liu, and L. G. Hudson. 1 University of New Mexico Health Sciences Center, Albuquerque, NM; and 2 The Ohio State University, Columbus, OH.

Human epidemiological studies show a correlation between arsenic and ultraviolet radiation (UVR) exposure with respect to the development of skin cancer. Previous studies have shown that exposure to environmentally relevant arsenic levels, particularly in conjunction with UVR exposure, results in oxidative damage to DNA and proteins via the generation of reactive oxygen species (ROS). However, arsenic and UVR generate ROS by different mechanisms, with evidence supporting arsenic induced ROS via stimulation of NADPH Oxidase (NOX). Additionally, it has been shown that exposure to arsenic can result in the inhibition of poly(ADP-ribose) polymerase-1 (PARP-1) activity, resulting in retention of DNA damage. Together, the evidence supports the hypothesis that arsenic hinders the function of specific DNA repair proteins, and consequently sustains DNA damage induced by UVR. In our previous studies, we found that arsenite exposure resulted in decreased smooth muscle cells and collagen within the plaque. This change is indicative of a less stable phenotype that could increase the risk of rupture and subsequently, myocardial infarct or stroke. In addition, we observed that lipid increased within the plaque without concomitant increase in macrophage content, suggesting the macrophages were retaining more lipid intracellularly. We also assessed these plaque components in apoE-/- mice exposed to 10-200 ppb arsenite. Interestingly, we observed the macrophage lipid accumulation occurred at lower concentrations than the decreased smooth muscle cell/collagen content. Together these data suggest that in the apoE-/- model, low concentrations are pro-atherogenic and that macrophage lipid homeostasis is more sensitive to arsenite-induced perturbation than the smooth muscle cells.
2180 Arsenic Inhibits Autophagic Flux by Disrupting STX17-SNAP29-VAMP8 Complex Formation

M. Dodson, and D. Zhang, University of Arizona, Tucson, AZ.

Chronic exposure to arsenic has been linked to an increased risk of a number of diseases, including cardiovascular disease, diabetes, and cancer. While the adverse health effects associated with arsenic exposure are well known, the mechanisms underlying arsenic-associated disease pathogenesis remain unclear. As such, a better understanding of the pathways targeted by arsenic and its derivatives is much needed. Previous work in our lab has shown that environmentally relevant doses of arsenic can inhibit the autophagy-lysosome pathway, resulting in protein aggregation and the non-canonical activation of the antioxidant transcription factor Nrf2. Both the prolonged activation of Nrf2, as well as chronic autophagic dysfunction, can have pronounced effects on overall cellular function and metabolism, and thus may be key contributors to the progression of arsenic-linked pathologies. Here, we demonstrate that arsenic inhibits autophagy by disrupting formation of the STX17-SNAP29-VAMP8 SNARE complex, where SNAP29 mediates the fusion of STX17-containing autophagosomes with VAMP8-bearing lysosomes. Mechanistically, arsenic disrupts SNARE complex formation by increasing OGlcnAcylation of SNAP29, which has been shown to prevent the interaction between STX17 and VAMP8. Mutation of four key OGlcnAcylation sites in SNAP29, knockdown of OGT, the enzyme responsible for protein OGlcnAcylation, or pretreatment with rapamycin, a known activator of autophagy, can all rescue arsenic-induced autophagic dysfunction. Interestingly, arsenic can also disrupt autophagosome/lysosome and lysosome trafficking, inferring there may be multiple mechanisms by which arsenic affects the autophagy pathway. These findings reveal two distinct mechanisms by which environmentally relevant concentrations of arsenic can perturb proteostasis and alter cellular metabolism, providing a novel subset of therapeutic targets for disease intervention in people exposed to unsafe levels of arsenic.

2181 Effects of Embryonic Exposure to Arsenic on Hepatic IGF-1 Signaling

K. Schwendinger, K. Sims, D. Szmykowicz, and L. Bain, Clemson University, Clemson, SC.

Arsenic (As) is a naturally occurring mineral that often exists as a contaminant of food and drinking water. While the World Health Organization (WHO) has set a global drinking water standard of 10 ppb, there are areas of the world where water concentrations are much higher. Arsenic exposure has been shown to decrease birth weight and reduce weight gain during childhood, and impair skeletal muscle differentiation. One potential mechanism for the reduced growth is through interference of the insulin-like growth factor (IGF) pathway. Killifish (Fundulus heteroclitus) were exposed from fertilization until hatching to 0, 10, 50, and 200 ppb arsenite. After hatching, they were transferred to clean water and grown out to 8, 16, 28, and 40 weeks to assess changes in growth, arsenic metabolism, and transcript levels of hepatic IGF-1 and IGFBP-1. As they age, hepatic IGF-1 and IGFBP-1 expression greatly increased, allowing the exposed fish to compensate and catch up with their control counterparts. As they age, hepatic IGF-1 and IGFBP-1 expression greatly increased, allowing the exposed fish to compensate and catch up with their control counterparts. However, IGF-1 and IGFBP-1 mRNA levels remain significantly elevated, even 40 weeks after the exposure has ended.

2182 SPARC in a Cell Culture Model of Arsenic and Cadmium-Induced Bladder Transitional Cell Carcinoma

E. Biggane, S. Somji, S. H. Garrett, D. A. Sens, and J. R. Dunlevy, University of North Dakota School of Medicine and Health Sciences, Grand Forks, ND.

Bladder cells that have been exposed to long-term, low doses of either arsenic (As^3+) or cadmium (Cd^2+) resulted in significant repression of SPARC (Secreted Protein Acidic and Rich in Cysteine). This metal exposure gave rise to 13 independent transformed cell populations with SPARC levels at or below detectable limits. SPARC was the most repressed gene in the microarray analysis across all of these cell lines. This expression change indicates a possible fundamental role for SPARC in order for cell transformation to occur. SPARC has been shown to have tissue-specific roles and acts as either an oncogene or a tumor suppressor dependent upon the tissue being studied. Its role in bladder and bladder cancer is unknown. SPARC is known to interact with collagen and inhibit integrin receptor signaling pathways affecting cell adhesion, proliferation, and survival. Thus, SPARC’s role in cell attachment and spreading of the As^3+ or Cd^2+ transformed cell lines was assessed. Cells were seeded on collagen, and cell attachment and spreading was observed every 15 minutes then analyzed using Fiji and LASX software from NIH and Leica. Preliminary results show that cell attachment appears to be delayed or deterred in cells expressing SPARC compared to metal transformed cells not expressing SPARC. Results also show a tendency for increased spreading in SPARC expressing cells when compared to the non-SPARC expressing counterparts. These results suggest that SPARC is binding to collagen and delaying or deterring cells from attaching; however, once attached SPARC appears to promote cell spreading. This indicates that SPARC may play a critical role in the metastatic ability of bladder tumor cells. Ultimately, SPARC may be initially acting as a tumor suppressor in bladder cancer induced by exposure to As^3+ or Cd^2+ suggesting its need to be repressed.

2183 Arsenic Enhances Influenza Virus Infection in MDCK Cells

E. A. Amouzougan, S. Malm, and W. T. Klimiecki, University of Arizona, Tucson, AZ.

Arsenic is a ubiquitous environmental toxicant that has been associated with both infectious and non-infectious human respiratory diseases. Published studies in mice revealed that exposure to arsenic through drinking water alters the antiviral immune response, increasing susceptibility to influenza infection. Given the well-known impact of arsenic on epithelial cell biology, we posited that arsenic exposure could increase the infectivity of respiratory epithelial cells to viral infection. In this study, we have characterized influenza virus A/H1N1 infectivity in arsenite-exposed (29 weeks) and unexposed MDCK cells. We assessed the production of viral proteins in MDCK using western blotting and quantified viral mRNA levels using qRT-PCR. We observed a 9.5-fold increase in viral matrix (M2) protein and a 0.35-fold increase in viral mRNA levels in arsenite-exposed MDCK compared to unexposed MDCK (48h post-infection). Using plaque assay, we tested infectivity of influenza A virus in arsenite-exposed and unexposed MDCK. Arsenite exposure resulted in 66.18% increase in number of plaques, 125.53% increase in plaque area, and 40.55% increase in plaque size in arsenite-exposed MDCK compared to unexposed MDCK (48h post-infection). Using plaque assay, we tested infectivity of influenza A virus in arsenite-exposed and unexposed MDCK. Arsenite exposure resulted in 66.18% increase in number of plaques, 125.53% increase in plaque area, and 40.55% increase in plaque size in arsenite-exposed MDCK compared to unexposed MDCK (48h post-infection). Additionally, chronic exposure to arsenic reduced the efficacy of anti-viral drug Oseltamivir. Arsenite-exposed MDCK treated with Oseltamivir also showed increase in plaque number, plaque area, and plaque size (48h p.i.). Taken together, we demonstrated that MDCK cells chronically exposed to 1 μM of sodium arsenite for 29 weeks showed increased susceptibility to influenza A virus infection. This study could help reveal new potential mechanisms through which arsenic increases the risk of influenza virus infection in exposed human populations.
Exposure to inorganic arsenic (iAs) is a persistent global public health problem. An individual’s iAs metabolism is a critical factor in determining susceptibility to iAs-induced diseases. Recent population-based studies have shown that obesity may influence iAs metabolism, with higher body mass index (BMI) associated with a greater proportion of dimethylated iAs in urine (%DMAs). This study aimed to characterize the association of obesity with urinary iAs metabolites, namely inorganic arsenic (i-As), urinary monomethylated arsenic (U-MMAs) and U-DMAs. We analyzed cross-sectional associations between BMI and each urinary metabolite using a cohort of 1,166 iAs-exposed adults recruited from 2008-2013 in Chihuahua, Mexico. Potential covariates were sex, age, smoking, alcohol consumption, education, and drinking water iAs. All analyses were done using multivariable linear regression models. In the overall cohort, the median (IQR) BMI was 28.4 kg/m² (7.4). The median (IQR) proportion of metabolites was 8.9% (5.8), 14.1% (6.8) and 76.6% (10.8) for U-As, U-MMAs, and U-DMAs, respectively. In unadjusted models, the change in the proportion of urinary iAs metabolites was -1.08% (95% CI: -1.42, -0.75) for %U-iAs, -1.53% (95% CI: -1.83, -1.22) for %U-MMAs, and 2.61% (95% CI: 2.12, 3.10) for %U-DMAs per 1-SD increase in BMI. After adjusting for confounders, the estimated change in the proportion of urinary metabolites associated with a 1-SD increase in BMI was -0.95% (95% CI: -1.30, -0.59), -1.31% (95% CI: -1.64, -0.98) and 2.26% (95% CI: 1.74, 2.79) for %U-As, %U-MMAs, and %U-DMAs, respectively. In support of previous studies, these findings indicate that obesity is associated with a decrease in %U-iAs, %U-MMAs, and %U-DMAs and higher excretion of %DMAs. This suggests that obesity may alter iAs metabolism, and therefore, may alter susceptibility to iAs-induced disease.

Inorganic arsenic (As) exposure is a global public health problem. Chronic exposure to iAs, either through drinking water or food, has been associated with increased risk of disease. Metabolism of iAs occurs through sequential methylation steps catalyzed by arsenic (+3 oxidation state) methyltransferase (As3mt), S-adenosylmethionine (SAM) provides methyl groups for this reaction. Differences in iAs metabolism are associated with differing risks of diabetes and efficiency of iAs metabolism has been linked to dietary intake of folate, an essential substrate for SAM synthesis. The goal of this project was to determine if modifying iAs metabolism using genetic (As3mt-knockout) or nutritional intervention (folate intake) would modify the diabetogenic effects of iAs exposure. We also assessed the combined effects of iAs exposure and a high-fat diet (HFD). 7-week old male and female C57BL6 (WT) and As3mt-KO mice were exposed to 100 ppb As in drinking water for 37 weeks. Mice were fed a purified low-fat diet (<50 ppb As) with either low (0.2 mg/kg) or high (10 mg/kg) levels of folate for 24 weeks, followed by a HFD with the same low/high folate levels for 8 weeks. Metabolic phenotype and body composition were examined after 24 weeks of iAs exposure on the low-fat diet and after 8 weeks of iAs exposure on HFD. After 24 weeks, As3mt-KO mice gained more fat and had higher fasting plasma insulin compared to WT mice, regardless of exposure. Interestingly, male KO mice were more insulin resistant than female KO mice though there were no differences in %fat mass. At 24 weeks, iAs exposure had minimal effect on metabolic parameters in WT mice. High fat intake had little effect on iAs metabolism and metabolic phenotype. HFD for 8 weeks increased %fat mass in all mice and increased the difference in insulin resistance between WT and KO mice and between males and females. Notably, with HFD, iAs-exposed male KO and WT mice with low folate had higher %fat mass and insulin resistance compared to iAs-exposed unexposed controls. Our data suggest that folate intake and low, chronic iAs exposure have little effect on metabolic parameters in WT mice. However, iAs exposure may elicit adverse effects when combined with a HFD, highlighting potential toxicant-nutrient interactions. Male As3mt-KO mice are more prone than females to develop an adverse metabolic phenotype, possibly due to iAs exposure through diet or drinking water.
Inorganic arsenic (iAs) is a naturally occurring element that contaminates the groundwater in multiple countries worldwide. This is of public health concern because chronic ingestion of arsenic-contaminated drinking water increases the risk of multiple cancers, cardiovascular and respiratory disease, diabetes, and adverse developmental and neurological effects. Disruption of the endocrine system provides a possible mechanism linking iAs exposure to a vast array of disease processes. Early-life iAs exposure alters plasma glucocorticoid (GC) levels in adult mice. GCS are steroid hormones that have widespread effects on the metabolic, cardiovascular, immune, reproductive, and central nervous systems. Consequently, arsenic-related health effects may result in part from the effect of iAs on GC homeostasis. This is the first study to investigate the long-term effect of early-life iAs exposure on GC homeostasis in humans. Lifetime iAs exposure estimates and plasma samples were collected in 2013 from 101 subjects born during 1958-1970 and currently living in Antofagasta, a city in northern Chile historically exposed to drinking water containing an average iAs concentration of 860 μg/L over this 13-year period. Differences in plasma GC levels between individuals with high (N=54) versus low (N=47) early-life iAs exposure were measured using a novel cell-based bioassay. Individuals in the highest tertile of cumulative iAs exposure had lower plasma GC levels than those in the lowest tertile of exposure. A flatter diurnal GC slope was also observed among the highest cumulative exposure group. These results demonstrate that early-life iAs exposure may have long-term effects on GC homeostasis and highlights the potential endocrine disrupting effects of iAs in humans. Future studies should evaluate the role of GCS in the etiology of arsenic-related disease in order to inform interventions and policy aimed at reducing iAs exposure, particularly during early-life.

Manganese (Mn) is an essential metal and nutrient yet toxic in excess. Individuals at risk of Mn toxicity include patients receiving total parenteral nutrition supplemented with Mn, patients with liver cirrhosis, and miners and welders exposed to Mn rich fumes and particulates. In 2012, the first known inherited disease of Mn excess was reported in patients with mutations in SLC30A10, a Mn efflux transporter that is highly expressed in the liver, brain, and duodenum and hypothesized to be essential for Mn excretion. Characterized by increased blood Mn levels, dystonia, polycthemia (increased red blood cell counts), and liver cirrhosis, SLC30A10 deficiency is a novel disease that offers a unique opportunity to investigate systemic Mn regulation. The overall goal of this project is to establish the role of SLC30A10 in mammalian Mn homeostasis by generating and characterizing mouse models of SLC30A10 deficiency. Our studies indicate that mice globally deficient in Slc30a10 develop tissue Mn excess and polycthemia, similar to patients with SLC30A10 deficiency. As Mn is eliminated predominantly in the feces via hepatobiliary excretion, we hypothesized that hepatocyte-specific Slc30a10 deficiency would lead to a phenotype similar to that of global Slc30a10 deficiency. Surprisingly, mice with hepatocyte Slc30a10 deficiency have minimal tissue Mn excess. To explore the role of Slc30a10 in hepatobiliary Mn excretion, we employed a surgical approach in which we ligate the bile duct, cannulate the gallbladder, and inject 54Mn into the portal vein. From this surgery, we can determine the rate of 54Mn excretion into bile. Results indicate that global and hepatic Slc30a10 deficient mice have impaired hepatobiliary Mn excretion, suggesting that hepatic Slc30a10 is required for hepatobiliary Mn excretion. However, systemic 54Mn excretion studies show no impairment in fecal excretion. Instead, 54Mn absorption studies reveal increased Mn absorption in global Slc30a10 deficient mice, which may reflect a direct role for intestinal Slc30a10 in regulating Mn levels. Characterization of intestinal Slc30a10 deficient mice is underway. Understanding these mechanisms of Mn homeostasis is important for developing pharmacological treatment for both inherited and acquired Mn toxicity.

Manganese is an essential metal, but elevated levels are toxic. Loss-of-function mutations in SLC30A10, a manganese efflux transporter, cause a heritable disorder of manganese metabolism resulting in elevated manganese levels and motor deficits. To understand the consequences of loss of SLC30A10 function at the organism level, we generated Scl30a10 knock-out mice. During early development, knockouts were indistinguishable from controls. Surprisingly, after weaning and compared with controls, knock-out mice failed to gain weight, were smaller, and died prematurely (by 6-8 weeks of age). At 6 weeks, manganese levels in the brain, blood, and liver of the knock-outs were 20-60-fold higher than controls. Unexpectedly, histological analyses revealed that the brain and liver of the knock-outs were largely unaffected, but their thyroid exhibited extensive alterations. Since hypothyroidism leads to growth defects and premature death in mice, we assayed for changes in thyroid and pituitary hormones. At 6 weeks and compared with controls, the knockouts had markedly reduced thyroxine levels (50-80%) and increased thyroid-stimulating hormone levels (800-1000-fold), indicating that Scl30a10 knock-out mice develop hypothyroidism. A low-manganese diet produced lower tissue manganese levels in the knock-outs and rescued the phenotype, indicating that manganese toxicity was the cause. Our unanticipated discovery highlights the importance of determining the role of thyroid dysfunction in the onset and progression of manganese-induced disease and identifies Scl30a10 knock-out mice as a new model for studying thyroid biology.
Pb in soil can be a significant source of exposure to this toxic metal, particularly for young children with high levels of hand-to-mouth activity that increase soil ingestion. Among approaches used to reduce exposure to Pb in soil are remediation strategies that alter physical and chemical properties of Pb in soil. Remediation is undertaken with the goal of reduced bioavailability of Pb in ingested soil, although effects of remediation on Pb bioavailability are not commonly quantified. Here, we determined effects of several remediation strategies on Pb RBA using an untreated soil from a Pb-contaminated site in Joplin, Missouri, and the same soil that underwent *in situ* treatment with trisodium phosphate (TSP), with Iron Rich (Fe) and TSP (Fe/TSP), with compost (C) and TSP (C/TSP), or with rototilling (R) and phosphoric acid (PA) (P/RPA). Diets used in the mouse assay were prepared by addition of test soils to powdered purifiedAIN-93G rodent diet at 0.15, 0.3, and 0.6% (w/w) basis, yielding diets with ~ 3 to 25 ppm Pb. For these assays, young adult female C57BL/6 mice had free access to soil-amended diet for 9 days during which cumulative consumption of diet was monitored. At termination, blood, bone, and kidney were collected for determination of Pb contents. Using dietary soil level as the basis for comparison, remediation of the soil with TSP, Fe/TSP, and C/TSP significantly reduced Pb levels in blood, bone, and kidney. Analyses of relations between cumulative ingestion dose of Pb and levels of Pb in blood, bone, and kidney in mice receiving soil-amended diets provided tissue-specific estimates of Pb RBA for remediated soils relative to bioavailability of Pb from untreated soil. These tissue-specific RBA estimates for remediated soils were used to define a range of values for each treatment tested. Ranges of estimated fractional RBA were 0.35-0.77 for TSP, 0.2-0.5 for Fe/TSP, 0.33 to 0.65 for C/TSP, and 0.23-0.43 for R/P/PA treatment. Thus, remediation procedures applied to this Pb-contaminated soil reduced Pb RBA compared to that found in mice that received diets amended with untreated soil. The mouse assay should be a useful tool for evaluation of the efficacy of various soil remediation strategies and for assessing the performance and duration of treatment effects under field conditions. **2193 Dynamics of Community Lead Dust and Children’s Blood Lead 10 Years after Hurricane Katrina in Metropolitan New Orleans**

H. Mielke1, C. Gonzales1, and E. P. Powell2. 1Tulane University, New Orleans, LA; and 2Lead Lab, Inc., New Orleans, LA.

The sustainability of urban communities is associated with environmental quality. One factor negatively affecting environmental quality is lead pollution. A safe threshold for lead exposure in humans has not been identified and this is accompanied by the lack of an effective primary prevention of lead exposure. Previous research focused on 176 Census Tracts (communities) located in the city of New Orleans4. These were matched for soil lead and children’s blood lead in pre- and ten years post-Hurricane Katrina. This report extends the study to 268 communities in New Orleans. GIS tools were used to describe, and map the pre- and post-Katrina data. Comparing pre- and post-Katrina results, decreases in both soil lead and children’s blood lead response were observed. Disparities in lead exposure continue to exist between children living in the interior compared to children in outer communities of New Orleans. This investigation demonstrates that reduction of soil lead is beneficial in urban communities and an effective method for primary prevention of lead exposure.

**2194 Lead Levels in Eggs in Kabwe, Zambia: Implication of Human Exposure**

H. Toyomaki1, J. Yabe2, S. M. Nakayama1, Y. B. Yohannes1,3, K. Muzandu1, H. Mizukawa1, Y. Ikenaka1,4, H. Nakata1, T. Kuritani1, M. Nakagawa1, and M. Ishizuka1. 1Hokkaido University, Sapporo, Japan; 2The University of Zambia, Lusaka, Zambia; 3University of Gonder, Gonder, Ethiopia; and 4North-West University, Potchefstroom, South Africa.

Lead (Pb) is one of the earliest metals used by humans and the toxicity causes neurological symptoms and even death in the worst cases. Kabwe, Zambia is one of the World’s Most Polluted Places” reported in 2016. Our research group has been investigating heavy metal pollution in Kabwe and found high Pb accumulation in environmental and biota samples. The present study was undertaken to assess the levels of Pb in eggs and to investigate the human exposure through the consumption of eggs in Kabwe, Zambia. Eggs and soils around houses, where chickens are kept at, were collected in Kabwe, Zambia. Commercial eggs sold at local shops were also collected. The metals were extracted from shells, contents (yolk and white protein were mixed) of eggs and soils using microwave digestion system and the concentrations were analyzed by ICPMS. The mean Pb concentrations in local egg shells (n = 40) and commercial egg shells (n = 13) were 550 μg/kg and 0.7 μg/kg dry weight, respectively. The mean Pb concentrations in local egg contents (n = 37) and commercial egg contents (n = 13) were 310 μg/kg and 33 μg/kg dry weight, respectively. There was a significant correlation between Pb concentrations in shells and egg contents (p = 0.01, Spearman’s p = 0.9). Pb concentration in egg shells was significantly negatively correlated with thickness of egg shells (p < 0.01, r = -0.7) and whole weight of eggs (p = 0.01, r = -0.6). The mean Pb concentration in local eggs was 678 mg/kg dry weight. There were significant correlations between Pb concentrations in egg shells and soils (p < 0.01, r = 0.6) as well as egg contents and soils (p < 0.01, r = 0.8). The mean amount of Pb in the local egg contents was 0.01 mg per egg. Thus, current Pb levels of local eggs were lower than the level of tolerable weekly intake (2 μg/P). High Pb exposure in chickens could affect the reproductive function, the hatching rate and the survival rate of chicks negatively.

**2195 Hypoxia Signaling and Hepcidin Deficiency in Inherited Manganese Excess Due to slc30a10 Mutation**

M. Pralapati, C. Mercadante, M. Dash, H. Conboy, and J. Bartnikas. Brown University, Providence, RI.

Manganese (Mn) is an essential metal, yet toxic in excess. The first disease of inherited Mn excess was reported in 2012 due to mutations in SLC30A10, a novel Mn transport protein. Such mutation in patients was presented with hypermanganesemia, dystonia, polycythemia (increased red blood cell counts) and cirrhosis. These phenotypes are attributed to Mn excess, however the exact molecular mechanisms have yet to be elucidated. To address this issue, the lab has generated a Slc30a10 knock-out mouse model that recapitulates several aspects of the human disease, including Mn excess and increased red blood cell counts. These mice also show increased Epo levels and decreased hepcidin levels, both known hypoxia-regulated genes. Gene expression analysis of liver tissues revealed up-regulation of 55% of hypoxia-regulated genes suggesting activation of hypoxia signaling. Mice also exhibited increased radiolabeled Fe absorption and tissue iron levels, consistent with hepcidin deficiency. Results from these experiments suggest that Mn excess can lead to a hypoxia mimetic state, in absence of true tissue hypoxia, leading to aberrant Epo levels, polycythemia, hepcidin deficiency, increased radiolabeled Fe absorption, and tissue overload of Fe.

**2196 Lead-Induced Cholesterologenesis and Alterations in 3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Activity in Rat**

E. O. Abam1, O. O. Ogunrinola1, A. D. Wusu2, O. K. Afolabi1, O. A. Dosumu3, O. B. Onunkwo4, E. A. Balogun5, O. O. Odukoya6, and O. Ademuyiwa1. 1Bells University of Technology, Ota, Nigeria; 2Lagos State University, Ojo-Lagos, Nigeria; 3Ladoke Akintola University, Ogbomosho, Nigeria; 4Federal University of Agriculture, Abeokuta, Nigeria; and 5University of Ilorin, Ilorin, Nigeria.

Lead poisoning is currently one of the most common disease of environmental origin and is increasing in developing countries. Exposure to lead induces a variety of biochemical responses. To investigate the effect of lead on cholesterol metabolism, male albino rats (n=34) were exposed to distilled water for the same periods. Total, HDL, VLDL, hepatic (200, 300 and 400ppm) for 4, 8 and 12 weeks. Control animals (n=18) received distilled water for the same periods. Total, HDL, VLDL, hepatic and hepatic micromolar, brain and brain micromolar cholesterol levels were determined spectrophotometrically. Lead accumulated to various levels in the tissues of the rats. Hypercholesterolemia was generally observed in the dose groups ranging from 5% (the 200ppm groups at 4 weeks) to 10% (in the 200ppm group at 8 weeks). Lead inhibited reverse cholesterol transport in a time-dependent manner as evidenced by decrease in HDL cholesterol (17% in 4-week 400ppm, 35%, 43% and 49% in 200ppm, 300ppm and 400ppm groups respectively at 8 weeks). Increased hepatic and brain cholesterologenesis was observed with highest increase occurring at 8 weeks; 41%, 39% and 94% for the liver and 57%, 54% and 25% for the brain. Hepatic and brain 3-Hydroxy-3-Methylglutaryl Coenzyme A (HMG-CoA) reductase activities were up-regulated in most of the dosage groups with highest increase (35%)
2197 Role of RE1-Silencing Transcription Factor (REST) in Manganese-Induced Repression of Excitatory Amino Acid Transporter 2 (EAAT2) in Astrocytes

E. Pajarillo1, J. Kim1, J. Johnson2, D. Son3, M. Aschner2, and E. Lee1. 1Florida A&M University, Tallahassee, FL; 2Memorial Medical College, Nashville, TN; and 3Albert Einstein School of Medicine, New York, NY.

Chronic overexposure to manganese (Mn) induces a neurological disorder referred to as manganism, sharing pathological features with Parkinson’s disease (PD). Mn-induced excitotoxic neuronal death is considered one of the critical molecular mechanisms of Mn-induced neurodegeneration. The astrocytic excitatory amino acid transporter 2 (EAAT2) plays a pivotal role in preventing excitotoxic neuronal death by eliminating excess glutamate from the synapse. Previously, we have shown that Mn decreased the EAAT2 expression at the transcriptional level via the activation of Mn-dependent yin yang 1 (YY1) transcription factor. The repressor element 1-silencing transcription factor (REST) contains multiple YY1 binding sites in its promoter region and is known to be neuroprotective in Alzheimer’s disease (AD). In the present study, therefore, we tested if REST is involved in Mn-induced repression of EAAT2 in human astrocytes. We have found that Mn repressed the REST gene by decreasing its promoter activity and mRNA levels, suggesting that YY1-repressed REST mediate Mn-induced decrease in EAAT2 expression and function. We also found that chemical activation of epigenetic modifiers histone deacetylases (HDAC) 1 and 2 abolished the effects of REST on EAAT2 promoter activity, indicating epigenetic histone modification can influence on REST activity on EAAT2 gene regulation. Taken together, our findings suggest that REST is involved in Mn-induced repression of EAAT2 via activation of YY1. This result could contribute to finding molecular targets for the development of therapeutics to treat neurological disorders associated with excitotoxicity including AD, PD, and manganism.

2198 Blood Lead Levels Are Associated with Hemoglobin, Nitric Oxide Levels, and Proximity to Mining in Adults Residing in the Peruvian Highlands

A. Childebayeva1, J. M. Goodrich1, M. Rivera-Chira2, F. Leon Velarde3, M. Kiyamu2, T. Brutsaert3, D. C. Dolinoy1, and A. W. Bigham1. 1Peruana Cayetano Heredia, Lima, Peru; and 2Albert Einstein School of Medicine, New York, NY.

A significant positive association was observed between blood lead and hemoglobin (β = 0.10, p = 0.025). We also found a significant negative association observed between blood lead and hemoglobin (β = 0.47, p < 0.001). An inverse association was observed between blood lead and HDL cholesterol (r = −0.191, p = 0.01), while an inverse association was observed between blood lead and LDL cholesterol (r = 0.122, p = 0.001). These findings indicate that up-regulation of HMG-CoA reductase activity may mediate lead-induced hepatic and brain cholesterologenesis.

2199 Effects of N-Acetyl Cysteine on Mitochondrial Biogenesis in Lead-Mediated Neurotoxicity

H. Kim1, J. D. Laskin2, and R. A. Heck1. 1New York Medical College, Valhalla, NY; and 2Rutgers, The State University of New Jersey, Piscataway, NJ.

Exposure to lead (Pb) can lead to neurological pathologies such as cognitive impairment and Alzheimer’s disease. Increasing evidence supports the theory that brain injury due to high-level lead exposure is mediated, in part, by mitochondria dysfunction. However, the molecular mechanisms underlying neurotoxic effects following lower level lead exposure remain largely undefined. In these studies, we hypothesized that lead exposure to low doses of lead contribute to brain injury through mitochondrial malfunction. To identify genes with altered expression in response to lead exposure and important in mitochondrial functioning we examined changes in transcript levels of genes regulating mitochondrial biogenesis and repair in neuronal PC12 cells. In these studies we evaluated genes known to be causal to mitochondrial dysfunction using a PCR array platform; we analyzed expression of mitochondrial biogenesis genes, expression of their relevant transcriptional regulators and also employed a micro RNA (miR, miRNA) PCR array platform to analyze alterations to the expression of miRNA species. We found that Pb-exposure resulted in a >10-fold increase in specific mRNA species encoding solute carrier family 25 species, inner mitochondrial membrane peptidase-like (Immp1) protein, uncoupling protein 3 (mitochondrial, protein carrier) and superoxide dismutase 2 (MnSOD). We also found >10-fold decrease in expression encoding mitochoendrial biogenesis complex components including a distinct subset of solute carrier family 25 species as well as decreases in SOD1 gene expression. Using the miR PCR array platform we observed that four microRNA species miR-22-3p, miR-25-3p, miR-125b-5p, and miR-32-5p levels were increased more than 2-fold in lead treated PC12 cells. Interestingly, alteration of expression of these mammalian levels were decreased in the presence of the anti-oxidant drug N-acetyl cysteine (NAC). It was noteworthy that we also found a different pattern of microRNA expression in the presence of NAC. Taken together these results, indicate that NAC may mitigate neuronal changes following exposure to low levels of lead. We speculate that these results may provide important clues to approaches for preventing mental health consequences following lead exposure. Supported by NIH AR055073 (DEH).

2199a Exposure to MMA III Modiﬁes the Expression of Genes Involved in mRNA Methylation of 6 Adenosine (m6a) and Those Related to Cancer Stem Cells in UROtsa Cells

Among the mechanisms of gene expression regulation involving the post-transcriptional modification of mRNA, the N6-methylation at the adenosine (m6a) is the most prevalent. In mammals, such modification is catalyzed by a methyltransferase complex, which is composed by the methyltransferase-like 3 (MTTL3), methyltransferase-like 14 (MTTL14), and the Wilms’-tumor 1-associated protein (WTAP); the proteins involved in the removal of this mark are the fat-mass associated protein (Fuin) and the Alkb homolog 5 (ALKBHS). The m6a mark in mRNAs influences a variety of RNA processing steps including splicing, mRNA stability, and translation. Studies have shown that the tumor initiation, cancer progression, relapse, and resistance to therapy in many cancers are due to the existence of a population of abnormal stem cells, known as cancer stem cells (CSC). Interestingly, genes associated with pluripotency and lineage-specific differentiation are controlled by m6a levels; therefore, reduced m6a levels can lead to a mis-regulation of these genes and the acquisition of stem cell characteristics; hence all these enzymes’ expression is frequently deregulated in cancer. Human exposure to inorganic arsenic (iAs) is associated with bladder cancer development; UROtsa cells have been used as a model to reveal the involved molecular mechanisms. To evaluate the role of m6a mRNA in iAs-induced bladder cancer, in this work we evaluated the methyltrans-
Manganese (Mn) exposure from welding fume continues to be an occupational hazard for welders in the United States. Currently, the recommended threshold limit value (TLV) for respirable Mn in the United States is set at 0.02 mg/m³. While epidemiological studies suggest that this limit is not adequate, the risk of Mn exposure for welders is substantial, as evidenced by increased SOX2 and NANOG mRNA demethylation by FTO.

Manganese (Mn) is an essential bioactive metal that serves as a cofactor for numerous enzymes and kinases, such as glutamine synthetase and ATM. To study mechanisms of cellular Mn homeostasis, a practical and accurate method of intracellular Mn measurement (MRS), an observable difference in thalamic GABA (a major inhibitory neurotransmitter) was only seen between high-exposed (average 0.22 mg/m³) and low-exposed (avg. 0.13 mg/m³) welders (p<0.01), but not between low-exposed welders and controls. Trends were similar, but not significant, for R1 (an imaging parameter proportional to Mn accumulation in the region) between low-exposed welders, high-exposed welders, and controls in the substantia nigra (SN). We utilized a segmental regression analysis to assess whether a threshold for exposure to Mn over the past year prior to scanning may exist for these imaging markers. A Bayesian model was used to incorporate prior knowledge from past study results and the information in the current data set. The model shows that there exists a probable exposure threshold of approximately 0.075 mg/m³ (95% CI: 0.03 - 0.23) for changes of thalamic GABA to occur. Additionally, there exists a probable exposure threshold of 0.16 mg/m³ (95% CI: 0.075 - 0.225) when assessing the changes of R1 in the SN across all exposures in the cohort. This preliminary analysis shows that the relationship between exposure to Mn and its effects in humans is non-linear at these occupational exposure levels, and that a probable threshold for changes in imaging markers is around 0.16 mg/m³. However, the experience of the exposed welders generally suggests that Mn toxicity occurs in the brain.

Restless Legs Syndrome (RLS) is a common neurological disorders seen in ~10% of the US population. RLS-associated sleep deprivation can seriously impact life quality, causing anxiety, depression and attention-deficit/hyperactivity disorder (ADHD) symptoms. Moreover, RLS may portend hypertension, heart disease and stroke. RLS exhibits both familial and non-familial (idiopathic) forms, with ~60% of cases seen in ~10% of the US population. RLS-associated sleep deprivation can seriously impact life quality, causing anxiety, depression and attention-deficit/hyperactivity disorder (ADHD) symptoms. Moreover, RLS may portend hypertension, heart disease and stroke. RLS exhibits both familial and non-familial (idiopathic) forms, with ~60% of cases being the result of Fe deficiency or elevated concentrations of another metal that opportunistically increases when Fe levels are low. Here we present novel data that BTBD9 functions to regulate Mn homeostasis in Caenorhabditis elegans. A blast search identified hpo-9 as the BTBD9 homolog in C. elegans, with ~75% sequence similarity. A mutant strain tm3719 (hpo-9⁻⁰⁻⁻) carrying 761 bp deletion of hpo-9 was obtained. We found that hpo-9⁻⁻ worms were more sensitive to Mn exposure. Upon Mn treatment, hpo-9⁻⁻ worms showed a significantly lower survival rate and more severe DAergic neurodegeneration compared with wild type worms. Interestingly, no difference was seen when worms were exposed to Fe. However, a low level of Fe (0.1 μM) pretreat-
ment was able to protect Mn-induced lethality. To better characterize HPO-9 protein, a transcripntional fusion construct was created with green fluorescent protein (GFP) driven under hpo-9 promoter. We found that GFP was present high in the head and pharynx and low in the intestine and seam cells. Using a confocal microscopy, we found that hpo-9 was expressed in dopaminergic neurons, indicating that HPO-9 might play a role in dopamine signaling. To confirm that, we over-expressed HPO-9 in DAergic neurons of hpo-9/- worms and found that it rescued Mn-induced DAergic neurodegeneration. Together, our results suggest a novel role for hpo-9/BBT9 in regulating Mn homeostasis and possibly dopamine signaling in C. elegans. Supported by NIEHS ES010563.

2204 Expression of Matricellular Proteins following Neurotoxic Injury

The CNS extracellular matrix (ECM) influences molecular events critical for CNS development, synaptic plasticity, and injury repair. Many ECM elements (e.g. laminin, collagen) found in other tissues are transiently expressed during CNS development and are nearly absent in the adult brain. Matricellular components of the ECM support long term neuronal survival and also play a role within the adult neural stem cell niche by modulating the behavior of newly-generated cells, but their response to injury is poorly understood. Matricellular proteins including fibronectin, members of the SPARC superfamily (SPARC, hevin), tenascin-c, and Fibronectin were examined by immunofluorescence microscopy and qPCR in a toxicant model of hippocampal injury. Perineuronal nets (PNNs) and associated proteins were also examined. 8-week old C57BL/6 mice were given trimethyltin (TMT, 2.8 mg/kg, i.p.) then euthanized up to 30 days post-treatment. Immunofluorescence showed weak hippocampal expression of SPARC and hevin, which was unchanged by TMT injury across all time points. Tenascin-c was highly expressed in the rostral migratory stream of control and treated mice with weak deficits, but hippocampal markers showed no detectable alteration in expression after TMT treatment. Increased expression of thrombospondin-1 was detected in the dentate gyrus and molecular layer between 4 to 10 days post-TMT in a subpopulation of activated astrocytes co-expressing nestin. Wisteria floribunda agglutinin (WFA) and anti-aggregan antibody, markers of perineuronal nets, showed prominent labeling in the injured dentate gyrus at 96h post-treatment and remained elevated at 30 days. Staining with microglial markers (Iba1, Isoleucin B44) indicated co-localization with WFA+ cells in the dentate gyrus, in addition to increased WFA labeling by granule cell neurons. qPCR of hippocampal tissue showed a 2-fold decrease in transcription activity of tenascin-c between 12 and 24h post-TMT with return to baseline at later time points. SPARC mRNA was increased transiently between 48 and 96h post-TMT, while mRNA for other matricellular proteins showed no significant changes with injury. TMT induced a limited repertoire of ECMs in the CNS, which may help explain the modest repair of CNS tissues after chemical injury. Supported by ES-005022.

2205 Manganese Exposure Modulates AKT/mTOR Signaling by Acting Directly on Insulin-Like Growth Factor Receptors: Implications for Huntington’s Disease

M. Bryan1, K. Nordham1, D. Rose1, M. O’Brien1, P. Joshi1, M. O’Brien1, I. Iliev1, M. Aschner2, and A. B. Bowman1. 1

Manganese is essential to cellular function but toxic in excess. While studies have observed potent activation of critical cell signaling pathways by Mn exposure (AKT, mTOR, JNK, p38) how Mn activates these pathways is still unknown. Insulin-like growth factor 1 (IGF1) is a potent growth factor, similar to insulin, which can activate AKT/mTOR pathways. Interestingly, prior studies have shown that Mn and IGF1 may be coregulated in cell and mouse models. Furthermore, IGF1 may be coregulated in cell and mouse models. Additionally, models of HD exhibit decreased Mn uptake and Mn-induced signaling. In this new study we aimed to elucidate the relationship between Mn and IGF1 signaling in HD and determine whether Mn acts through IGF1 and its receptor, IGFR, to signal to AKT/mTOR. Using multiple cell models of HD (SThdh, PC12, human inducible neuronal cell lines), we have observed reduced Mn-induced phosphorylation of AKT and S6 (mTOR) in HD cells after 24hr exposures. Of a panel of seven other metals tested at similar concentrations in the SThdh model, this genotype-treatment interaction was specific to Mn. However, we found that the addition of Mn (50-200uM) to IGF1 (1-10nM) exposures results in additive responses to p-AKT(Ser473) and p-S6(Ser235/236) in all lines. Treatment with IGF1 and Mn also restores HD cell signaling. While Mn did not increase phosphorylation of IGFR, itself, the addition of Mn and IGF1 caused an additive increase in p-IGFR which suggest Mn increases the kinase activity of IGFR in the presence of saturating concentrations of its ligand, IGF, allowing increased autophosphorylation and downstream signaling. Using an siRNA knockdown (e.g. IRS-1) and pharmacological signaling. Using a BM3S63024 IuM approach, we isolated the molecular target of Mn to the IGFR receptor (IGFR) itself. Further, HD cells displayed basal impairments in Mn-induced IGFR signaling which mirrors the effects of pharmacological/genetic inhibition in WT cells. Together, our data substantiate a hypothesis in which Mn dyshomeostasis in HD may contribute to inadequate AKT/mTOR signaling via interactions at the IGFR.

2206 The Sidechain of Asn-43 of Human SLC30A10 Is Not Required for Manganese Efflux Activity in Hepatic and Neuronal Cell Lines

C. E. Zogzas. University of Texas at Austin, Austin, TX.

Homozygous mutations in SLC30A10 lead to the development of familial manganese-induced parkinsonism. SLC30A10 functions as the cell’s primary manganese efflux transporter, and parkinsonism-causing mutations block its efflux activity. Interestingly, other transporters in the SLC30 family mediate zinc efflux. Thus, determining the mechanisms that confer manganese transport capability to SLC30A10 is essential to understanding its role in parkinsonism. We previously generated a predicted structure of SLC30A10, based on the crystal structure of the bacterial zinc transporter YiiP, and performed functional studies. In this study we established that residues corresponding to Zn binding residues in YiiP, were not all required for Mn efflux activity. Although alanine substitution of Asp-248 abolished manganese efflux, that of Asn-43 and Asp-47 did not, suggesting the mechanism of ion coordination in the transmembrane domain of SLC30A10 may be substantially different from that of YiiP/other SLC30 proteins. Furthermore, Nishido et al. published differing findings on the manganese efflux activity of SLC30A10. The authors expressed human SLC30A10WT or mutants in a chicken cell line and assessed transport activity of SLC30A10 mutants indirectly via cell viability. In this system, Asn-43 was shown to be required for manganese efflux activity, while when mutated to histidine, to mimic other Zn-transporting SLC30 members, SLC30A10Asn43His gains Zn efflux activity. So in order to discern between these divergent results, the requirement of the Asn-43 residue of SLC30A10 was rigorously tested in neuronal and hepatic cellular systems, which most closely resemble the physiological site of action of the brain and the liver, respectively. SLC30A10WT or Asn-43-Ala was stably expressed in HepG2 hepatic and AF-S neuronal cell lines. We then assayed the cells using three rigorous analyses. SLC30A10 subcellular expression was monitored using confocal microscopy, viability against manganese toxicity was performed using the MTT assay, and lastly intracellular metal content was quantitatively measured using ICP-MS. Our findings demonstrate that overexpression of the Asn-43-Ala mutant was not statistically different from cells expressing SLC30A10WT in both of these physiologically relevant systems. This corroborates our findings in the HeLa cell system and suggests that Asn-43 is, in fact, not required for manganese efflux activity.

2207 Differential Copper-Induced Death and Regeneration of Olfactory Sensory Neuron Populations in Zebrafish

E. Ma, K. Hefern, and E. Gallagher. University of Washington, Seattle, WA.

Fish rely heavily on olfaction to maintain behaviors essential for survival, including predator detection and avoidance, prey selection, social behavior, imprinting, and homing. Environmental exposures to copper (Cu) ions are known to cause olfactory toxicity. In this study, zebrafish were used as a model system to study olfactory death and regeneration in teleost fish following Cu exposure. Confocal imaging of double-transgenic zebrafish larvae with differentially labeled ciliated and microvillus olfactory sensory neurons (OSNs) was used to image and analyze OSN changes following Cu-induced death and recovery. Following a 3-hour or 24-hour exposure to Cu at 5 days postfertilization, both ciliated and microvillus OSN populations exhibited cell injury and death in a dose-dependent manner. Differential recovery and regeneration between the two OSN populations were observed following exposure, with more extensive damage and recovery observed in microvillus than ciliated OSN populations after 24 h at higher Cu concentrations. Cell
2208 High-Throughput and Sensitive Quantification of α-Synuclein Protein Aggregation in Welder’s Serum: Relevance to Development of Circulating Biomarkers for Manganese Neurotoxicity

S. Manne1, N. Kondru1, D. Rokad1, A. Abdalla1, D. H. Jin1, L. E. Young2, M. Lewis2, V. Anantharam1, X. Huang1, A. Kanhasamy1, and A. G. Kanthasamy1. 1 Iowa State University, Ames, IA; and 2 The Pennsylvania State University, Hershey, PA.

Chronic exposure to Mn is known to affect the extrapramidal motor control system resulting in Parkinsonian like neurological symptoms. Welders exposed to Mn-rich welding fumes are particularly prone to Mn neurotoxicity. Recently, we demonstrated that Mn interacts with α-synuclein (αsyn) protein and promotes its aggregation in cell culture and animal models of Mn neurotoxicity. Although brain Mn is traditionally used to diagnosis Mn neurotoxicity in humans, no reliable blood-based biomarker is available. In this study, we developed a sensitive quantification method that detects the effect of Mn exposure on αsyn aggregation by a real-time quaking-induced conversion (RT-QuIC) assay. First, we generated a highly 4-phenyl-1-butylamino human wild-type αsyn substrate and synthesized the αsyn filaments, or pre-formed fibrils (PFFs), from this substrate. The PFFs generated were tested vigorously for internal quality control using defined criteria set by the Michael J. Fox Foundation. The seeding ability of these PFFs were also tested in the RT-QuIC assay with αsyn as a substrate. Next, we optimized RT-QuIC assay conditions to further quantify αsyn aggregation in cell cultures and slice culture models of αsynucleinopathies. We also determined the amyloid formation rate for aggregated αsyn. Importantly, we also examined the utility of RT-QuIC assay in detecting αsyn aggregation in welder serum samples. Serum exosomes from 25 welders exposed to welding fumes and 16 welder-matched control subjects were tested for αsyn seeding activity in a blinded RT-QuIC assay. We could differentiate the welders from controls with >95% sensitivity and specificity using this assay, suggesting that exosomal αsyn aggregates can act as a novel biomarker for Mn neurotoxicity. Comparative analysis of RT-QuIC analysis and brain MRI data showed a positive correlation between amyloid seeding activity and years of Mn-containing welding fume exposures. Collectively, our findings demonstrate the efficacy of using a highly sensitive and rapid, high-throughput RT-QuIC diagnostic assay for detecting Mn-induced αsyn aggregation in occupationally exposed individuals. 2209 Putrescine Accumulation and Associated Polyamine Metabolism Is Responsive to Physiological and Toxicological Cellular Manganese in Human SH-SYSY Neuroblastoma Cells

J. Fernandes, J. D. Chandler, K. H. Liu, K. Uppal, Y. M. Go, and D. P. Jones. Emory University School of Medicine, Atlanta, GA.

Manganese is an essential nutrient and is required for normal cellular processes. Manganese influences polyamine uptake and stimulates arginase activity, an enzyme upstream of the polyamine, putrescine. While increased manganese (Mn) exposure leads to parkinsonian symptoms and neurological disorders like depression, increased polyamines have also been observed in rapid progression of Parkinsonism in humans and in suicidal cohorts with major depression. Despite the observed similarities, the effect of Mn on polyamine metabolism has not yet been studied. Our aim was to test the hypothesis that dose-dependent increase in Mn causes increased polyamine accumulation and altered polyamine metabolism in a human neuroblastoma cell line. SH-SYSY cells were treated with a series of MnCl2 concentration (0 to 100μM) that resulted in cellular Mn representative of normal to pathological range (4 to 49 μg/mg protein) in human brain. Polyamines and other metabolites were analyzed by liquid chromatography-ultra high-resolution mass spectrometry. Among the polyamines detected, putrescine showed the most significant dose-dependent increase with cellular Mn over the normal to pathologic range (P < 0.0014). Metabolome wide association study of putrescine showed the highest positive correlation with the polyamine metabolite, N-acetylserpine (r= 0.79, P< 0.001, FDR<0.01). Putrescine was also positively correlated with other polyamines, methionine-related precursors, and arginine-associated urea cycle metabolites (rP>0.4, P<0.001, FDR<0.01). γ-Aminobutyric acid (GABA)-related and succinate-related metabolites were negatively correlated with putrescine (rP<0.4, P< 0.001, FDR<0.01). Pathway enrichment analysis showed that methionine and cysteine metabolism was the top altered metabolic pathway, while 29% of the total metabolites correlated with putrescine were involved in amino acid metabolism. In summary, high cellular Mn putrescine was positively associated with other polyamine metabolites in human SH-SYSY neuroblastoma cells suggestive of disrupted neurotransmitter, energy and oxidative homeostasis. Studies are warranted to investigate whether disruption of putrescine related metabolism could be a potential target of Mn toxicity leading to neurological disorders in humans.

2210 Comparing Parkinsonian Toxicants Effects on Dopa-Neurons Reveals Pathways and Biomarker

D. Gerhold, Z. Tong, J. Braisted, P. Chu, P. Shinn, R. Huang, R. Huang, M. Xia, and A. Simeonov. NCATS, Rockville, MD.

Parkinson’s disease (PD) has a small genetic component of ~5-10%, indicating environmental causes. Pesticides such as rotenone, paraquat, and ziram only moderately increase risk for PD, suggesting that chemical(s) causing PD remain to be identified. First, we compared the toxic mechanisms of two chemicals that cause parkinsonism, 6-hydroxydopamine and 1-methyl-4-phenylpyridinium (MPP+), in killing three human neuronal cell models: SH-SYSY, neural stem cells, and LHUMES-immortalized dopaminergic neurons (Tong et al. 2016, Pubmed: 27143523). By screening for chemical interactions, we found that all three cell lines were sensitized to MPP+ by Sirintu activator SRT1720. Since SRT1720 increases substrate flow to the mitochondrial electron transport chain (ETC), wherein MPP+ blocks Complex I, we hypothesize that this interaction increased toxic radical formation from the ETC. All three models were also sensitized to 6-hydroxydopamine toxicity by buthionine sulfoximine, which blocks glutathione synthesis, and protected by 2,3-dimethoxy-1-naphalene (DMN), which chelates Fe2+. This study identified different pathways for response to oxidative stress caused by the two toxicants. Next, we used RNAseq transcriptional profiling to study how differentiated LHUMES dopa-neurons respond to neurodegenerative toxicants including the five parkinsonian chemicals: 6-hydroxydopamine, MPP+, rotenone, paraquat, and ziram. These five chemicals are induced overlapping sets of responsive genes in LHUMES-immortalized dopa-neurons, indicating commonalities in response pathways. Common responses included CNN2, FIBIN, ELF2N, PDK4, CMKR1, SLC30A2, and several metallothionein genes. For one biomarker gene that responded dynamically to all five toxicants, a promoter-reporter gene construct is being engineered in LHUMES cells using the CRISPR technique. This engineered cell line will enable us to screen chemical libraries for neurodegenerative potential using NCATS quantitative high-throughput screening format. Thus, we plan to use the dynamic response of the biomarker gene(s) in LHUMES neurons, and in human stem cells, to screen for environmental chemicals with the potential to cause PD or neurodegeneration.

2211 Roles of Microglia in Diesel Exhaust Particulate Extract-Induced Neuron Loss and Clearance of α-Synuclein Aggregates in the Larval Zebrafish Brain

H. Murata. University of California Los Angeles, Los Angeles, CA.

Parkinson’s Disease (PD) is the second most common neurodegenerative disease and is caused by both genetic and environmental factors. The main hallmarks of PD include aggregation of the protein alpha-synuclein leading to the formation of Lewy bodies, neuroinflammation, and loss of dopaminergic neurons in the substantia nigra. Epidemiological studies have reported an association between exposure to air pollutant (AP) and incidence of PD. One major component of AP is diesel exhaust (DE). We hypothesize that AP activates microglia, interferes with alpha-synuclein processing and contributes to neuronal injury. Transgenic zebrafish (ZF) embryos were utilized to determine the effect of a major component of AP, diesel exhaust particulate extract (DEPe), on microglia’s interactions with alpha-synuclein and their role in neurotoxicity. DEPe exposure led to a significant loss of dopaminergic neurons in the ZF brain and activation of microglia. Reduction of microglia using morpholino oligonucleotides did not alter DEPe-induced neuron loss. Microglia were found to engulf GFP-tagged human α-synuclein expressed in the ZF brain suggesting that they play a role in synuclein homeostasis. These data suggest that microglia do not play a significant role in DEPe-induced dopamine loss in our ZF model but do play a role in clearing aggregated α-synuclein.
alpha-synuclein. Current studies are focusing on the effects of DEPe-induced microglial activation on alpha-synuclein kinetics since both of these processes have been implicated to play a pathological role in the pathogenesis of PD. Ultimately, these studies will help elucidate the mechanisms by which AP contributes to neurodegeneration in PD.

2212 Neuroprotective Effect of Glycyrhiza glabra and Mucuna pruriens Extract on Rotenone-Induced Parkinsonism in the Wistar Rat Model

M. V. Patel1, H. Dave1, D. Gohel1, S. Jadhav1, K. Shah1, R. Kala1, F. Parikh1, and V. J. Piccirillo1. 1Jai Research Foundation, Valvada, India; and 1VJP Consulting, Inc, Ashburn, VA.

The objective of this research was to evaluate the effect of combined Glycyrhiza Glabra root extract (GG) and Mucuna Pruriens seed extract (MP) on Rotenone-induced Parkinsonism in the Wistar rat model following daily administration through oral gavage for 28 consecutive days. Rotenone (2.5 mg/kg) was administered intraperitoneally to 6 groups of 10 male rats each (G2 to G7) to induce Parkinson-like symptoms. GG at 600 mg/kg b.wt and MP at 800 mg/kg b.wt were administered orally for 28 days to groups G4 and G5, respectively. A concurrent vehicle control group (G1) of male rats was dosed with 1% CMC alone. Group G2 served as a rotenone control. Group G3 served as a positive control group and was dosed with Levodopa (20 mg/kg). A combination of GG and MP was given orally to group G6 while GG and Bromocriptine (DOPA agonist) were given in combination orally for 28 days to group G7. A Functional Observational Battery (FOB) and bar test for catalepsy were performed as pre-treatment and on Days 8, 15, 21, and 28 of treatment to evaluate differences in the neurotoxic and behavioral findings. At termination, all animals were sacrificed and subjected to gross and neuropathological examination. Lipid peroxidation, SOD, and reduced glutathione were measured from brain tissue homogenate. GG + MP treatment (G6) revealed weight loss and higher grip strength compared to vehicle control and rotenone treated groups. The virally-mediated approach, group G6 was the only group in which significantly reduced motor activity was not seen. Lipid peroxidation, SOD, and reduced glutathione of GG + MP treated group (G6) were comparable to vehicle control group while significantly reduced (SOD and Reduced Glutathione) or increased (Lipid peroxidation) in rotenone treated groups. Histopathological evaluation of brain tissue revealed degeneration of dopaminergic neurons in animals treated with individual herbal extract (G4 and G5) which disappeared when animals were treated with herbal extract in combination (GG + MP, G6). Rotenone produced neurotoxicity at a dose level of 2.5 mg/kg b.wt./day when injected intraperitoneally. Combined treatment of GG + MP extracts revealed potential neuroprotective effects which can be useful in reducing the symptoms of Parkinson's disease.

2213 Cytochrome C as a Peroxidase Plays Role in α-Synuclein Radial Formation: Implications of α-Synuclein in Alterations of Biological Pathways and Neuronal Death II Maneb- and Parquat-Induced Model of Parkinson's Disease

A. Kumar, D. Ganini, and R. Mason. NIHES, Research Triangle Park, NC.

The pathological features of Parkinson's disease (PD) include accumulation of the protein α-synuclein in the surviving dopaminergic neurons. Though PD is multifactorial, several reports show an increased incidence of PD with coexposure to pesticides such as Maneb and parquat (MP). In pesticide-related PD, mitochondrial dysfunction and α-synuclein oligomers have been strongly implicated, but the link between the two has not yet been understood. Similarly, the biological effects of α-synuclein or its radical chemistry in PD is largely unknown. Mitochondrial dysfunction or α-synuclein inclusions leads to loss of cytochrome c in the cytosol. Once in the cytosol, cytochrome c has one of two fates: It either binds to apaf1 and initiates apoptosis or can act as a peroxidase. We hypothesized that as a peroxidase, cytochrome c leaked out from mitochondria can form radicals on proteins in proximity such as α-synuclein. We investigated cytochrome c release in response to MP with α-synuclein in dopaminergic neurons of MP co-exposed (Maneb: 30 mg/kg, ip and parquat:10 mg/kg, ip for 6 weeks) mice. Based on co-localization of cytochrome c and α-synuclein in vivo we used an in vitro system to study the reaction of cytochrome c and α-synuclein and used immuno-spin trapping (IST) to investigate the role of cytochrome c as a peroxidase in α-synuclein radial formation. IST experiments of samples from a reaction mixture consisting of cytochrome c, α-synuclein, and hydrogen peroxide indicated that cytochrome c plays a role in α-synuclein radial formation and oligomerization. Experiments with MP co-exposed α-synuclein knock out mice in which cytochrome c-α-synuclein co-localization can’t occur, mice showed diminished protein radical formation, and diminished neuronal death in compare to wild type MP co-exposed mice. Microarray data also showed that the absence of α-synuclein per se or its co-localization with cytochrome c confers protection from MP co-exposure as several pathways were unaffected in α-synuclein knock out mice. Taken together, these results show for the first time that peroxidase activity of cytochrome c contributes to α-synuclein radical formation and oligomerization, and α-synuclein through its co-localization with cytochrome c or at its own, affects several pathways which contribute to increased neuronal death in MP-induced model of PD.

2214 Viral-Mediated Dysregulation of Vesicular Monoamine Packaging Is Toxic to Dopaminergic Neurons

Dopaminergic (DAergic) neurotransmission underlies reward-motivated behavior and motor output, is the target of many drugs of abuse, and has been implicated in several diseases. DA handling is tightly regulated, and the sequestration of DA into synaptic vesicles is required to maintain neuronal health. The vesicular monoamine transporter 2 (VMAT2) loads DA into synaptic vesicles from the cytosol. Cytosolic DA is susceptible to metabolism and oxidation, which can generate reactive oxygen species and the toxic DA-quinone. DA sequestration is critical to maintaining neuronal health as evidenced by neurodegeneration occurring in a mouse model expressing 5% of the normal levels of VMAT2 (Caudle et al. 2017). Furthermore, VMAT2 overexpression attempts to target toxicity induced by MPTP (Lohr et al. 2014) and methamphetamine exposure (Lohr et al. 2015). To understand the mechanisms underlying neurotoxicity induced by dysregulated DA packaging, VMAT2 expression can be decreased through viral-mediated delivery of small-hairpin ribonucleic acids. This viral-mediated approach allows for specific neuroanatomical targeting, the manipulation of the extent of VMAT2 knock-down, and the dysregulation of DA packaging in an adult animal thereby circumventing the potential of compensatory changes that occur through development. Adult rats unilaterally injected with an AAV2 virus to knock-down VMAT2 within the nigrostrial pathway show decreased VMAT2 protein expression by 36.6% in transduced nigral neurons and by 44% in the striatal terminals (paired t-test, n=5, p<0.05). In the striatum, there was a corresponding loss of DA by 49.6%, increased DA turnover by 64.6%, and increased DA oxidation by 27.5% (paired t-test, n=5, p<0.05). The dysregulation of DA packaging resulted in a loss of TH+ neurons in the substantia nigra by 38.7% as determined by stereology (paired t-test, n=5, p<0.05). The administration of 5-HT agonists in animals demonstrated significant asymmetrical DA-mediated behavioral impairments through posturing and cylinder testing. These results demonstrate that viral-mediated targeting of VMAT2 can be used to dysregulate DA packaging, thereby generating a model by which cytosolic DA mediated toxicity can be studied.

2215 Activation of Lrrk2 and α-Synuclein in Specific Brain Regions after Chronic Exposure to Arsenite

Z. Drobná1, and E. F. Rissman2. 1North Carolina State University, Raleigh, NC; and 2Center for Human Health and the Environment, Raleigh, NC.

Increased life expectancy contributes to increased incidence of chronic neurodegenerative diseases such as Alzheimer’s and Parkinson’s diseases. The etiology of these disorders has not been elucidated; however, several genetic and environmental factors are known to contribute to the onset and/or development of these illnesses. Arsenic is a known neurotoxic metalloid adversely affecting neurodevelopment, cognitive and motor functions. As reported by the FRONTIER project, chronic exposure to low levels of arsenic correlates with a decline in cognitive functions and memory, reflecting the earliest manifestations of Alzheimer disease. Higher prevalence of Alzheimer disease was found in countries with higher levels of arsenic exposure. Epidemiological studies also suggest that the exposure to pesticides, including those containing arsenic, increase the risk of developing Parkinson’s disease. This progressive neurological disease is characterized by the loss of dopaminergic neurons in substantia nigra pars compacta leading to motor dysfunction. The hallmark of Parkinson disease is the presence of Lewy bodies in surviving neurons containing aggregates of the α-synuclein, which may result from LRRK2-mediated inhibition of chaperon-mediated autophagy (lysosomal) degradation pathway. Here, chronic exposure
of C57BL/6 male mice to arsenite negatively affected their grip strength. This may mimic neuropathy observed in population studies from arsineosis areas. Using organotypic brain slice cultures, short-term exposure to arsenite led to increased phosphorylation of Lrrk2 and α-synuclein in substantia nigra. Next, we evaluated the effect of arsenite on activation of Lrrk2 and α-synuclein after chronic exposure of C57BL/6 male mice to 50, 500 or 5,000 ppb of arsenite. Significant correlations between phosphorylated forms of Lrrk2 and a-synuclein (r2 = 0.85) were observed in substantia nigra and for Lrrk2 levels between substantia nigra and striatum (r2 = 0.9), which were completely disrupted by arsenite at either high or low exposure levels. These data suggest that arsenite interferes with process linked to α-synuclein pathology, which is associated with neurodegenerative diseases. This work was funded by CHHE grant P30ES025128.

2216 Expression of the Histone Methyltransferase Ezh2 Is Increased in Parkinson’s Disease Brain, and Ezh2 Inhibition Reduces the Astrocyte Inflammatory Response: Potential Role for Epigenetic Alterations in Neurodegeneration

M. Neal1, K. Budge1,2, F. Safadi1, and J. R. Richardson1. 1Northeast Ohio Medical University, Rootstown, OH; and 2Kent State University, Kent, OH.

Neuroinflammation, mediated by microglia and astrocytes, is a hallmark for both Alzheimer’s (AD) and Parkinson’s (PD) diseases, and evidence indicates that it contributes to the progression of these diseases. Emerging evidence also indicates that reactive astrocytes play a prominent role in both AD and PD. Inflammatory cytokines can induce astrocytes to shift towards a reactive state, causing these cells to produce more inflammatory factors and increase neurotoxicity. Although a relatively new field, studies have found that epigenetic modifications, including DNA and histone methylation, contribute to the regulation of inflammation. Here, we used datamining techniques and found increased expression of the histone methyltransferase Ezh2 in the substantia nigra of PD patients with 5% more expression than age-matched controls. Treatment of mouse models with the dopaminergic neurotoxin MPTP increased Ezh2 gene expression by 70% in the striatum 2 days following treatment. In cultured mouse primary astrocytes and an immortalized mouse astrocyte line, treatment with a mix of pro-inflammatory cytokines (CM) caused a 9-fold increase of NO levels and significantly increased mRNA expression of cytokines (CM). This was followed by a 16-fold increase in Ezh2 gene expression. Next, we investigated the effects of GS126, a selective pharmacological inhibitor of Ezh2, on CM-treated cultured astrocytes. GS126 co-treatment significantly attenuated the levels for all of these inflammatory factors. Interestingly, our qRT-PCR, Western blot and ICC analyses also revealed that Ezh2 upregulated mRNA and protein levels of Rab27a, a key endosomal protein that mediates exosome release through fusion of MVBs with plasma membrane, suggesting Rab27a upregulation also contributes to Mn-induced exosomal release. Since aggregated αSyn can get degraded via autophagic/lysosomal degradation pathways, we examined if Mn impairs this pathway to promote exosomal αSyn release. Our Western blot analysis of M9N9D_αSyn cells shows that Mn upregulated expression of autophagosomal markers LC3-II and Beclin-1, but downregulated lysosomal marker LAMP2 suggesting impairment of autophagosome formation. Taken together, these novel findings suggest Mn compromises endosomal trafficking, leading to autophagic/lysosomal impairment, thereby promoting MB formation and the exosomal release of misfolded αSyn. NIH grants ES026892, NS088206 and Eugene & Linda Lloyd endowed Chair.

2217 Mechanism of Manganese Impairment Mitochondria Dynamics in Dopaminergic Neurons

P. Morcillo1, B. Ferrer1, A. Bowman2, and M. Aschner1. 1Albert Einstein College of Medicine, New York, NY; and 2Vanderbilt University Medical Center, Nashville, TN.

Excess accumulation of Manganese (Mn) in the brain results in a neurological syndrome with cognitive, psychiatric, and movement abnormalities called Parkinsonism. In addition, Mn accumulates in the basal ganglia triggering damage in dopaminergic neurons and gliosis. Thus, Mn neurotoxicity increases reactive oxygen species (ROS), damage in ATP synthase, disrupt Ca2+ homeostasis and apoptosis. However, few studies have evaluated the perturbations of Mn in mitochondrial dysfunction, the latter representing a site of predominant Mn accumulation. Thus, in this study, we have exposed in vitro rat embryonic primary cell culture derived from the midbrain for 6 and 24 h to Mn and the neurotoxicity was evaluated. The results showed that Mn exposure induced alternation in the dynamin-related protein 1 (DRP-1) as well as other proteins associated with susceptibility to Parkinson’s disease, such as PINK1 and Parkin. Moreover, we evaluated whether Mn exposure alters mitochondrial bioenergetics in cultured neurons. The results showed a variation in the basal mitochondrial oxygen consumption rate as well as the ATP-linked respiration. Finally, Mn produced a regulation in the expression of mitochondrial fission factor (Mff) as well as Park7. This study reports for the first time role of Mn in the abnormal imbalance in fusion/fission equilibrium in a neuronal cell culture. We expect that our results will contribute to therapeutic targets for Parkinsonism. This study was supported by NIHES R01ES01563 to MA and ABB.

2218 Manganese Exposure Enhances the Release of Misfolded α-Synuclein Via Exosomes by Impairing Endosomal Trafficking Machinery

Environmental exposure to excessive manganese (Mn) increases the risk for chronic neurological diseases including Parkinson’s disease (PD). Aggregated α-synuclein (αsyn) is a key pathophysiological feature of PD, and as summarized in our recent review in Toxicological Sciences; oligomeric proteins like αsyn can be released from neurons by exosomes, enabling misfolded proteins to propagate to neighboring cells, thereby inducing a neurotoxic response. We recently revealed that Mn increases the release of exosomes containing misfolded αsyn from dopaminergic neurons, but the underlying molecular signaling mechanisms are unclear. Herein, we examined how Mn modulates endosomal protein trafficking to promote exosomal αsyn release. MN9D dopaminergic neuronal cells stably expressing human wild-type (WT) αsyn (MN9D_αsyn) were exposed to Mn (300 μM) for 24 h. Mn significantly suppressed expression of key endosomal-recycling protein Rab11a, both at the protein and mRNA levels, suggesting Mn downregulates endosomal-recycling mechanisms, thus forcing large exocytic cargo to be internalized into multivesicular bodies (MVBs). Moreover, exocytic expression of WT Rab11a significantly attenuated exosomal release in both untreated and Mn-stimulated MN9D_αsyn cells, whereas ectopic expression of dominant negative mutant Rab11a (S25N) enhanced exosomal release. Interestingly, our qRT-PCR, Western blot and ICC analyses also revealed that Mn exposure upregulated mRNA and protein levels of Rab27a, a key endosomal protein that mediates exosome release through fusion of MVBs with plasma membrane, suggesting Rab27a upregulation also contributes to Mn induced exosomal release. Since aggregated αSyn can get degraded via autophagy/lysosomal degradation pathways, we examined if Mn impairs this pathway to promote exosomal αSyn release. Our Western blot analysis of M9N9D_αSyn cells shows that Mn upregulated expression of autophagosomal markers LC3-II and Beclin-1, but downregulated lysosomal marker LAMP2 suggesting impairment of autophagosome formation. Taken together, these novel findings suggest Mn compromises endosomal trafficking, leading to autophagic/lysosomal impairment, thereby promoting MBV formation and the exosomal release of misfolded αSyn. NIH grants ES026892, NS088206 and Eugene & Linda Lloyd endowed Chair.

2219 Mitochondria-Targeting Pesticides Modulate Elongator Protein 3 (ELP3) Function to Enhance Dopaminergic Neurotoxicity in Cell Culture and Animal Models of Parkinson’s Disease

Exposure to neurotoxic pesticides targeting mitochondria is linked to pathogenesis of Parkinson’s disease (PD), but the molecular mechanisms underlying the enhanced vulnerability of dopaminergic neurons to mitochondrial toxicants are not fully understood. In a serendipitous finding, we observed that mitochondria-targeting pesticides affect the novel lysing antigen ELP3 and map in the trafficking machinery of cell cultures and in rodent models of PD. Exposing N27 dopaminergic neuronal cells to tebufenpyrad (Tebu; 3 μM) increased ELP3 mRNA expression within 1 hr and then subsided over time. After further characterization of ELP3 expression in the mouse brain, we found high expression of full length ELP3 (62 KDa) in the cytosolic fraction from different brain regions, while the shorter form (~40 KDa) was detected in the mitochondrial fraction of the olfactory bulb (OB). Immunocytochemical analyses revealed that ELP3 is highly expressed in TH-positive neurons of the OB. Furthermore, OB slice cultures treated with Tebu showed reduced expression of short ELP3 in the mitochondrial fraction when treated for 6 hr. We also found that ELP3 expression was reduced significantly in the mitochondrial fraction of OB from A353 rat model as well as MitoPark.
While cell signaling mechanisms underlying neurotoxic injury have been actively studied in recent years, signaling molecules contributing to compensatory survival signaling are largely unknown. Recently, we reported that the secretory neuroepitope prokinetin-2 (PK2) is upregulated during early stages of neurotoxic stress and plays a major compensatory protective function in nigral dopaminergic neurons. In this study, we characterized the transcriptional regulatory mechanisms of MPP+-induced PK2 upregulation. In silico analysis of the PK2 promoter region detected binding sequences for the key oxidative stress-related transcription factor, hypoxia-inducible factor (HIF), and the early growth response (EGR) transcription factors associated with neuronal survival and differentiation. We validated the in silico findings by cloning the 5’-flanking region (1 kb) of the human PK2 gene into a luciferase reporter vector, which was then transfected into MIN9D dopaminergic neuronal cells to study the PK2 gene regulatory mechanism. Overexpression of EGR1 or HIF1α, and treatment with the HIF1α activator 3,4-dihydroxybenzoate (DHB), significantly upregulated PK2 promoter activity and upregulated PK2 expression in MIN9D dopaminergic neuronal cells, suggesting that EGR1 and HIF1α are potent transcriptional activators of PK2 expression. MPP+ treatment in N27 dopaminergic cells also induced PK2 upregulation, which correlated with HIF1α and EGR1 protein levels. Next, we generated stable EGR1 knockdown (KD) N27 cells using a CRISPR-Cas9-based method. Time-course studies with EGR1-KD cells revealed that MPP+-induced PK2 mRNA expression was not significantly reduced until the later stages of neurotoxicity (6-12 h). These results suggest that EGR1 is required to induce a sustained PK2 upregulation during neurotoxic stress. Taken together, these data suggest that HIF1α and EGR1 families of transcription factors play a key role in PK2 upregulation and its compensatory response during early stages of neurotoxic insults in dopaminergic neuronal cells. NIH grants NS0728247, ES027245, Eugene Linda Lloyd Chair and Salsbury Chair.

2220 Transcriptional Regulation of the Compensatory Signaling Neuropeptide Prokinetin-2 by HIF1α and EGR1 during Neurotoxic Stress in Dopaminergic Neuronal Cells

2221 Pesticide Exposure Induces Mitochondrial Dysfunction and Inflammation in Enteric Glial Cells

Commonly used pesticides such as rotenone and tebufenpyrad are known to inhibit mitochondrial respiratory chain (complex I). Persistent pesticide-induced mitochondrial dysfunction and the resulting oxidative damage can promote chronic inflammation and have been linked to various disease conditions including Alzheimer’s disease (AD) and Parkinson’s disease (PD). In the present study, we examined the effects of rotenone and tebufenpyrad exposure on mitochondrial function and inflammation in enteric glial cells (EGCs). Despite evidence of gastrointestinal inflammation in PD, the mechanism of this inflammation in gastrointestinal abnormalities has not been studied in detail. Exposure to these two pesticides significantly reduced cellular metabolic activity with no effect on cell death as revealed by cell viability and cytotoxicity assays. Morphological analysis revealed that rotenone and tebufenpyrad significantly increased mitochondrial circularity, indicating augmentation of mitochondrial fission. Furthermore, pesticide exposure in EGCs led to a decrease in the mitochondrial fusion protein Mfn2, which according to colocalization studies, was shuttled out of mitochondria, indicating a loss of mitochondrial fusion. Furthermore, pesticide exposure further enhanced mitochondrial superoxide generation in EGC. The Seahorse mitochondrial bioenergetics analysis in pesticide-exposed EGCs showed impaired mitochondrial function as evident from reductions in ATP generation and basal respiratory rate. We recently demonstrated that mitochondrial dysfunction leads to inflammation in astrocytes and microglia. Here, we show that pesticide exposure increased pro-inflammatory factors in EGCs, and that this increase correlates with the loss in mitochondrial mass. ICC analysis revealed that rotenone and tebufenpyrad treatments led to formation of stress granules in EGCs, suggesting a possible role of stress-induced inflammation. Collectively, our studies demonstrate for the first time that neurotoxic pesticides impair mitochondrial bioenergetics, activate inflammatory pathways in EGCs, and induce stress granule formation, further augmenting proinflammatory events in the gut. Our findings have important implications in the pathogenesis and progression of environmentally-linked PD. NIH grants ES026892 and ES027245 and Eugene and Linda Lloyd Endowed Chair.

2222 Mechanisms of Harmane-Induced Selective Dopaminergic Neurotoxicity in Caenorhabditis elegans

S. R. Sammi, Z. S. Agim, and J. R. Cannon. Purdue University, West Lafayette, IN.

Dietary factors are of emerging interest in the etiology of Parkinson’s disease (PD). Heterocyclic amines (HCA) have attracted significant attention over the last few years due to structural resemblance to known PD-relevant toxicant and also because of prevalence in the diet. 1-methyl-9H-pyrido[3,4-b]indole (harmane) is a β-carboline (a HCA subclass). Harmane is a known tremorigenic agent which is found in cooked meat, roasted coffee beans, and tobacco. Given the structural similarity to other neurotoxicants and published clinical reports, we hypothesized that harmane would be selectively toxic to dopamine neurons. Here, we used C. elegans as a model system to allow determination of selectivity toxicity across numerous doses. Nematodes were exposed for 48 hours within dose range 100 to 500 μM. These doses were based on established neurotoxic nematode PD models and recommended guidelines for neurotoxicity testing in this species. Using numerous reporter strains, we found that dopaminergic neurons were selectively sensitive to harmane-induced neurodegeneration versus serotoninergic, GABAergic and cholinergic neurons. Further, we examined mechanisms of harmane-induced dopaminergic neurotoxicity. Harmane treatment caused decreased mitochondrial viability and increased reactive oxygen species. Inhibition of the dopamine transporter (DAT) was protective, suggesting that harmane does not enter dopamine neurons through DAT, as do many other dopaminergic neurotoxicants. In contrast, treatment with the mitochondrial complex I activator partially ameliorated neurodegeneration, reducing harmane-induced behaviors consistent with dopamine depletion (1-nanomol assay). Our studies suggest that in vivo harmane is selectively toxic to dopaminergic neurons. Further, mitochondria are a likely primary neurotoxic target. Our results suggest that additional mechanistic studies and neuropathology studies in higher order species be conducted to determine relevance in PD etiology.

2223 A Platform to Study the Effects of Complex Environmental Exposures on Aging and Neurodegeneration in Caenorhabditis elegans

V. Kalia, J. Bradner, M. A. Johnson, M. Chen, T. Durham, M. Niedzwiecki, D. Walker, D. Jones, and G. Miller. Emory University, Atlanta, GA.

Neurodegeneration has a complex etiology, driven by genetic, environmental, and aging risk factors. Interactions between these factors remain unclear. We propose an experimental framework to assess the relationship between environmental exposure, dopamine homeostasis, and aging in C. elegans that uses a multi-faceted approach combining high-resolution metabolomics (HRM), exposomics, and high-content imaging through parallel electron microscopy over >350 environmental chemicals and their metabolites using gas-chromatography (GC) with high-resolution mass spectrometry and associated biological response by HRM, this framework provides a measure of exposure, internal dose, and biological response. As proof of principle, we measured effects of exposure in wild-type worms to a known neurotoxicant, manganese. Exposed worms showed depleted levels of glutathione, measured by HPLC. Using HRM, we were able to detect ∼3,000 features post-processing and blank subtraction. Using the Mummichog pathway analysis tool, pathways related to amino acids, glutathione and keratan sulfate metabolism were altered in exposed worms. These results support a role of HRM in detecting metabolic perturbations from environmental exposures in worms. Research from our lab and others has shown that disruption of vesicular monoamine transporter 2 (VMAT2; SLC18A2) confers vulnerability to dopamine toxicity in mice and Parkinson’s disease (PD) patients. Using automated lifespan analysis, wild-type worms had a median (SD) survival time of 11.4 (6.0) days, which increased to 13.5 (4.0) days in cat-1 (worm VMAT2 orthologue deletion) mutants. The short-lived
Parkinson’s disease (PD) is a devastating neurological disorder affecting over 1.5 million people in the United States. Over 85% of cases are idiopathic and exposures to certain environmental chemicals have been suggested to play a role in disease etiology. To this end, a screening of the published literature was developed using systematic review methods to identify studies reporting on neuropathological endpoints associated with PD and environmental exposures. A PubMed search identified 91,598 records potentially relevant to PD endpoints, which were further screened in a systematic manner. Evidence from in vivo and in vitro studies was also included. A total of 44,340 original research records reporting potential studies of PD and environmental chemicals was identified with most studies reporting well-established PD-related pharmaceutical and environmental chemicals including dopamine (DA), α-synuclein (α-syn) and environmental stress. Evidence from both PD patients and general populations was included. The results of this review are presented in a systematic evidence map that allows users to interactively visualize and query the dataset.

### 2222 Structure-Function Studies in Caenorhabditis elegans of the Organometallic Fungicide Manzate Indicate Mechanisms for Neurodegeneration

S. Kennedy^1^, S. B. Cole^1^, R. Frye^1^, L. Vaughan^1^, and V. A. Fitkanakis^2^,^3^.

^1^King University, Bristol, TN; and ^2^Northeast Ohio Medical University, Rootstown, OH.

Exposure to the commercial fungicide Manzate (cMZ) has been associated with the development of neurodegenerative diseases. The contribution of each component of this organometallic pesticide (manganese [Mn], zinc [Zn], and ethylene-bis-dithiocarbamate) to human toxicity remains unknown, although some epidemiology studies suggest Mn exposure may increase the risk of PD or parkinsonism. Since we previously observed neurodegeneration of dopaminergic and GABAergic neurons in Caenorhabditis elegans (C. elegans) treated with cMZ, we sought to investigate which chemical components of the active ingredient might promote this neurodegeneration. Therefore, we treated various strains of C. elegans with cMZ, the purified active ingredient, mancozeb (MZ), or two structural analogs, maneb (MB; Mn only, no Zn), or zineb (ZB; Zn only, no Mn). After a 24-h incubation with the respective compounds, general nervous system morphology was evaluated by assessing the pattern and intensity of green fluorescent protein tagged (GFP-labeled) neurons in transgenic worms. In these studies, treatment with MZ resulted in a statistically significant decrease in fluorescence compared to controls (**p < 0.01) in the nerve ring, which is predominantly dopaminergic neurons, compared to all other compounds. We then assayed the mitochodrial proton gradient using tetramethylrhodamine ethyl ester (TMRE). Although there were no statistically significant differences in overall fluorescence, we did observe a punctuated mitochondrial pattern in worm strains with PD-related genetic mutations. This pattern was qualitatively different from that of control worms, and is consistent with changes in mitophagy, mitochondrial fusion and fission, and general mitochondrial trafficking. Finally, we observed increases in oxidative stress, as assessed by increased fluorescence in worms treated with cMZ-labeled glutathione-S-transferase, when these worms were treated with cMZ. Data from all three studies are consistent with our previous work using the commercial formulation of this fungicide. Taken together, these data suggest that treatment with cMZ, as well as the purified MZ, may negatively affect the dopaminergic neurons in C. elegans, and may do so by altering mitochondrial trafficking and increasing oxidative stress.

### 2225 Parkinson’s Disease and Environmental Chemical Exposure: A Systematic Evidence Map

Parkinson’s disease (PD) is a devastating neurological disorder affecting over 1.5 million people in the United States. Over 85% of cases are idiopathic and exposures to certain environmental chemicals have been suggested to play a role in disease etiology. To this end, a screening of the published literature was developed using systematic review methods to identify studies reporting on neuropathological endpoints associated with PD and environmental exposures. A PubMed search identified 91,598 records potentially relevant to PD endpoints, which were further screened in a systematic manner. Evidence from in vivo and in vitro studies was also included. A total of 44,340 original research records reporting potential studies of PD and environmental chemicals was identified with most studies reporting well-established PD-related pharmaceutical and environmental chemicals including dopamine (DA), α-synuclein (α-syn) and environmental stress. Evidence from both PD patients and general populations was included. The results of this review are presented in a systematic evidence map that allows users to interactively visualize and query the dataset.

### 2226 Autophagic Dysfunction in Brainstem Nuclei in a Preclinical Parkinson’s Disease Model

Purdue University, West Lafayette, IN.

A lesion to the nigrostriatal dopamine system is primarily responsible for cardinal motor features of PD. MRI studies of Parkinson’s disease (PD) patients have found abnormalities in many other brain regions are affected, where widespread α-synuclein pathology occurs. α-Synuclein is a pivotal protein in PD, as it is a major component of intracellular aggregates known as Lewy bodies. Interestingly, α-synuclein pathology occurs systemically and in other brain nuclei before the nigrostriatal dopamine system is affected, where it is postulated that pathology ascends from the lower brainstem, through the nigrostriatal pathway until it reaches the neocortex. Autophagy is one route of α-synuclein clearance and autophagy dysfunction occurs in PD prior to Lewy body formation. We hypothesized that a PD relevant dopaminergic neurotoxin would produce autophagic dysfunction in a pattern similar to that in PD. Thus, we expected brainstem nuclei to be affected prior to the substantia nigra. To test our hypothesis, we utilized a rat rotenone PD model, where rats were treated with 3.0 mg rotenone/kg per day for either 24 h, 5 d, or until death. The 24 h and 5 d rats were analyzed at PD phenotype developed. The 24 h and 5 d rats exhibited an abnormal brainstem morphology. We previously showed autophagic disruption and α-synuclein aggregation in this model is associated with co-localization of optineurin (OPTN), a known cargo adaptor in autophagy. OPTN has also been implicated as a genetic risk factor for PD. The present study focused brain regions identified in early-stage PD (DAVY, P97, RMG, LC, SNpc). Autophagic stress in these regions was assessed through LC3 staining. We detected OPTN expression in all tested regions, and OPTN was colocalized with LC3 or α-synuclein. Further, we found OPTN expression and average number of puncta were significantly increased in all stages and in multiple brain regions. Our results indicate these brain regions may be inherently distinct in their basal autophagic activity (e.g. the locus coeruleus had twice as many LC3 puncta than the nigra in control rats). Our data suggest that these regions likely vary in their autophagy response to rotenone, with the substantia nigra pars compacta being the most sensitive. These data suggest OPTN may have a role in PD. Further research is necessary to determine whether α-synuclein aggregates for autophagic degradation. Finally, these data implicate basal autophagic activity as a potential factor for neuronal vulnerability in PD pathogenesis.

### 2227 Levodopa and Dopamine Dynamics in Parkinson’s Disease Metabolomics

Emory University, Atlanta, GA.

Parkinson’s disease (PD) is a progressive neurological disorder caused by a combination of genetic and environmental factors. Metabolomics is a powerful tool that can help answer the question of how thousands of chemicals within a biological sample. Metabolomics is used to identify potential biomarkers, exogenous toxicants, and metabolic network changes that predict disease states. Here, we used liquid-chromatography-mass spectrometry-based high-resolution metabolomics to characterize and compare over 10,000 plasma metabolites from older adults with and without PD in an untreated way. We perform a network analysis that demonstrates that the presence of the PD drug levodopa influences variation observed between PD and control patients. We also perform metabolome wide t-tests, OPLS-DA, and PCA analyses. These analyses show a significant differentiation in the metabolomics profile of older adults with and without PD. Notably, 15 metabolites (ten of which we putatively identified) were significantly different between PD and control adults with p-values less than 0.05 and a corrected false discovery rate less than 0.2. Furthermore, 13 metabolic networks were identified to be functionally different between PD and disease patients. Lastly, dopaminergic toxic intermediates (DOPAL, m/z 153.0548) differed between patient populations, supporting the dopaminergic dysfunction in this model. This work suggests that levodopa may contribute to the metabolic perturbations observed in PD.
sequestration model of PD. These individual metabolites and metabolic networks have been implicated in past PD pathogenesis models, including the beta-carboline harmalol (m/z 223.0846) and the glycosphingolipid metabolism pathway (including the ganglioside GM2, m/z 1427.752). We recommend that future studies take into account the confounding effects of levodopa in metabolic analysis of disease versus control patients, and encourage validation of several promising metabolic markers of PD.

Epidemiological studies have given rise to possible etiologies of Parkinson’s disease (PD), especially farmers exposed to toxicants. The herbicide paraquat is similar in structure to the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and redox cycling of MPTP to NADPH-oxidase to reactive oxygen species (ROS). Excessive ROS and microglial activation can damage neurons and is thought to contribute to the initiation and progression of neurodegenerative diseases, including PD. HV1 is a voltage-gated proton channel selectively found in microglia and other immune cells where it regulates NADPH-oxidase-dependent production of ROS. Deletion of HV1 in mice has been found to protect neurons from oxidative damage during ischemic stroke, but there have been no studies of HV1 in PD. The purpose of this study was to determine the role of HV1 in paraquat-induced neurodegeneration. In vitro studies with the BV2 mouse microglial cell line demonstrated that while paraquat does not directly activate microglia, it induces HV1 gene expression by 2-3-fold. To assess the effect of HV1 in the microglial response to paraquat-induced neuronal damage, we exposed primary microglial cells from C57BL/6J and HV1KO (HV1 knockout) mice to conditioned media from N27 dopaminergic neuronal cells treated with paraquat. The paraquat-treated N27 conditioned media induced HV1 and iNOS gene expression by 4- and 3-fold, respectively, in C57BL/6J microglia, which was significantly attenuated in HV1KO microglia. Similarly, conditioned media from paraquat-treated N27 cells increased ROS formation in C57BL/6J microglia, an effect that was completely abolished in HV1KO microglia. Preliminary data from in vivo studies with C57BL/6J and HV1KO mice exposed to repeated injections of paraquat showed that there was no significant dopamine neuron loss in HV1KO mice. These data demonstrate that paraquat regulates HV1 expression, HV1 is involved in the paraquat-induced production of microglial ROS, and genetic knockout of HV1 reduces this microglial inflammatory response. Thus, HV1 appears to be a key regulator of microglial activation and dopamine neuron vulnerability to paraquat. Supported by R01ES021800 and The Michael J. Fox Foundation.

Role of Reactive Metabolites of Dopamine in Pesticide Neurotoxicity

Pesticide exposure has been shown to be linked with Parkinson’s disease (PD) and other neurodegenerative disorders. One hypothesis is that pesticides lead to interuption in dopamine metabolism and trafficking, yielding a buildup of toxic intermediates such as aldehydes, which is termed the “catechol-aldehyde hypothesis.” Dopamine (DA) is metabolized to a toxic catechol-aldehyde - 3,4-dihydroxyphenylacetaldehyde (DOPAL) - by monoamine oxidase (MAO) and then detoxified by aldehyde dehydrogenase (ALDH). ALDH has been shown to be inhibited by lipid peroxidation products such as malondialdehyde and 4-hydroxynonenal which increase in the presence of pesticides such as dieldrin. Therefore, pesticide exposure can cause inhibition of ALDH leading to increased DOPAL concentrations. DOPAL can cause toxicity in several ways including modifying proteins or forming protein adducts, as well as oxidation to a reactive semiquinone radical which leads to additional toxicity. One protein of interest is the dopamine transporter (DAT). This work shows that treatment of dopaminergic N27 cells with DOPAL at non-toxic concentrations lead to decreased expression of DAT possibly through protein modification. DOPAL modified DAT could have decreased functionality leading to irregularities in dopamine (DA) cell trafficking. We have isolated proteins modified by DOPAL using an affinity resin. In addition, this study examined how DA metabolism is affected by organophosphate and pyrethroid pesticides, specifically chlorpyrifos and cypermethrin. These are both insecticides that are neurotoxic to insects as well as humans. Cypermethrin has been shown to cause nigrostriatal degeneration with long-term exposure and may be acting synergistically with chlorpyrifos. Using dopaminergic N27 cells, it was found that neither cypermethrin nor chlorpyrifos were toxic at low micromolar concentrations; however, a decrease in the level of DAT was observed following cypermethrin treatment. Understanding the mechanism of these insecticides and how they affect dopamine metabolism will further our understanding of PD and neurodegenerative diseases and be helpful in developing therapeutic strategies.

Toxicity, Recovery, and Resilience in a 3D Dopaminergic In Vitro Model Exposed to Rotenone

G. Harris1, M. Eschment2, D. Freeman1, D. Freeman1, P. David1, H. Hogberg1, J. Delp1, T. Hartung2, and L. Smirnova1. 1 Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; and 2 University of Konstanz, Konstanz, Germany.

The paradigm shift towards pathway-based toxicology involves moving away from animal tests into 3D in vitro models which could be more predictive for human toxicity. To date, most in vitro toxicity testing focuses on acute effects of compounds at high concentrations. This testing strategy does not reflect real-life exposures contributing to long-term disease outcome. In the area of Parkinson’s disease, we still do not understand the mechanisms behind gene-environment interactions which modulate risk. Studying recovery mechanisms can indicate which genes are important in repair after an environmental exposure. Using a well-characterized 3D-human, dopaminergic, in vitro model we investigated whether acutely-induced molecular effects are permanent or reversible. We analyzed the effects of rotenone (100 nM), a known Parkinson’s inducer, after acute exposure (24h) and 7 days after compound wash-out using cell viability, qPCR, cellular ATP, electrical activity, dopamine release and neurite outgrowth assays. We identified in vitro pathways (NOSA, OPTN and PKIN1) and reversible changes in gene expression (ATF4, ATP50 and KEAP1). Acute exposure to 100 nM rotenone (non cytotoxic) led to a decrease in neurite outgrowth (~50%) and cellular ATP (~25%), however, cells recovered after wash-out. To further study cellular neuroprotective mechanisms, cells were re-exposed after recovery. Pre-exposed cells showed higher metabolic activity (resilience, ~50% increase in resazurin reduction) than controls and changes in gene expression (VAMP1, PKIN1, PARK7) were observed. To compare cellular recovery to repeated-dose effects, we treated 3D Luhmes with 30 nM rotenone (a relevant in vivo concentration) every 48 h. This exposure is shown to induce Parkinson’s in animal models. Our results indicate that cells are able to recover from low-dose rotenone-induced decrease in ATP production and neurite outgrowth after wash-out, however, some changes to gene and protein expression are maintained after compound removal. Furthermore, pre-exposed cells may carry resilience to second exposures, shown by metabolic activity (resazurin reduction). This is the first study showing the complexity of recovery and delayed effects after compound removal and re-exposure in vitro.

The Effect of Paraquat on Cognitive Function and Emotional Reactivity in Mice Overexpressing Human a-Synuclein

Exposure to pesticides is an established risk factor for Parkinson’s disease (PD). PD is characterized by the degeneration of dopamine neurons in the substantia nigra and the development of alpha-synuclein (αsyn) positive Lewy bodies. Behaviorally, patients develop both motor and non-motor impairments. The non-motor impairments associated with PD can include cognitive and neuropsychiatric symptoms, and can be more debilitating to patients than the motor symptoms. Paraquat (PQ) is an herbicide strongly linked to PD, with systemic administration causing degeneration of nigrostriatal dopamine neurons and αsyn pathology in animals. However, the role of PQ in cognitive and neuropsychiatric function is unclear. In the present study, the effect of PQ on cognition and fear reactivity was tested in an established transgenic model of PD, αsyn overexpressing mice (Thy1-αsyn). Male and female Thy1-αsyn mice received injections of vehicle or PQ solution starting at 6-8 weeks of age (10 mg/kg b.w./day, 5x/week for 8 weeks, 5x/week for 8 weeks, and 5x/week for 8 weeks, 5x/week for 8 weeks, and 5x/week for 8 weeks, 5x/week for 8 weeks, and 5x/week for 8 weeks). One day following the third injection, mice were tested behaviorally for PQ alone or in combination with increased aSyn expression. In object recognition and elevated plus maze tests, PQ impaired sensorimotor function, object recognition, and emotional reactivity. PQ caused a significant decrease in spontaneous activity only in Thy1-αsyn mice. In object recognition and elevated plus maze tests, PQ impaired recognition and reduced reactivity in both WT and Thy1-αsyn mice. These data indicate that PQ alone or in combination with increased αsyn burden is associated with cognitive and neuropsychiatric alterations in vivo.
2233 Potential Protective Effect of Silybin against Central Nervous System Dysfunction

Silymarin is obtained from Silybum marianum (milk thistle), an edible plant with an excellent hepatoprotective action. The mayor component of the silymarin complex is silybin, which is the most active phytochemical. Silybin [(2R,3R)-3,5,7-trihydroxy-2-(2R,3R)-3,4-hydroxy-3-methoxyphenyl]-2-(hydroxy-methyl)-2,3-dihydro-benz[b][1,4] dioxin-6-yl]isochroman-4-one] is a flavonoid with anti-inflammatory and antioxidant activity of glutamatergic motoneurons. We will now use pharmacological and genetic probes to test this hypothesis. We suggest that interactions between aminergic and glutamatergic neurons we are investigating could be relevant to early events in the pathophysiology of PD.

2234 Determination of Pyrethroid Toxicodynamic Differences in Adult and Juvenile Rat Brain Tissue Microtransplanted into Xenopus Oocytes

S. B. Symington1, A. C. Toltin1, E. Murenzi2, and J. Clark2. 1Salve Regina University, Newport, RI; and 2University of Massachusetts, Amherst, MA.

Microtransplantation of mammalian neurolemma is a tool to examine the endogenous structure and function of transmitter receptors and ion channels associated with the central nervous system. Microtransplanted neurolemma can originate from a variety of sources, posses ion channels and receptors in their native configuration, and are applicable to examine diseases associated with different channelpathies. In these experiments, we examined the age-related differences in VSSC expression and concentration-dependent responses to pyrethroids in juvenile and adult rat brain tissue microtransplanted in Xenopus oocytes. Automated western blotting results indicate that adult neurolemma exhibited 2.5-fold higher level of expression. These results correlated with juvenile neurolemma when normalized to the housekeeping protein β-tubulin. The predominate isoform expressed in both tissues was Na1.2 with both showing a significant difference from zero. Adult neurolemma, however, expressed 2.8-fold more Na1.2 than juvenile and also express Na1.6 at a higher level (2.2-fold). In addition, neurolemma tissue microtransplanted into Xenopus oocytes showed reconstituted native ion currents in the plasma membrane of oocytes that was sensitive to TTX and abolished by choline ion replacement, functionally demonstrating the presence of VSSC. Increasing concentrations of permethrin and deltamethrin exhibited concentration-dependent increases in TTX-sensitive current from both adult and juvenile tissues. Concentration-dependent response curves were analyzed using the equivalence test and the slopes of the curves were different. VSSCs associated with juvenile neurolemma was up to 2.5X more sensitive to pyrethroid than VSSCs in adult neurolemma. In contrast, VSSCs from juvenile neurolemma were less sensitive than adult VSSCs at lower concentrations (0.6-0.8X) and more sensitive at higher concentrations (up to 2.4X). However, because the expected brain concentrations in humans following realistic exposure levels are approximately 21- (deltamethrin) to 333- (permethrin) times below the threshold for response in rat neurolemma, age-related differences, if any, are not likely to be toxicologically relevant.

2235 Effects of Acute Exposure to Deltamethrin in the Nucleus Accumbens

C. M. Tapia, and F. Laeza. University of Texas Medical Branch, Galveston, TX.

Deltamethrin (DM), a commonly used pyrethroid insecticide, exerts its effect on insects by delaying onset of inactivation in voltage gated sodium (Nav) channels fundamental for neuronal excitability. Due to species cross reactivity and the high evolutionary conservation of Nav channels, there is reason to study the effects of DM in humans. Epidemiological data showed a correlation between pyrethroid metabolites in urine and increased risk of ADHD diagnosis in children. In rats, exposure to DM results in behavioral phenotypes that mimic aspects of ADHD and are associated with the dopaminergic (DA) reward pathway in the nucleus accumbens (NAc). Disregulation of DA medium spiny neurons (MSNs) in the NAc is thought to play a critical role in neuropsychiatric disorders like ADHD, anxiety, and depression. The Nav 1.6 channel, critical in synaptic transmission, is abundant in the MSNs. All this evidence provided a strong scientific basis to investigate a possible causative link between exposure to DM and dysfunction of MSNs as the source of increased risks of ADHD. Previous electrophysiological studies in HEK 293 cells stably expressing human Nav 1.6 identified DM induced alterations in Nav channel function. After 1hr of 10 uM DM treatment, Nav 1.6-mediated persistent and tail currents were significantly potentiated. At ~20mV, Nav 1.6 encoded persistent current densities were increased from DMSO control (~0.4±0.6 pA/pF, n=6) with 10uM DM application (9.2±2.4 pA/pF, n=20, p<0.01). Tail currents were also significantly potentiated from 5.9±1.5 pA/pF (n=10) in DMSO control cells to 25.1±4.1 pA/pF (n=20, p<0.001) with 10μM DM. Use dependent activity was studied to determine how DM affects the fraction of Nav 1.6 channels at the open state. Use dependent protocol at 50mV for DM exposed cells, significantly increased amount of persistent (DMSO -3.5±1.8pA/pF, n=12, p<0.01). DM 11.8±2.5 pA/pF, n=19) and tail currents (DM 14.3±3.6 pA/pF, n=12, p<0.01. DM 45.5±5.7 pA/pF, n=20, p=0.01). Ongoing studies aim to investigate DM effects on MSN intrinsic excitability after acute exposure to brain slices. These studies will advance our knowledge of the toxic activity of DM in the brain and help assess risk exposure in the human population.
E. Santos, M. Gray, E. Church, E. Vu, E. Hawkins, K. Phillips, and L. S. Deshpande. Virginia Commonwealth University, Richmond, VA.

Chronic exposure to organophosphates (OP) during deployment is considered a leading cause for Gulf War Illness (GWI), yet its pathobiology is not fully understood. Disruptions in neuronal calcium (\(Ca^{2+}\)) homeostasis are observed in many neurological disorders and in line with this, we recently observed chronic elevations in neuronal \(Ca^{2+}\) levels in an OP: diisopropyl fluorophosphate (DFP) based rat model of GWI. Sustained release of \(Ca^{2+}\) from the intracellular stores was found to be a major source for these \(Ca^{2+}\) elevations since in vitro treatment with levetiracetam, a mixed IP3/RyR antagonist, normalized \(Ca^{2+}\) levels in GWI neurons. In this study, we investigated whether treatment with levetiracetam could help improve neurological symptoms in GWI rats. Male Sprague-Dawley rats (9 wks) were exposed to DFP (0.5 mg/kg, s.c. 1x daily, 5 d). At 6 mos post-DFP exposure, rats were assessed using forced swim test (FST) for depression, elevated plus maze (EPM) for anxiety, and novel object recognition (NOR) for memory deficits. Levetiracetam (50 mg/kg, ip) was injected 30 min prior to behavioral assays in both GWI and age-matched control rats. Rats were tracked using Ethovision XT 10.2 and behavior was scored by two independent observers. DFP-treated rats exhibited significant deficits on FST, EPM, and NOR compared to control rats, indicating presence of chronic GWI neurological morbidities. GWI rats treated with levetiracetam exhibited significantly decreased immobility time on the FST (81 ± 7 vs 127 ± 12s respectively), exhibited increased exploration the open-arm of the EPM (12 ± 3 vs 29 ± 4% respectively), and spent more time with the novel object on the NOR test compared to non-treated GWI rats (69% vs 55% respectively, n= 6 rats). No such effects were observed in levetiracetam-treated age-matched control rats. Levetiracetam treatment in GWI rats significantly improved performance on FST, EPM, and NOR tests compared to non-levetiracetam-treated GWI rats. Interestingly, levetiracetam had no effect on the behavior of age-matched control rats. Our studies suggest that therapeutic targeting of intracellular \(Ca^{2+}\) stores with drugs like levetiracetam could be effective therapy for GWI neurological symptoms.

L. S. Deshpande, K. F. Phillips, and R. E. Blair. Virginia Commonwealth University, Richmond, VA.

About one-third of the Persian Gulf War veterans exhibit Gulf War Illness (GWI) symptoms, particularly depression and memory deficits. Chronic exposure to organophosphates (OP) is among multiple causes for GWI, yet its pathobiology remains ill understood. The role of calcium \(Ca^{2+}\) signaling in memory and mood is well established. In an OP:diisopropyl fluorophosphate (DFP)-based rat model of GWI, we observed disruptions in neuronal \(Ca^{2+}\) levels (\(Ca^{2+}\)i). This study is aimed at identifying mechanisms underlying elevated \(Ca^{2+}\) and investigating whether their therapeutic targeting could improve GWI neurological morbidities. Male Sprague-Dawley rats (9 wks) were exposed to DFP (0.5 mg/kg, s.c. 1x-daily for 5 d) and behavior was assessed at 3 mos post-DFP exposure. Ratiosmetric \(Ca^{2+}\) indicator Fura-2AM was used for \(Ca^{2+}\) estimation in acutely isolated hippocampal neurons. Pharmacological blockers for different routes of \(Ca^{2+}\) entry were used in vitro. Levetiracetam was used to target calcium stores in vivo and rats were assessed for behavioral symptoms. CA1 neurons from GWI rats manifested \(Ca^{2+}\)i of 399 ± 36 nM, that were significantly higher than \(Ca^{2+}\)i from age-matched control rats (208 ± 16 nM). Application of nifedipine (5 μM), DNQX (10 μM), or GdCl3 (100 μM) did not significantly affect \(Ca^{2+}\) in GWI neurons. In contrast, application of dantrolene (50 μM) or levetiracetam (100 μM) significantly lowered elevated \(Ca^{2+}\) in GWI neurons (240 ± 11 nM and 250 ± 19 nM, respectively, n= 5 animals, paired t-test). GWI rats treated with levetiracetam (50 mg/kg, ip) showed a significant reduction in immobility time on the forced swim test and improved performance on the open-arm of the elevated plus maze. Sustained \(Ca^{2+}\) elevations in GWI neurons had their origin in \(Ca^{2+}\) release from intracellular \(Ca^{2+}\) stores. The application of rydonanide (IP3 receptor antagonist) dantroline or levetiracetam produced greater than 50% reduction in their levels. Treatment with levetiracetam significantly improved symptoms of depression and anxiety in GWI rats. Since \(Ca^{2+}\) is a major second messenger molecule, such chronic increases in its levels could produce pathophysiological changes that express itself as GWI morbidities. Our studies show that treatment with drugs targeted at blocking intracellular \(Ca^{2+}\) release could be effective therapies for GWI.

Chemical warfare nerve agents (CWNAs) such as sarin and VX continue to be a global threat. Animal models are critical for evaluating the efficacy of Cyna medical countermeasures, and a thorough characterization of available animal models is important for translating results to humans. Disruption of cholinergic function due to inhibition of acetylcholinesterase (AChE) is the primary mechanism of toxicity of CWNAs, and reactivation of inhibited AChE with pralidoxime (2-PAM) is one of the primary therapeutic strategies. CWNAs also inhibit butyrylcholinesterase (BChE) without any apparent toxic effects; rather, BChE acts as a bioscavenger that binds CWNAs and removes them from circulation. The degree of inhibition of AChE and BChE by CWNAs and selectivity of 2-PAM are known to vary between species. The objective of this study was to compare key properties of human AChE and BChE to the same enzymes derived from six commonly used large animal models. The enzyme activity and the characteristics of inhibition and reactivation of AChE and BChE were evaluated in isolated RBC membranes and plasma from the whole blood of human volunteers, as well as from different animal species. As these effects occur at concentrations below effect concentrations for AChE inhibition, the combined results indicate that other nerve agents may play a role in the neurotoxicity of OP insecticides. Funded by ZomMW (#114027/001) and the Faculty of Veterinary Medicine (Utrecht University, The Netherlands).
Temporal Variation in Rat Pulmonary Mechanics following Single Chlorpyrifos Exposure

F. Shaffo, P. Lein, A. Grodzki, and E. Schelegle, University of California Davis, Davis, CA.

Occupational and environmental organophosphorus pesticides (OP) exposures are associated with increased incidence of asthma and other pulmonary diseases. While the canonical mechanism of OP neurotoxicity is inhibition of acetylcholinesterase (AChE), this inhibition is short-lived and likely not involved in persistent pulmonary dysfunction. It was previously demonstrated that the OP chlorpyrifos (CPF) causes airway hyperreactivity (AHR) in rats 24 hours after a single exposure to a dose that causes significant AChE inhibition in the lung, but not in the brain or blood. Preliminary data also suggested that neurogenic inflammation progresses after this exposure, as determined by an increased expression of the neuropeptides substance-P (SP) and calcitonin gene-related peptide (CGRP) in sensory neurons of the dorsal root ganglia (DRG) that innervate the lung. Based on these observations, it was hypothesized that AHR persists after 24 h, and that this persistence is driven by neurogenic inflammation. To test this hypothesis, eight-week old male Sprague Dawley rats were dosed with CPF (30 mg/kg s.c.) and their pulmonary mechanics in response to electrical stimulation of the vagus nerves were assessed at 1, 2, 3, or 7 days post exposure using a Flexivent mechanical ventilator. Following physiological assessment, DRG were collected, fixed, and immunostained for SP and CGRP. CPF significantly increased airway resistance response to electrical vagal stimulation at 24 hours post-exposure, but did not significantly increase this response at later time points. Unexpectedly, lung elastance response to electrical vagal stimulation was significantly increased at 7 d post-exposure. While changes in resistance correspond to constriction of the large conducting airways, increased elastance is consistent with greater constriction in the small distal airways. The latter coincides with an increase in SP and CGRP immunoreactivity in DRG. These data indicate that CPF-induced AHR may manifest in different lung compartments at different times post-exposure, and suggest that constriction of the distal airways at delayed times post-exposure is mediated by neurogenic inflammation. These findings have significant implications for assessing the risk posed by CPF, and potentially other OPs, to human health and safety. Work was supported by the NIH (grants 5RO1 ES017592 and T32 HL07013).

Copper Activation of Organophosphorus Compounds Detoxication by Chicken Serum Albumin

A. Monroy1, M. Sogorb2, and E. Vilanova2. 1 Universidad Autonoma del Estado de Morelos, Cuernavaca, Morelos, Mexico; and 2 Instituto de Bioingenieria, Universidad Miguel Herndez, Alicante, Spain.

O-hexyl O-2,5-dichlorophenyl phosphoramidate (HDCP) is a chiral analog of methamidophos insecticide that induced delayed neuropathy, the R(+-)HDCP inhibitor, and aging of the brain NTE. This enantiomer is not hydrolyzed by calcium-dependent phosphotriesterases in mammals tissues including the human serum paraoxonase-1 (PON1). Recently, our group has reported a relevant Cu2+-dependent hydrolysis of R(+-)HDCP in chicken serum using 20-250 µM copper in the ex vivo assays, calling it "antagonistic stereoselectivity". This study reported the identification of the responsible protein of "antagonistic stereoselectivity" in chicken serum using commercial animals metalloc-proteins with high affinity to Cu2+ and chiral chromatography method. Two hundred micrograms of human serum ceruloplasmin and horse kidney metallothionein did not show Cu2+-dependent hydrolysis of HDCP with low copper concentration (100 µM). Both proteins showed around 15% of hydrolysis of HDCP without stereoselectivity using 1 mM of copper. On the other hand, 10 µL of chicken serum or 216 µg of chicken serum albumin (CSA) (amount of albumin content in this serum volume) showed the same level (>30%) of Cu2+-dependent R(+-)HDCP hydrolysis at 60 and 120 minutes of incubation with 100 µM of copper. The incubation of CSA or human serum albumin (HSA) (216 µg) with 100 µM of different divalent cations (Cu2+, Zn2+, Fe2+, Ca2+, Mn2+ and Mg2+) showed that both proteins do not have this metal phosphotriesterase activity, except the copper in the CSA. These results confirm that the albumin is the protein responsible for "antagonistic stereoselectivity" in the chicken serum.

Increased Expression of Glial Cell-Derived Neurotrophic Factor (GDNF) and Transforming Growth Factor Beta 1 (TGF-β1) in the Hippocampus of Rats Exposed to Mancozeb Perinatally and during Adulthood

M. Akhtar, and L. D. Trombetta. St. John’s University, Jamaica, NY.

Mancozeb is a widely utilized pesticide with millions of pounds applied annually in the United States to control plant diseases in the field and during storage. Mancozeb and its metabolite ethylendithionoureia are known for causing thyroid toxicity, leading to altered thyroid function. Thyroid hormones are essential for the development of the mammalian nervous system. Hypothyroidism may lead to the reduction of newly generated neurons and altered differentiation in immature neurons of the dentate gyrus of the hippocampus. Impaired neurodevelopment due to environmental toxins, in this case Mancozeb, may lead to increased sensitivity to neurodegenerative changes, especially upon further challenge to environmental stressors during adulthood. GDNF and TGF-β1, both neurotrophic factors, have potential neuroprotective and cell survival effects especially during an insult. This study investigated the effects of Mancozeb on the modulation of GDNF and TGF-β1 in the hippocampi of rats exposed perinatally followed by re-exposure during adulthood. Time-pregnant Long-Evans dams were exposed to 0, 50, or 100 mg/Kg body weight Mancozeb from gestational day 7 (GD-7) to postnatal day 21 (PND-21). Pups from each group were re-exposed with the same dose as dams from PND-60 to PND-90. At the end of exposure, total blood thyroid (T4) levels were measured. Hippocampi were isolated and stored for later analyses by either qPCR for gene expression profiling or immunoprobing. Whole brains were also preserved for histological evaluation. T4 levels in Mancozeb exposed dams and all re-exposed treatment groups were significantly decreased. Mancozeb exposure significantly up-regulated the gene expression of Gdnf and Tgfb1 in the hippocampus of 50, and 100 mg/Kg re-exposure groups and 100 mg/Kg groups with or without re-exposure, respectively. Immunoprobing revealed significantly elevated proteins levels of GDNF and TGF-β1, which correlated with the qPCR data. In addition, hematoxylin and eosin (H&E) stained dentate gyrus showed multiple foci of vacuolated distended neurons with increased eosinophilic Mancozeb treated animals. These findings indicate that Mancozeb injury in the hippocampus leads to increased levels of neuroprotective and cell survival factors such as GDNF and TGF-β1, which warrant further investigation to elucidate their exact roles.
2244 A Mouse Model for Human Poisoning by Tetramethylenedisulfotetramine (TMDT): Parameters Influencing Intoxication and Treatment

M. Laukova1, F. Sannoh1, S. Pervez1, R. Rosman1, M. Veillard1, and M. P. Shakarjian1,2,1. New York Medical College, Valhalla, NY; and 2Rutgers- Robert Wood Johnson Medical School, Piscataway, NJ.

TMDT is a seizure-producing neurotoxic rodenticide. Banned worldwide due to human toxicity and environmental persistence, it has been responsible for many individual and mass poisonings, often intentional. TMDT is easily synthesized, highly potent, water soluble, tasteless and odorless. Thus it is an ideal food or drink adulterant, raising concern regarding its utility for terrorist acts. No current standardized, effective treatment against TMDT intoxication exists. We sought to understand how exposure route and treatment time post-exposure alter intoxication and outcome. C57BL/6 adult male mice were exposed to TMDT via intraperitoneal (IP), subcutaneous (SC) and oral (PO) routes in a dose range of 0.1 to 0.7 mg/kg. Mice were observed for onset of twitches, clonic and tonic-clonic seizures, and survival 1 hr after exposure, and up to 24 hrs thereafter. Treatments were selected based upon performance in a Ca2+ flux assay using cerebral cortical cell cultures. TMDT produced a similar sequence of symptoms for different routes, however the doses at which the symptoms appeared varied. Seizure symptoms appeared at lower doses after IP as compared to SC exposure. Incidence of death at 1 hr peaked at 0.25 mg/kg for these routes. Two modes of PO administration demonstrated how rapidly and reliability of symptom appearance could vary by this route. While administration of selected treatments at the time of a tonic-clonic seizure was uniformly ineffective, treatment after the first or second clonic seizure yielded similar outcomes. To conclude, 1) exposure route, as well as mode of PO exposure, significantly influences key parameters of TMDT toxicity and 2) an effective treatment against TMDT intoxication exists. We sought to understand how exposure route and treatment time post-exposure alter intoxication and outcome.

2245 Amitraz Changes Monoaminergic Neurotransmitter Biosynthesis and Metabolism by E2 Content Alteration in Central Nervous System

Amitraz is a formamidine insecticide/acidaricide that alters different neurotransmitters levels, among other neurotoxic effects. Oral amitraz exposure (20, 50 and 80 mg/kg bw, 5 days) has been reported to increase serotonin (5-HT), norepinephrine (NE) and dopamine (DA) content and to decrease MAO and Metyoxytyramine (MTO) metabolites in the male rat brain, particularly in the striatum, prefrontal cortex, and hippocampus. However, the mechanisms by which these alterations are produced are not completely understood. One possibility is that amitraz monoamine oxidase (MAO) inhibition could mediate these effects. Alternatively, it alters serum concentrations of sex steroids that regulate the enzymes responsible for these neurotransmitters synthesis and metabolism. Thus, alterations in sex steroids in the brain could also mediate the observed effects. To test these hypothesis regarding possible mechanisms, we treated male rats with 20, 50 and 80 mg/kg bw for 5 days and then isolated tissue from striatum, prefrontal cortex, and hippocampus. We then measured tissue levels of expression and/or activity of MAO, catechoI-O-methyltransferase (COMT), dopamine-b-hydroxylase (DBH), tyrosine hydroxylase (TH) and tryptophan hydroxylase (TRH) as well as estradiol levels in these regions. Our results show that amitraz did not inhibit MAO activity at these doses, but altered MAO, COMT, DBH, TH and TRH gene expression, as well as TH and TRH activity and estradiol levels. The alteration of these enzymes was partially mediated by dysregulation of estradiol levels. Our present results provide new understanding of the mechanisms contributing to the harmful effects of amitraz.

2246 Effects of Low-Level Chlorpyrifos Exposure on Endocannabinoid Metabolism and Immune Function

B. Szafrań, A. Borajani, B. Carr, M. K. Ross, and B. L. Kaplan. Mississippi State University, Mississippi State, MS.

Prior research from our group demonstrated that neonatal rats treated with chlorpyrifos (CPF) exhibited decreased 2-arachidonylglycerol (2-AG) metabolism and increased levels of eCBs in brain at doses too low to inhibit acetylcholinesterase activity. Because eCBs are known to have immunomodulatory effects, we are investigating the link between the catabolism of these lipids and immunity in both adult and neonatal rodents. We hypothesized that CPF exposure would inactivate eCB metabolism leading to immunosuppressive effects in adult mice. In vitro and in vivo studies were conducted. Isolated naive splenocytes (SPLCs) from adult female C56BL/6 mice were pretreated with either vehicle (ethanol) or 1 μM chlorpyrifos oxon (CPO) for 30 min, followed by incubation in the presence or absence of lipopolysaccharide (LPS, 1 μg/ml, 3.5 h). Although LPS alone had no effect on 2-arachidonylglycerol (2-AG) hydrolysis activity in SPLCs, CPO treatment could significantly reduce this activity (>6-fold). CPO had no effect on LPS-induced IL-6 production. Next, adult female C56BL/6 mice (n=5 per group) were treated with vehicle or CPO (2.5 mg/kg, PO, 7 days); 4 hr after the final dose, tissues were harvested for analysis. Immunophenotyping of SPLCs by flow cytometry revealed that the proportion of CD8+ cells was significantly increased (1.3-fold) in CPF-treated mice compared to those of vehicle controls. CPF treatment did not affect 2-AG or anandamide hydrolysis activities in spleen and brain homogenates, while hepatic and lung carboxylesterase activity was inhibited in CPF-treated mice relative to vehicle controls. Resident peritoneal macrophages (RPMs) and SPLCs from vehicle- and CPF-treated mice were also stimulated ex vivo with LPS (100 ng/ml). No CPF-dependent differences were noted in IL-6 levels in the stimulated RPMs or SPLCs, although IL-6 levels were significantly lower in non-stimulated RPMs from CPF-treated mice compared to those from vehicle controls. 2-AG levels in non-stimulated RPMs from CPF-treated mice were significantly higher than those from vehicle controls. These data suggest that CPF can alter the immunophenotype of murine T-cell populations in the absence of effects on the splenic eCB hydroytic activity, while 2-AG levels were inversely associated with IL-6 levels in basal RPMs from CPF-treated mice. Further analyses are necessary to determine if CPF-mediated immunomodulatory effects are noted in other tissues. Studies funded by the MSU-CVM.

2247 Acetylcholinesterase Activity and Oxidative Stress Status of Subjects Occupationally Exposed to Organophosphate Pesticides in Nigeria

O. M. Akinosun1, T. Adewole2, and E. B. Bolajoko3. 1University of Ibadan and University College Hospital, Ibadan, Ibadan, Nigeria; 2University College Hospital, Ibadan, Ibadan, Nigeria; and 3University of Ibadan, Ibadan, Nigeria.

Environmental contamination with pesticides is a problem of regional and worldwide significance. In Africa it has been estimated that 3.2% of workers suffer pesticide poisoning each year, with a possible further 0.8% suffering chronic effects of long-term exposure to pesticides. Organophosphate agents constitute about half of all pesticides used globally. Because of their actions, the public fear of risk of affected by occupational exposure to organophosphate pesticides. Fifty-two apparently healthy farmers occupationally exposed to organophosphate pesticides were compared with apparently healthy unexposed controls. Blood levels of acetylcholinesterase (AChE) activity were determined in peripheral erythrocytes using the spectrophotometric method described by Ellman. Total antioxidant status (TAS) by the method described by Koracevic et al., 2001, were assayed and Vitamins A, C, and E were assayed using HPLC, and total antioxidant production. Next, adult female C56BL/6 mice (n=5 per group) were treated with vehicle or CPO (2.5 mg/kg, PO, 7 days); 4 hr after the final dose, tissues were harvested for analysis. Immunophenotyping of SPLCs by flow cytometry revealed that the proportion of CD8+ cells was significantly increased (1.3-fold) in CPF-treated mice compared to those of vehicle controls. CPF treatment did not affect 2-AG or anandamide hydrolysis activities in spleen and brain homogenates, while hepatic and lung carboxylesterase activity was inhibited in CPF-treated mice relative to vehicle controls. Resident peritoneal macrophages (RPMs) and SPLCs from vehicle- and CPF-treated mice were also stimulated ex vivo with LPS (100 ng/ml). No CPF-dependent differences were noted in IL-6 levels in the stimulated RPMs or SPLCs, although IL-6 levels were significantly lower in non-stimulated RPMs from CPF-treated mice compared to those from vehicle controls. 2-AG levels in non-stimulated RPMs from CPF-treated mice were significantly higher than those from vehicle controls. These data suggest that CPF can alter the immunophenotype of murine T-cell populations in the absence of effects on the splenic eCB hydroytic activity, while 2-AG levels were inversely associated with IL-6 levels in basal RPMs from CPF-treated mice. Further analyses are necessary to determine if CPF-mediated immunomodulatory effects are noted in other tissues. Studies funded by the MSU-CVM.
2248 Corneal Effect in Animals Exposed to Inhibitor of 4-Hydroxyphenylpyruvate Dioxygenase: How Relevant for Human Risk Assessment?

F. Metrullo1, G. Garramone1, I. Eberini2, L. Palazzolo2, V. Di Mare2, L. Tosti1, and A. Moretto1,2. 1International Centre for Pesticides and Health Risk Prevention ASST Fatebenefratelli Sacco, Milano, Italy; 2Università degli Studi di Milano, Milano, Italy.

Isoxaloflote and several other herbicides inhibiting 4-Hydroxyphenylpyruvate Dioxygenase (4-HPPD) in plants have been designed in the last decades. These compounds also inhibit mammalian (and human) 4-HPPD, an enzyme involved in the tyrosine catabolism. Such inhibitors increase the free tyrosine in plasma which, in rats, is associated to the occurrence of corneal opacity. Interestingly, nitisinone (NTBC), a 4-HPPD inhibitor, has been used in human as drug for type 1 tyrosinemia; in those patients, no corneal lesions have been reported. The reason for the different sensitivity, has been hypothesized to derive from species differences in tyrosine metabolism. We carried out a further analysis of the tyrosine metabolism by evaluation of available toxicological studies considering the critical enzymes of tyrosine catabolism (TAT, 4-HPPD and MDHC) combined with in silico biochemistry approach, in order to better assess the relevance for humans of corneal lesions in animals. Comparative modelling showed a high sequence identity (> 87%) for the enzymes between rat, mouse and human; structures and binding sites are highly preserved too. Free energy values calculated by docking for enzymes binding to main physiological substrates (e.g. tyrosine and 4-Hydroxyphenylpyruvate for TAT) are comparable in the different species, as well as the calculated binding affinities. However, differences in the tyrosine aminotransferase (TAT) basal activity are evident among species (e.g. mouse is 3-5 times higher than in rats). Taking into consideration results from homology modelling and docking that showed no significant species differences, other factors should be investigated to explain different sensitivity of mammals in terms of accumulation of free tyrosine and corneal effects following 4-HPPD inhibition. A further step to better clarify one of the possible factor responsible of species differences could be an experimental study measuring TAT expression in different species using hepatocytes primary cultures.

2249 Comparative Toxicity of Ziram and Zineb on Rat Hippocampal Astrocytes

J. Chen, and D. Hardej. St. John’s University, Queens, NY.

Ziram and zineb are agricultural dithiocarbamate (DTC) fungicides used on a wide range of crops including nuts, fruits, and ornamentals. Although both compounds are complexed with zinc, they differ in their chemical background. Ziram is a zinc-(bis-dimethyldithiocarbamate) while zineb belong to the ethylene bisdithiocarbamate category of DTC pesticides. The widespread use of these fungicides are owed to their component metal moieties. Previous work has demonstrated that one mechanism of action of these compounds involves the induction of oxidative stress via Fenton-like reactions. In the current study, cell viability, metal accumulation, and oxidative stress were evaluated. Rat hippocampal astrocytes were chosen for this study because of the key role they play in normal brain physiology and their response to toxic injury. In this investigation, astrocytes were treated with concentrations of zineb (10-50 uM) and ziram (2-5 µM) for 24 hours. MIT and LDH analysis shows significant decreases in cell viability from treatment concentrations 30-50 µM of zineb and 4.5-5 µM of ziram. Phase contrast microscopy demonstrated morphological changes and decreased cell number consistent with cell viability data. Metal analysis was conducted using inductively coupled plasma optical emission spectrometry (ICP-OES) in order to determine the metal accumulation with each compound. Astrocytes treated with 20 and 30 µM of zineb showed significant increases in zinc levels while cells treated with 4 and 4.5 µM of ziram demonstrated significant increases only in the 4.5 µM treatment group. Previous work in our lab has demonstrated that DTC fungicides not only alter metal concentrations of the metal complexed with the compound, but also copper levels due to their ability to trans-chelate this metal. Cells treated with 4.5 µM of zineb and 20-30 µM of ziram showed significant increases in copper levels. Use of the total antioxidant capacity assay demonstrated significant increases in the antioxidant activity as compared to controls. These data lead us to conclude that exposure to these agents reduce cell viability and alter metal homeostasis. Induction of antioxidant proteins by Ziram indicates oxidative stress.

2250 Role of Chlorpyrifos in Generation of Oxidative Stress and Reduction of Cell Proliferation Capacity in Human Breast MCF-7 Cells

M. M. Bushra, A. Elnabawi, and A. Ishaque. University of Maryland Eastern Shore, Princess Anne, MD.

Chlorpyrifos (CPF) is one of the most widely used organophosphate insecticides in the US. The primary target of CPF toxicity is the central and peripheral nervous system due to its ability to inhibit acetylcholinesterase activity. However, CPF is considered one of the endocrine-disrupting chemicals (ECDs) that alter the normal functioning of both wildlife and humans. EDCs can act at very low doses and affect the synthesis of natural hormones, their release and/or transport. Estrogen is mediated by the two receptors isomers: estrogen receptor alpha (ERα) and beta (ERβ). Both receptors are expressed in human tissues and have different action profiles. Estrogen receptor alpha (ERα) is the major regulator of breast cancer tumor behavior. In mammary gland, 17β-estradiol (E2) promotes cell proliferation in both normal and transformed epithelial cells by modifying the expression of hormone responsive genes involved in the cell cycle and/or programmed cell death. In addition, there are a number or reports that establish a link between estrogen-induced breast cancer and oxidative stress. Serum markers for oxidative damage have been shown to increase in women diagnosed with breast cancer. The aims of the present study were to examine the potential effects of CPF on estrogen-induced proliferation of human breast MCF-7 cells, and to test the effect of CPF on cellular production of oxidative stress (ROS). Also, we further examine whether the toxic effects would be mediated through ER. MCF-7 cells were treated for different exposure times and various concentrations of CPF in absence and presence of 17β-estradiol (E2). Cell proliferation, viability, ROS production and cell death were assessed. Exposure to CPF significantly decreased cell proliferation in a concentration-dependent manner in MCF-7 cells. The ERα antagonists, ICI 182,780, and ERβ antagonist, PHTPP, did not block these effects. By contrast, these antagonists inhibited E2-induced cell proliferation. Low concentrations (0.001µM to 10µM) of CPF significantly induced ROS production after exposure for one or three hours. This study demonstrated that exposure to CPF may cause toxic effects irrespective of ER receptor activation. It also suggests that CPF may act as an environmental risk factor for breast cancer. Supported by Title III.

2251 Maneb and Mancozeb Trigger Cellular Senescence via AKT and FOXO

Manganese ethylene-bis-dithiocarbamates, Maneb (MB) and mancozeb (MZ), are fungicides used to prevent blight and mildew on plants. Exposure to MB and MZ has been linked to the pathogenesis of neurodegeneration. However, the toxic mechanism of MB and MZ is not so clear. Preliminary studies from our laboratory demonstrated that exposure to MB and MZ in PC12 cells triggered cellular senescence and caused G1 phase cell cycle arrest. Studies have shown that down-regulation of a forkhead transcription factor, FOXO3a, will up-regulate p53 and p21 expressions to accelerate cellular senescence in human fibroblast cells. Our preliminary results also showed increases in p33 expression and p21 activation in response to MB and MZ in PC12 cells. In this study, we focused on unveiling the FOXO involvement in MB and MZ induced senescence in PC12 cells. Since phosphorylation of AKT can inactivate FOXOs resulting in their accumulation in the cytoplasm, western blot analysis was applied to evaluate the status of AKT. The FOXO reporter encoded with GFP from Qiagen was transfected into cells and used to determine the activity of FOXO. The results showed that phosphorylated AKT levels increased after MB and MZ treatment for 24 hours in a dose-dependent manner, and MZ has a stronger effect on AKT activation as compared to MB. FOXO reporter analysis showed that PC12 cells treated with 5-50 µM MB and MZ for 24 hours have lowered (at least 50% reduction) FOXO activity as compared to control cells. In summary, MB and MZ activated AKT by increasing the phosphorylated AKT level, and decreased the activity of downstream effector, FOXO. In the future, the relationship between AKT/FOXO and MB/MZ induced cellular senescence will be elucidated. This study will help to understand the role of environmental toxins in the pathogenesis of neurodegeneration.
2252 A Risk-Based Approach to an Accidental Exposure of Livestock to Chlorophacinone

K. Keteles1, and A. Kadry2. 1US EPA, Lakewood, CO; and 2US EPA, Washington, DC.

The mission US Environmental Protection Agency (EPA) is to protect the environment and human health. EPA is responsible for the safety of pesticides by implementation of several laws and regulations (Federal Insecticide, Fungicide, and Rodenticide Act, the Federal Environmental Pesticide Control Act, Food Quality Protection Act and the Pesticide Registration Improvement Act). We investigated a case of accidental exposure of a herd of 850 bison to the rodenticide chlorophacinone. Chlorophacinone, is an anticoagulant rodenticide. Its mode of action is through depressing hepatic synthesis of prothrombin and clotting factors VII, IX, and X. It causes direct damage to capillary permeability. Products that contain chlorophacinone are not registered for use near crops or where livestock may graze. A reference dose and final limit have not been established for chlorophacinone. In response to this, a reference dose of 0.005 µg/kg/day was calculated using standard uncertainty factors and risk-based screening level of 0.2 µg/kg was calculated using conservative exposure assumptions based upon reasonable maximum exposure for a susceptible population. The screening level is below analytical detection limits, residue levels in bison were modeled using worst case scenario exposure parameters. Based on the modeled residue levels and the half-life of diphacinone from a ruminant exposure study (Crowell et al. 2013), a hold time of 16 months for the potentially exposed bison was calculated to ensure that the risk-based screening levels were not exceeded.

2253 2,4-D (2,4-Dichlorophenoxyacetic Acid)-Altered Gut Microbial Pathways and Metabolic Profile Involved in Kidney Disease

P. Tu. The University of North Carolina at Chapel Hill, Chapel Hill, NC. Sponsor: K. Lu

Gut microbiota critically contributes to various host metabolic functions, whereas environmental chemicals are able to affect its constitution and functionality thereby resulting in host metabolic disorders. In the present study, we aimed to evaluate the functional effects of a widely-used herbicide 2,4-Dichlorophenoxyacetic acid (2,4-D), on gut microbiome. A mouse model was used combined with metagenomic sequencing and metabolic profiling to investigate functional alterations in gut microbiome by 2,4-D treatment. The metagenomics result showed that 2,4-D significantly perturbed the gut microbial functions with pronounced changes in a series of bacterial pathways involved in urea cycle and amino acid metabolism. Moreover, the metabolomics result revealed distinct metabolic profiles in both fecal and serum samples. Additionally, these functional perturbations induced by 2,4-D were associated with the progression of kidney disease. These findings suggest that 2,4-D may lead to kidney disease by targeting the gut microbiota, indicating that the relationship between environmental contaminants and microbiota is largely underestimated for comprehensive consideration of the toxicity of environmental agents.

2254 Alpha-Cypermethrin (αCM) and Lambda-Cyhalothrin (λCH) Metabolism and Exposure Assessment in Egyptian Agriculture Workers

R. A. Abdallah1, M. M. Himmel1, B. P. McGarrigle1, L. Chi1, A. A. Ismail2, G. Abdel Rasou1, O. Hendy1, M. R. Bonner1, D. S. Rohilman3,4, and J. R. Olson1. 1University at Buffalo, Buffalo, NY; 2Menoufia University, Shebin El-Kom, Egypt; 3University of Iowa, Iowa City, IA; and 4Oregon Health and Science University, Portland, OR.

Pyrethroids (PYRs), including αCH and λCH, are insecticides used in both agricultural and residential settings in Egypt and other parts of the world. PYR usage has increased during the past decade with the decline of organophosphate (OP) pesticide use, although they are often used in combination. αCH and λCH are neurotoxic, acting by prolonging the open time of voltage-gated sodium channels. They are metabolized by cytochrome P-450 (CYP) and carboxylesterase (CE), resulting in the formation of inactive metabolites that serve as biomarkers of exposure. Pooled human liver microsomes were used to assess kinetic parameters (Km and Vmax) for αCH and λCH metabolism, through the formation of non-specific metabolites, 3-phenoxbenzyl alcohol (PBO alcohol), 3-phenoxbenzonic acid (3-PBA), and the specific metabolites, cis-3,2,2-dichlorovinyl)-2,2-dimethylcyclopropane carboxylic acid (cis-DCCA) from αCM and lambda cyhalothric acid (LC acid) from λCH. The formation of 3-PBA and LC acid from αCH have Vmax values of 199 and 943 pmol/min/mg protein, and Km values of 14.1 and 36.3 μM, respectively. Similarly, the formation of 3-PBA and cis DCCA from αCH have Vmax values of 364 and 1476 pmol/min/mg protein, and Km values of 31.4 and 48.8 μM, respectively. Incubation in the absence of NADPH resulted in a marked reduction in the formation of 3-PBA and 3-PB alcohol, suggesting that these metabolites resulted from CYP-mediated metabolism, while CE mediated cis DCCA and LC acid formation. To assess the impact of co-exposure of αCH and λCH with an OP pesticide, incubations were conducted with CYP-oxon, the active metabolite of chlorpyrifos, resulting in an inhibition in the formation of all metabolites of αCM and λCH. These metabolites were also detected in urine samples of Egyptian adolescent agriculture workers that applied λCH and αCM to the cotton fields. Adolescent non-applicants primarily only had elevated levels of 3-PBA, suggesting environmental and domestic exposure to other PYRs. Together, in vivo exposure and in vitro metabolism can be used in risk assessment for occupational and residential exposures and to assist efforts to reduce exposures. NIEHS and the Fogarty Institute R21 ES017223 and R01 ES022163, Rohilman.

2255 Evaluation of Repellent Activities of Essential Oils Camphor, Norcamphor, and Thujone in Two Drosophila Species

S. W. Sanchez1, Q. Wang2, and K. Dong2. 1St. Mary’s University, San Antonio, TX; and 2Michigan State University, East Lansing, MI. Sponsor: W. Atchison

Essential oils derived from various plants have been shown to repel insects including flies and mosquitoes. Camphor and thujone are two essential oils found, respectively, in the wood of the camphor laurel, a large evergreen tree found in Asia, and in several plants, such as the arborvitae, cypress, and wormwood. Norcamphor is an analog of camphor, but without the three methyl groups. The objective of this study was to test the potential repellency of camphor, norcamphor and thujone against two species of the fruit fly D. melanogaster and Drosophila suzukii. D. melanogaster is a model insect and D. suzukii is an invasive pest known for its tendency to attack healthy, ripening fruit leading to crop loss and threatening fruit production. Electrophysiological recording experiments show that camphor, norcamphor and thujone activate specific olfactory neurons in both insect species. Preliminary T-maze behavioral assays showed that these compounds exhibit repellency against adult flies. Findings from this study suggest that camphor, norcamphor and thujone are potent repellents that may be further evaluated to be incorporated as a strategy for D. suzukii control.

2256 Effects of Dithiocarbamates, Mancozeb, and Disulfiram on Myocardial and Skeletal Muscle in Long Evans Rats

O. Stephenson, and L. D. Trombetta. St. John’s University, Queens, NY.

Mancozeb (MZ) and Disulfiram (DS) are dithiocarbamates (DTC) used widely throughout agriculture, medicine, and industry. MZ is an ethylene bis-dithiocarbamate complexed with manganese and zinc and is used as a fungicide on fruits, vegetables, and seeds. DS, a diethylthiocarbamate, is used for alcohol aversion therapy under the brand name Antabuse®. Both of these compounds have been implicated in neurotoxicity however their effects on muscle have not been fully studied. The focus of this investigation was to determine the effects of MZ and DS on muscle degeneration in vivo. Adult, male Long Evans rats were treated with either 250mg/kg MZ or 750mg/kg DS via oral gavage in PEG 400 vehicle, three times a week for four weeks. Animals were euthanized four hours after final dose. Serum was separated from whole blood obtained via cardiac puncture for analysis of myoglobin (MYO). A significant increase in myoglobin (p < 0.05) was observed in DS treated animals [8.12 ± 1.27 ng MYO/mg Total Protein (TP)] when compared to control [4.31 ± 0.53 ng MYO/mg TP]. No difference was seen in MZ treated groups. Body weights of all animals were recorded before each treatment. As a result of DS treatment, a significant decrease in body weight gain was observed compared to control and MZ treated animals. Vastus medialis and right ventricular myocardium were isolated and fixed in 3.0% phosphate buffered glutaraldehyde followed by further processing for transmission electron microscopy (TEM). TEM micrographs of Vastus medialis from control rats showed typical skelatal muscle morphology of aligned sarcomeres with prominent, straight Vastus medialis micrographs of the ripening fruit leading to crop loss and threatening fruit production.
with defined sarcomeres and prominent intercalated discs. MZ-treated ventricular myocardium was seen to contain multi-vesicular bodies and extensive mitochondrial damage including destruction of the internal membrane. DS-treated ventricular myocardium showed myofibril splitting and disintegration and flocculent material within the mitochondria. This initial study demonstrates alterations to muscle architecture in both skeletal and cardiac musculature after treatment with MZ and DS however the myopathy is different for each toxicant.

2257 Toxicological Effects of Ethophrophos, Cadmium, and Their Mixture on Biochemical, Hematological, and Genotoxic Parameters in Albino Mice

Humans are usually exposed to a variety of chemical mixtures in the air he breathes, the water he drinks, and the food he eats. There are concerns regarding the presence of these toxicants individually and also interactive if co-exposure takes place due to their biochemical, mutagenic, and carcinogenic potential for humans and animals. The present study aims to evaluate the toxicity of ethophosphos and cadmium in male mice by determining the median lethal doses (LD50) and investigate the effects of sublethal doses (1/10 LD50) of ethophosphos, cadmium, or their combination either as a single dose or repeated doses for 7, 14, or 28 days on some biochemical, genotoxic, and reproductive toxicity parameters in Albino male mice. The results indicated that the oral LD50 values of ethophosphos and cadmium were found to be 8.12 and 31.50 mg/kg b.w, respectively. Sublethal doses of ethophosphos, cadmium, or their combination were found to alter the levels of WBCs, % of hematocrite, hemoglobin, and protein, as well as AST and AChE activities. Genotoxic studies revealed an increasing in total of chromosomal aberrations, mitotic index, and sperm abnormalities following single or repetitive treatment with either ethophosphos, cadmium, or their combination and the percentages of changes were dose-dependent. Moreover, the mixture had the most dramatic effects to produce the genotoxic effects. It can be concluded that the exposure to a pollutant alone or combined with others may produce a wide variety of toxic effects.

2258 Toxicokinetics (TK) of Permethrin as a Function of Isomer and Age of Rats

T. B. Mortuza, J. Pang, T. S. Osimitz, M. R. Creek, J. V. Bruckner, B. S. Cummings, and C. A. White, University of Georgia, Athens, GA; Science Strategies LLC, Charlottesville, VA; and Valient USA, Dublin, CA.

Permethrin, a class I pyrethroid, is used extensively as an insecticide throughout the world. Nevertheless, there are limited TK data for development and validation of physiologically based pharmacokinetic (PBPK) models for subpopulations, notably children. The objective of this study was to assess the relative TK of cis- versus trans-permethrin (CIS vs. TRANS) as a function of stage of maturity. Groups of preweanlings (PND 15), weanlings (PND 21), and adult (PND 90) rats were given a series of doses of CIS or TRANS as a single oral bolus and euthanized at intervals for up to 24 hr for collection of plasma, brain, liver, muscle, and fat for isomer analysis by HPLC. Both CIS and TRANS were absorbed more rapidly and attained higher concentrations in plasma, brain, liver, and muscle of pups than in adults. The lower clearance and higher peak concentrations in pups resulted in significantly higher plasma and brain levels for both isomers. TRANS clearance and AUCs were inversely related to age in the PND 15, 21, and 90 animals. TRANS half-lives diminished from 5.2 to 3.6 to 0.9 h in the PND 15, 21, and 90 groups, respectively. CIS plasma Cmax and AUC levels were 3 to 4 times higher than TRANS levels, reflecting the more rapid metabolic clearance of TRANS. These data demonstrate that the TK of permethrin in rats is both isomer- and age-dependent. Supported by the Council for the Advancement of Pyrethroid Human Risk Assessment (CAPHRA).

2259 Redox Cycling Chemicals as Fungicides for the Prevention of Biodiesel Degradation

A. Troise, T. A. Wright, T. M. Bull, and J. P. Gray, US Coast Guard Academy, New London, CT.

Biodiesel is a renewable fuel composed of mono-alkyl esters of long chain fatty acids derived from vegetable oils or animal fats. It is also susceptible to biodegradation by contaminating microorganisms such as bacteria or fungi. Degraded fuel contains less overall energy and contains byproducts that can clog fuel filters and necessitate premature repairs. One approach to preventing fuel degradation is the addition of biocides that inhibit the growth of these fungi. Bactericides and fungicides may be added to biodiesel to prevent degradation, but these chemicals may come with potentially negative effects, such as being poisonous to humans or the environment, being non-degradable (such as metal-containing compounds), or by being detrimental to com-bustion of the fuel. One class of chemicals that may be of use are redox cycling chemicals which consist of carbon and oxygen and are readily combustible with no byproducts. Biodiesel is frequently contaminated with water, with the fungi primarily growing at the biodiesel/water interface. Selective choice of redox cycling chemicals that target the oil, water, or interface layer might therefore differentially inhibit fungal growth. We investigated several redox cycling chemicals with differing water/octanol coefficients to determine their efficacy in inhibiting the growth of two fungal strains isolates from contaminated biodiesel: Wickerhamomyces and Byssoschlamys. Wickerhamomyces was more susceptible to lipid soluble compounds including menadione, 1,2-naphthoquinone, and 2-methoxy-1,4-naphthoquinone, whereas Byssoschlamys was more broadly susceptible to toxicants and at lower concentrations. We next tested the effect of solvents on the toxicity of the menadione against both species. DMSO, ethyl acetate, and acetone all exhibited lower LD50 values, with ethanol, Tween 20, and biodiesel itself exhibiting higher LD50 values. These data show that solvents increase the toxicity of redox cycling fungicides and that the combination of a lipophilic toxicant with a solvent miscible in both oil and water exhibits the greatest toxicity to fungal contaminants. Taken together these data suggest that redox cycling chemicals may be useful in preventing the degradation of biodiesel by contaminating microorganisms.

2260 Evidence for Hepatic CYP4A1 Induction and Peroxisome Proliferation in Rats following Pyrethroid Insecticide Lambda-Cyhalothrin Exposure

Lambda-cyhalothrin, a synthetic pyrethroid insecticide, has been extensively used in the last two decades to control agricultural pests and insects of veterinary as well as human concern. Studies have reported links between insecticide exposure and adverse health effects including damage to the liver, endocrine disruption, fertility problems, neurological disorders, and cancer. Because there have been no data demonstrating whether lambda-cyhalothrin affects CYP induction and/or hepato cellular proliferation and because all peroxisome proliferators examined to date induce cytochrome CYP4A1 enzyme responsible for the omega-hydroxylation of fatty acids, this study examined lambda-cyhalothrin effects on CYP4A1 enzyme activity in liver microsomes and peroxisome proliferation determining hepatic peroxisomal enzyme activities (carnitine acetyltransferase and palmitoyl-CoA oxidation). Treatments of Wistar rats with lambda-cyhalothrin (1, 2, 4, and 8 mg/kg, i.p. over 2 days) gave rise to an increase in hepatic fatty acid hydroxylase activities reflecting CYP4A1/2 activity. Lambda-cyhalothrin produced, in a dose-dependent manner, a significant increase in the 12- and 11-hydroxylation of lauric acid (85% and 107%, respectively, P<0.001 for the dose 6 mg/kg bw). Lambda-cyhalothrin increased in rat liver the cyanide-insensitive β-oxidation of palmitoyl-CoA, enzyme marker for peroxisomes, and carnitine acetyltransferase activity (60% and 57%, P<0.001, respectively). The fact that lambda-cyhalothrin increased CYP4A1 activity and peroxisomal β-oxidation of lipids would support the classification of lambda-cyhalothrin as a potential peroxisome pro liferator with possible implications for oxidative stress. This subject is of considerable importance because many peroxisome proliferators are the prototype to exhibit epigenetic mechanism of hepatocarcinogenicity. Work supported by Projects (ALIBIRD-CM Program) Ref. S2013/ABI-2728 from Comunidad de Madrid, and Ref. RTA2015-00010-C03-03 from Ministerio de Economía, Industria y Competitividad, Spain.
Transferable Residues of Dinofuran, Pyriproxyfen, and Permethrin from Dogs Topically Treated with Vectra 3D to Humans

R. C. Gupta1, K. Clark1, R. B. Doss1, M. A. Lasher1, and T. D. Canerdy2.
1Murray State University, Hopkinsville, KY; and 2Murray State University, Murray, KY.

The present investigation was undertaken with two specific objectives: one, to evaluate the safety of dinofuran, pyriproxyfen, and permethrin in dogs after topical application of Vectra 3D®, and two, to determine the transferable residue of these insecticides from dogs to humans. Six healthy, adult dogs with medium hair length received topical application of Vectra 3D® (3.6 mL; dinofuran, 4.95%; pyriproxyfen, 0.44%; and permethrin, 35.06%) on the back between the shoulder blades. At pre-determined intervals, dogs were given a full physical exam, and residues of these insecticides were determined in dog blood and cotton glove extracts using GC/MS. Peaks of dinofuran, pyriproxyfen and permethrin were identified and confirmed based on retention time and characteristic ions. At no time was dinofuran, pyriproxyfen or permethrin detected in blood samples. In glove extracts, residues of dinofuran, pyriproxyfen, and permethrin were detected 24 hr post-treatment (19.87±1.39; 25.79±3.65; and 399.6±100.45 ppm, respectively). At 48 hr post-treatment, the residues of dinofuran and pyriproxyfen were maximum (33.69±1.16 and 31.36±4.11 ppm, respectively), while the residue of permethrin was decreased (273.40±79.94 ppm). Permethrin residue persisted on canine coat in a significant amount until 3 weeks and in trace amount until 4 weeks post-treatment, while the residues of pyriproxyfen were undetectable after 1 week. At no time did dogs show any side effects. These findings suggest that Vectra 3D® is safe for dogs and transferable residues of dinofuran, pyriproxyfen, and permethrin pose no health concern to pet owners or veterinary personnel. Of course, veterinary personnel may require proper protection to avoid cumulative ecotoparasiticide exposure.

Exposure Levels of Organophosphorus Insecticides in 1.5- and 3-Year-Old Children in Japan

N. Oya1, Y. Toi1, T. Ebara1, K. Hickoi1, J. Ueyama2, S. Kato1, M. S. Ogasawara1, S. Saitoh1, and M. Kamijima1.
1Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; and 2Nagoya University Graduate School of Medicine, Nagoya, Japan.

Several epidemiological studies suggested that exposure to organophosphorus insecticides (OP) could elicit adverse health effects on children. It is thus important to clarify their exposure levels in each age group during infancy. In this study, we prospectively measured OP exposure level at 1.5 and 3 years old in a birth cohort in Japan. We recruited 283 children and 263 families participating in the Japan Environment and Children’s Study (JECS) at Aichi Regional Center of JECS when they became 1.5 and 3 years old between June 2015 and July 2017, and collected urine taken directly or extracted from disposable diapers by acetone. Six urinary dialkylphosphates (DAPs) and creatinine (C) were measured by ultraperformance liquid chromatography with tandem mass spectrometry. The absorption of OP into the diapers was corrected. The median concentrations (nmol/g Cr) of the urinary total dimethylalkylphosphates (DDMAP), total diethylalkylphosphates (DEAP), and total dialkylphosphates (DAP) were 165.3, 57.9, and 263.8 in 1.5-year-old children and 767.9, 66.1, and 257.8 in 3-year-old children, respectively. Reproducibility of exposure categories at both ages classified using quartile DAP concentrations was poor; the highest Cohen’s kappa coefficient was 0.052 for dimethylphosphate. The medians of DAP concentrations in each season (nmol/g Cr) at 1.5 and 3 years old were 215.2 and 214.3 for spring (Apr-Jun), 238.6 and 247.2 for summer (Jul-Sep), 345.8 and 476.9 for fall (Oct-Dec), and 293.2 and 260.9 for winter (Jan-Mar), respectively. The concentrations in fall at both ages were higher than those in other seasons (p<0.05 except for a difference between fall and winter at 1.5 years old). It was suggested that the difference in OP exposure levels between the ages was smaller than that between seasons.

Morphological Changes in Rat Colon after Mancozeb Exposure as Seen by Light and Scanning Electron Microscopy

B. Kistinger, and D. Hardei. St. John’s University, Queens, NY.

Mancozeb is a broad-spectrum fungicide whose polymeric structure consists of an ethylene bisdithiocarbamate backbone complexed to the metals manganese and zinc. The ratio of manganese to zinc in Mancozeb is 10:1. Oral exposure to Mancozeb can occur to manufacturers, applicators of the fungicide, and consumers of produce sprayed with this fungicide. Several human studies have shown immunomodulatory effects of Mancozeb in pesticide workers, and that uses of pesticide workers that handle Mancozeb have high concentration of manganese found in house dust, suggesting that families of Mancozeb applicators are also at risk for exposure. Oral exposure and the risk of reported potential toxicity of the agent warrants investigation of the effects of this compound on the gastrointestinal tract. Previous studies by our lab demonstrated the toxicity of Mancozeb on transformed human colon cells resulting in disrupted, rounded cells and showed increased caspase 3/7, 8, and 9, which indicated apoptosis. The purpose of the present pilot study was to conduct an in vivo histopathological examination of rat colon after treatment with Mancozeb. In this investigation, 8-week old Sprague-Dawley male rats were treated with either 100 mg/kg Mancozeb or vehicle control (50% v/v PEG 400) by oral gavage once a week. Colon sections were collected after four weeks of treatment and stained with hematoxylin and eosin. Scanning electron micrographs of H&E stained control tissues showed simple columnar epithelium with large nuclei and goblet cells. Mancozeb treated colon showed normal epithelium with the additional presence of cells containing pyknotic nuclei and increased eosinophilia. Microvilli on the surface of the colon were undamaged in the control group, while Mancozeb treatment caused a decrease in microvilli and increased eosinophilia on the surface of the colon. Damage to mucus pores was also observed. Toxicity observed in the current study is consistent with the gastrointestinal toxicity of Mancozeb as described in previous in vitro studies.
**Effect of Malathion on Bacterial Ingestion in Caenorhabditis elegans**

L. Hall, J. Odom, C. Powell, and M. Pomeroy-Black. LaGrange College, LaGrange, GA.

Malathion is an insecticide that is widely used for agricultural and residential purposes. When malathion is introduced to the soil and water, it can be toxic to the organisms exposed to the compound. Malathion affects both the peripheral and central nervous system. We hypothesized that if *C. elegans* were exposed to malathion, then the amount of *E. coli* ingested by *C. elegans* will decrease. In order to test this hypothesis, WT *C. elegans* were exposed to four concentrations of malathion (0.2 mM, 0.5 mM, 1.5 mM, and 10 mM) in M-medium and LB broth with *E. coli* (OP50). The optical density (OD) of the bacteria was measured at 0.5 hours, 1 hour, and 24 hours after exposure. There was a trend of increased OD from the control across all timepoints (*p = 0.1*). There was also a significant increase in OD from the control at a 1 hour exposure time (1.5 mM, *p = 0.01*). There was also a significant increase in OD for the 1.5 mM malathion treatment from 0.5 hours to 1 hour (*p = 0.05*). The results suggest that high concentrations of malathion are toxic to organisms in the soil within 1 hour of exposure, in part by slowing feeding behavior, but that lower concentrations can be tolerated without significant adverse effects for at least 24 hours.

**Impact of Chronic Glyphosate Exposure on Hepatic and Ovarian Signaling in Female Mice**

S. Ganesan, and A. F. Keating. Iowa State University, Ames, IA.

Representing approximately 50% of US herbicide usage per annum, glyphosate (GLY) usage is extensive. Previously, we discovered that chronic GLY (2 mg/kg; 20 weeks; 5 days per week) exposure decreased primordial follicle number and altered ovarian folliculogenesis and steroidogenesis associated proteins. This study investigated the hypothesis that shorter GLY exposure would also affect ovarian signaling pathways and deplete primordial follicles. Postnatal day 45 C57BL6 female mice were exposed to GLY (2 mg/kg) 5 days per week for 5 or 10 weeks. Mice were euthanized in the pro-oestrus phase of their estrous cycle. GLY exposure for 5 weeks did not impact (*P > 0.05*) body or any organ weight. After 10 weeks, there was no effect (*P > 0.05*) of GLY on body, kidney, heart, or uterus weight; however, ovarian and liver weights were reduced (*P < 0.05*). There was no impact (*P > 0.05*) of either 5 or 10 weeks of GLY exposure on healthy primordial, primary, secondary, or antral follicle numbers. The phosphatidylinositol-3 kinase (PI3K) pathway is critical for oocyte viability, primordial follicle activation, and steroidogenesis. GLY exposure did not impact (*P > 0.05*) abundance of ovarian mRNA encoding the PI3K members kit ligand (*Kit*), Kit proto-oncogene receptor tyrosine kinase (*c-Kit*), nor the insulin receptor (*Insr*), insulin receptor substrate 1 (*Irs1*) or *Irs2*. Neither ovarian thymoma viral proto-oncogene 1 (*AKT*) protein nor phosphorylated AKT protein were affected (*P > 0.05*) by GLY exposure. GLY did not alter (*P > 0.05*) ovarian mRNA or protein abundance of steroidogenic acute regulatory protein (*Star*), 3β-hydroxysteroid dehydrogenase (*Hsd3b*), cytochrome P450 (*Cyp11a1* or *Cyp19a*). Circulating 17β-estradiol and progesterone concentration were unaffected (*P < 0.05*) by GLY exposure. Hepatic protein analysis revealed that 42 proteins were increased and 26 decreased (*P < 0.05*) by GLY compared to control. KEGG pathway analysis revealed greatest alterations to proteins involved in metabolic pathways, carbon metabolism, and nonalcoholic fatty liver disease. These data support hepatic impacts of GLY exposure after 10 weeks, which could reflect metabolic changes in the organism. Unfortunately, we could not discover any effect on the ovarian endpoints examined by 5 or 10 weeks of chronic GLY exposure. Supported by R21ES026282 from the NIHES to AFK.

**Risk of Insecticides Usage to Control Grain-Stock Pests**

S. Sergeiev, M. Prodanchuk, O. Kravchuk, A. Gryanko, N. Kolontaeva, and V. Lyshavskyi. L.I. Medved’s Research Center of Preventive Toxicology, Food and Chemical Safety, Kyiv, Ukraine.

Treatment of grain stocks with insecticides before storage is a common technology to control insect pests. Deltamethrin (pyrethroid), pyrimiphos-methyl, and chlorpyrifos-methyl (organophosphorus compounds) are used for disinfestation of grain stocks in Ukraine. The use of grain stocks with residues of insecticides can pose a significant risk to human health. Work purpose is risk assessment of insecticide residues for humans after the protection of grain stocks. To identify the hazard and assess the exposure, physicochemical characteristics, LD50 per os, application rates of insecticides active ingredients (AI), ratio of application rate and LD50 per os, results of residues measuring of AI in grain stocks (gas-liquid chromatography), period of insecticide retention in grain (DT50), ratio of possible daily intake (DI) of AI residues to acceptable daily intake (ADI), processing factors (PF), and daily consumption of grain processing products were analyzed. The integral exposure vector (combination of ADI, DI, DT50) was calculated and evaluated according to the proposed scale. Insecticides AI have sufficient selectivity of action: their effective application rates range from 180-640 times lower than LD50 per os. Low water solubility, hydrolytic stability, and high lipophilicity are promote resistance of AI, their concentration in brain and grain germ after processing of stocks. Due to the high persistence, the absolute residues amount in grain at the end of the study (up to 90 days) is affected by the initial application rate. The application rates and residues increase in the deltamethrin—chlorpyrifos-methyl—pyrimiphos-methyl series. With a conservative approach in 80-90 days after treatment, the theoretical DI of deltamethrin did not exceed ADI, while the pyrimiphos-methyl DI exceeded the ADI by 5 times, and chlorpyrifos-methyl by 11 times. When exposed on residual levels, insecticides with the highest values of the integral exposure vector— pyrimiphos-methyl and chlorpyrifos-methyl—are at greatest risk. With a more realistic approach, the largest exposure of pyrimiphos-methyl is associated with the consumption of bread from whole-meal flour (at the level of ADI), chlorpyri- fos-methyl—with consumption of bread from whole wheat and bran (2.4 and 2.3 times higher than ADI, respectively); the lowest level of exposure of pyrimiphos-methyl and chlorpyrifos-methyl is possible with the consumption of white flour and white bread.

**New Models to Assess Isoxaflutole Rodent Liver and Thyroid CAR/PXR Mode-of-Action**

T. Kormos1, E. Shippl2, A. Blacker3, C. Haines1, B. Elcombe1, and A. Vardy1.1 Bayer CropScience LP, Research Triangle Park, NC; 2 Bayer SAS, Sophia Antipolis, France; and 3 Concept Life Sciences (formerly CXR Biosciences Ltd), Dundee, United Kingdom.

In rodent oncogenicity studies conducted with the herbicide isoxaflutole (IFT), increases in the incidences of hepato-cellular adenomas and carcinomas in rats and mice and of thyroid follicular cell adenomas in male rats were observed. Previously, traditional mode of action (MoA) studies (ex: mutagenicity, enzyme induction, BrdU proliferation, thyroid hormone kinetics) suggested constitutive androstane receptor (CAR) and/or pregnane X receptor (PXR) activation. Additional more novel studies were recently performed and found to support IFT as a novel thyroid and anti-thyroid MoA. The recent development of CAR/PXR double KO rats enabled the use of both mouse and rat to explore the essentiality of CAR/PXR causing the rodent-specific liver and thyroid proliferative effects of IFT. Wild type (WT) and KO rats and mice were administered IFT via the diet for 7 days at the highest doses from the oncogenicity studies (6,000 and 6,500 ppm, respectively). Results obtained in the liver with rats and mice confirmed that IFT acts through the CAR/PXR MoA. Induction of specific cytochrome P450 isoforms linked to the CAR/PXR receptors, increased liver weight, proliferation, and hepato-cellular hypertrophy were observed only in rats but not KO control rat models. The thyroid labeling index did not increase, increased relative thyroid weight, follicular hypertrophy, thyroid stimulating hormone (TSH), and induction of specific hepatic Phase II enzymes were observed in the male WT rats but not in the KO. While both triiodothyronine and thyroxine were decreased in the WT rat, high variability of TSH and unexpected thyroid hormone results in the KO rat require further investigation to assess the utility of this model for examining secondary thyroid effects. In vitro, replicative DNA synthesis indicating hepatocellular proliferation was only increased in rodent hepatocyte cultures, while specific P450 isoforms were increased in both rodent and human hepatocytes. These new models thus support that the hepatocellular and thyroid follicular cell tumors observed in IFT rodent oncogenicity studies are due to activation of the CAR/PXR MoA. As humans do not show the proliferative changes in the liver and are less susceptible to thyroid hormone perturbation secondary to liver induction, the tumors observed in rodent oncogenicity studies with IFT are not relevant for human risk assessment.

**Threshold Hormonal Disturbance Is the Cause of Leydig Cell Tumors in Rats after High Doses of Iprodione**

Z. Liu1, T. Luu2, and B. Robaire3. 1 FMC Corporation, Ewing, NJ; and 2 McGill University, Montreal, QC, Canada.

Leydig cells tumors (LCT) were observed only after high doses (75 and 69 mg/kg) of iprodione, a fungicide active ingredient, in male rats in two 2-year studies. The primary objective of this study was to determine a NOAEL (threshold dose) based on changes of sensitive hormonal endpoints that regulate cell proliferation and functionality, and morphom-
etriy of Leydig cells in testis. Six groups of male SD rats aged at 13-14 weeks (30 rats/group) were administered 0 (control), 2, 6, 24, 140 or 250 mg/kg equivalent of iprodione via the diet for 90 consecutive days. Decreases in body weight (11% and 24%), body weight gains (29% and 77%), and epididymal sperm reserves (17% and 34%) were observed at the two high doses 140 and 250 mg/kg, respectively. Serum LH and FSH were significantly increased at both high doses (days 0, 21, 42, and 90) during the treatment. However, the contents of the beta subunits of LH and FSH were significantly increased only at the highest dose (250 mg/kg). Neither intra-testicular testosterone (T) concentrations nor the ability of isolated Leydig cells to synthesize T under simulated conditions was affected by any treatment. Furthermore, the mRNA or the protein concentrations for key steps in Leydig steroidogenesis was not affected even at the highest dose tested, at basal or stimulated conditions. Mitotic index of Leydig cells at the end of the 90 day treatment, as determined by EDU incorporation, revealed that none of the treatments resulted in a change in the low, basal rate of mitosis. The numbers of Leydig cells per testis and their volume density, as determined using morphometry, were not affected at doses up to 24 mg/kg/day; however, the number of Leydig cells per testis did increase to a similar extent (25%) with the two higher doses. The results clearly suggest a threshold hormonal disturbing mode of action for LCT formation in male rats, and therefore, a GI* based on LCT does not appear to be necessary; a reference dose approach should be protective of LCT.

**2270 Dissipation and Residues of Butralin in Tobacco under Field Conditions**

Butralin is applied as a plant growth regulator for the control of auxiliary bud growth on various types of tobacco in the maturation stage. The dissipation and residues of butralin in tobacco were investigated by modified QUECHERS method combined with gas chromatography tandem mass (GC-MS/MS). The average recoveries were in the range of 89-94% with relative standard deviations (RSD) less than 10%. The limit of detection (LOD) and limit of quantification (LOQ) of butralin was 3.3 and 11 μg/kg at the signal-to-noise ratio (S/N) of 3 and 10, respectively. Field experiments including residue dynamic experiment and final residue experiment were conducted in Enshi, Linyi, Qujing and Zunyi during the year of 2016. The dissipation of butralin appeared to follow the first-order kinetic reaction with half-lives of 2.78 - 3.38 days at four geographical experimental plots, which suggested that the dissipation of butralin in the field might be affected by some physical and chemical factors. The results clearly demonstrate that powdered butralin powder does not affect Leydig cell number or steroid production at doses up to 24 mg/kg. A NOAEL of 24 mg/kg determined from this study is consistent with observed LCT only at high doses but not at the mid doses (15/12 mg/kg) in two 2-year rat studies. These results strongly suggest a threshold hormonal disturbing mode of action for LCT formation in male rats, and therefore, a GI* based on LCT does not appear to be necessary; a reference dose approach should be protective of LCT.

**2271 A Species-Comparative Pharmacokinetic and Dynamic Investigation into the Inhibition of Glutamine Synthetase by the Herbicide Glufosinate**

T. Jeitner1, A. Cooper1, Z. Zhang1, S. Lovell2, N. Mehzabeen2, K. Battalle1, L. Gorlitz2, K. Hatz2, D. Lasserre3, and D. Geter1. 1New York Medical College, Valhalla, NY, 2University of Kansas, Lawrence, KS, 3Argonne National Laboratories, Lemont, IL; 4Bayer, CropScience Division, Monheim, Germany; 5Bayer, CropScience Division, Sophia Antipolis, France; and 6Bayer, CropScience Division, Research Triangle Park, NC.

The mode of action for the herbicide glufosinate is through inhibition of glutamine synthetase (GS), which catalyzes the condensation of glutamate and ammonia to form glutamine. This reaction is involved in the glutamine synthase in processes as diverse as ammonia detoxification, energy metabolism, and neurotransmission. Despite conserved sequences and structures, dogs are very sensitive to intoxication by GS inhibitors when compared to rats and humans. The differences were hypothesized to be due to species-specific brain uptake and/or enzymatic processes. Our aim was to evaluate the pharmacokinetic and -dynamic factors involved in the inhibition of human, dog, and rat GS by glufosinate. PBPK analysis showed roughly 7:1 and 2:1 higher levels of glufosinate in dog and rat brain respectively compared to extrapolated human levels. Pharmacodynamic studies revealed the structure of human GS as a dimer of two concentric pentameric rings with 10 active sites; structurally conforming to earlier dog models. Glufosinate appears to be phosphorylated at the terminal phosphate upon entry to the active site, with the resulting pyrophosphate compound responsible for the inactivity of the GS. The human, dog, and rat enzymes also exhibit differential sensitivity to inhibition by glufosinate. Maximal inhibition occurs at inhibitor-to-active site ratios of 10:1, 1:1, 5:1 for the human, dog, and rat enzymes, respectively. Together, the pharmacokinetic and dynamic analysis shows the dog and rat are roughly 70 and 10 times more sensitive to GS inhibition compared to humans.

**2272 The Organophosphorus Pesticide Chlordrinfos Induces Neuron Differentiation of SH-SY5Y Neuroblastoma Cells**

The acute toxicity of the organophosphorus insecticide chloridrinfos (CPF) is primarily due to the irreversible inhibition of acetylcholinesterase (AChE). However, exposure of the developing brain to CPF levels that are insufficient to cause a substantial degree of AChE inhibition has been associated with neurological deficits in children and animal models (reviewed in Burke et al., J Neurochem 142,162, 2017). Yet mechanisms that contribute to the developmental neurotoxicity of CPF remain poorly understood. This study was designed to test the hypothesis that, acting via AChE-unrelated mechanisms, CPF disrupts neuronal differentiation, a critical process that shapes the nervous systems structurally and functionally from the earliest stages of embryogenesis. To address this hypothesis, SH-SY5Y cells (neuroblastoma cells used to model neuronal differentiation in vitro) were exposed for 7 days to CPF (0.1-30 μM) and processed for analysis of cellular differentiation, protein expression and phosphorylation, and histone modifications. In SH-SY5Y cell extracts, 0.1-3.0 μM CPF caused no significant inhibition of AChE, whereas 10-30 μM CPF caused a small, albeit significant degree of AChE inhibition. Following 7-day exposure of SH-SY5Y cells to 3 μM CPF, expression of nestin (a marker of progenitor cells) decreased while expression of NeuN (a marker of mature neurons) increased significantly. In addition, 3 μM CPF increased phosphorylation of a number of mitogen-activated protein kinases, including p38, and the p38 activity was required for CPF (3 μM)-induced increase in the levels of dimethylated histone 3 lysine 4. This is the first study to demonstrate that CPF, acting via AChE-independent mechanisms, may act at least in part as an oxidative stress activator and may involve p38 activation and histone modifications, induces neuronal differentiation. Supported by NIH ES019282 grant.

**2273 Effects of Glyphosate and Its Formulations on Markers of Oxidative Stress and Cell Viability in Heparg and Hacat Cell Lines**

Glyphosate (GLY) is the active ingredient found in herbicide formulations worldwide. GLY is toxic to plants by disrupting the shikimate amino acid synthesis pathway. The present day intensive use of GLY began with the introduction of GLY-resistant crops in the late 900s. A.C. Guthy GLY has a low toxicity profile for humans and mammals, conflicting reports exist as to whether it poses a cancer risk for humans. The US EPA and European regulatory agencies have described GLY as unlikely to pose a carcinogenic hazard to humans. However, the International Agency for Research on Cancer and the California EPA have classified GLY as “probably carcinogenic to humans” and “known to the State of California to cause cancer,” respectively. It has been proposed that oxidative stress may be a mechanism by which GLY could potentially cause cancer. To address this hypothesis, we are testing GLY in human cell lines using several assays that detect reactive oxygen species (ROS) or their effects. Studies were designed to compare the point of departure for the effects of GLY on cell viability (CellTiter-Glo assay) to the point of departure for effects in oxidative damage assays. We also directly compared the effects of GLY versus GLY salts, as well as GLY and adjunct active ingredients versus formulations. We used a high content, 384-well plate approach to generate extensive dose-response curves for multiple comparisons.
Assays (CellTiter-Glo, ROS-Glo, and JC-10) were performed after 1 or 24 h of exposure to test articles. GLY and GLY isopropylamine decreased cell viability and altered mitochondrial membrane potential (MMP) at ≥ 10 mM, but did not affect ROS production. The formulations were more efficacious and potent than GLY alone. Cell viability and MMP were significantly altered at 1 h by the formulations. Based on GLY concentrations, the mixture formulations were over 1000x more potent than GLY alone. In contrast to the robust induction of ROS by positive controls at both time points, formulations had no effect on ROS at 1 h and showed a marginal increase in ROS at 24 h. These data suggest that GLY does not induce oxidative stress. In addition, the formulations marginally increased oxidative stress only after significant loss of cell viability. The results were very similar for both HepaRG and HaCaT cell lines, suggesting that xenobiotic metabolism has little impact on toxicity.

2274 Histopathologic and Inflammatory Changes in the Respiratory Tract of Mice following Chlorine Gas Inhalation

C. R. Gardner1, R. Malaviya1, E. Abramova1, K. Vayas1, J. D. Laskin2, and D. L. Laskin1. 1 Rutgers, The State University of New Jersey, Piscataway, NJ; and 2 Rutgers University School of Public Health, Piscataway, NJ.

Chlorine (Cl2) gas is a cytotoxic pulmonary irritant that causes acute damage to the upper and lower respiratory tract. In the present studies we used a genetically modified model of chlorine poisoning to further investigate inflammatory mechanisms of lung injury. Spontaneously breathing male C57BL/6 mice were exposed to 325 ppm Cl2 for 15 min in whole-body chambers. Bronchoalveolar lavage fluid (BAL) and lung tissue were collected 24 h later. Exposure of mice to Cl2 resulted in peribronchial and perivascular edema, hemorrhage, and marked congestion in the pulmonary vasculature. Extensive loss of the epithelium was observed in the large bronchi resulting in denuded bronchial surfaces. This was correlated with increases in BAL cell and protein content, epithelial expression of phospho-histone H2AX, a marker of double-strand DNA breaks, and macrophage expression of heme oxygenase-1, indicating alveolar-epithelial barrier injury and oxidative stress. Cl2 exposure also resulted in increased numbers of lung macrophages and epithelial cells expressing cyclooxygenase, inducible nitric oxide synthase, and high-mobility group box 1 (HMGB1), proteins important in inflammatory lung injury; receptor for advanced glycation end products (AGE), the purine receptor for HMGB1, and tumor necrosis factor a were also increased in BAL. Whereas macrophage expression of mannose receptor was downregulated following Cl2 exposure, expression of Ym-1 was upregulated. A mechanistic understanding of Cl2-induced injury will be useful in the identification of efficacious countermeasures for mitigating morbidity and mortality following exposure to this highly toxic gas. Supported by NIH grants AR055073, ES004738, and ES005022.

2275 Inhibition of Chlorine-Induced Airway Fibrosis by Budesonide

Rationale: Chlorine gas is a commonly used, highly toxic compound that is also considered a chemical threat agent. Many victims of acute chlorine poisoning recover normal lung function, but a subset develops persistent adverse effects on respiratory health. We showed that chlorine-exposed mice developed fibrosis in large airways that was associated with inflammation and inefficient epithelial repair. In the current study, we investigated the effect of the corticosteroid budesonide on chlorine-induced airway fibrosis. Methods: FVB/NJ mice were exposed to 240 ppm-hr chlorine, and the effect of budesonide treatment was analyzed. Airway pathology was analyzed by H&E staining, and airway collagen content was quantified by image analysis of sections stained with picrosirius red. Analysis of pulmonary mechanics was performed by forced oscillation technique. Immunostaining was performed for markers for airway epithelial cells and alternatively activated macrophages. Results: Daily budesonide treatment starting 1 hour after the end of chlorine exposure prevented the development of airway fibrosis, inflammation, and abnormal lung function analyzed 7 days after exposure. In chlorine-exposed, budesonide-treated mice 7 days after exposure, large airways contained extensive denuded areas, indicating a poorly repaired epithelium. Examination at later times following 7-day budesonide treatment showed continued absence of fibrosis after cessation of treatment and regrowth of airway epithelium by 14 days after exposure. Staining for epithelial markers suggested a process of regrowth from isolated progenitor cells and revealed a poorly differentiated epithelium at 14 days after exposure. Delaying initiation of treatment until 1 or 2 days after chlorine exposure still resulted in significant inhibition of fibrosis. Conclusions: Damaged or poorly repaired epithelium has been considered a trigger for fibrogenesis, but the present results suggest that inflammation is the ultimate driver of fibrosis in this model. Budesonide represents a potential countermeasure for treating persistent effects of acute chlorine exposure.

2276 Heat Shock Protein 90 Is a Molecular Target for Sulfur Mustard and Nitrogen Mustard in Human Lung Epithelial Cells

R. C. Racourt1, Y. Jan2, D. E. Heck3, D. L. Laskin1, and J. D. Laskin2. 1 Rutgers University Ernest Mario School of Pharmacy, Piscataway, NJ; 2 Rutgers University School of Public Health, Piscataway, NJ; and 3 New York Medical College, Valhalla, NY.

Heat shock protein 90 (Hsp90) is a molecular chaperone important in post-translational protein folding, stability and maturation. It is an essential mediator of proliferative and anti-apoptotic signaling, as well as cell cycle control. Mustard vesicants including nitrogen mustard mechlorothamine (bis[2-chloroethyl]methylyamine, HN2) and sulfur mustard (bis[2-chloroethyl] sulfide, SM) are bifunctional alkylating agents known to selectively bind to proteins on nucleophilic sites leading to the formation of mono-functional and cross-linked protein adducts, processes contributing to cytotoxicity and tissue injury. The present studies demonstrate that Hsp90 is a molecular target of mustard in human epithelial A549 and Calu-1 cells leading to inhibition of cell cycle progression and cytotoxicity. HN2 treatment (24 hr) was found to be cytotoxic for both lung cell types (LD50 = 22.3 ± 1.2 and 10.5 ± 0.7 μM for A549 cells and Calu-1 cells, respectively) and also induced a concentration-dependent arrest of the cells in the S and G2/M phases of the cell cycle. This was associated with decreases in expression of cell cycle regulatory proteins including p27Kip1, CDK2, cyclin D1, and Rb, as measured by Western blotting. HN2 and SM also induced the formation of high-molecular-weight Hsp90 cross-links in A549 cells, a process leading to protein dysfunction. This is supported by our findings that HN2 caused the depletion of Akt, an Hsp90 client protein, and induction of Hsp72. These data indicate that inhibition of Hsp90 by HN2 and SM is important in the mechanism of vesicant-induced cell cycle arrest and cytotoxicity. Understanding the mechanisms of action of mustards will be useful in the identification of efficacious countermeasures to mitigate tissue injury. Supported by NIH grants AR055073, NS079249, ES004738, and ES005022.

2277 Receptor for Advanced Glycation End Products (RAGE) Expression in Nitrogen Mustard-Induced Acute Lung Injury in Rats

A. Bellomo1, E. Abramova2, R. Malaviya3, J. D. Laskin3, and D. L. Laskin1. 1 Kean University, Union, NJ; and 2 Rutgers, The State University of New Jersey, Piscataway, NJ.

Nitrogen mustard (NM, mechlorothamine hydrochloride) is a toxic vesicant known to cause severe damage to the respiratory tract by alkylating DNA and proteins and generating oxidative stress. Exposure to NM results in rapid structural changes including perivascular edema and thickening of the alveolar wall followed by bronchiolization of the epithelium which progresses into lung fibrosis. Extensive loss of HMGB1, a critical mediator of proliferative and anti-apoptotic signaling, as well as high-mobility group box-1 protein (HMGB1) and promotes a pro-inflammatory response. In the current study, we determined if RAGE is involved in NM-induced lung injury. Male Wistar rats were exposed intratracheally to 0.125 mg/kg NM or PBS control. Bronchoalveolar lavage fluid (BAL) and lung tissue were collected 3 d later and analyzed for markers of injury and inflammation. Exposure of rats to NM caused an increase in BAL protein and cell content indicating alveolar epithelium injury and inflammation. Significant increases in soluble RAGE and HMGB1 were detected in BAL from NM-exposed rats when compared to PBS treated controls. This was associated with increased expression of RAGE in alveolar epithelial cells and HMGB1 in alveolar macrophages. These findings suggest that RAGE and HMGB1 play a role in regulating mustard induced lung inflammation and injury. Understanding the mechanisms of action is essential to develop novel strategies to counter the pneumotoxic effects of mustard exposure. Supported by NIH grants ES020721, US4AR055073, R01ES004738, and P30ES005022.
Inhalation of sulfur mustard (SM, 2-bis-chloroethyl) sulfide), a bifunctional alkylating agent, is known to cause severe debilitating lung injury in humans. Previously, we have demonstrated that TNFα, a pro-inflammatory cytokine, plays a key role in the pathogenic response to mustard injury. In these studies, we analyzed the ability of anti-TNFα antibody to mitigate SM-induced lung injury. Spontaneously breathing male Wistar rats were anesthetized, intratracheally intubated, and exposed to 0.4 mg/kg SM by vapor inhalation. Animals were sacrificed 3 days post-exposure and bronchoalveolar lavage fluid (BAL) and lung tissue collected. SM inhalation resulted in increases in TNFα in BAL; increases in soluble receptor for advanced glycation end products (sRAGE), a pattern recognition receptor that binds to High Mobility Group-1 protein (HMGB1) to promote pro-inflammatory vascular responses, were also observed. This was associated with increased levels of BAL cell and protein content and tissue expression of HMGB1, indicating damage to the alveolar-epithelial barrier, and inflammation. SM exposure also resulted in increased numbers of lung macrophages expressing heme oxygenase (HO)-1, consistent with oxidative stress. Treatment of rats with anti-TNFα antibody (15 mg/kg, i.v., 1x) 15 min after SM inhalation reduced lung injury and inflammation, as measured by BAL cells and protein content and SM-induced expression of sRAGE and TNFα. SM-induced levels of HO-1 and HMGB1 proteins were also suppressed by anti-TNFα antibody treatment. These data demonstrate that that blocking TNFα represents an important approach to mitigating acute lung injury induced by vesicants. Supported by NIH Grants U54AR050573, 8R01ES004738, and P30ES005022.

Nitrogen Mustard Modulates Cell Cycle Progression via the DNA Damage Response in Human Lung Epithelial A549 Cells

Y. Jan1, D. E. Heck2, D. L. Laskin4, and J. D. Laskin1. 1Rutgers University School of Public Health, Piscataway, NJ; 2New York Medical College, Valhalla, NY; and 4Rutgers University Ernest Mario School of Pharmacy, Piscataway, NJ.

The nitrogen mustard mechlorethamine (bis[2-chloroethyl][methyl] amine; HN2) and sulfur mustard are bifunctional alkylating agents that target cellular macromolecules leading to cytotoxicity and tissue injury. HN2 is known to damage DNA and result in induction of DNA damage signaling pathways including ataxia telangiectasia mutated (ATM), ataxia telangiectasia, and Rad3-related (ATR), as well as DNA-dependent protein kinase (DNA-PK). In the present studies, the crosstalk between the HN2-induced DNA damage response and cell cycle progression were investigated in human lung epithelial A549 cells. HN2 treatment (1-20 µM; 24 hr) caused a concentration-dependent arrest of cells in the S and G2/M phases of the cell. This was associated with an inhibition of DNA synthesis as measured by incorporation of 5-ethynyl-2’-deoxyuridine (EdU) into cells in S phase. HN2-mediated cell cycle arrest was correlated with the activation of DNA damage and cell cycle checkpoint signaling. Thus, immunoblotting revealed that HN2 treatment led to time- and concentration-dependent increases of the expression of DNA damage response and checkpoint proteins including phosphorylation on ATM (S1981), H2AX (Ser139), and p53 (ser15). The activation of DNA damage signaling was most pronounced in S-phase cells followed by G2/M-phase cells. The induction of cell cycle arrest was partially suppressed by pretreatment with the ATM and DNA-PK inhibitors, KU55933 and NU7441. These data indicate that activation of ATM and DNA-PK signaling may be effective countermeasures for vesicant-induced tissue injury. Supported by NIH grants AR055073, NS079249, ES004738, and ES005022.
that genetic knockout of reganase-1 and roquin by their siRNA significantly enhances arsenical-induced production of inflammatory mediators IL6, IL18, and COX2. The 5Gs disassemble with concomitant degradation of roquin and reganase-1 provides a novel molecular mechanism by which warfare arsenicals cause skin inflammation and tissue damage. oxidative stress. Taken together, these data indicate that NM-induced DNA damage is associated with epidermal oxidative stress. Antioxidants may be an important strategy for the development of countermeasures to mitigate mustard-induced epidermal injury. Supported by NIH/NIEHS grants AR055073, ES050022, and T23ES007148.

2282 Ebselen Oxide Reduces the Dermatotoxicity of Mechloethamine In Vivo: A Comparison with Ebselen

H. Turnii,1 B. Cuffari1, M. A. Pino1, P. M. Ottlik2, and B. Billack1. 1St. John’s University, Jamaica, NY; and 2Rutgers University, Technology, Wroclaw, Poland.

Mechloethamine (HN2) is an alkylating agent and sulfur mustard mimetic which is also used in antitumor therapy. Dermal exposure of HN2 leads to epidermal necrotic tissue blistering. Previous work in our lab has shown that ebselen (EB-1) possesses anti-vesicant, anti-inflammatory, anti-bacterial, anti-fungal and cytoprotective properties, both in vivo and in vitro. We recently reported that ebselen oxide (EB-2), an analog of ebselen with a tetravalent selenium atom, also possesses anti-inflammatory and anti-fungal activity and confers cytoprotection against HN2 in vitro. The purpose of the present study was to determine the vesicle countermeasure potential of EB-2 in comparison to EB-1. To this end, the mouse ear vesicle model (MEVM) was used, with male Swiss Webster mice serving as the test strain. Compared to control ears, mouse ears exposed to a single dose of HN2 (0.500 µmol/ear) showed an increase in wet weights, ear thickness, edema, hyperplasia, vesication and inflammatory cell infiltration after 24 h. Fluorescence microscopy of TUNEL stained sections showed that the occurrence of apoptosis extended from the epidermis of the HN2 treated side all the way to the contralateral epidermis. In contrast, HN2 exposed mouse ears treated topically with EB-2 at a test dose of 0.250 mg/ear showed a significant decrease in wet weight (12% less compared to HN2 alone), morphometric thickness (13% less than HN2 alone) and vesication. Moreover, TUNEL staining revealed that HN2 ears treated with EB-2 (0.250 mg/ear) showed a decrease in apoptosis and vesication as compared to the HN2 group. In comparison to EB-2, topical treatment with EB-1 decreased HN2-induced changes in ear wet weights and morphometric thickness by 10% and 13%, respectively. Taken together, our study demonstrates that EB-2 is an equally efficacious test countermeasure to EB-1. Additional studies will be required to determine whether or not EB-2 exhibits more favorable pharmacokinetic parameters than EB-1 (e.g., bioavailability, duration of action, etc.).

2283 Oxidative Stress and DNA Damage in Mouse Epidermis following Exposure to Nitrogen Mustard

G. M. Composto1, T. Arunachalam1, D. L. Laskin1, D. E. Heck2, J. D. Laskin1, and L. B. Joseph1. 1Rutgers, The State University of New Jersey, Piscataway, NJ; and 2New York Medical College, Valhalla, NY.

Nitrogen mustard (SM, bis[2-chloroethyl] sulfide) is a potent vesicant that has been used in chemical warfare. It is a bifunctional alkylating agent known to target many tissues, particularly the skin. SM can cause inflammation, edema, necrosis, and blistering, depending on dose and time following exposure. Epidermal damage is associated with delayed wound healing and persistent dermatitis. The precise mechanism leading to skin damage induced by SM is not known. In the present studies, a modified semi-occlusive patch test model was used to analyze alterations of oxidative stress and DNA damage markers in mouse ear skin following exposure to the SM surrogate, nitrogen mustard (NM, bis[2-chloroethyl]methylene). NM (40 micromoles dissolved in 80% acetone/20%water) or vehicle control was applied onto 24 mm glass microfiber filters affixed to the shaved dorsal skin of CD-1 mice for 6 min. Epidermis was removed and analyzed 1-24 hr post-treatment by western blotting and immunohistochemistry. Within 1 hr of NM exposure, Akt, a serine/threonine-specific protein kinase known to play a role in apoptosis, was downregulated. This was associated with a 2.5-5-fold increase in expression of the double-strand DNA break marker, phosphorylated H2AX (pH2AX). And the DNA chain break-activated poly (ADP) ribose polymerase (PARP). Heme oxygenase-1, a marker of oxidative stress, also increased (1.5-4.5-fold) 1-12 hr post-NM exposure, along with proteins modified by 4-hydroxynonenal (2-3.6-fold over 1-24 hr), a lipid peroxidation end product. This was correlated with increased epidermal expression of 8-oxodeoxyguanosine (8-oxo-dG), an oxidized derivative of deoxyguanosine and a product of DNA oxidation, as well as expression of cytochrome oxidase-2 and inducible nitric oxide synthase. Infiltration of macrophages and neutrophils into the skin as well as mast cell degranulation suggested that cytokines and chemokines, as well as lipid mediators released in the tissue post-NM exposure contributed to

2284 Induction of DNA Damage and Stress Responses by the Sulfur Mustard Analog Mechloethamine in Human HaCaT Keratinocytes

R. Navarro1, Y. Jan2, D. E. Heck3, D. L. Laskin4, and J. D. Laskin2. 1University of Puerto Rico, Mayagüez, Puerto Rico; 2Rutgers University School of Public Health, Piscataway, NJ; 3New York Medical College, Valhalla, NY; and 4Rutgers, The State University of New Jersey, Piscataway, NJ.

Mustard compounds, including sulfur mustard and nitrogen mustards, are vesicants known to cause inflammation and blistering in the skin. These agents have been used in chemical warfare and continue to be chemical threats. Nitrogen mustard (mechloethamine, bis[chloroethyl][methyl]amine; HN2) and several derivatives including chlorambucil and melphalan, are also used in cancer chemotherapy. In the present studies, the effects of HN2 on DNA damage/stress responses were assessed in HaCaT human keratinocytes with the goal of elucidating mechanisms of cytotoxicity. We found that HN2 caused a time- and concentration-dependent inhibition of cell proliferation as well as a 2-50µtka of S/G2/M phases of the cell cycle. Western blotting revealed that HN2 treatment caused time-dependent changes in cell cycle regulatory proteins including increased expression of the cyclin-dependent kinase inhibitor, p27 Kip1, and decreased expression of cyclin D1 and the Ser/Thr cyclin-dependent kinase, CDK2. In addition, HN2 treatment increased expression of DNA damage/stress response proteins including auto-phosphorylation on H2AX (Ser139), p53 (ser15), HSP27 (Ser82), and protein acetylation on histone H4 (Lys16). HN2 also caused an upregulation of heme oxygenase-1 (HO-1). HN2 induced differential protein expression of DNA damage markers, but not stress-response markers, within cell cycle phases. The induction of H2AX (Ser139) and p53 was most pronounced in S-phase cells followed by G2/M-phase cells. Taken together, our studies demonstrate that HN2 modulates cell cycle checkpoints and activates DNA damage responses. We hypothesize that these signaling pathways are critical to the mechanism of vesicant-induced cell cycle arrest and cytotoxicity. Supported by NIH grants ES020721, AR055073, NS079249, ES047438, and ES050022.

2285 Role of Chemokine Signaling in Delayed Skin Inflammation following Exposure to Nitrogen Mustard

D. E. Heck1, L. B. Joseph2, G. M. Composto1, J. D. Laskin2, and H. Kim1. 1New York Medical College, Valhalla, NY; and 2Rutgers, The State University of New Jersey, Piscataway, NJ.

It is well established that dermal wounding is delayed following exposure to the vesicants nitrogen mustard (NM) and sulfur mustard. The molecular mechanisms underlying this effect remain poorly defined. Hallmarks of early responses to chemical burns are noted for infiltration of immune cells, which clear the tissue of dead cells and debris, these cells also release mediators that promote wound healing. Compelling evidence supports the thesis that malfunction of cyto-kine/chemokine signaling results in impaired neutrophil recruitment to sites of injury and contributes to skin destruction. We hypothesize that these signaling pathways are critical to the mechanism of vesicant-induced cell cycle arrest and cytotoxicity. Supported by NIH grants ES020721, AR055073, NS079249, ES047438, and ES050022.
Sulfur mustard (SM; bis (2-chloroethyl) sulﬁde) is a bifunctional alkylation agent used in chemical warfare. Depending on the dose and duration of exposure, SM can induce ocular irritation, tearing, photosensitivity, and short-term blindness. In the present studies, we examined the effects of ocular SM exposure on meibomian glands and goblet cells in the conjunctival eyelid borders of New Zealand white male rabbits. Twentyeight days post-SM exposure (0.4 microliters of neat SM applied directly to the central cornea), rabbits were sacriﬁced, eyelids removed, trimmed, and ﬁxed in paraformaldehyde/sucrose, embedded in parafﬁn, sectioned, and stained with hematoxylin and eosin (H&E) and Gomori’s trichrome (for analysis of collagen III). H&E staining revealed erosions in the epithelial surface of the eyelid borders along with an inﬂammatory cell inﬁltrate in the palpebral conjunctiva. The grape cluster-like appearance of the meibomian glands was still evident although the acini had lost their rounded structure and the specialized sebocytes were not as prominent as in control. These structural changes correlated with altered expression of fatty acid synthase (FAS) within the meibomian gland sebocytes of the lower eyelids of the SM exposed rabbits. Trichrome staining of the upper and lower eyelids revealed SM induced compaction of the dermis surrounding the meibomian glands. Interestingly, there were no differences in the size or total number of goblet cells in the conjunctiva of the upper and lower inner eyelid borders post-SM exposure when compared to the control. Periodic acid-Schiff (PAS, a differential mucin stain) staining revealed a 32% and 40% increase in neutral mucin containing goblet cells in the lower and upper eyelids of the SM exposed rabbits when compared to the control, respectively. Taken together these data suggest that SM injures the palpebral conjunctiva may in part modify goblet cell and meibomian gland function such that ocular barrier integrity may be compromised. Supported by NIH/NIEHS grants AR055073, ES05022, and T32ESE007148 (GMC).

2289 Warfare Agent and Pesticide Chloropicrin-Induced Toxic Reponses in Ex Vivo Rabbit Cornea and Primary Human Corneal Epithelial Cells

University of Colorado Denver, Aurora, CO.

Lack of research efforts to evaluate the mechanism of corneal toxicity in relevant injury models following chloropicrin (Trichloronitromethane; PS, CP), exposure has hampered the development of effective treatments against ocular injury from this ubiquitous agricultural pesticide which was employed during World War I as a chemical warfare agent. In addition to its accidental exposure, toxic effects of CP together with easy availability and lack of antidotes make it a potential agent for warfare and terrorism. Here, we analyzed the effects of CP exposure in ex vivo rabbit corneas and primary human corneal epithelial cells (HCE) to understand the mechanisms involved in CP-induced corneal injury. In ex vivo rabbit corneas, CP exposure induced signiﬁcant epithelial degradation and cell death. In HCE cells, CP exposure caused a dose-dependent decrease in viability and apoptotic cell death. These toxic effects could be related to DNA damage (p53 and H2AX phosphorylation) observed in HCE cells. In addition, CP exposure also induced caspase-3 and poly (ADP-ribose) polymerase (PARP) cleavage, suggesting their involvement in CP-related HCE cell death. CP exposure also led to increased cyclooxygenase-2 (COX-2) levels in both ex vivo rabbit cornea and HCE cells, indicating the role of cyclooxygenase and related pathways in CP-induced epithelial degradation. CP exposure in HCE cells also instigated an increase in phosphorylation of mitogen activated protein kinase-JNK as well as an increase in hemeoxygenase-1 (HO-1) expression and lipid peroxidation, further suggesting the role of oxidative stress in the activation of signaling pathways. In conclusion, CP caused an increase in protein carbonylation in ex vivo rabbit cornea and HCE cells. Proteomic analysis revealed an increase in the carbonylation of 179 proteins following CP exposure and further bioinformatics analysis found enrichment of the Pathways and cell processes affected by CP exposure in rabbit corneas and HCE cells.

2288 Corneal Injury following Ocular Exposure to Vesicating Agent Nitrogen Mustard

N. Tewari-Singh, D. G. Goswami, D. A. Ammar, R. Kant, D. Kumar, J. Petras, and R. Agarwal.
University of Colorado Denver, Aurora, CO.

Sulfur mustard (2,2’-dichloroethyl sulﬁde; SM) causes severe ocular injury, especially to the outermost corneal layer. Ocular exposure results in devastating acute and delayed injuries including inﬂammation, corneal edema, ulceration, opacity, neovascularization, and impaired vision. Effective therapies for SM-induced ocular injuries, mainly to the most affected corneal tissue, are not available. Hence, for screening therapeutic agents, we have established primary human corneal epithelial cells and rabbit corneal organ culture models with the SM analog nitrogen mustard (NM; Bis (2-chloroethyl) methyamine, HN2), which have helped to test the efficacy of potential therapeutic agents. To further test the therapeutic agents in vivo, establishment of suitable animal model and detailed understanding of the acute and chronic pathophysiology are essential. In the present study, using cornea from relevant ocular (in New Zealand white rabbits) and established clinical, histopathological and molecular markers. Right eye of each anesthetized rabbit was exposed to 100µL NM, and left eye was exposed to saline served as control. Clinicopathological observations and lesion quantiﬁcation showed that NM exposure induced corneal opacity (peak 1 day post-exposure), corneal ulceration (peak at day 14 and 21 post-exposure), eyelid, and conjunctival swelling (peak at day 1 post-exposure). NM induced an increase in corneal thickness, epithelial degradation, epithelial-stromal separation, and a surge in the number of inﬂammatory cells and blood vessels from day 3 to day 28 post-exposure. NM exposure also caused a signiﬁcant keratocyte cell death at 3 to 28 days post-exposure. NM also induced the expression of proteolytic and angiogenic mediators Metalloproteinase-9 and vascular endothelial growth factor, and elevated the levels of inﬂammatory cytokine IL-8, with maximal response at day 14 post-exposure. The ongoing studies in this ongoing effort will help in understanding the pathophysiology involved in NM-induced corneal injury, and in the evaluation of effective therapies.
proteasome pathway, catabolic process, intracellular protein transport, and tRNA aminoclylation for protein translation. Major pathways and processes identified in the molecular and proteomic analyses following CP exposure could be lead-hit targets for further biochemical characterization and therapeutic intervention.

2290 Development of a Novel Yorkshire Swine Model of Potassium Cyanide Poisoning with Improved Relevance toward Mass Casualty Care

M. C. Babini, C. M. Wilhelm, C. G. Fetzek, T. Vinci, J. Laney, and K. D. Herring

Exposure to cyanide (CN) poses a threat to both civilian and military populations, either through unintentional distribution involving plastic-containing fires or through intentional distribution as a weapon by terrorists. Current CN countermeasures are administered through intravenous (IV) infusion, ultimately complicating rapid and safe treatment in a mass casualty environment. The difficulties involved in the medical treatment of CN exposed patients are important to model when developing animal platforms for CN countermeasure testing. To address this, the study objective was to establish a well characterized large animal model that provided a more accurate representation of care during a mass casualty event to properly evaluate medical countermeasures for potassium cyanide (KCN) exposure. To properly represent this scenario, criteria for the animal model included: delayed onset of care, delayed lethality (>20 mins), and sufficient lethality to occur in >75% of untreated animals to allow for countermeasure efficacy comparisons in treated animals. Secondary endpoints evaluated arterial lactate, methemoglobin, pH, blood gases, glucose, blood pressure, heart rate, STsegment depression, body weight, and effectiveness of F2A (dimethyl trisulfide) during challenge. Dose rates of KCN ranged from 0.17 to 0.32 mg/kg/min. Models were fitted to the data to identify any significant effects among the dose administered, isoflurane concentration, SpO2, fraction of inspired oxygen (FiO2), and body weight. Control of these parameters prior to KCN challenge provided less variability for a sound animal model. The final model challenged anesthetized Yorkshire swine IV at a target rate of 0.185 mg/mL/min with an approximate 4.0 mg/mL KCN solution via a central line catheter. Upon injection, DMTS serves both as a sulfur donor forCN and as a metal chelator. Cyanide Antidote Dimethyl Trisulfide (DMTS) is a potent next-generation antidote against CN poisoning. Upon injection, DMTS serves both as a sulfur donor for CN and as a metal chelator.

2291 Developing and Testing a New Intramuscular Formulation for the Cyanide Antidote Dimethyl Trisulfide

Sam Houston State University, Huntsville, TX and US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.

Cyanide (CN) is an extremely toxic inorganic molecule that can readily cross biological membranes. It has been shown that dimethyl trisulfide (DMTS) is a potent next-generation antidote against CN poisoning. Upon injection, DMTS serves both as a sulfur donor for CN and as a metal chelator. Cyanide Antidote Dimethyl Trisulfide (DMTS) is a potent next-generation antidote against CN poisoning. Upon injection, DMTS serves both as a sulfur donor for CN and as a metal chelator.

2292 Transcriptomic Profile Analysis of Brain Inferior Colliculus following Acute Hydrogen Sulfide Exposure

D. Kim, P. Anantharam, E. M. Whitley, and W. K. Rumbeila

Iowa State University, Ames, IA; MBI Global, Kansas City, MO; and Pathogenesis LLC, Gainesville, FL.

Hydrogen sulfide (H2S) is a gaseous molecule produced endogenously and in the environment. Endogenously, it plays important roles in many physiological functions. Nonetheless, acute exposure to high concentration of H2S causes severe brain damage and induces long-term neurological sequelae. The cellular and molecular mechanisms underlying the H2S-induced dysfunction of central nervous system have not been clearly elucidated. To better understand the mechanisms of H2S-induced neurodegeneration, we performed RNA sequencing analysis to identify differentially expressed genes (DEG) and pathways that contribute to H2S-induced neurotoxicity. CS7BL/6j black mice were exposed by whole body inhalation to 765 ppm of H2S for 1, 2 or 4 days for 40 min on the first day and 10 min on subsequent days. The H2S-treated groups showed behavioral motor deficits and developed lesions in inferior colliculus (IC), among other regions. The IC was dissected at 2 hr post H2S exposure for each group and used for the transcriptomic analysis. RNA-Seq libraries were prepared using poly (A) enrichment and miRNAs were sequenced at 20 million reads per sample on an Illumina Hiseq2000 system. Acute exposure to H2S induced 283, 193 and 296 DEG (q-value < 0.05, fold-change > 1.5) for day 1, 2 and 4, respectively. Dysregulated biological pathways were further analyzed using Ingenuity Pathway Analysis. Transcriptomic analysis results and key molecular mediators deregulated biological pathways were validated using quantitative RT-PCR and Western blot assay. Acute exposure to high concentration of H2S was shown to activate Akt, Fas, c-Fos, ATF2, and TNFα in the IC. These results indicate that exposure to H2S induces dysregulation of multiple pathways leading to activation of the inflammation response. The obtained transcriptomic data may hold a role in elucidating the mechanisms of H2S-induced neurotoxicity, and neurodegeneration following acute H2S exposure.

2293 ButyrylcholinesteraseG117H as a Catalytic Bioscavenger: Structure-Dynamics-Activity Relationships of Surface Peptide Network Variants

K. Hester, K. Bhattachari, H. Jiang, P. Agarwal, J. Liu, and C. Pope

Oakland State University, Stillwater, OK; Oak Ridge National Laboratory, Oak Ridge, TN; and Charles River Laboratories, Reno, NV.

The use of human butyrylcholinesterase (BChE) as a bioscavenger for organophosphorus (OP) anticholinesterases is limited by its stoichiometric reaction with OP toxicants. After over 2 decades of searching for catalytic variants, the most promising mutant (BChE G117H) has a turnover rate that is too slow to be toxicologically relevant. There is a growing body of evidence that links protein dynamics to enzyme catalysis. Surface peptide networks exhibit dynamic fluctuations in concert with the catalytic reaction and may be hypothesized to play a role in energy transfer from the solvent to the active site. Molecular simulations with paraoxon as the substrate identified a catalytically active surface peptide network at residues 276-286 of human BChE G117H. We hypothesized that increasing the number of peptides in this network with long side-chain hydrophobic peptides could lead to higher transfer to catalytic residues and increased catalytic activity. We constructed six His4-tagged mutants with three peptide insertions into this region with an identity of ENX, where “X” is one of 6 different amino acids (A, G, I, P, R, and T). These mutants were produced by transfecting Spodoptera frugiperda Sf9 cells with a bacmid DNA-CellFECTIN mixture, and purified using a Ni2+-NTA agarose column. Substrate kinetics with butyrylthiocholine iodide were determined using a modified Ellman assay and fit to the Michaelian model. Resistance to inhibition was determined as rate of butyrylthiocholine hydrolysis in the presence of concentrations of paraoxon, ecothiophate and disopropylfluorophosphate (DFP) that elicited complete inhibition of wild-type BChE. Substrate kinetics indicated a reduction in kcat in all six surface network mutants compared to BChE G117H. In contrast, some BChE G117H mutants were relatively more resistant to inhibition by echaithiophate (three mutants; 12-18%) and DFP (five mutants; 15-19%). BChE G117H was more resistant to inhibition by paraoxon than all surface network mutants. These results provide further evidence that this network of surface peptides may influence OP catalysis. Further computational and biochemical studies could aid in optimizing catalytic bioscavenger development.
Seizure Behavior and Neurodegeneration Are Not Predicted by Acetylcholinesterase Inhibition in a Rat Model of Acute Disopropylfluorophosphate (DFP) Intoxication

E. A. González, A. C. Rindy, M. A. Guignet, D. A. Bruun, D. J. Harvey, and P. J. Lein. University of California Davis, Davis, CA.

Several organophosphates (OP) can trigger seizures that rapidly progress to status epilepticus (SE) in humans and preclinical models. It is thought that inhibition of acetylcholinesterase (AChE), the enzyme responsible for terminating cholinergic neurotransmission in the central and peripheral systems, mediates OP-induced seizures. However, in a rat model of acute DFP intoxication, 10-15% of animals exhibit minimal to no seizure behavior upon injection with a dose of DFP that typically induces robust seizure behavior in rats of the same strain, sex, and age. Therefore, this study examined whether varying levels of AChE inhibition explained the differences in seizure response between low and high responders to DFP. Adult male Sprague-Dawley rats were acutely intoxicated with DFP (4 mg/kg, s.c.) followed by a combined injection of atropine sulfate (2mg/kg, i.m.) and 2-PAM (25 mg/kg, i.m.) and monitored for seizure activity for 4 h post-exposure. AChE activity was measured in the cortex, hippocampus, cerebellum, and amygdala using the Ellman assay at 1 and 4 d post-exposure. Neuronal damage was measured using Fluoro-Jade C staining at 1, 2, 4, and 6 d post-exposure. No significant differences in AChE activity between high-responding and low-responding animals were detected in any brain region at any time point, with the exception of the cerebellum at 4 d. At 1 d post-exposure, high responders showed significant neuronal damage in the somatosensory cortex, piriform cortex, and hippocampus, whereas low responders did not. However, delayed neuronal damage was observed in the piriform cortex of low responders at 2 and 4 d post-exposure. At 60 d, degenerating neurons remained present in the cortex of high responders but were no longer detected in low responders. These findings suggest that AChE activity is not predictive of seizure behavior or neurodegeneration in animals intoxicated with DFP, and suggests that there are SE-independent mechanisms contributing to the delayed neurodegeneration caused by acute OP intoxication. Supported by the NIH CounterACT program (NS079202); predoctoral fellowship to EAG (GM5676520, Initiative for Maximizing Student Development); predoctoral fellowship to MAG (NHMG099608, David and Dana Looury Foundation).

Novel Brain-Penetrating Oxime Acetylcholinesterase Reactivators Attenuate Organophosphate-Induced Neuropathology in the Rat Hippocampus

M. B. Dail, C. A. Leach, R. B. Pringle, E. C. Meek, and J. E. Chambers. Mississippi State University, Mississippi State, MS.

The nerve agent sarin and the active metabolite of the insecticide parathion, paraoxon (PXN), inhibit acetylcholinesterase, causing excess synaptic acetylcholine and seizures which, if not stopped, result in neuronal damage in the rodent brain. Our lab invented substituted phenoxyalkyl pyridinium oxime acetylcholinesterase reactivators (US Patent 9,227,937) that penetrate the rat blood-brain barrier in vivo tests with a sarin surrogate (nitrophenyl isopropyl methylphosphonate, NIMP) or PXN, and reduce the time to cessation of seizure-like behaviors compared to 2-PAM. To test the ability of our novel Oxime 20 to prevent neuropathology, changes in the levels of Nissl, NeuN, and Fluoro-Jade B histological staining were used as indicators of neuronal damage in the CA1 hippocampal region after either 0.6 mg/kg NIMP, 0.8 mg/kg PXN, or vehicle (MultiSol) SC and 1 hour later 146 µmol/kg of a novel oxime or 2-PAM in vehicle (MultiSol) IM. Animals were euthanized 4 days after challenge and assigned a numeric code to blind participants to their positive charge and the highly restrictive blood-brain barrier (BBB), thus allowing the potential for brain damage to occur. A box containing the BBB is to deliver the oximes via this route can provide direct nose-to-brain drug transport along the olfactory and trigeminal nerves while bypassing the BBB, potentially allowing for rapid therapeutic action and protection against CNS damage. Our laboratories have synthesized a series of novel phe-noxyalkyl pyridinium oximes (US patent 9,227,937) that have shown the ability to reactivate AChE, with novel Oxime 20 showing promise as an effective reactivator. This study explored the intranasal delivery potential of Oxime 20 and 2-PAM, the current oxime for the US, to decrease brain AChE inhibition after exposure to a sublethal challenge (65-75% brain AChE inhibition) of a sarin surrogate (nitrophenyl isopropyl methylphosphonate, NIMP). Sprague-Dawley rats received 1.46µmoles in 10µl multisol vehicle of either Oxime 20 or 2-PAM bilaterally 1 hr after OP administration and were euthanized 5 min after oxime delivery. Ofactory bulbs were harvested, and brains were dissected into three regions: midbrain, midbrian, and hindbrain. Acetylcholinesterase (AChE) reactivation in the olfactory bulbs, and 20% reactivation in each of the forebrain, midbrain, and hindbrain. These data suggest rapid delivery of the oximes into all regions of the brain and a fast therapeutic onset. Use of this alternative delivery could provide a novel way in protecting against OP neurotoxicity and address the current deficiencies in OP therapy. Supported by the Defense Threat Reduction Agency HDTA 1-15-0-0046.

Assessment of Nerve Agent Reactivators Using the Mouse Phrenic Nerve Hemidiaphragm Preparation

Nerve agents are highly potent acetylcholinesterase (AChE) inhibitors, which lead to an inability of the AChE enzyme to hydrolyze the neurotransmitter acetylcholine (ACh). The resulting build-up of ACh leads to overstimulation of neuromuscular junctions, glands, and central nervous system, which results in salivation, bronchoconstriction, tremors, seizures, and central respiratory failure. Treatment with atropine, a reactivator and an anticonvulsant, can provide a fast recovery. We have employed an ex vivo mouse phrenic nerve hemidiaphragm preparation to evaluate a variety of reactivators for their ability to restore physiologic function following inhibition by the nerve agent sarin (GB). Male C57BL/6 mice 8-10 weeks old were used for all studies. Hemidiaphragm/phrenic nerve bundles/ribs were dissected and maintained in tissue baths with oxygenated (95%O2/5%CO2) Tyrode's buffer solution at 37°C. Tetanic stimulation parameters are 100 Hz, 2 sec train, 5 volts, resting tension ~3.5 g every 10 min. The experimental protocol consisted of five phases: Acclimation (buffer only), 1 hr; Baseline (buffer only), 30 min; GB exposure, 30 min; Reanimation, 1 hr; and Recovery (buffer only), 30 min. The GB bath concentration was used 5 x 10-6 M, and bath concentrations for each reactivator were 200, 100, or 50 µM. The reactivators evaluated, in relative order of efficacy at the 200 µM dose, were Hlo-7, MMB-4, H-6, SWI-80A(+), SWI-80A(-), SWR-80A, and 2-PAM. All reactivators significantly improved peak area, action potential amplitude, and twitch tension during the Reanimation phase in the absence of treatment. The oxime reactivators currently fielded by the US Army is 2-PAM. Several of the reactivators tested provided an improvement over 2-PAM and have the benefit of also being centrally active, which could better protect the CNS in an in vivo model. Disclaimers: The views expressed in this abstract are those of
the authors and do not reflect the official policy of the Army, DoD, or the US Government. The experimental protocol was approved by the Animal Care and Use Committee at the US AMRICD and all procedures were conducted in accordance with the principles stated in the most current Guide for the Care and Use of Laboratory Animals; Animal Welfare Act and implementing Animal Welfare Regulations, as amended; and Public Health Service Policy on Humane Care and Use of Laboratory Animals.

2298 Delayed Treatment with Midazolam, Allopregnanolone, and Perampanel Terminates Benzodiazepine-Refractory Seizure Activity following Acute Diisopropylfluorophosphate (DFP) Exposure

D. A. Bruun, A. Dhiné, B. Hobson, S. Supasai, M. Rogawski, and P. J. Lein. University of California Davis, Davis, CA; and University of California Davis, Sacramento, CA.

Organophosphorus (OP) nerve agents are potent neurotoxins. OPs can trigger seizures that rapidly progress to status epilepticus (SE). If not terminated within minutes, OP-induced SE leads to extensive neuropathology and long-term behavioral deficits. Current standard-of-care includes atropine, a cholinesterase reactivator (e.g., 2-PAM), and a benzodiazepine (e.g., midazolam). In a rat model of acute intoxication with DFP, delayed administration of midazolam (40 min after seizures begin) reduces EEG amplitude but does not terminate electrographic seizures. To identify a better treatment for benzodiazepine-refractory OP-induced seizures, we are investigating adjunct therapies to standard-of-care. Adult male Sprague-Dawley rats were permanently implanted with cortical EEG leads prior to administration of DFP (4 mg/kg, s.c.). Immediately following DFP, animals were treated with atropine (2 mg/kg, i.p.), diazepam (2-PAM; 25 mg/kg, i.p.), or perampanel (2 mg/kg, i.p.), singly or in combination. Combining midazolam with allopregnanolone, a neurosteroid that acts as a positive allosteric modulator of the GABAA receptor, modestly attenuates electrographic seizure activity compared to midazolam alone. Combined treatment with midazolam, allopregnanolone, and a low dose of perampanel, a selective non-competitive antagonist of AMPA receptors, completely eliminates electrographic seizures. Neuropathology was examined by magnetic resonance imaging (MRI) and histology in a separate cohort of animals who were not surgically implanted for EEG. The combination treatment stopped behavioral seizures in 100% of DFP-treated animals within a few minutes of administration. MRI and histology data suggest that combined therapy is more efficacious than midazolam alone in mitigating the neuropathological effects associated with DFP-induced SE. In summary, post-intoxication treatment with a combination of midazolam, allopregnanolone, and perampanel holds significant promise as a more effective medical countermeasure for acute OP intoxication relative to current standard-of-care. Supported by NIH CounterACT Program (NS079202).

2299 Acute Diisopropylfluorophosphate (DFP) Intoxication Promotes Degeneration and Senescence in Neurons in the Rat Hippocampus and Thalamus

Y. Tsai, S. Supasai, A. C. Grodzi, D. A. Bruun, and P. J. Lein. University of California Davis, Davis, CA.

Organophosphates (OPs) can cause acute neurotoxicity by irreversibly inhibiting acetylcholinesterase (AChE), the enzyme responsible for terminating cholinergic neurotransmission by hydrolyzing acetylcholine (ACh). Acute intoxication with the OP, DFP, leads to excessive buildup of ACh at synaptic clefts resulting in cholinergic crisis, which in preclinical models includes seizures that can rapidly develop into status epilepticus. It is postulated that traumatic brain injury increases the risk for late-onset neurodegenerative disease, but whether acute OP-induced status epilepticus promotes neuropathological phenotypes consistent with late-onset neurodegeneration is not known. To address this question, this study investigated whether acute DFP intoxication promotes cellular senescence in rat brain. Adult male Sprague-Dawley rats were randomly divided into 2 groups: (1) animals that received a single dose of DFP (4 mg/kg) and (2) animals that received an equal volume (300 microliter) of vehicle (saline). Both groups were administered atropine sulfate and 2-PAM one minute later. Brain tissues were evaluated at 3 months post-DFP intoxication. Neurodegeneration was assessed using Fluoro-Jade C staining; senescence, by immunohistochemistry for the senescence marker p16. Senescent cell type was determined by co-localization of p16 immunoreactivity with biomarkers for endothelial cells (CD31/PECAM-1), astrocytes (S100beta), and neurons (NeuN). The data indicate that a single acutely toxic dose of DFP induces senescence in neurons but not endothelial cells or astrocytes. Moreover, neuronal expression of p16 was especially upregulated to the hippocampus, particularly the hilus region of dentate gyrus and the CA3 region, and thalamus. Significant neurodegeneration was also detected in these same brain regions as determined by Fluoro-Jade C staining. These data suggest that acute DFP intoxication may increase risk of neurodegenerative disease. Supported by NIH CounterACT grant # NS079202.

2300 In Vitro Reactivation of Organophosphate-Inhibited Acetylcholinesterase by Novel Pyridinium Oximes in Brain Tissue from Juvenile and Adult Rats

J. M. Garcia, and J. E. Chambers, Center for Environmental Health Sciences, Mississippi State University, Mississippi State, MS.

Organophosphorus (OP) compounds are best known for their acute neurotoxicological effects as acetylcholinesterase (AChE) inhibitors. Treatment includes an oxime, such as pralidoxime (2-PAM), which is utilized to reactivate AChE phosphorylated by an OP compound. Novel OPPs (OPPAs) and pyridinium pyrophosphonates (US Patent 9,203,905) have been developed for penetration of the blood-brain barrier to prevent or attenuate seizures and central nervous system damage. To further enhance our understanding of OP intoxication with the goal of developing more effective antidotes, information regarding the effective- ness of the novel oximes in brain tissue from both sexes and age differences is needed. Previous studies in rats have indicated no differences in the sensitivity of brain AChE to oxon inhibition at different ages. Paraoxon (the active metabolite of the insecticide parathion) and a nerve agent (sarin surrogate, 4-nitrophenyl isopropyl methylphosphonate (NIMP), were incubated with pooled rat brain homogenate from five animals in adult males, females, and 12-day-old male rats. At 40 min post-exposure, the animals were pretreated with pyridostigmine (0.1 mg/kg, im) prior to DFP (4 mg/kg, s.c.) and at 40 min post-exposure, diazepam (DZP, 5 mg/kg, ip), midazolam (MDZ, 0.7 mg/kg, im) or vehicle. Acute DFP intoxication caused calcification in the thalamus and hippocampus as early as 14 days post-exposure, as detected using micro-CT and confirmed by Alizarin staining. The area of calcium deposition was positively correlated with increased time post-DFP, but not with behavioral seizure severity. Calcium deposition paralleled the appearance and amount of immunoreactivity for osteopontin and B-amyloid, both markers of neurodegeneration. Post-DFP treatment with DZP or MDZ did not prevent calcium deposition or other neuropathological abnormalities at 90 and 180 days. Neuroinflammation (microglial activation and astrogliaosis as detected by IBA-1/CD68 and GFAP/S100B immunoreactivity, respectively) and neurodegeneration (assayed by Fluoro-Jade C labeling) were significantly increased in the thalamus, hippocampus, periform cortex, and amygdala at 90 and 180 days. Neither DZP nor MDZ effectively pro-
Novel phenoxyalkyl pyridinium oximes (US Patent 9,227,937) designed to increase their ability to cross the blood-brain barrier (BBB) have previously shown the ability to reactivate inhibited brain cholinesterase (ChE) in vitro and in vivo.

In vivo, the novel oximes at the onset of seizure-like behavior (25 min) scored for signs of seizure-like behavior was scored on a scale of 1-5. Twenty-four-hour survival was moderate for the novel oximes. Five of the novel oximes alone yielded 30-65%, and 30-85% survival and a novel oxime in combination with 2-PAM (33-50%) but due to its inability to cross the BBB, seizure-like behavior persisted over the 8 hours.

Exposure of guinea pig brain ChE reactivation was generally lower than in human equivalent dosages of atropine (0.65 mg/kg) and the currently approved oxime, PAM-146 (µmoles/kg), or novel oximes at the onset of seizure-like behavior (25 min).

The HPLC and GC-MS-SPME analysis revealed good retention of DMTS formulations in glass ampules. The DMTS stability of a DMTS formulation (IM-DMTS) was stored at 4, 25 and 37 °C temperatures in hermetically sealed glass ampules. The DMTS concentrations of these samples were measured by HPLC-UV at periodic time intervals. Each sample was analyzed by breaking open an individual ampule. Over the nine month period of the study, no significant DMTS loss was observed in the samples stored at 4 and 25 °C.

It has been previously reported that GABA<sub>A</sub> receptor (GABA<sub>A</sub>R) antagonists, including pentylenetetrazole (PTZ), tetramethylenedisulfotetramine (TETS), and picrotoxin (PTX), which are potent convulsants in mammalian models, trigger seizure-like behavior in zebrafish (Danio rerio) larvae. Extracellular field potential recordings obtained from the optic tectum of 5 days post-fertilization (dpf) zebrafish confirmed that acute exposures to all three GABA<sub>A</sub>R antagonists elicited extra-cellular spiking patterns consistent with seizure activity. However, the pattern of electrical activity varied between the individual GABA<sub>A</sub>R antagonists, which is consistent with data from primary mammalian neuronal cell cultures and rodent models of TETs and PTX-induced seizures. Collectively, these data suggest the possibility of differential GABA<sub>A</sub>R subunit profile binding for each convulsant. To address this question, genetic knockdown using morpholinos (MO) targeting GABA<sub>A</sub>R subunit-specific mRNA was used to delineate the full receptor subunit profile critical for TETs- and PTX-induced seizures. At 3 dpf, tropical wildtype zebrafish injected with MO were acutely exposed to seizure-causing concentrations of TETs or PTX added to fish water. Behavior was recorded for 20 min post-exposure using the Noldus automated tracking system to determine whether MO knockdown prevented chemical-induced seizure behavior. Based on these experiments, a differential GABA<sub>A</sub>R subunit binding profile was identified for TETs vs. PTX. The subunits a2, b2, and extrasynaptic δ are essential to the seizure-inducing activity of both TETs and PTX, whereas α1 and β3 were important for TETs but not PTX-induced seizures, while γ2 was uniquely important for PTX-induced seizures. Phylogenetic analyses demonstrate homologous subunits between zebrafish and mammalian GABA<sub>A</sub>R.
The aryl hydrocarbon receptor (AhR) mediates the toxic effects of dioxin-like compounds, such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). Sequence and structural features of AhR can underlie species- and population-specific differences in its affinity for TCDD and other agonists. While most vertebrates possess at least one AhR that binds TCDD tightly, all characterized amphibian AhRs bind TCDD with very low affinity. Our previous analyses of AhRs from Xenopus laevis (a frog; order Anura) and Ambystoma mexicanum (a salamander; order Urodela) identified three key amino acid residues in the ligand-binding domain (LBD) that underlie low-affinity binding. In X. laevis AhR1β, these are A354, A370, and N325. In studies of the AhR of the amphibian Gymnopus multiplicata, we sought to determine if AhRs from all three amphibian orders share the low-affinity phenotype. *G. multiplicata* represents Order Apoda (caecilians), a clade of legless amphibians that diverged early from the class’s common lineage, prior to the split between frogs and salamanders. cDNA was isolated by RT-PCR from tissue provided by the Museum of Vertebrate Zoology at the University of California, Berkeley. The encoded protein (92.7 kDa) is monophyletic with vertebrate AhR1s, sharing 59% identity with *X. laevis* AhR1β and 63% identity with *A. mexicanum* AhR. An LBD homology model suggests that the basic architecture of the caecilian AhR closely resembles that of other species, and the LBD sequences include the three signature residues of low TCDD affinity. We measured the TCDD responsiveness with transactivation assays employing pGudLuc6.1, a luciferase reporter construct driven by the mouse *CYP1A1* enhancer region. For *G. multiplicata* AhR, the EC50 for reporter gene induction by TCDD was 28.46 nM, similar to *X. laevis* AhR1β (26.8 nM) and dramatically less than a chimeric frog AhR containing the mouse LBD (0.2 nM). Taken together, low TCDD responsiveness and sequence conservation with the frog and salamander AhRs suggest that this caecilian AhR also binds TCDD with low affinity. We predict *G. multiplicata* is similarly resistant to the toxic effects of TCDD and other xenobiotic AhR agonists.

### 2307 Metatranscriptomic and Metabolomic Investigation of Dietary 2,3,7,8-Tetrachlorodibenzo-p-dioxin Exposure in Mice

R. G. Nichols, J. Zhang, P. B. Smith, G. H. Perdew, and A. D. Patterson, Pennsylvania State University, University Park, PA.

Understanding the interaction between the gut microbiome and the host following toxicant exposure is an important, emerging area of investigation and one that will hopefully improve the understanding of toxicological mechanisms. 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) is a persistent organic pollutant that has been reported to cause compositional changes within the gut microbiome while also promoting liver damage and intestinal inflammation. In the current study, we conducted metatranscriptomic, 16S rRNA amplicon sequencing, and metabolomic analysis to further understand how TCDD modulates the host-gut metabolic axis. Following a newly optimized bacterial ribosomal RNA depletion method to remove 16S and 23S RNA and RNA sequencing of the isolated mRNA on the Illumina HiSeq, several metatranscriptomics analysis pipelines were used including MetaTrans, SAMSA (Simple Annotation by Metatranscriptomes by Sequence Analysis) and COMAN (Comprehensive Metatranscriptomics Analysis). Due to the depth of sequencing, specific mRNA were matched to the bacterial species that created them, further increasing analytic potential. Within the same isolated cecal contents we completed long read 16S RNA sequencing to better facilitate species level identification of the gut microbiome community. Additionally, 1H NMR, gas chromatography-coupled mass spectrometry and liquid chromatography-coupled mass spectrometry were used to measure host and microbiome metabolic changes after TCDD exposure. Through an integrated network analytics approach, the metabolomics, 16S rRNA amplicon sequencing, and metatranscriptomic data were integrated to uncover microbiome and metabolite interactions that help provide a more detailed view of the toxicological mechanisms associated with TCDD exposure in mice.

### 2308 Inducible Loss of Hepatocyte Aryl Hydrocarbon Receptor Increases Epididymal White Fat Thermogenesis through the Activation of Fibroblast Growth Factor 21

N. Girer, E. Hossain, and C. Elferink, University of Texas Medical Branch, Galveston, TX.

The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor with numerous physiological roles. Fibroblast growth factor 21 (FGF21) is an important metabolic hormone that has recently been shown to be under the regulation of AhR. FGF21 is secreted from the liver in response to prolonged cold exposure and promotes thermogenesis in white fat deposits. Exogenous FGF21 administration results in weight loss, reduced fat mass, and improved insulin sensitivity in various models of obesity. Consistent with recent data showing that a hepatocyte-targeted loss of the AhR results in elevated hepatic FGF21 mRNA and protein, we utilize a novel tamoxifen-inducible AhR knockout mouse model (AhR<sup>fl/fl</sup>Alb<sup>CreERT2</sup>) to demonstrate that a loss of hepatocyte AhR results in significant 2-fold induction of hepatic FGF21 transcription and significant 3-fold increase of serum FGF21 protein concentrations relative to AhR<sup>fl/fl</sup> control mice. Epididymal white adipose tissue (eWAT) isolated from AhR<sup>fl/fl</sup>Alb<sup>CreERT2</sup> mice further reveals that increased hepatic FGF21 is associated with the promotion of thermogenesis, as evidenced through greater immunohistochemical staining for uncoupling protein 1 (UCP1) in AhR<sup>fl/fl</sup>Alb<sup>CreERT2</sup>- and a significant 2.1-fold increase in the rate of mitochondrial respiration relative to AhR<sup>fl/fl</sup>. To demonstrate that FGF21 is necessary for the thermogenic phenotype observed in eWAT, we generated a doubleconditional, tamoxifen-inducible AhR-FGF21 knockout mouse model (AhR<sup>fl/fl</sup>FGF21<sup>-/-</sup>Alb<sup>CreERT2</sup>). Compared to AhR<sup>fl/fl</sup>FGF21<sup>-/-</sup> control mice, AhR<sup>fl/fl</sup>FGF21<sup>-/-</sup>Alb<sup>CreERT2</sup> mice do not exhibit any evidence of increased thermogenesis within eWAT. The data therefore suggest that the AhR can influence white adipose physiology directly through the modulation of hepatic FGF21. Given the ability of increased FGF21 to counteract the obese phenotype, our laboratory is currently investigating the potential use of AhR antagonists and/or selective aryl hydrocarbon receptor modulators as a therapeutic means of increasing de novo FGF21 production. This work is supported by grants R01ES026874 and T32ES007254.

### 2309 Agonist-Specific Aryl Hydrocarbon Receptor-Mediated Differential Gene Expression

A. D. Joshi, E. Hossain, and C. J. Elferink, University of Texas Medical Branch, Galveston, TX.

The aryl hydrocarbon Receptor (AhR) is a ligand-activated transcription factor known to regulate adaptive and toxic responses to a variety of chemicals, pollutants including the polycyclic aromatic hydrocarbons, most notably 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). Upon activation by TCDD, the AhR translocates into the nucleus and binds to DNA at the Xenobiotic Response Element (XRE) in partnership with the Aryl hydrocarbon Receptor Nuclear Translocator (ARNT) to drive target gene expression, most notably cyp1a1. Our recent studies identified stanniocalcin 2 (st2c) as a novel AhR target gene responsive to the endogenous AhR agonist cinnamonic acid (CA). CA-dependent AhR-XRE-mediated st2c upregulation is responsible for cytoprotection against endoplasmic reticulum/oxidative stress-induced apoptosis both in vitro and in vivo. Significantly, CA but not TCDD induces expression of st2c in hepatocytes. In contrast to TCDD, CA is unable to induce the cyp1a1 gene, thus revealing an agonist-specific mutually exclusive transcriptional response. Studies reported here provide a mechanistic explanation for this dichotomous response by identifying an interaction between the AhR and the metastasis-associated protein 2 (MTA2). Immunoaffinity purification using an anti-AhR antibody followed by LC-MS/MS identified MTA2 as a novel - agonist specific - cofactor recruited by the AhR. Moreover, co-IP and ChIP studies confirmed the AhR-MTA2 interaction reported here provide a mechanistic explanation for this dichotomous response by identifying an interaction between the AhR and the metastasis-associated protein 2 (MTA2). Immunoaffinity purification using an anti-AhR antibody followed by LC-MS/MS identified MTA2 as a novel - agonist specific - cofactor recruited by the AhR. Moreover, co-IP and ChIP studies confirmed the AhR-MTA2 interaction...
gene-editing strategy was employed to assess role of chromatin architecture in agonist-specific stc2 expression. Our data suggest that the stc2 XRE cassette can transfer CA responsiveness to the cypl1a1 gene in context of chromatin packaging but not in vitro. In summary, this study describes a novel physiological role for AhR and highlights the complexities and potential biological ramifications resulting from agonist-specific AhR activation.

2310 Synergistic Interactions of Ah Receptor Ligands and Short Chain Fatty Acids in Colon-Derived Cells

U. Jin. Texas A&M University, College Station, TX.

Short chain fatty acids (SCFAs) including acetate, propionate, and butyrate are gut microbiota metabolites that are highly produced in animals on fiber-rich diets and SFCA production is associated with health-protective responses in the intestine. Microbiota-derived tryptophan metabolites that act through the aryl hydrocarbon receptor (AhR) also induce similar protective effects in the intestine and this study investigates interaction of SCFAs and AhR ligand on expression of Ah-responsive genes such as Cyp1a1/CYP1A1 in YAMC mouse colonocyte and Caco2 human colon cancer cell lines. Butyrate slightly induced CYP1A1 but synergistically enhanced AhR ligand-induced Cyp1a1/CYP1A1 in these cells with comparable enhancement being observed for 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and also microbiota-derived AhR ligands tryptamine, indole, and 1,4-dihydroxy-2-naphthoic acid (DHNA). The effects of butyrate on enhancing induction of Cyp1b1/CYP1B1, AhR repressor (Ahhr/Ahrr) and TCDD-inducible poly(ADP-Ribose) polymerase (Tiparp/TIPARP) by AhR ligands were gene- and cell-context-dependent with Caco-2 cells being the most responsive cell line. Like butyrate and propionate, the prototypic hydroxyacids acid-derived histone deacetylase (HDAC) inhibitors Panobinostat and Vorinostat also enhanced AhR ligand-mediated induction and this was accompanied by enhanced histone acetylation. Acetate also enhanced basal AhR ligand-inducible Ah responsiveness and histone acetylation demonstrating for the first time that acetate is an HDAC inhibitor. These results demonstrate SCFA-AhR ligand interactions in YAMC and Caco-2 cells where SCFAS synergistically enhance basal and ligand-induced expression of AhR-responsive genes.

2311 Urolithin A Is a Natural Human AhR Antagonist That Exhibits Anti-Inflammatory Activity

G. Muku, I. Murray, and G. Perdew. Pennsylvania State University, University Park, PA.

Aryl hydrocarbon receptor (AhR) is characterized as a xenobiotic receptor. However, recent studies have pointed to a role of AhR in myriad of different cellular mechanisms, including cell proliferation, tumor invasiveness, and cytokine signaling. We have previously demonstrated that AhR antagonism attenuates aggressive phenotype in head and neck tumor cell lines. Discovery of its numerous physiological functions raised the hypothesis of the existence of endogenous ligands for AhR. Over the last decade, a number of endogenous and natural AhR ligands has been identified, including the agonists indole, kynurenic acid, indirubin, and natural antagonists flavonoids that are abundant in plants. Here, we investigated whether urolithins, gut microbiota-derived AhR ligands tryptamine, indole, and 1,4-dihydroxy-2-naphthoic acid (DHNA). The effects of butyrate on enhancing induction of Cyp1b1/CYP1B1, AhR repressor (Ahhr/Ahrr) and TCDD-inducible poly(ADP-Ribose) polymerase (Tiparp/TIPARP) by AhR ligands were gene- and cell-context-dependent with Caco-2 cells being the most responsive cell line. Like butyrate and propionate, the prototypic hydroxyacids acid-derived histone deacetylase (HDAC) inhibitors Panobinostat and Vorinostat also enhanced AhR ligand-mediated induction and this was accompanied by enhanced histone acetylation. Acetate also enhanced basal AhR ligand-inducible Ah responsiveness and histone acetylation demonstrating for the first time that acetate is an HDAC inhibitor. These results demonstrate SCFA-AhR ligand interactions in YAMC and Caco-2 cells where SCFAS synergistically enhance basal and ligand-induced expression of AhR-responsive genes.

2312 Agonist-Activated Aryl Hydrocarbon Receptor Suppresses Fibroblast Growth Factor 21 Gene Expression Through Binding to a Novel Upstream Putative Xenobiotic Response Element within the Promoter Region

E. Wright, N. Giner, and C. Efflerink. University of Texas Medical Branch, Galveston, TX.

The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor that plays a critical role in many physiological processes. Recent data implicate the AhR in transcriptional modulation of the metabolic hormone fibroblast growth factor 21 (FGF21). FGF21 is secreted from the liver in response to various stressors, promotes a brown adipocyte-like phenotype in white fat deposits, and improves glucose metabolism when administered to various models of obesity. The precise mechanism by which the AhR regulates Fgf21 transcription remains unclear, given previous observations that show AhR agonists can both induce and suppress Fgf21 transcription. The data from these studies nevertheless consistently demonstrate that the AhR binds to a xenobiotic response element (XRE) located 72 bp upstream of the Fgf21 transcriptional start site. Here, we demonstrate that the AhR can also bind to two additional upstream putative XRE sequences located at -862 bp and -1744 bp. We hypothesize that these sites may be critical for directing the AhR agonist-mediated induction or suppression of Fgf21 transcription. Through chromatin immunoprecipitation studies and quantitative PCR in mouse hepatic tissue, we observe that maximal, agonist-driven Fgf21 transcription is associated with decreased AhR binding to the distal putative XRE from constitutive levels detected in vehicle-treated animals. Additional data reveal that agonist-dependent Fgf21 transcription is transient, reaching a minimum at 24 h. Ligand-induced AhR binding to the proximal XRE is increased relative to vehicle, whereas AhR binding to the mediol XRE is constitutive and not influenced by agonist. Introduction of a point mutation targeting the distal putative XRE in a luciferase reporter construct that abolishes AhR binding showed that loss of constitutive binding increased promoter activity. We therefore conclude that AhR binding to the distal putative XRE may be required for agonist-mediated suppression of Fgf21 gene expression. We are currently working to further elucidate this novel mechanism of agonist-mediated repression and XRE selectivity, as well as its potential therapeutic applications within the context of hepatic FGF21 expression and obesity. This work is supported by grants RO1ES266874 and T32ES007254.
The aryl hydrocarbon receptor (AHR) is a basic helix-loop-helix, PER-ARNT-SIM (bHLH-PAS) cytosolic transcription factor that is responsible for mediating the toxic effects of halogenated hydrocarbons (such as 2,3,7,8-tetrachloro-dibenzo-p-dioxin, TCDD) and polycyclic aromatic hydrocarbons (such as benzo[a]pyrene, BaP). Xenobiot-bound AHR dimers interact with aryl hydrocarbon receptor nuclear translocator (ARNT) to activate the transcription of targets that include cytochrome P450 genes. In this way AHR is the principle factor responsible for the biological toxicity, carcinogenicity, and mutagenic effects of a large number of environmental pollutants. A complete picture of the genetic pathways that regulate AHR expression and activity has yet to be determined. Using a BaP sensitivity assay based on (ARH-induced) CYP1A1 metabolism of BaP in mouse Hepa1 cells, previous work in our laboratory identified AHR signaling mutants that fell into four complementation groups. Complementation groups A, C and D were found to correspond to mutations in CYP1A1, ARNT and AHR, respectively. The gene responsible for BaP resistance in complementation group B mutants remained unidentified. Here we report the use of whole-exome sequencing (WES) to identify four candidate genes that have undergone loss of heterozygosity from parental BaP-sensitive Hepa1 cells in each of three independently derived B mutant lines. We are now using CRISPR-Cas9 reverse-genetics approaches to target these genes with multiple synthetic guide RNAs (sgRNAs) to determine which, if any, of these genes correspond to complementation group B. We further report that we have simultaneously performed multiple genome-wide screens of Hepa1 mouse and HepG2 human hepatoma cells using CRISPR-Cas9 and sgRNA libraries targeting all the known protein coding genes and microRNAs to identify the totality of possible gene disruption mutations, other than (and including) the complementation group B mutations, that affect AHR signaling and expression, in an effort to identify all possible genes that influence AHR signaling in response to xenobiotic binding. Supported by NIHES grant 1R21ES026392, and a postdoctoral fellowship to GDS from NIEHS training grant T32ES051547.

The aryl hydrocarbon receptor (AHR) is a physiologic sensor of both chemical environmental pollutants and ligands of natural origin. Quinones, which may be of xenobiotic or endogenous origin, are a less well-defined chemical class of AHR activators. Among the large diversity of quinone chemical structures, it is unclear whether all activators occur through reversible, bimolecular interactions or through interactions involving AHR alkylation. In this study, differences were observed in the toxicity and AHR activation profile of fully substituted and unsubstituted para-quinones. For example, we found that alpha-tocopherylquinone (TQ), a complex, fully substituted para-quinone showed low toxicity. Gene expression analyses showed a clustering of AHR responsive genes, of CYP1A1 by TQ, while wild-type MEF cells responded to TQ treatment established where knockout MEF cells showed little change in the expression of CYP1A1 by TQ, while wild-type MEF cells responded to TQ treatment with increased CYP1A1 expression. Though TQ showed a low toxicity profile, simple unsubstituted para-quinones, such as tert-butyl quinone (tBQ), were found to be more toxic. We and others found tBQ to be a moderately potent activator of the AHR. Initial studies support a mechanism in which simple unsubstituted para-quinones, such as tBQ, may alkylate the AHR through electrophilic sites present in these structures. As fully substituted quinones, such as TQ, do not possess electrophilic carbons, they cannot alkylate proteins. Thus, substituted quinones that activate the AHR may do so through reversible, bimolecular interactions similar to known ligands of the AHR. These results support that simple, unsubstituted and complex, fully substituted quinones may activate the AHR through distinct mechanisms.

Vitamin D (1α, 25-dihydroxyvitamin D3) is a steroid hormone traditionally associated with mineral ion homeostasis; however, accumulating evidence suggests a wider biological role for VD and its importance in immune function, xenobiotic metabolism, cell differentiation, and neurodevelopment. Like other members of steroid hormones, the biological effects of VD are mediated through the binding of 1α, 25-dihydroxyvitamin D3 ligand to its hormone receptor, VDR. In this study, we examined the Tox21 qHTS data set generated against VDR and have identified 21 potential VDR agonists and 19 VDR antagonists with putative VDR activity. Select orthogonal assays including transient transfections, mammalian two hybrid and molecular modeling were conducted to assess VDR ligand interactions. In vivo studies were additionally conducted to demonstrate proof of principle for a role of VD/VDR signaling axis in obesity. Three dietary cohorts of zebrafish were established and placed on engineered diets: a standard lab diet (1.4 iu/g) as a control, a VD null diet (0 iu), and a VD enriched diet (400,000 iu/g). When zebrafish switch over from a standard lab diet to a VD null diet at 2 months of age, they develop obesity within 3-4 months of age. Histopathological examinations consistently show that this phenotype is attributed to significantly elevated levels of visceral and subcutaneous fat compared to controls. Concordantly, preliminary gene expression data shows an overall upregulation of adipogenic and lipogenic markers presence of VD deficient fish at 4 months of age. The gene expression data shows a significant differential regulatory of genes specific to lipid metabolism. Hepatic triglycerides are also significantly elevated in the VD deficient fish at 6 months of age. RNA-Seq data is currently being utilized to identify key obeseogenic genes being regulated by VD and to understand the molecular mechanisms associated with both VD deficiency and its effects in progression of obesity and associated diseases such as diabetes.
2319 Coordinated Regulation of Molecular Chaperones and the Ubiquitin-Proteasome System Determines the Activation and Translocation of Human Constitutive Androstane Receptor

2322 Characterization of Aryl Hydrocarbon Receptor Knockout HepG2 Cell Lines Using CRISPR-Cas9 Genome Editing Technology

Each compound. Further characterization used 100 µM and 10 µM concentrations. Results: Several compounds were shown to have significantly greater inhibition than the previously studied monoterpenoid, Carvacrol (maximal current 80.6% of acetylcholine control), including geraniol (maximal current 63.0% of acetylcholine control). No monoterpenoids showed agonist activity on the ACR-16 receptor. Concentration response curves showed that the compounds, across the array, had a significant effect on the EC50 values of the acetylcholine response. Several monoterpenoids gave significantly lower maximal currents than the control. Conclusions: This research confirms previous findings that monoterpenoids as a class of compounds have varied but noticeable neurotoxic effects at a nicotinic acetylcholine receptor. We plan to characterize those compounds most active at our chosen target site.

The constitutive androstane receptor (CAR; NR1I3) is a member of the nuclear receptor family members (e.g., AHR, PXR). Previous studies demonstrated that CAR’s interaction profile with CoRegs likely differs between rodents and humans, among the human CAR splice variants, and even between hepatocytes across the liver lobule. To begin to test this hypothesis, we used a MARCoNi platform (micro array assay for real-time CoReg-NR interaction). CAR interactions across a solid phase matrix of 154 CoReg peptides were simultaneously quantified. Since wild type CAR is constitutively active, the 5 amino acid insertion present in the ligand-activated human CAR3 splice variant was used to assess CAR interactions, in the presence and absence of both direct and indirect CAR activators. Similarly, the 4 amino acid-substituted human CAR2 splice variant was also tested. A protocol was developed enabling ε-coli expression of His-tagged ligand binding domains of various CARs from human and mouse as a non-competitive antagonist on the expressed receptors. ACR-16 competitively and non-competitively inhibited hCAR transactivation in a dose-dependent manner. Although several CAR-CoReg interactions have been identified, over 300 proteins to modulate transcriptional activity across CAR target genes. Although several CAR-CoReg interactions have been identified, over 300 proteins to modulate transcriptional activity across CAR target genes. Although several CAR-CoReg interactions have been identified, over 300 proteins to modulate transcriptional activity across CAR target genes. Although several CAR-CoReg interactions have been identified, over 300 proteins to modulate transcriptional activity across CAR target genes. Although several CAR-CoReg interactions have been identified, over 300 proteins to modulate transcriptional activity across CAR target genes. Although several CAR-CoReg interactions have been identified, over 300 proteins to modulate transcriptional activity across CAR target genes.

As a pyrantolet/tribendimidine preferring heteromeric subtype comprising UNC-29, UNC-38 and UNC-63 subunits; and a levamisole preferring subtype comprising UNC-29, UNC-38, UNC-63 and ACR-8 subunits. For each subtype tested, monepantel applied in isolation produced no measurable currents. When monepantel was continuously applied, it reduced the amplitude of acetylcholine induced currents in a concentration-dependent manner. In all three subtypes, monepantel acted as a non-competitive antagonist on the expressed receptors. ACR-16 from A. suum was particularly sensitive to monepantel inhibition (IC50 values: 1.6 ± 3.1 nM and 0.2 ± 2.3 µM). We also investigated the effects of monepantel on muscle flaps isolated from adult A. suum. The drug did not significantly increase baseline tension when applied on its own. As with acetylcholine induced currents in the heterologously expressed receptors, contractions induced by acetylcholine were antagonized by monepantel. Further investigation revealed that the inhibition was a mixture of competitive and non-competitive antagonism. Our findings suggest that the mode of action of monepantel is more complex than previously described.

Characterization of Aryl Hydrocarbon Receptor Knockout HepG2 Cell Lines Using CRISPR-Cas9 Genome Editing Technology

2018 SOT Annual Meeting
Knock It Down: Improved Methods for Functional Genomics in the Parasitic Nematode, *Brugia malayi*, Reveal Diverse nAChRs That Can Be Exploited for Selective Toxicity

R. J. Martin, S. Verma, S. S. Kashyap, and A. P. Robertson. Iowa State University, Ames, IA.

Parasitic nematodes are a scourge on animals and humans and for control require treatment with selective chemicals (anthelmintics) that kill the parasite but not their host. To identify suitable drug targets, many techniques for studying functional genomics of target sites of anthelmintics have been restricted to *Caenorhabditis elegans* because they have failed when used on animal or human parasites. To overcome these limitations, we have focused our research on the human nematode parasite, *Brugia malayi*, which causes elephantiasis. We have combined single-cell PCR, whole-muscle cell patch-clamp, motility phenotyping (Worminator), and RTNAI for functional genomic studies that reveal *in vivo*, four different muscle nAChRs (*M*-, *L*- and *N*-). Selective cholinergic nematode anthelmintics have different selectivities for these receptors. We find that motility and patch-clamp responses to the compounds levamisole and pyrantel, but not morantel or nicotine, require unc-38 and/or unc-29 genes. Derquantel behaves as a competitive antagonist (*M*- and *L*-nAChRs) activated by morantel (Kᵩ 13.9 nM), *P*-nAChRs activated by pyrantel (Kᵩ 126 nM) and *L*-nAChRs activated by levamisole (Kᵩ 0.96 µM) and bephenium. Derquantel is a non-competitive antagonist of nicotine, and exposes *N*-type nAChRs. The presence of four distinct nAChRs in the muscle is surprising and not predicted by the *C. elegans* model. The diverse nAChRs represent distinguishable drug targets with different functions: knock down of *unc-38-unc-29-16-acer-26* (M- and N-receptors) inhibited motility but knock down of *ac-16-acer-26* (M- and N-receptors) did not. These studies, describing improved methods for the field, are relevant to toxicologists interested in the developing selective nematocides and anthelmintics. Supported by NIH ROI AI047194-15 to RJM and the E. A. Benbrook Foundation for Pathology and Parasitology.

Knockdown of Diacylglycerol Kinase Zeta in Human T Cells by Short Hairpin Ribonuclease Technology

N. K. Thomas, B. Johnson, M. Riese, and J. Gershon. Claffin University, Orangeburg, SC; and Medical College of Wisconsin, Milwaukee, WI. Sponsor: L. Williams

When T cells are activated through the T cell receptor (TCR), phosphorylase C (PLC) is phosphorylated and activated. Activated PLC produces the second messengers diacylglycerol kinase or DAG. DAG assists with T cell development and function. In T cells, DAG activity is regulated by diacylglycerol kinases (DGKs). DGK catalyzes the conversion of DAG into phosphatidic acid (PA). In CD8 cells, reduced DGK activity is associated with enhancing primary T cell responses against viruses and tumors. We hypothesized that knock down of DGK, expression in human T cells, will increase their effector function. The goal of this study was to test lentivirus encoding four different short hairpin RNA (short hairpin RNA) complementary to human DGK, for the ability to reduce expression of DGK in Jurkat (immortalized human) T cells. The lentiviral vector also encodes green fluorescent protein (GFP) (used to identify transduced cells using flow cytometry), and a puromycin resistance gene. The methodologies included the transfection of Stable 3 E coli with the shRNA lentiviral plasmids, followed by a plasmid preparation to purify the plasmid DNA. The plasmids were then transfected into 293FT cells (immortalized human embryonic kidney cells) to produce the virus. Jurkat cells were transduced with each of the four viruses produced. Transduced Jurkat cells were selected in the antibiotic, puromycin, and the percentage of transduced cells was assessed by GFP expression using flow cytometry. The transfected 293FT virus producing cells were green which indicated the expression of GFP. The initial transductions of the Jurkat cells were suboptimal as only a small percentage of GFP expressing cells (0.9% to 3.3%) survived selection with puromycin. The transduction efficiency was improved by concentrating the virus using centrifugal devices. Using this technique, transduction efficiency increased GFP expression to 98%. Transduced cells are being selected to be used for analysis of DGK expression by western blot. We produced virus using shRNA constructs and successfully transduced Jurkat cells. Future short-term goal is to analyze the effector functions of human T cells with reduced DGK expression, and long-term goal is to use these cells for adoptive cell therapy for patients with leukemia.

Bystander Effects of Antibody Drug Conjugates on the Hematopoietic Compartment

F. Clarke, Y. Huang, and G. dos Santos. ReachBio LLC, Seattle, WA.

ADCs represent a relatively new class of cancer therapeutics. Their design involves a tumor-specific antibody, a linker and a potent payload. In addition to the targeted killing of antigen-positive tumor cells, some ADCs appear to have significant off-target effects, which necessitated some clinical trials to be terminated early. However, the success of some ADCs at treating diseases has stimulated the continued research of ADCs as well as increases in the complexity of ADC development. Publications by Zhao et al. (2017) suggested that extracellular cleavage of the linker was responsible for cytotoxicity to differentiating neutrophils, whereas internalization of the ADCs by macrophagocytes induced thrombocytopenia. We developed a platform to assess ADCs and address the specific bystander effects of the payload. Both Trastuzumab and Trastuzumab-vc-MMAE (Creative Biolabs), neither of which target hematopoietic cells, were incubated in medium containing bone marrow nucleated cells derived from normal human donors (NorCal Biologics) and NHP (non-human primates from SNBL). The compounds were added at concentrations ranging from 30 to 0.1 µg/mL for 72 hours and then the treated cells were transferred to methylcellulose-based or collagen-based media for 14 days to support the growth of erythroid, myeloid and megakaryocyte progenitors. Trastuzumab did not cause inhibition of colony growth in human or NHP cultures over the concentration range tested but Trastuzumab-vc-MMAE significantly impacted all three lineages with IC₅₀ values ranging from 0.4 µg/mL (human megakaryocyte progenitor) to 3.8 µg/mL (NHP megakaryocyte progenitor) to 8 µg/mL (NHP megakaryocyte progenitor) to 11 µg/mL (NHP megakaryocyte progenitor). This specialized primary cell based platform can evaluate differences between antibodies with and without payloads, can rank lead compounds in terms of progenitor toxicity and can identify differentiating features of molecules in human and NHP systems. These assays may be of use pre-clinically for screening antibodies to identify potential off-target effects.

The Effect and Mechanism of Hypoxia-Inducible Factor-1a in Benzene-Induced Hematopoietic Toxicity

R. Sun, X. Meng, F. Sun, J. Zhang, L. Yin, and Y. Pu. School of Public Health, Southeast University, Nanjing, China. Sponsor: P. Zhou

Benzene exposure can cause bone marrow toxicity and hematopoietic disorders by oxidative stress. In this study, the effect and mechanism of Hif-1α on hematopoietic toxicity by benzene exposure were explored. Male C57BL/6 mice were exposed to 0 and 150 mg/kg/d benzene by subcutaneous injection for 13 days. Blood parameters, ROS level and Hif-1α expression were then detected. ChIP-Seq analysis in bone marrow cells was performed to identify Hif-1α downstream target genes and pathways associated with benzene hematotoxicity. The K562-NC cell and K562-HIF-1α+ cell, which express high HIF-1α, were treated with 1,4-BQ for 24h. The cell proliferation, apoptosis, and cell cycle were detected. The results revealed that mice in 150 mg/kg/d benzene group displayed decreased red and white blood cell counts, reduced platelet count, diminished hemoglobin content, and lower number of hematopoietic stem cells in bone marrow (BM). In BM there was a significant increase in ROS levels at 150 mg/kg benzene exposure. Genes associated with Hif-1α-binding sites showed a highly significant enrichment for certain gene ontology classifications, including cellular process, phosphorus metabolic process, organelle organization, cellular response to stress. ChIP-Seq results showed Hif-1α peaks were significantly associated with 245 downregulated genes after benzene exposure. Of the 40 genes contain Hif-1α specific binding site HRE, including 24 annotated genes and 4 micRNA. Hif-1α targets genes were significantly enriched for KEGG pathways specific for Jak-STAT signaling, natural killer cell-mediated cytotoxicity, Fc epsilon RI signaling, pyrimidine metabolism, and T cell receptor signaling. It revealed the relative growth rate was significantly increased in K562-HIF-1α+ cell than in the controls group, when used along with wild-type cells and may eventually serve as an tool for the field, are relevant to toxicologists interested in the developing selective nematocides and anthelmintics. Supported by NIH ROI AI047194-15 to RJM and the E. A. Benbrook Foundation for Pathology and Parasitology.
Cadmium Exposure Inhibits Branching Morphogenesis and Causes Alterations Consistent with HIF-1α Inhibition in Human Primary Breast Organoids

S. A. Rocco, L. Koneva, L. Middleton, T. Thong, S. Solanki, S. Karam, K. Nambunmee, C. Harris, L. S. Rozek, M. A. Sartor, Y. Shahi, and J. A. Colacino. 1University of Michigan, Ann Arbor, MI; and 2Mae Fah Luang University, Chiang Rai, Thailand.

Breast cancer is the most common cancer in women, yet the environmental risk factors for it are still not well understood. The toxic heavy metal cadmium is a naturally occurring known human carcinogen, but its role in breast cancer is controversial. Developmental cadmium exposure in vivo disrupts mammary gland differentiation, while exposure of breast cell lines to cadmium causes invasion consistent with the epithelial-mesenchymal transition (EMT). The effects of cadmium on normal human breast stem cell development have not been measured. Here, we sought to quantify the effects of cadmium exposure on normal breast stem cell proliferation and differentiation. Using the mammosphere assay and organoid formation in 3D hydrogels, we tested the effects of two commercially available (iCell® Hepatocytes 2.0) 250nM and 2.5μM on mammosphere and organoid formation by 68%. RNA-seq showed cadmium treatment downregulated HIF-1α target genes and genes associated with extracellular matrix formation by 83%, respectively. Despite no changes in mammosphere formation, 250nM cadmium inhibited branching organoid formation in hydrogels by 68%. RNA-seq showed cadmium treatment downregulates HIF-1α and HIF-1α target genes and genes associated with extracellular matrix formation and EMT. To validate these findings, we used a HIF-1α activity assay and target genes and genes associated with extracellular matrix formation. Cadmium treatment significantly inhibited HIF-1α activity in a luciferase assay, and the HIF-1α inhibitor acriflavine ablated mammosphere and organoid formation while producing a similar phenotype as cadmium treatment. These findings show that cadmium, at doses that do not affect cell health, inhibits HIF-1α in mammospheres and organoid formation assays. Cadmium treatment significantly inhibited HIF-1α activity in a luciferase assay, and the HIF-1α inhibitor acriflavine ablated mammosphere and organoid formation while producing a similar phenotype as cadmium treatment. These findings show that cadmium, at doses that do not affect cell health, inhibits HIF-1α in mammospheres and organoid formation. Our flow cytometry results accordingly suggest that support cadmium being a breast cancer initiator via induction of stem cell proliferation, but do implicate cadmium as an inhibitor of mammary gland morphogenesis.

Comparison of Different Sources of Stem Cell-Derived Hepatocyte-Like Cells with Respect to Hepatocyte Functionality

I. Frei, T. Waltermann, M. Baierlein, P. Schulze-Matz, J. Adjaye, and H. C. Ellinger-Ziegelbauer. 1Bayer AG, Wuppertal, Germany; and 2Institute for Stem Cell Research and Regenerative Medicine, Heinrich Heine University, Duesseldorf, Germany.

Human induced pluripotent stem cell-derived hepatocytes (hiPSC-HLCs) are suggested as in vitro model for drug research and development. However, compared to freshly isolated human primary hepatocytes, currently available hiPSC-HLCs exhibit a fetal phenotype, as revealed by e.g. expression profiling (1) and CYP activity. Yet since basal and inducible CYP activity is a prerequisite of a functional hepatocyte model, we tested the effects of two commercially available (iCell® Hepatocytes 2.0 (CDI-HLCs)) and in-house derived HLCs for CYP activity as well as other hepatocyte characteristics. Our in-house differentiation efforts are based on a published protocol (2) with modifications shown to enhance definitive endoderm (DE) differentiation (3), a key prerequisite in HLC differentiation. Our flow cytometry results accordingly suggest that inclusion of several pathway inhibitors appears beneficial for DE differentiation as reflected by increased CXCRI4/SOX17 expression on day 3 and 7. qPCR analysis confirmed DE differentiation by increasing levels of SOX17/CXCRI4/GATA4 expression at day 7 and decreasing levels of these genes at later stages. Further differentiation up to the hepatocyte stage was indicated by increasing albumin, α-fetoprotein and CYP expression levels. Concerning CYP3A1 inducibility we were able to observe up to 10-fold induction with the reference inducer Rifampicin at the mRNA level. Yet when measuring effective enzyme activity, hardly any increase was detected in a 3D spheroid model of CDI-HLCs. Therefore, our current research will be focused on enhancing the maturation of HLCs, especially CYP activity/inducibility, from both commercial sources and in-house activities. This includes culture of HLCs in 3D configuration and further molecular analyses of critical hepatic characteristics to potentially identify inadvertently activated, or inhibited but required pathways, which might be targetable. Transcriptome Profiling Reveals That the Aryl Hydrocarbon Receptor Influences Distinct Gene Regulatory Networks in Long-Term Hematopoietic Stem Cells and Multipotent Progenitors

K. P. Singh, S. Bhattacharya, E. C. Henry, C. Donegan, T. A. Gasiewicz, and B. P. Lawrence. School of Medicine and Dentistry, University of Rochester, Rochester, NY.

The continuous production of blood cells is orchestrated by tightly controlled cellular quiescence, proliferation, and differentiation. Mounting evidence indicates that the aryl hydrocarbon receptor (AHR) plays a key role in hematopoiesis and hematopoietic stem cells (HSC) function. However, the molecular mechanisms and signaling pathways regulated by AHR remain poorly defined. Long-term HSC (LT-HSC) can self-renew and differentiate. Multipotent progenitors (MPP) arise from LT-HSC, are highly proliferative, and differentiate to all lineage cell. To better understand the role of AHR in LT-HSC and MPP function, we used transcriptome profiling by RNA-Seq to identify differentially expressed genes (DEG) in cells from global AHR knock-out (AHR-KO) and wild type (WT) mice. There were 103 DEG in LT-HSC of AHR-KO mice, compared to WT; yet there were only 8 DEG in MPP. In addition to a markedly different number of DEG, Ingenuity Pathways Analysis (IPA) revealed distinct pathways among the DEG from LT-HSC versus MPP. In LT-HSC, DEG represented pathways of oxidative stress, notch signaling, hematopoiesis, cell cycle, and DNA repair. However, DEG in MPP were primarily involved in hematopoiesis and hematopoietic regulation. As LT-HSC transition from quiescence and differentiate to MPP, many signaling pathways are involved. To better understand how AHR regulates differentiation from LT-HSC to MPP, we compared the gene expression changes between LT-HSC and MPP from AHR-KO and WT, with gene changes between LT-HSC and MPP from WT. This comparison revealed 1643 DEG in WT and 2474 in AHR-KO, with 1138 DEG common between genotypes. AHR gene expression was down regulated in WT MPP, in comparison to LT-HSC, which indicates that AHR is more highly expressed in quiescent LT-HSC cells than in highly proliferative MPP. These analyses indicate that AHR regulates signaling pathways that are essential in HSC function, but it may play a less central role in MPP. Understanding cell stage specific pathways in LT-HSC and MPP provides critical insight regarding how AHR signaling regulates hematopoiesis and influences hematopoietic diseases.

The Use of Phytochemicals to Combat the Detrimental Consequences of Cigarette Smoke on Osteogenic Differentiation

Cigarette smoking has been shown to inhibit bone healing and increase the risk of pseudarthrosis after spinal fusion. We previously reported that activation of the aryl hydrocarbon receptor (AhR) by dioxin inhibits bone regeneration and spine fusion in rat model and in vitro. Since dozens of dioxin-like AhR ligands are present in cigarette smoke, here we investigated the downstream mechanisms of cigarette smoke action on osteogenic differentiation to identify potential therapeutic options to mitigate the effects of cigarette smoke on bone. Particulate phase extract (PPE) was prepared. Primary rat bone marrow stromal cells (BMSC) were cultured under basal standard or osteogenic media. BMSC were subsequently exposed to either the vehicle control (DMSO) or dioxin or PPE. Some cells received co-treatment with AhR antagonists, including α-naphthoflavone (ANF), resveratrol (Res), and 3,3-diindolylmethane (DIM). PPE-treated cells showed increased activity of CYP1A1 subfamily proteins, demonstrating AhR activation. PPE treatment inhibited ALP activity and part of the co-treatment with each of the AhR antagonists. A similar response was seen in and mineralization and cell proliferation assays. RNA expression studies showed that PPE downregulated numerous pro-osteogenic genes, such as ALP, Runx2, OCN, and Phex, whereas co-treatment with AhR antagonists prevented PPE-mediated inhibition of those RNA. Interestingly, we observed a trend in the ratio of active/inactive β-Catenin, an effect which was recapitulated by treatment with dioxin (TCDD). Our results suggest that AhR hyper-activation may play an important role in the adverse effects of cigarette smoke on bone healing—potentially by perturbation of canonical Wnt pathways.
signaling—and that Ahr antagonists may be protective in combating cigarette smoke-mediated inhibition of bone regeneration and healing. This study identified naturally available phytochemicals that antagonize the AHR receptor to provide a protective effect against the harmful consequences of compounds found in cigarette smoke on bone healing.

### 2331 Impact of the Aryl Hydrocarbon Receptor on Mitochondria in Hematopoietic Stem Cells

M. Laiosa. University of Wisconsin-Milwaukee, Milwaukee, WI.

We published that Aryl hydrocarbon receptor (AHR) activation by the environmental contaminant 2,3,7,8 Tetrachlorodibenzo-p-dioxin (TCDD) during fetal development leads to a loss of long-term self-renewal potential of hematopoietic stem cells. This loss was due in part to elevated reactive oxygen species (ROS) in these cells. These studies combined with the work of others are consistent with the hypothesis that the AHR regulates hematopoiesis by acting as a negative regulator of oxidative phosphorylation-dependent ROS. To test this hypothesis we conducted a series of studies on mitochondria function in murine hematopoietic stem cells that lacked the AHR. Specifically, we analyzed mitochondria superoxide production, number, and performed a mitochondria stress test to measure spare respiratory capacity in hematopoietic stem cells from WT, and AHR-/- mice. We found that in fetal hematopoietic stem cells that lack the AHR, there is a significant increase in mitochondria-produced superoxides. This particular assay is impacted by both superoxide level and number of mitochondria and so we next used a quantitative PCR-based assay to enumerate mitochondria DNA copy number relative to genomic DNA as a proxy for mitochondria number. We found that the number of mitochondria was elevated in AHR deficient fetal hematopoietic stem cells for six times fewer mitochondria than WT cells using this assay. These data are consistent with the conclusion that superoxide production is not an artifact of elevated mitochondria number and suggests elevated superoxides are coming from fewer mitochondria per cell. Finally, we performed a mitochondria stress test on AHR-deficient cells to measure spare respiratory capacity. Using a Seahorse extracellular flux analyzer for these assays we found a significant reduction in the spare respiratory capacity of hematopoietic stem cells from both fetal AHR-/- and AHR DNA binding domain mutant (DBD-/-) mice. It is critical to note that the reduced superoxide production is not suggestive of the mitochondria DNA copy number. Superoxide production was normalized by itself explain this data. This is because the spare respiratory capacity is based on the basal rate of each cell population and thus normalizes any potential differences in mitochondria content. The potential implications of this data are that the AHR acts as a negative regulator of oxidative phosphorylation in hematopoietic stem cells. This conclusion is made in part from the stress test failing to raise oxygen consumption above basal levels indicating that the AHR-/- cells are already at maximal electron transport capacity.

### 2332 Inter-Individual Differences in Electrophysiology, Pharmacology, and Drug Responses in a Cohort of hiPSC-Derived Cardiomyocytes—Endorsing Clinical-Trials-in-a-Dish

B. Ferrimi, D. Sullivan, J. Chal, E. Fine, B. Hamilton, S. Coyne, and K. Coyne. Coyne Scientific, LLC, Atlanta, GA.

The concept of “clinical trials in a dish” or in vitro clinical trials has received significant attention lately because of emerging technologies that allow testing novel compounds on patient cells before they move into actual clinical trials. Moreover, recent studies have shown that individual serious adverse events (SAEs) susceptibility in a population of volunteers with unknown genetic background can be recapitulated in human-inducible pluripotent stem cell cardiomyocytes (hiPSC-CMs) derived from the same individuals, providing a proof of concept for in vitro preclinical trials. Hence, leveraging genetic diversity in preclinical testing may hold the key to reducing clinical attrition, based on an increased ability to predict SAEs in a population. In this study, we examined the electrophysiological and pharmacological properties of hiPSC-CMs derived from 12 healthy neonatal donors. We first established the full transcriptome profiling of all of our cell lines, and found significant inter-line differences in the expression levels of important cardiac markers, and key ion channels. We then defined individual electrophysiological and pharmacological fingerprints of each line by measuring a number of parameters extracted from recording spontaneous beating activity (beat rate and amplitude, pulse width, pulse kinetics), and extracellular field potential (EFP) signals. All studies were performed on at least five technical replicates. Our results showed consistency for beating activity and EFP across technical replicates, but significant differences in these endpoints when compared across lines. Furthermore, we studied six different CiPA drugs (from all three risk categories for arrhythmia liability), for cardiac effects on our cohort of hiPSC-CMs. Our results showed similarities in the magnitude of responses for beating activity and EFP across technical replicates, but significant dispersion when studied across different lines. Our data demonstrate that hiPSC-CMs derived from healthy donors exhibit electrophysiological and pharmacological profiles that are unique to each donor, resulting in a clear distribution of drug effects and potencies. Our study supports the validation and implementation of testing for safety and toxicity of drugs across a cohort of donors, rather than a single cell line, endorsing the concept of clinical trials in a dish.

### 2333 CXCR7 Agonist TC14012 Improves Angiogenic Function of Endothelial Progenitor Cells in Diabetic Limb Ischemia

K. Wang,1,2, X. Dai,1, J. Chen,1, P. N. Epstein,1,3, L. Cal,1,3, K. A. Wintergerst,1,3, Y. Qian,2, and Y. Tan,1,3. 1University of Louisville, Louisville, KY; 2The First Affiliated Hospital of Wenzhou Medical University, Wenzhou, China; and 3Wendy L. Novak Diabetes Care Center, Louisville, KY.

Stromal cell-derived factor 1 (SDF-1)- chemokine receptors CXCR4/7 axis plays a vital role in diabetic limb ischemia. Our previous studies demonstrated that elevated CXCR7 improves therapeutic efficacy of EPCs in diabetic limb ischemia. The effects of a specific CXCR7 agonist TC14012 on diabetic hind limb ischemia remains untested. We hypothesize that CXCR7 expression is reduced in diabetic EPCs and study the angiogenic function of EPCs in diabetic limb ischemia. Early WT-EPCs were transfected with siRNA against CXCR7, and early db/db-EPCs were infected with CXCR7 lentivirus. Tube formation was assessed by capillary density of ischemic gastrocnemius muscle (GS) and soleus muscle (SS) at day 28 post-ischemic surgery. Total and (C-X-C motif) chemokine receptor type 4 (CXCR4) expression of CXCR7 were significantly decreased in EPCs from db/db mice compared with those from WT mice, whereas no significant differences of CXCR4 expression were observed. Tube formation by EPCs from db/db mice was also impaired compared with WT-EPCs. siRNA knockdown of CXCR7 was accompanied by impaired tube formation and increased CXCR7 levels in diabetic EPCs completely reversed impaired tube formation function. High glucose (HG) dose-dependently decreased the expression of CXCR7 in vitro but not that of CXCR4. HG also impaired tube formation of EPC from WT mice. Tube formation function of HUVEC was impaired after treated with HG (25 mM) for 24 hours, which could be prevented by TC14012. Most importantly, TC14012 significantly improved blood flow recovery in diabetic hind limb starting from 2 weeks after ligation and promoted angiogenesis of ischemic GS and SS. Diabetes attenuates CXCR7 expression and impairs angiogenesis of EPCs. TC14012 improves blood reperfusion of diabetic hind limb ischemia.

### 2334 Toward a More Mature hiPSC Model for Physiologically- Relevant In Vitro Cardiotoxicity Testing

R. Ketenhofen,1, C. Conn,2, M. Schwalfenberg,2, G. Luerman,3, and J. Hynes.2 1Ncardia, Cologne, Germany; 2Luxcel Biosciences, Cork, Ireland; and 3Ncardia, Plymouth Meeting, PA.

Human induced pluripotent stem cell (hiPSC)-derived cardiomyocytes are an attractive model for in vitro cardiotoxicity testing; however, cell immaturity and limitations surrounding the panel of assays available hamper a disease phenotype characterization that translates in vivo. While fatty acid oxidation (FAO) can be responsible for up to 90% of ATP in vivo, cardiomyocytes in vitro are typically maintained in high glucose. This negatively impacts physiological relevance, leading to a functional insensitivity to mitochondrial insult; a significant gap considering the implication of mitochondrial dysfunction in the etiology of drug-induced cardiotoxicity. To address these issues, we have developed and characterised an FAO-conditioned hiPSC-derived cardiomyocyte model (ConHiCM), and, using a multiparametric assay suite, have evaluated their utility in assessing the impact of drug treatment on cardiomyocyte function and metabolism. This is achieved by integrating impedance measurements (CardioExyte) with a fluorescence-based bioenergetics assessment, measuring O2 consumption (MitoXpress®-Intra), cellular oxygenation (MitoXpress®-Intra). O2 consumption is used as an interrogation parameter, with sensitivity to the CPT-1 inhibitor etomoxir used to identify the portion of respiration linked to long chain FAO. While current cell models show minimal etomoxir sensitivity, this increases on FAO conditioning, with additional
sensitivity observed when substrate demand is increased (FCCP treatment). FAO-conditioned cells also exhibit reduced reserve capacity, suggesting increased dependence on oxidative metabolism. Treatment with a panel of classical mitochondrial modulators (antimycin, rotenone, FCCP), reveals that, while glucose-grown cells are functionally insen-
sitive to perturbation, FAO-conditioned cells show impaired contrac-
tility due to a reduced capacity to maintain mitochondrial repair.
FAO-conditioning also reduces cell oxygenation (<15% O2) which
decreases further at increased beat rate (<5% O2). Data is also presented
demonstrating that beat rate modulation (Isoproterenol, Amiodarone,
Nifedipine) impacts metabolic flux, with increasing beat rate increasing
FAO. This was demonstrated through physiologic relevant in vitro
model for the identification of drug-induced cardiotoxicity.

2335 Leveraging Genetic Diversity In Vitro: A New Approach in Cardiac Safety Assessment
E. Fine, D. Sullivan, A. Nguyen, J. Chal, B. Fermini, B. Hamilton, K.
Coyne, and S. Coyne. Coyne Scientific, LLC, Atlanta, GA.

Although models for detecting preclinical toxicity and safety have
improved in recent years, predicting serious adverse events (SAEs) in
preclinical studies remains a challenge because these events often occur
in a small subset of patients. In addition, cellular or animal models cur-
rently being used are not suited for the interrogation of inter-individual
differences in drug susceptibility. Over the past few years, cardiomyo-
cytes derived from human induced pluripotent stem cells (hiPSC-CMs)
have shown promise for cardiac safety screening. Moreover, recent
studies have shown that individual SAEs susceptibility in a population
of volunteers with known genetic background can be recapitulated in
hiPSC-CMs derived from the same individuals, providing a proof of
concept for in vitro preclinical trials. Hence, leveraging genetic diversity
in preclinical testing may hold the key to reducing clinical attrition by
predicting SAEs in that population, potentially resulting in reducing clin-
ical attrition of drugs.

2336 Assessment of Gut Organoid Models from Several Species Ability to Predict Intestinal Toxicity of Drug Development Candidates
M. Hong, R. Visconti, and K. Kolaja. Celgene, Summit, NJ.

*An in vitro* organoid model was developed from intestinal epithelial
cells in order to predict predictivity of *in vivo* gastrointestinal
toxicity. Historically, *in vitro* models of the GI used tumor derived, trans-
formed intestinal cell lines (e.g., HT-29, Caco2, and HCT-8), which can be
limited in the cell morphology, cell type distribution, and ultimately,
suboptimal system for studying drug induced toxicity. Small intestinal
organoids (enteroids) were generated from commercially available
small intestinal epithelial cells (C57BL/6 mouse, rat, canine, cynomolgus
monkey, and human) using established culture reagents for organoids
(Ibiza E et al. 2016). The morphology of the absorptive (enterocytes)
and secretory (goblet, Paneth, enteroendocrine, and tuft) cells, assessed
with hematoxylin and eosin, PAS, and Alcan blue staining, confirmed
that enteroids have similar cell types and morphologic attributes to
*in vivo* intestinal epithelium. The toxicity of various known GI toxicants
was assessed using two independent cell death assays, CellTox Green
and CellTiter-Glo. Interestingly and correlated with *in vivo* findings, the
toxicity (IC50 values) was species dependent, with dogs being the GI
most adversely amongst the five-tested species. In particular, a, develop-
ment test compound QC8222, which was toxic proximal to dog GI
epithelial barrier in *in vivo* was also toxic in vitro. The most susceptible
cell type to toxicity was examined using a cell death (anti-caspase 3) and
a proliferation (anti-Ki67) markers combined with cell-specific immuno-
taining (mucin 2 for Goblet cells, lysozymes for Paneth cells, chromog-
arin A for enteroendocrine cells, and succrose isomaltase for absorptive
enterocytes). This study showed that QC8222 generally prevented the
expression of stem cells from stem cells and induced caspase 3 medi-
ated cell death, which prevents the protective mechanism of secreting
anti-microbial peptides, and may be related to its epigenetic mecha-
nism of action. Elevated cell death marker gene expression in the Paneth
cells was confirmed by RNAseq. In conclusion, this study reveals that
enteroids models from multiple species can be used to infer potential
effects in whole organisms but additional validation is needed.

2337 3D Organotypic Co-Culture System: A Simple High-Throughput Mini-Liver Tissue for Toxicology Study
H. Ardalan1, V. Vickersman Kelley2, S. Sengupta3, J. A. Thomson2, and
W. L. Murphy1. 1University of Wisconsin-Madison, Madison, WI; and
2Morgridge Institute for Research, Madison, WI.

The liver is the primary site for drug metabolism, and cultured hepatocytes
are indispensable for drug development and toxicity testing. Traditionally,
liver slices, microsomes, and primary hepatocytes are used for such purposes,
but a large gap exists between demand and availability of primary human hepatocytes. This problem of availability is further complicated by differdetermination of primary cells in vitro. The advent of hepatocytes derived from induced pluripotent stem (iPS) cells and embryonic stem cells may help close that gap, but they function more like fetal hepatocytes than mature cells and do not display many metabolic behaviors. In this study, we studied the use of hepatocytes in co-culture for cell-cell interaction on human iPS-derived hepatocytes maturation in a 3D organotypic culture system. The all the cell types originate from human origin. To our knowledge this is the first 3D in vitro model that co-cultures iPS derived hepatocytes with non-parenchymal cells all from within one species. Historically, hepatic stellate cells and biliary epithelial cells (cholangiocytes) on human iPS-derived hepatocytes. We tested the hepatocyte matu-

2338 Multiparametric Assessment of Networked Electrical Activity Using Induced Pluripotent Stem Cell-Derived Glutamatergic Neurons
K. Kim, C. B. Carlson, C. Kannemeier, T. K. Feaster, B. Swanson, D.
Schlesinger, B. D. Anson, and K. P. Mangan. Cellular Dynamics
International, a FUJIFILM Company, Madison, WI.

The lack of a predictable preclinical test system to identify CNS adverse
effects greatly hinders the drug development process and contributes to
the drug attrition rate. Three-dimensional *in vitro* test system of human neuronal cultures with synchronized network electrical (bursting) for assessment of compound effects on neuronal function and network communication including seizurogenic liability. Human induced pluripotent stem cell (iPSC) derived neurons, mixture of 75% glutamatergic and 25% GABAergic were cultured for 3 days on multi-electrode array (MEA), alone or in combination with human iPSC-derived astrocytes, and assessed for compound effects. Known excitatory compounds were measured for concentration-dependent effects, at clinically relevant concentrations, including bicuculline, picro-
toxin, glutamate, penetrenetrazol, 4-aminopyridine, and chloroproma-
mine. Activity parameters displaying concentration-dependent changes
with pharmacology include: mean firing rate, ‘single-channel’ burst rate,
together with pharmacology include: intensity duration, ‘network-level’ burst rate, intensity and duration, and synchrony measures. Furthermore, while both cultures of gluta-
marergic and GABAergic co-cultures with neurons and astrocytes
exhibited the expected pharmacology, the bursting behavior of neu-
ronal and astrocyte co-culture was more clearly defined. The presented
data demonstrate how iPSC technology coupled with MEA technology
create a noninvasive human neuronal test system, previously limited to
rodent models, and provide an unprecedented investigatory space for

Drug development. Furthermore, overall activity can be modulated by titrating different levels of neuronal subtypes and support cells (astrocytes). Together, this methodology allows quantification of neuronal networked electrical activity in a human model which should be valuable to identify CNS liability and support preclinical toxicity programs.

### 2339 Induction of Epileptiform Activities in Cultured Human iPSC-Derived Neuronal Networks

I. Suzuki1,2, A. Odawara1, N. Matsuda2, Y. Ishibashi1, and R. Yokoi1. 1Tohoku Institute of Technology, Sendai, Miyagi, Japan; 2INCENS, Tokyo, Japan; and 3CSAH, Tokyo, Japan. Sponsor: S. Lantz

The functional network of human induced pluripotent stem cell (hiPSC)-derived neurons is a potentially powerful in vitro model for evaluating drug toxicity. Epileptiform activity is one of phenomena in neuronal toxicology. To evaluate the dynamics of epileptiform activities and the effect of anti-convulsant drug in cultured hiPSC-derived neurons, we used the high-throughput multielectrode array (MEA) system, where we simultaneously record extracellular potentials for 16 channels per well across 24-well plates. We examined chemically evoked epileptiform activity. Epileptiform activities were induced by 4-Aminopyridine (4-AP), pilocarpine, chlorpromazine, and pentylenetetrazole (PTZ). The number of synchronized burst firings were increased in a concentration dependent manner at 4-AP, Pilocarpine, and Chlorpromazine administration. On the other hand, the duration and spikes in a synchronized burst were increased at PTZ administration. Phenytoin used in anti-convulsant drug suppressed electrophysiological activities. From these results, we suggest that the electrophysiological assay in cultured human iPSC-derived neuron using MEA system has the potential to investigate the neuronal toxicity in drug discovery.

### 2340 Electrophysiological Pain Responses in Cultured Human iPSC-Derived Sensory Neurons Using High-Throughput Multi-Electrode Array System

Dorsal root ganglion (DRG) sensory neurons are pain-related neurons and have a variety of sensory receptors that are activated by chemical, thermal, and mechanical stimuli. Establishment of a pharmacological assay in pain research and drug screening is an important issue. In addition, human-induced pluripotent stem cell (hiPSC)-derived sensory neurons may be effectively used for drug discovery and toxicity testing. The purpose of this study was to evaluate the physiological responses against typical pain-related molecules, temperature change, and anticancer drugs in cultured sensory neurons using the high-throughput multi-electrode array (MEA) system. Firstly, we confirmed human iPSC-derived sensory neurons expressed typical sensory neural markers Nav1.7, TRPV1, and TRPA1 using immunostaining. Next, we detected the physiological responses to temperature change, capsaicin, menthol, and wasabi by change of spike rate using MEA system. Phenytoin administration. We examined chemically evoked epileptiform activity. Epileptiform activities were induced by 4-Aminopyridine (4-AP), pilocarpine, chlorpromazine, and pentylenetetrazole (PTZ). The number of synchronized burst firings were increased in a concentration dependent manner at 4-AP, Pilocarpine, and Chlorpromazine administration. On the other hand, the duration and spikes in a synchronized burst were increased at PTZ administration. Phenytoin used in anti-convulsant drug suppressed electrophysiological activities. From these results, we suggest that the electrophysiological assay in cultured human iPSC-derived neuron using MEA system has the potential to investigate the neuronal toxicity in drug discovery.

### 2341 Simultaneous Measurement of Contractility, Electrophysiology, and Biomarker Secretion to Determine Cardiotoxicity in hiPSC-Derived Cardiomyocytes

Drug-induced cardiotoxicity has been the major cause of drug withdrawal from the market. For example, many novel oncology therapeutic agents are associated with cardiodepressive effects, including in vitro overexpressing human cell lines or use in vivo animal models. These models often lack the complexity of human cardiomyocytes, whereas animal models may lack predictivity due to inherent species differences. Therefore, there is a need for the development of more predictive and specific assays that allow for multi-parametric assessment of potential cardiotoxic side effects of new drugs in humans. Using proprietary hiPSC-derived ventricular cardiomyocytes (Pluricyte® Cardiomyocytes) that recapitulate a human myocyte’s contractile and electrophysiological profile, as well as mature sarcomere organization, we developed a multiparametric assay to measure potential cardiotoxic effects in vitro. Here, both acute and long-term drug effects on contraction, electrophysiology, and cardiac troponin I release are determined simultaneously from each well of a 48-well plate. To assess the effects of anticancer drugs on the physiology of Pluricyte® Cardiomyocytes, the cells were incubated with concentration ranges of nilotinib, lapatinib, doxorubicin, and ponatinib for up to 64 hours, and analyzed simultaneously using microelectrode array (MEA), impedance, and cardiac troponin I (cTnI) release assays. This resulted in defined cardiotoxicity profiles for each compound. Whereas treatment with nilotinib and lapatinib caused a transient, short-term (functional) contractile/electrophysiological deficit, doxorubicin exhibited a continuous long-term toxic effect in both MEA and impedance measurements. While lapatinib and nilotinib did not cause structural toxicity as measured by cTnI release, ponatinib induced a cTnI dependent increase in cTnI release. The dose-dependent increases in cTnI release correlated with reduced cell index values obtained in the impedance assay. These data suggest that a multiplexed analysis is crucial to investigate short- and long-term cardiac liabilities as it provides a more comprehensive readout that generates mechanism-specific cardiotoxicity profiles, leading to better prediction of drug-induced cardiotoxicity.

### 2342 Optimization of Optogenetic Transduction of Stem Cell-Derived Cardiomyocytes with Adeno-Associated Virus for Optically Paced Cardiac Electrophysiology Assays

Commercially available stem cell derived cardiomyocytes beat spontaneously, offering a simple assay solution for evaluation of cardiac risk in vitro. However, the spontaneously beat rate may differ across wells, particularly after pharmacological manipulation, necessitating the reliance on correlation formulae for determining the relationship between repolarization timing and beat frequency. Optogenetics, a technique whereby light sensitive ion channels allow depolarization of electro-active cells upon incident light, allows pacing of cardiomyocytes to control beat frequency. Here, we use a multi-well microelectrode array (MEA) assay with integrated multi-well light delivery to optimize the viral transduction of commercially available stem cell derived cardiomyocytes. Increasing amounts of virus were added to wells across the 48-well plate in half-log increments, with six replicates per multiplicity of infection (MOI). At high MOI’s, the spontaneous beat frequency decreased, and the depolarization amplitude decreased, suggesting an effect of cHR2 on the cardiomyocyte electrophysiology. Meanwhile, low MOI’s produced no change from control for beat frequency or amplitude. A pacing light stimulus was delivered simultaneously to each well on the plate, with increasing light intensity, such that the number of wells paced at each light intensity could be quantified. As expected, the wells with highest MOI responded to optical pacing at the lowest intensity and the wells with the lowest MOI did not respond differently than control wells. Using the optimal MOI, the cardiomyocytes were paced at increasing rates to quantify the relationship between repolarization timing and the paced beat frequency.

### 2343 Human iPSC-Derived Hepatocytes with Advanced Functionality and Longevity: An Innovative In Vitro Model for Studying Metabolic Diseases

L. Quinn1, A. Asplund2, B. Ulfenborg3, J. Synnergren2, C. Brandsten2, and B. Küppers-Munther2. 1Takara Bio USA, Mountain View, CA; 2Takara Bio Europe AB, Gothenburg, Sweden; and 3University of Skövde, Gothenburg, Sweden.

Generating accurate liver disease models requires a reliable and reproducible source of well-characterized, functionally mature, and long-lasting human hepatocytes. However, existing primary cell and tumor-derived model systems lack proper functionality, do not last long in culture, have limited batch sizes, or have high batch-to-batch variation. To pave the way for better liver disease models, we have created human iPSC-derived hepatocytes (hiPSC-HEP) that are more mature and show improved functionality, and consistent performance between batches and over extended time in culture. These cells secrete albumin and urea and overexpress human cell lines and are used in vivo animal models. These models often lack the complexity of human cardiomyocytes, whereas animal models may lack predictivity due to inherent species differences. Therefore, there is a need for the development of more predictive and specific assays that allow for multi-parametric assessment of potential cardiotoxic side effects of new drugs in humans. Using proprietary hiPSC-derived ventricular cardiomyocytes (Pluricyte® Cardiomyocytes) that recapitulate a human myocyte’s contractile and electrophysiological profile, as well as mature sarcomere organization, we developed a multiparametric assay to measure potential cardiotoxic effects in vitro. Here, both acute and long-term drug effects on contraction, electrophysiology, and cardiac troponin I release are determined simultaneously from each well of a 48-well plate. To assess the effects of anticancer drugs on the physiology of Pluricyte® Cardiomyocytes, the cells were incubated with concentration ranges of nilotinib, lapatinib, doxorubicin, and ponatinib for up to 64 hours, and analyzed simultaneously using microelectrode array (MEA), impedance, and cardiac troponin I (cTnI) release assays. This resulted in defined cardiotoxicity profiles for each compound. Whereas treatment with nilotinib and lapatinib caused a transient, short-term (functional) contractile/electrophysiological deficit, doxorubicin exhibited a continuous long-term toxic effect in both MEA and impedance measurements. While lapatinib and nilotinib did not cause structural toxicity as measured by cTnI release, ponatinib induced a cTnI dependent increase in cTnI release. The dose-dependent increases in cTnI release correlated with reduced cell index values obtained in the impedance assay. These data suggest that a multiplexed analysis is crucial to investigate short- and long-term cardiac liabilities as it provides a more comprehensive readout that generates mechanism-specific cardiotoxicity profiles, leading to better prediction of drug-induced cardiotoxicity.
over a two-week assay window and show mRNA expression levels of albumin and urea cycle enzymes that are comparable to those of human primary hepatocytes (hphep). Moreover, activity of cytochrome P450 enzymes and expression of genes essential for the drug metabolizing machinery are stably detected for up to 19 days in hiPS-HEP compared to hphep after one day in culture. Finally, we demonstrate that our iPSC-derived hepatocytes exhibit critical metabolic features. First, genes involved in both glucose and lipid metabolism are expressed at similar levels to hphep. In addition, the cells respond to insulin by phosphorylation of AKT and show capacity to take up low-density lipoproteins and become steatotic if incubated with fatty acids. The availability of robust and consistent human pluripotent cell-derived hepatocytes (hphep) with mature hepatic functions represents an important step toward advancing the discovery of new treatments for metabolic disease, reducing the incidence of drug-induced liver injury, and developing new strategies for liver regeneration and transplantation.

**2344** Characterization of the Local Extracellular Action Potential Signal for Use in Cardiac Safety Evaluation

D. C. Millard, H. Hayes, A. Nicolini, C. Arrowood, and M. Clements. Axion Biosystems, Inc., Atlanta, GA.

The comprehensive in vitro Proarrhythmia (CiPA) Assay is the result of a public-private collaboration to improve the assessment of Proarrhythmic risk using *in silico* and cell-based *in vitro* assays. A central component of the cell-based track of the CIPA assay is the evaluation of stem cell derived cardiomyocyte electrophysiology using the field potential acquired from microelectrode array (MEA) recordings. Although the FP signal acquired from MEA assays has performed exceedingly well in CiPA Phase I and Phase II studies, there are several advantages to the FP signal shape. Namely, many scientists are trained in the context of the cardiac action potential signal, and wish to interpret FP data from the CM-MEA assay in the same way. Also, while repolarization irregularities, such as EADs, are clearly present in the FP signal, they can be difficult to detect in automated analysis. Here, we characterize a new signal type, termed the local extracellular action potential (LEAP), acquired from extracellular microelectrodes for use in CIPA-like cardiac safety assays. The LEAP signal occurs through increased coupling of the cardiomyocyte syncytium to the microelectrode, resulting in a 5-20mV signal with an action potential-like morphology. The LEAP signal was further characterized pharmacologically with E-4031, a potent potassium blocker, nifedipine, an L-type calcium channel blocker, and verapamil, a multi-ion channel blocker affecting potassium and calcium channels. Nifedipine and verapamil caused a dose-dependent decrease in the duration of the LEAP signal and E-4031 caused a dose-dependent increase in LEAP duration, all of which is consistent with previous field potential or action potential assays. Also, E-4031 produced EADs at higher concentrations. Finally, previous action potential experiments using dog perikine fibers to evaluate cardiac liabilities for tolterodine and terodiline from the market due to proarrhythmic risk.

**2345** Comparison of the Proarrhythmia Liability of Standard and Functionally Mature Human iPSC-Derived Cardiomyocytes

X. Zhang, and Y. A. Abassi. ACEA Biosciences Inc., San Diego, CA. Sponsor: L. Zhao

Human iPSC-derived cardiomyocytes (hiPSC-CMs) display a repertoire of ionic currents and channels, which makes them a relevant model for safety/toxicity assessment. However, standard hiPSC-CMs resemble fetal cardiomyocytes and may not have the appropriate composition of ionic currents and channels, appear to be more sensitive to hERG channel blockade, and even show early after depolarization (EAD)-like response after treatment of compounds, which typically have low risk for torsades de pointes (TdP) (Qu et al., 2015). In order to address these limitations we wanted to investigate if improvements in the maturation status of hiPSC-CMs could increase the extent of predictivity of hiPSC-CMs assay for drug proarrhythmia liability. We utilized long-term electrical pacing provided by the xCELLigence RTCA CardioECR system to enhance the maturation status of hiPSC-CM. The contraction and electrophysiology of hiPSC-CMs were monitored by simultaneous measurement of impedance and field potential, respectively. After 15 days of continuous electrical pacing, paced cardiomyocytes displayed more mature characteristics compared to non-paced cells, as demonstrated by two factors: 1) the inherent negative impedance amplitude-frequency relationship of hiPSC-CMs was reversed after pacing, 2) paced hiPSC-CMs displayed better organization of calcium handling proteins, as well as increased expression of genes that are critically involved in the cardiomyocyte maturation process after chronic pacing. A panel of ion channel modulators, including hERG channel blocker and mixed channel modulators, were tested using the functionally mature/enhanced hiPSC-CMs. Our data clearly show that the response of the functionally enhanced/mature cardiomyocytes (paced) to the ion channel modulators, especially multi-ion channel modulators, are more comparable to the clinical outcome than the control non-paced hiPSC-CMs. In summary, our data suggest that maturation status of hiPSC-CMs can be improved after employment of chronic electrical pacing, resulting in enhanced predictivity for proarrhythmia liability of drugs.

**2346** A Novel Maintenance Medium Enables Long-Term Applications for Both Human Primary Hepatocytes and Human Pluripotent Stem Cell-Derived Hepatocytes in Conventional 2D Cultures

L. Quinn1, A. Asplund2, B. Ulfenborg3, J. Synnergren1, C. Brandsten2, and B. Kppers-Munther2. 1 Takara Bio USA, Mountain View, CA; 2Takara Bio Europe AB, Gothenburg, Sweden; and 3University of Skovde, Gothenburg, Sweden.

Human primary hepatocytes (hphep) are the current gold standard for drug development and toxicity assays *in vitro*. However, their rapid loss of viability in conventional 2D cultures limits their utility. In contrast, human pluripotent stem (hPS) cell-derived hepatocytes have a potential to become a more predictive *in vitro* model system for these applications if they possess a relevant window and function. To address this problem, we developed a novel hepatocyte maintenance media which enables culturing of both hhep and hiPS cell-derived hepatocytes (hiPS-HEP) with viable cells and stable activity of key enzymes for several weeks. Cryopreserved hiPS-HEP cultured in our medium express essential genes involved in drug metabolism, such as CYPs, phase II enzymes, and transporters. Importantly, they also demonstrate mature and functional features as shown by multiple analyses including immuno-stainings and functional assays such as albumin secretion and CYP activity assays. Additionally, this extended culture time enables long-term experiments, such as chronic compound exposure. Here, we performed a proof-of-concept chronic toxicity test with compound exposure for up to 14 days. In this study, our hiPS-HEP responded expectedly to known hepatotoxins, demonstrating their utility for chronic toxicity studies. To determine if similar improvements in viability and functionality were possible with hheps, we also reformulated the novel maintenance medium for hhep. The novel culture medium clearly showed stable morphology, viability, and functionality of hhep for four weeks post-thawing. We observed, functional, stable CYP activities and albumin secretion during the four week-period. Additionally, hhep cultured for four weeks showed inducible expression of CYP1A2, 2B6, 2C9, and 3A4. Taken together, our novel medium prevents the typical rapid loss of functionality and viability of hhep *in conventional* 2D cultures. Also, this medium allows long term culture of cryopreserved hiPS-HEP, from multiple lines, with preserved functionality. This increased longevity and functionality of hepatocytes in 2D cultures significantly advances the applications and uses of *in vitro* hepatocyte models.

**2347** A Cell-Based BoNT Potency Assay Using Electrophysiological Activity Measured with Microelectrode Arrays

The standard for measuring botulinum neurotoxin (BoNT activity) has been the mouse L5D0 (mLD50) bioassay. Although the mLD50 bioassay is highly sensitive, there have been efforts to replace this with an *in vitro* assay which will cost less to perform, provide a more controlled testing environment, reduce the inherent variability associated with animal bioassays, and reduce the use of animals. In support of this effort, we have developed an *in vitro* neuronal-cell based assay to evaluate BoNT potency which will include key steps in BoNT toxicity. These steps include cellular binding, uptake, translocation, and proteolytic cleavage of the target SNARE proteins involved in vesicular fusion, which can be evaluated by measuring electrophysiological changes. The goal of this effort was to show a dose dependent change in electrophysiological activity within rat primary neuronal cells after exposure to pure BoNT serotype A (BoNT/A) or BoNT/A in complex. A cell-based BoNT potency assay was conducted by exposing rat primary neuronal cells to BoNT/A and using a microelectrode array (MEA) output to measure electrophys-
iodological activity. Using fresh and frozen primary rat neurons exposed to pure BoNT/A concentrations ranging from 0.5 to 500 pM, statistically significant, dose dependent reductions in electrophysiological activity were observed. Exposing cells to BoNT/A in complex also showed statistically significant reductions in electrophysiological activity, but this was not explored to the same extent as pure BoNT/A, and a dose dependent reduction was not established. This cell-based BoNT/A potency assay was capable of detecting BoNT toxicity at concentrations as low as 0.5 pM in 4-5 replicates of up to 5 treatment conditions simultaneously on a single plate. Although the assay was developed using BoNT/A, it is likely capable of detecting toxicity from other BoNT serotypes and even other neurotoxins or neurotrophic chemicals. This assay appears to have the necessary sensitivity and throughput to replace the mLD50 assay.

**2348 Validation of a Co-Culture Cell Model for Identifying Angiogenesis Inhibitors on a High-Content and High-Throughput Screening Platform**

S. Li1, C. Hsu1, S. Sakamura2, C. Zou2, R. Huang1, and M. Xia1.

1NCATS, Rockville, MD; and 2American Type Culture Collection, Gaithersburg, MD.

Angiogenesis is a fundamental developmental and physiological process of forming new blood vessels that is required for organ growth and repair. Recent studies have also drawn attention to the role of angiogenesis inhibitors that are closely related to cardiovascular toxicity. In vitro angiogenesis models for analyzing tube formation serve as useful tools to study these processes. However, current in vitro co-culture models using primary cells have limitations in usefulness and consistency. Therefore, in the present study, an in vitro co-culture assay system was optimized in a 1,536-well format for high-throughput screening using human terminal differentiated HUVEC (hTERT)-immortalized mesenchymal stem cells and aortic endothelial cells. The National Center for Advancing Translational Science (NCATS) Pharmaceutical Collection (NPC) library containing 2,816 drugs was evaluated using this in vitro co-culture assay system. The screen, 35 potential inhibitors (IC50 ≤ 1 µM) were identified, followed by 15 weaker inhibitors (IC50 ≈ 10 µM). Moreover, many known angiogenesis inhibitors were identified such as topotecan, docetaxel, and bortezomib. Several potential novel angiogenesis inhibitors were also identified from this study including thimerosal and podophyllotoxin. Some of these compounds were shown to be involved in the hypoxia-inducible factor-1-alpha (HIF-1α) and the nuclear factor-kappa B (NF-κB) pathways. In addition, many inhibitors, such as sunitinib, sorafenib, and vatalanib are closely related to increased cardiovascular risk. The co-culture model developed by using hTERT-immortalized cell lines described in this study provides a consistent and robust in vitro system for anti-angiogenic compound screening.

**2349 Establishment of In Vitro Cytotoxicity Assay Using Primary Monkey Cardiomyocytes**

T. Iguchi1, K. Fujimoto1, S. Nakamura2, T. Hideaki2, N. Niino1, H. Kishino1, and K. Mori1.

Cynomolgus monkey is one of the most commonly used animal species as a nonhuman primate in the toxicology field, but cytotoxicity assay using their primary cardiomyocytes have not been established. The aim of the current study is to establish in vitro cytotoxicity assay platform using primary monkey cardiomyocytes. Primary cardiomyocytes were isolated from newborn fetal hearts and cultured at different gestation day (from day 39 to 90). The cells were collected using commercially available isolation kit. Briefly, the whole fetal heart was digested by trypsin at 4°C for overnight. The cells were digested in collagenase solution at 300 units/ml for 45 minutes at 37°C, followed by being centrifuged at 100 x g for 10 minutes. Under the present condition, the percentage of living cells was more than 80% from all fetuses. Importantly, spontaneous contraction was observed only in the cells from gestation day at 63 or earlier. Transcriptome analysis of the isolated cells using microarray indicated that the cells have essential components of cardiac function such as myosins, α-actin, cardiac troponins, and calcium-released molecules, consistent with those in rat cardiomyocytes. Next, we evaluated the sensitivity of the monkey cardiomyocytes to doxorubicin. Exposure of monkey cardiomyocytes to doxorubicin at 300 nM or more for 72 hours increased LDH release and decreased ATP levels, but the sensitivity of monkey cardiomyocytes to doxorubicin was weaker than that of rat cardiomyocytes. The mechanism underlying the differential sensitivity to doxorubicin between monkey and rat was further characterized by microarray. The analysis revealed that doxorubicin predominantly increased several key genes involved in endoplasmic reticulum stress pathway in monkey cardiomyocytes compared to those in rats. In conclusion, primary monkey cardiomyocytes with spontaneous beating activity showed similar functional and transcriptional profiles to rat cardiomyocytes. Furthermore, monkey cardiomyocytes showed differential sensitivity to doxorubicin compared to rat cardiomyocytes through the upregulation of several key genes involved in endoplasmic reticulum stress pathway. The monkey cardiomyocytes would be valuable in investigating interspecies differences in drug-induced cardiotoxicity and its mechanism.

**2350 Human-Derived Cardiomyocytes for Testing Cardiotoxicity of Industrial Chemicals of Concern**

Cardiac toxicity, especially via sensitizing (or priming) the heart for a subsequent arrhythmia, has been reported for some industrial chemicals of concern (iCOC) including halogenated hydrocarbons and acrolein (an unsaturated aldehyde). Other iCOC are potential cardiocytosins via their modes of action (most commonly oxidative stress and/or calcium dysregulation). The applicability of a cardiomyocyte in vitro assay for screening and correctly identifying cardiotoxic iCOC was tested using several known reference compounds (sotalol, isoproterenol, and propafenone), known cardiotoxic compounds (digoxin, haloperidol, rotenone, and carbonyl cyanide 3-chlorohydrazone (CCCP)), active iCOC acrolein, chlorohydrin, acrylonitrile and phenol. Cardiomyocytes were maintained in culture for 9-11 days prior to testing, and a beating syn- chrony was confirmed prior to testing. The cells were pretreated with a fluorescent calcium-sensitive dye (Ex:Em: 485/535) so that the oscillation behavior of individual calcium could be measured spectrophotometrically. The cardiomyocyte response to the compounds was rapid with the compounds being observed after a 10 minute exposure. A dose dependent decrease in beat frequency was observed for acrolein and phenol while minimal changes in beat parameters were observed for chlorohydrin and acrylonitrile. Additionally, the intermediate doses of acrolein showed a decrease in the number of beats per minute (BPM) that preceded the drop in BPM observed at the higher doses. The increased BPM occurred between 10 and 200 µM acrolein. The cardiomyocyte response to phenol was a cessation of beating at approximately 1000 µM. Neither chlorohydrin nor acrylonitrile was cardiotoxic at concentrations as high as 2 mM. Rapid toxicity evaluations of iCOC and substances intended for military applications are key for timely environmental health and occupational safety recommendations. Based on the data presented here, the utility of an in vitro functional cardiotoxicity assay for the Army Public Health Center (APHC) screening level toxicity assessments on iCOCs was demonstrated. Further testing of this system for characterizing acrolein induced cardiac sensitization is ongoing.

**2351 Cardiovascular Toxicity Screening of Polychlorinated Biphenyls and Their Major Metabolites**

F. A. Grimm1, W. D. Klaren1, X. Li1, J. S. House1, W. Chiu1, H. J. Lehmer2, L. W. Robertson2, and I. Rusyn1. 1Texas A&M University, College Station, TX; 2University of Iowa, Iowa City, IA; and 3North Carolina State University, Raleigh, NC.

 Xenobiotic metabolism is complex and determines the physiologic fate and toxicological properties of drugs and environmental chemicals. Accounting for bioactivation and detoxification processes remains among the most challenging aspects of predictive in vitro toxicity. While co-culture systems with metabolically active components are currently being explored, the significance of the metabolic profiles remains unknown. Considering the physiological relevance of novel organotypic culture models and their high-throughput screening capacity, we hypothesize that direct characterization of chemicals and their major metabolites using multidimensional chemical-biological profiling is a sensible alternative. In this study, we tested 25 polychlorinated biphenyls (PCB 3, 11, 52, 95, 126, 136, 153) and their relevant metabolites (hydroxylated, methoxylated, sulfated, and quinone) for concentration-dependent (10 nM-100 µM) acute effects in iPS-derived human cardiomyocytes and endothelial cells. acute effects in iPS-derived human cardiomyocytes and endothelial cells. cardiac sensitization is ongoing.
fation and methoxylation of PCB resulted in diminished bioactivity. This study demonstrates a strategy for assessing metabolism in \textit{in vitro} screening and provides information from organotypic culture systems for human health assessments of PCBs and their metabolites. This work was supported by NIEHS grants P42 ES013661 and P42 ES027707A.

While the adverse outcome pathway (AOP) concept has been a key aspect of human cancer risk assessment for some time, it was recently adopted by the OECD as a pragmatic tool which may facilitate transition of chemical safety assessment from measurement of apical endpoints in animals to toxicity prediction based on mechanistic information. The concept is that identification of key events and systematic mapping of AOPs for a given hazard endpoint can form the basis for the development of alternative tests as part of an integrated testing strategy to eventually replace conventional guideline studies. With the overall aim to further develop the database of integrated animal- and human-based approaches to assessment of repeated dose systemic toxicity, we developed and critically evaluated AOPs for proximal tubule injury initiated by (1) covalent protein binding (2) lysosomal overload and (3) inhibition of mtDNA polymerase $\gamma$, as these present fairly well-defined mechanisms by which certain chemicals/drugs cause nephrotoxicity. The usefulness of AOPs provide a mechanistic framework for the development of \textit{in vitro} bioactivity assays that cover key events across these AOPs and that can be integrated with quantitative \textit{in vitro} to \textit{in vivo} extrapolation and exposure modelling to derive quantitative risk estimates. The selected and validated assays were used for high-content analysis of model nephrotoxins in rat and human proximal tubule cells to establish the quantitative relationships between upstream and downstream key events.

Assessing the acute toxic potential of a substance is necessary to determine the potential effects of accidental or deliberate short-term exposure. There are several approaches available, and few in \textit{silico} models, to predict acute oral toxicity. Until recently, a paucity of experimental \textit{in vivo} acute toxicity data was available for model development and evaluation. Here, a large acute oral toxicity dataset totaling 15,698 unique chemicals was compiled from different sources including the Organization for Economic Corporations and Development’s eChemPortal, the National Library of Medicine’s (NLM) Hazardous Substances Data Bank, NLM’s ChemIDplus via the Toxicity Estimation Software Tool, the European Union Joint Research Centre’s AcutoxBase and the National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Method’s Pesticide Active Ingredients Database. Many of the LD50 values originated from limit tests which estimate an LD50 value as being above/below a specific threshold, typically 2000 mg/kg or 5000 mg/kg. These limit tests present challenges for model development since they provide less information than an explicitly quantified LD50 value. To overcome this limitation, three approaches were used to model acute oral toxicity using ToxCast/Tox21 activities as biological descriptors and ToxPrints and physico-chemical properties as chemical descriptors. All models were developed and evaluated using 80% data as training set and 20% data as an external test set. The first approach was a global random forest model, and below a LD50 of 5000 mg/kg. The balanced accuracy of the model was 0.76 and 0.35, respectively. The third was a set of 10 cluster-based local

**2352** Mapping Adverse Outcome Pathways for Kidney Injury: Opportunities for Development of Mechanism-Based Animal-Sparing Approaches to Assessment of Nephrotoxicity

**2354** Variability of LD50 Values from Rat Oral Acute Toxicity Studies: Implications for Alternative Model Development

A. Karmaus1, J. Fitzpatrick2, D. Allen1, G. Patlewicz2, N. Kleinsteuber1, and W. Casey1, 1ILS Research Triangle Park, NC; 2US EPA, Research Triangle Park, NC; and 3NIEHS, Research Triangle Park, NC.

Alternative models developed for estimating acute systemic toxicity are generally evaluated using \textit{in vivo} LD50 values. However, \textit{in vitro} acute systemic toxicity studies can produce variable results, even when conducted according to accepted test guidelines. This variability can make a fair assessment of alternative models extremely challenging. To characterize the variability of \textit{in vivo} acute systemic toxicity data, we examined a large compilation of LD50 values reported in oral rat acute toxicity studies. Data were obtained from multiple curated databases including the NLM’s Hazardous Substances Data Bank and ChemIDplus, the OECD’s eChemPortal, and the JRC’s AcutoxBase. The resulting dataset comprised a total of 2,120 rat oral LD50 values representing 15,698 chemicals. A subset of chemicals was identified in at least three independent rat oral acute toxicity studies to be used to assess variability. Of this subset, 20% (234 chemicals) had at least one study generating an “extreme” LD50 value (i.e., falling outside 1.5 times the interquartile range of the LD50 distribution for that chemical). Furthermore, 30 chemicals had LD50 values ranging across at least two orders of magnitude, with some of these chemicals having LD50 values ranging across at least three orders of magnitude. This degree of variability can confound hazard categorization: LD50 values from 47 chemicals fell into at least three different Globally Harmonized System (GHS) oral toxicity labeling categories, and values from 10 chemicals fell into at least three EPA hazard categories. These findings underscore the importance of considering an appropriate margin of uncertainty when using \textit{in vivo} oral acute toxicity data to assess the performance of alternative methods and provide a reference dataset to ensure that appropriately representative LD50 data are routinely used for the development and validation of alternatives models. This project does not necessarily reflect US EPA policy and was funded in whole or in part with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C.
random forest models built using the k-means algorithm for deriving the clusters. The RMSEs and R² for the test sets ranged from 0.52-0.83 and 0.20-0.48, respectively. Overall, the local cluster-based models performed better than the global models. This abstract does not necessarily reflect US EPA policy and was funded in part with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C.

**2356 Single versus Repeated-Exposure Analysis for In Vitro Protein Hazard Characterization with Human Polarized Intestinal Epithelial Cell Line Monolayers**

B. B. Lanter1, A. D. Eaton1, C. Zimmermann1, B. Delaney2, and B. P. Hurley1. 1Massachusetts General Hospital, Boston, MA; 2DuPont Pioneer, Johnston, IA; and 1Massachusetts General Hospital/Harvard Medical School, Boston, MA.

Recent studies suggest that human derived intestinal epithelial cell (IEC) lines cultured as polarized monolayers on permeable Transwell® filters are effective at differentiating between hazardous and non-hazardous proteins. This experimental platform is based on a single exposure of IEC monolayers to a test protein followed by assessment of whether IEC monolayers display evidence of loss in barrier integrity or cell viability after overnight exposure. In this study, Caco-2 and T84 IEC polarized monolayers were evaluated for barrier integrity and cytotoxicity following a single overnight exposure to hazardous or non-hazardous proteins and compared to IECs exposed nine times over the span of 29 days to the same protein. The objective was to determine whether repeated exposures altered responses observed following a single exposure. Hazardous proteins included *Clostridium difficile* toxin A (ToxA), Streptolysin O (SLO), Wheat Germ Agglutinin (WGA), and *Phaseolus vulgaris* haemagglutinin-E (PHA-E). Non-hazardous proteins included bovine serum albumin (BSA), porcine serum albumin (PSA), peroxidase, and fibrinogen (Fbn). In general, evidence of diminished barrier integrity and/or cell viability following exposure to hazardous proteins was more pronounced in magnitude when IECs were subjected to multiple rather than single exposures. In some cases, an effect on IEC monolayers was observed only when the repeated exposure protocol was chosen. Non-hazardous proteins failed to elicit any effects following either single or repeated exposures. Results from these studies further support the utility of using cultured human IEC polarized monolayers to differentiate between hazardous and non-hazardous proteins and suggest that a repeated exposure protocol may reveal a greater magnitude of response when compared to a single exposure protocol.

**2357 Detecting GI Toxicity Earlier Than in Dog: Developing an In Vitro Assay to Predict Clinical Diarrhea**

M. Peters1, H. Bartholow1, C. Scott1, A. Armento2, and S. Ayehunie3. 1AstraZeneca, Waltham, MA, and 2MatTek, Ashland, MA.

GI toxicity is a common adverse event that limits pharmaceutical development across diverse therapy areas. Preclinical testing in dog (but not rat) shows good predictivity (Olson et al., 2000), however, the cost and throughput prevents routine testing needed to optimize GI safety during drug discovery. In vitro models have been developed to elucidate the role of molecules with lower risk and/or to develop dosing schedules that mitigate the risks. Traditional 2D in vitro cell cultures approaches using immortalized human colorectal Caco-2 cells have been successful for routine assessment of ADME properties. Here, the utility for predicting GI toxicity was assessed with 2D Caco-2 cultures and 3D GI microtissue prepared using the MatTek SureClick™ technology. Derived from primary human ileum and cultured on transwells, the microtissues develop structural features resembling villi, replicate diverse intestinal epithelial cell phenotypes, and replicate barrier function. Since, impaired epithelial barrier function is associated with clinical diarrhea, microtissue transepithelial electrical resistance (TEER) was evaluated to correlate with clinical incidence of diarrhea. Clinical correlation was assessed with compounds selected based on differing incidences of diarrhea; this included 17 drugs with low (<3%) and with 15 high (>40%) incidence. Two independent microtissue experiments conducted under blinded conditions revealed predictive accuracy of 84% and 81% compare to 72% with Caco-2. Microtissue sensitivity was 80% and 67% which was superior to similar experiments with Caco-2 cells (36%). The label-free nature of TEER readings enable daily measurement. Time course data showed low tissue-to-tissue variance as well as excellent day-to-day stability for at least 21 days. Follow-on experiments confirmed the ability to assess the kinetics of on-set and recovery. These data indicate that human 3D GI microtissue delivers excellent predictivity for high vs. low incidence clinical diarrhea and should provide a platform useful for lead optimization and candidate drug dose schedule exploration.

**2358 Gut-on-a-Chip: Toward a More Physiological and Predictive Human Intestinal Barrier Model**

A majority of the screening and predictive models do not reflect properly the physiology of the human intestinal tract and predictions remain unreliable by lacking the in vivo morphology and physiological circumstances. The often used Caco-2 cell models are not well suited to investigate the different processes involved in general gut health or toxicity aspects. Therefore, realistic models resembling the human in vivo situation are needed, for instance ex vivo models that successfully applied human intestinal tissue into the InTESTine™ two-compartmental disposable device. This set-up is suitable for standard 6- or 24-well plate format and allows the study of (regional) drug absorption, intestinal wall metabolism, mucus interactions and pathological and physiological effects. With this device we have extended our InTESTine platform by successfully using human intestinal tissue for repeated exposure protocol. This model has been applied as a reliable tool for the assessment of processes that determine human intestinal permeability, (long-term) toxicity and pathological effects.

**2359 Multicellular Human Bronchial Models Exposed to Diesel Exhaust Particles Induce Inflammation, Oxidative Stress, and Macrophage Polarization**

J. Ji1, S. Upadhyay1, X. Xiong1, M. Malmlöf2, P. Gerde1, and L. Palmberg1. 1Karolinska Institutet, Stockholm, Sweden; and 2Inhalation Sciences Sweden AB, Stockholm, Sweden.

Human airway epithelium forms the first line of defense in lung, and is a primary target of diesel exhaust particles (DEPs). Macrophages, with phagocytosis as main feature and inflammation as well as immunity as secondary features, have the ability to remove DEPs from the lung. We have reported that both bronchial epithelial cells and macrophages are equipped with Toll-like receptors (TLRs). In this study, we exposed a multicellular model consisting of primary bronchial epithelial cells (PBEC) and macrophages (MQ) to a diesel exhaust particle (DEP) during 6 days and measured changes in cell viability, cytokine release, and mRNA expression. PBEC cultured at ALI were co-cultured with MQ (PBEC-ALI/MQ), DEPs and MQ were separated by a liquid interface (ALI) with DEPs. We aim to identify the effects of DEPs in macro- or multicellular airway models. PBEC cultured at ALI were co-cultured without and with MQ (PBEC-ALI/MQ, respectively) and exposed to 63.5µg/cm² DEPs aerosols via Xpose™. Control exposures to clean air were performed. After exposure, the models were incubated for 24h. The secretion of CXCL8 and IL-6 in basal medium were measured by ELISA. The mRNA levels of CXCL8, CXCL12 to CXCL19, NFKB, TNFα, IL-10, IL-13, IL-4, and IL-13, MRC1, MRC2, and RETNLA were analyzed by qRT-PCR. The surface expression of CD14/CD204 were detected by FACS. Cell viability and apoptosis rate were analyzed with LDH-assay and FACS. In PBEC-ALI, the secreted level of CXCL8, CXCL12, expression of inflammatory markers (CXCL8, TNFα), oxidative stress markers (NFKB, HO1, GPx) were significantly induced by DEPs exposure. However, after DEPs exposure, mRNA expression of these markers (CXCL8, IL6, NFKB, HO1) were reduced in PBEC-ALI/MQ compared to PBEC-ALI. After sham exposure, the surface expression of CD14 and CD204 on PBEC in PBEC-ALI/MQ was significantly attenuated compared to PBEC-ALI. Exposure to DEPs increased surface expression of CD14 and CD204 on PBEC in PBEC-ALI/MQ. DEPs exposure resulted in similar expression pattern of CD14 and CD204 on PBEC-ALI/MQ. In PBEC-ALI/MQ, DEPs exposure increased M2 macrophage markers (IL10, IL4, IL13, MRC1, MRC2) transcription. DEPs induced an inflammatory and...
oxidative stress response in PBEC-ALI models which was attenuated in the presentence of MQ. In both PBEC and MQ, DEP's exposure increased TLR2 but decreased TLR4 surface expression. The combination of DEPs exposure and co-culture with PBEC drove the polarization of MQ to M2 phenotype.

2360 Metabolomics Approach for Toxicity Screening of Volatile Substances
B. R. Winters1, M. M. Angrish2, A. M. Wallace2, J. D. Pleil2, and M. C. Madden1.1 University of North Carolina at Chapel Hill, Chapel Hill, NC; and 2US EPA, Research Triangle Park, NC.

In 2007 the National Research Council envisioned the need for inexpensive, high throughput, cell-based toxicity testing methods relevant to human health. While there has been throughput in vitro screening approaches, these have largely addressed these problems by using robotics. However, the challenge is that many of these chemicals are volatile and not amenable to robotic liquid handling applications. We assembled an in vitro cell culture apparatus capable of screening volatile chemicals for toxicity with potential for miniaturization for higher throughput. BEAS-2B lung cells were grown in an enclosed culture apparatus under air-liquid interface (ALI) conditions, and exposed to a small subset of xenobiotics in 5% CO2. ALI conditions allows direct contact of cells with a gas xenobiotic, as well as release of endogenously-produced gaseous molecules without interference by medium on the apical surface. To identify potential xenobiotic-induced perturbations in cell homeostasis, we monitored for alterations of endogenously-produced gaseous molecules in air directly above the cells, termed “headspace”. Alterations in specific endogenously-produced gaseous molecules in headspace is indicative of xenobiotic-induced perturbations of specific cellular processes. Furthermore, endogenously-generated volatile organic compounds (VOCs) may be monitored in a nonspecific, discovery manner to determine whether cell processes are perturbed by xenobiotic exposure, potentially producing specific patterns of changes. Preliminary results indicate the novel cell culture system is capable of detecting gaseous products of specific enzyme pathways such as CYP2A6. Additionally, numerous VOCs were detected in the headspace of cells grown in the novel cell culture apparatus. We believe our novel cell culture apparatus, once refined and validated, will allow for screening of both volatile and non-volatile xenobiocs by measuring cellular responses detected as alterations in gaseous molecules released by cells. This abstract may not reflect official USEPA policy.

2361 Cell Line-Based In Vitro Models of Normal and Chronic Bronchitis-Like Airway Mucosa to Study Toxic Potential of Aerosolized Palladium Nanoparticles
L. Palmberg1, J. Ji1, S. Upadhya1, V. Kessler1, G. Seisenbaeva2, and P. Gerde1,2.1 Karolinska Institutet, Stockholm, Sweden; 2Swedish University of Agricultural Sciences, Uppsala, Sweden; and 3Inhalation Sciences Sweden AB, Stockholm, Sweden.

Physiologically-relevant cell line-based models of human airway mucosa are needed for assessment of nanoparticle-mediated pulmonary toxicity. We have developed a platform that can be used to test aerosol (PN) doses emitted from the catalytic converters in vehicles. We aimed at developing in vitro airway models to assess the toxic potential of PN in normal and chronic bronchitis-like mucosa. Bronchial mucosa models cultured at air-liquid interface were developed using epithelial cells (16HBE) and fibroblasts (MRC-5). Further both normal and chronic bronchitis-like models (IL-13 treatment) with increased number of goblet cells were used. Using XposeALI™ the models were exposed to three different doses of aerosolized PN ranging between 3.2 and 5.0 μg/cm² with clean air as control. After 24 hours incubation the expression of inflammatory (IL-6, CXCL8, TNFa, NFkB), oxidative stress (HO1, SOD3, GPx, GSTA1), and tissue injury/repair (MMP9/TIMP1) markers were assessed using qRT-PCR. Secretion of CXCL-8 and MMP-9 were measured with ELISA. P<0.05 was considered as significant. Significant (P<0.05) increased expression of CXCL8, TNFa, IL6, and NFkB were observed at highest dose of PN in chronic bronchitis-like models, whereas in normal mucosa models, a maximum effect on CXCL8, TNFa, and NFkB expression were observed at medium PN dose. In normal mucosa models, SOD3 showed clear dose response of PN, while GSTA1 and GPx expression were significantly increased (P<0.05) only at lowest dose of PN. HO1 decreased significantly (P<0.05) after exposure to the two highest doses of PN in normal mucosa models. Secretion of CXCL-8 increased dose-dependently in dose-response curves following exposure to PN. Dose-response curves followed exposure to PN. Our normal and chronic bronchitis-like mucosa models combined with exposure to aerosolized PN using XposeALI™ exposure system closely mimic cell-particle interactions observed under in vivo physiological condition in the lung. Further, the observed results (inflammatory and oxidative stress response) in both normal and chronic bronchitis-like mucosa models implicate strongly a relevance of these in vitro findings for human health risk assessment.

2362 Applying Concepts from Adverse Outcome Pathways to Assessment of Airway Irritants
L. T. Haber1, E. Frank1, M. Genter2, and A. Maijer1.1 Risk Science Center, University of Cincinnati, Cincinnati, OH; and 2University of Cincinnati, Cincinnati, OH.

Airway irritant exposures in the workplace cause rhinorrhea, cough, and bronchospasms, and are associated with intrinsic asthma, non-al-lergic rhinitis, and related chronic inflammatory conditions. Our objective is to apply the in vitro approaches to assess volatile organic chemicals (VOCs) for their potency to cause adverse outcomes. To this end, we have conducted a study to assess the induction of airway irritation from VOCs. The VOCs were identified through a literature search for chemicals that are able to produce airway irritation. The effects were measured in vitro using the rat isolated perfused lung (IPL) model and in vivo using human lung epithelial cells under air-liquid-conditions with the P.R.I.T.-ALL Technology. The objective was to identify VOCs that can mediate airway irritation and to develop a cost-effective screening system to identify chemicals likely to be airway irritants. We hypothesize that this can be done using in vitro measurement of molecular initiating events (MIEs) upstream of sensory irritation responses, similar in principle to the use of adverse outcome pathways. We reviewed literature relevant to sensory irritation responses and used a modified adverse outcome pathway method to evaluate a key event framework beginning with MIEs. Our assessment identified (1) activation of transient receptor potential and acid-sensing ion channels, (2) lipid peroxidation, and (3) pro-inflammatory changes as MIES upstream of sensory irritation. Downstream events include depolarization of nociceptive neurons and epithelial inflammation, both of which are events mediating airway irritation responses. Based on this framework, we have identified potential endpoints that can be evaluated in cultured human airway cells. A predictive assay suite based on multiple increased dose-distributions would allow for the identification of chemicals of low concern for which derivation of OELs from oral toxicity data may be allowable, and may ultimately lead to methods to reduce animal testing for sensory irritants. This would improve the efficiency of risk assessments for these chemicals of low concern (and perhaps ultimately other chemicals) without compromising health protection.

2363 Acute Inhalation Toxicity In Vitro and Ex Vivo Test Battery Prior to Regulatory OECD 403 Studies
K. Schwarz, T. Hansen, D. Ritter, D. Walter, and J. Knebel. Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany. Sponsor: C. Danenberg

New crop protection agents are usually tested for acute inhalation toxicity in vitro according to OECD Test Guideline 403. In order to reduce the amount of animals and test compound needed, this project aimed at the implementation of ex vivo and in vitro screening tests that can be used to estimate the acute inhalation toxicity prior to regulatory OECD 403 studies. Therefore, two reference substances (mancozeb and deet) were selected for the identification of chemicals of low concern. A combination of four test substances resulted in dose-dependent alterations of inflammatory and oxidative stress response and establishment of dose response curves. In both assays mancozeb showed a significantly lower toxic potential than chlorothalonil and thus confirms the findings of the in vivo studies. In the next step both assays will be used to predict the acute toxic potential of further substances with known and unknown toxic potential to broaden the data base and verify the reliability of this test battery.
Exposure, in occupational scenarios or at consumer levels, to chemicals such as acid anhydrides or fragrances can lead to the development of respiratory allergies. At present, no in vivo method is available for the prediction of respiratory sensitization potential of chemicals. To mimic the alveolar-capillary barrier we developed a 3D in vitro model grown at the air-liquid interface including alveolar type II epithelial cells (AS49), endothelial cells (EA.hy926), macrophage-like cells (PMA differentiated THP-1), and dendritic-like cells (DC) (non-differentiated THP-1). The model was exposed to the ALI to trimellitic anhydride (TMA) and phthalic anhydrid (PA), which are chemical respiratory sensitizers, to acrolein (Acr - respiratory irritant) and to house dust mite (HDM - protein allergen). The model was exposed to concentrations leading to a reduction of 25% cell viability or, whenever no cell viability reduction was observable, to the highest possible concentration. Several parameters were evaluated after exposure of the model to the different compounds, including surface markers of activation for DC (e.g., CD54, OX40L, TSLPR, etc.) and cytokines (e.g., MCP-1, IL-10, RANTES, etc.). In addition, a panel of genes related to respiratory inflammation and DC activation was analyzed by qRT-PCR. Exposure to PA and TMA led to the upregulation of CD54 and TSLPR on DC cells as compared to Acr or vehicle controls. HDM induced upregulation of the surface marker OX40L, which was unchanged after treatment with respiratory chemical sensitizers, while it resulted in downregulation with respiratory irritants. Taken together, surface markers for DC activation, gene expression, and cytokines constitute a panel of endpoints that allows prediction of respiratory sensitization potential. In conclusion, the presented in vitro model represents a useful tool for the prediction, in vitro, of respiratory sensitization, allowing discrimination between respiratory sensitizers, either chemicals or protein sensitizers, and respiratory irritants.

When combining multiphase aerosol (particulate and vapor) delivery and exposure with in vitro assays, knowledge of the delivered dose and its time course is critical to interpreting and extrapolating results. In this study the particle dosimetry of aerosol exposure of cells was measured using monodisperse fluorescent particles (0.5, 1.1, 2.1, & 3.2 µm in diameter) in each of the 48 wells of the Vitrocell AMES 48 exposure system (in vitro exposure system). Three different flowrates at each of the 48 wells were evaluated (5, 10, and 20 cc/min) in three replicate experiments. Fluorescent particle distribution across each well was photographed using fluorescent microscopy and counted using image analysis software. Particle losses throughout the in vitro exposure system were quantified by repeatedly washing each part with aqueous surfactant and counting the collected fluorescent particles using either flow-cytometry or a hemacytometer with fluorescent microscopy. Results indicate that overall deposition efficiency is below 1% for each well regardless of flowrate for each particle diameter tested. For each particle diameter there were characteristic deposition patterns across the wells. Depending on the particle diameter, different distances from the perimeter were completely particle free. These particle free areas should be considered when conducting in vitro studies in the in vitro exposure system to ensure that cellular responses are integrated only from cells that are directly exposed to particles. For multiphase aerosols, such as e-vapor aerosols, combination of our particle dosimetry results with predictions of vapor deposition using computational fluid dynamic techniques would provide a more complete picture of cellular exposure that occurs in the in vitro exposure system.
The current assumption for assessing carcinogenic risk of polycyclic aromatic hydrocarbons (PAHs) is that they function through a common mechanism of action; however, recent studies demonstrate that PAHs can act through unique mechanisms potentially contributing to cancer outcomes in a non-additive manner. In this study, we assessed potential differences in mechanism of action for PAHs in a primary human 3D bronchial epithelial culture (HBEC) model based on short-term bio-signatures that could be extrapolated from global transcriptional profiles. PAHs were divided into the groups of differentially expressed genes between PAHs and DMSO controls. Analysis of global gene expression and significantly enriched pathways between the AIR mixture, DBC, and BAP, while BAA, CTE, and BAA enriched a subset of unique pathways. Principal components analysis of global gene expression and significantly enriched pathways found groupings of lower potency PAHs (BAA, CTE, CTE, lower dose BAP) and grouping of BAP, DBC, and AM. Pathways were filtered to those significantly enriched with carcinogenic PAHs to classify the carcinogenic potential of PAHs and mixtures. These data suggest that bioactivity signatures from 3D HBEC can be used to identify mechanisms linked to carcinogenic risk of PAHs in humans. By profiling the short-term transcriptomic signatures of PAHs and mixtures of known components, we aim to develop a predictive model to assess carcinogenic potential of PAHs and PAH mixtures.

Cigarette smoking is a complex mixture of over 4,000 chemicals that is comprised of particulate and gaseous phases. The use of dosimetry (mass) plays a key role in understanding the exposure of cigarette smoke within in vitro systems. The goal of this study was to evaluate the utility of multiple dosimetry techniques in determining the amount of whole cigarette smoke delivered by a VITROCELL® VCT® smoking robot into two different exposure modules of the VITROCELL® system (4- and 12-well (12 mm)). Eight University of Kentucky 3R4F cigarettes were smoked under International Organization for Standardization (ISO), or Health Canada Intense (HCI) regimes, and assessed over a range of diluting airflows. Dosimetric tools utilized during exposure experiments were quartz crystal microbalances (QCM), laser photometers (area under the curve (AUC)), and fluorescence measurements (Ex/Em 355/485) of smoke particulate matter captured in DMSO. For each experiment, the first well contained a QCM and the second and third wells contained a set volume of DMSO. An in-line laser photometer was positioned between the smoke dilution system and the first well of the exposure module. QCMs were equilibrated to room temperature in the module until a stable baseline was achieved and the photometers were harmonized to each other prior to the study. Concentration of the captured particulate matter was determined by a standard curve generated for each module and type of smoke. Additionally, three endpoints (QCM - gravimetric mass, photometric - AUC, and laser photometer) can be used as tools to measure whole smoke dosimetry in real time and post experimental analysis.
The Nrf2 transcription factor controls expression of enzymes involved in defense against electrophilic and oxidative damage. In the current work, an organotypic model of human airway epithelium containing a luciferase reporter for Nrf2 activation was developed. The reporter model was characterized with 12 reference chemicals, whole tobacco smoke (WTS) and electronic cigarette (e cig) vapor. Primary human tracheobronchial epithelial cells (NHBE) from 2 donors were transduced with a lentiviral Nrf2 luciferase reporter. Stably transduced cells were expanded and cryopreserved to produce large pools of reporter-expressing cells which were then utilized to produce differentiated organotypic airway epithelial models. Organotypic structure and barrier properties of reporter models were found to be similar to untransduced models, as determined by histological evaluation and barrier assessment. The airway reporter models were exposed to test chemicals by apical application of solutions containing up to 0.6% DMSO. A smoking machine exposed the models to WTS or e cig vapor. Luciferase activity was evaluated using a commercial kit and a microplate luminometer. Toxicity was evaluated by LDH release. Dose response experiments were performed to determine a range that spanned non-toxic to moderately toxic concentrations. Test chemicals included: isothiocyanates (sulforaphane), oxidants (H2O2, menadione) and electrophilic chemicals (acrolein, iodoacetamide, nitrobenzyl bromide, cinnamaldehyde, dihydrochalcone, 2-butylnitrosoquinalone), parthenolide, quercetin, and cyclophosphamide (precursor of menadione) and electrophilic chemicals (acrolein, iodoacetamide, nitrobenzyl bromide, cinnamaldehyde, dihydrochalcone, 2-butylnitrosoquinalone). Only slight Nrf2 activity was observed following treatment with sulforaphane, a reversible thiol binding chemical. H2O2 and menadione produced only weak activity across the entire span of doses. However, strongly electrophilic chemicals (acrolein, iodoacetamide, nitrobenzyl bromide, cinnamaldehyde, dihydrochalcone, 2-butylnitrosoquinalone) elicited strong induction of Nrf2. WTS also induced strong Nrf2 activation. E cig vapor produced no to weak activity. The results demonstrate that the Nrf2 airway reporter model is a highly sensitive detector of reactive electrophilic chemicals or mixtures including WTS. The model may prove useful for safety evaluation of new generation nicotine delivery products.
isotopic labeling strategy by incorporating cells with a sterol upstream of DHCR7 metabolism, C27-Lanosterol, into the cholesterol biosynthetic pathway. It was determined by calculating the ratio of C27-DHCR7 to C27-CHOL that control cells exposed to HPD had significantly decreased DHCR7 activity, while having no effect in HD cells. These findings suggest that HD neuroprogenitors are unaffected to chemical inhibition of DHCR7. Supported by NIEHS T32 ES000267 (PW, ABB), ES016931 (ABB), and ES024133 (NP).

### 2376 Carbon Monoxide (CO) Poisoning in Cats

A. Sobhakumari1, R. Poppenga1, J. B. Pesavento1, and F. A. Uzal2.
1California Animal Health and Food Safety Laboratory System, Davis, CA; and 2California Animal Health and Food Safety Laboratory System, San Bernardino, CA.

Carbon monoxide is a colorless, odorless gas, the inhalation of which can be fatal. There is only one report on CO poisoning in cats in the literature. Two adult Singapurra brown ticked cats were submitted to the San Bernardino branch of CAHFS for necropsy. These animals had been found dead on 13th. The presentation along with their two decades owned. At necropsy, gross lesions were similar in both cats and consisted of multifocally large and irregular, bright red spots on the skin of the abdomen and the inner surface of ear pinna, bright red muscles and blood. The carcasses, and tissues fixed in formalin retained the bright red discoloration for up to two weeks. Microscopic lesions were also similar in both cats and included diffuse pulmonary congestion and edema, and multifocal intense basophilia of cardiomyocytes. The latter was seen mostly affecting whole fibers but it was occasionally affecting only a portion of the fiber, with a clear transverse line of demarcation from the red to the pale color. Rarely, discrete areas of hypercontraction bands were seen in individual cardiomyocytes. Based on the clinical history, gross and microscopic changes, cyanide or carbon monoxide poisoning was suspected, and frozen muscle and blood from the two animals were submitted for toxicologic analysis. The muscle samples were homogenized by DLC (PCB 126, the non-DLC PCB 153, and a mixture of PCB 126 and 153, which produced cancer and other non-neoplastic lesions of the liver and lung. In contrast, a general reduction in TL was observed with PCB 153 (non-DLC) treated rats that exhibited minimal toxicity. Telomere shortening may be an early indicator of carcinogenicity that occurs following two years of exposure to DLCs. Supported in part by the intramural research program of NCI/NIH.

### 2377 Telomeres as a Potential Target for the Chronic Toxicity of Polychlorinated Biphenyls (PCBs)

S. L. VanEtten1, M. R. Bonner1, X. Ren1, E. S. Birnbaum1, and J. R. Olson1. 1University at Buffalo, Buffalo, NY; and 2NIEHS, Research Triangle Park, NC.

Telomeres are DNA-protein complexes found at the ends of chromosomes that help protect the genome from degradation and interchromosomal fusion. Telomere length (TL) can be affected by various factors, including age and increased oxidative stress, and has been associated with higher risks for several types of cancer. The NTP conducted two year studies exposing animals to various doses of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), the dioxin-like compound (DLC) PCB 126, the non-DLC PCB 153, and a mixture of PCB 126 and PCB 153 (https://ntp.niehs.nih.gov/results/pubs/longterm/reports/longterm/index.html). Relative telomere length (RTL) is a biomarker that may be associated with neoplastic and/or non-neoplastic responses observed with chronic exposures to PCBs. DNA was isolated from liver and lung tissue obtained from the NTP studies and RTL was assessed by quantitative PCR. Relative to time-matched vehicle controls, increases in liver TL between 3% and 10% were seen in rats given various doses of TCDD for 13 weeks, while TL increased by similar ratios in rats dosed for 52 weeks. Similarly, the RTL increased between 7% and 13% in the liver of rats receiving PCB 126 for 13 weeks and increased 17% to 26% following 52 weeks of exposure. Rats dosed with the mixture of PCB 126 and PCB 153 saw increases in RTL in both the liver and lung tissues. Following 13 weeks of exposure to the mixture of PCB 126 and 153, TL increased 9% to 11% in the liver and 12% to 16% in the lung. After 52 weeks of exposure to the mixture, liver TL increased 13% to 34%, while lung TL increased 6% to 28%. In contrast, RTL decreased from 5% to 9% in the liver of rats receiving PCB 153 alone for 13 weeks. The association between RTL and test compound is congruent-specific and associated with the varying toxicological activity of PCB congeners. An increase in RTL was observed in rats treated with TCDD, PCB 126 and the mixture of PCB 126 and 153, which produced cancer and other non-neoplastic lesions of the liver and lung. In contrast, a general reduction in TL was observed with PCB 153 (non-DLC) treated rats that exhibited minimal toxicity. Telomere shortening may be an early indicator of carcinogenicity that occurs following two years of exposure to DLCs. Supported in part by the intramural research program of NCI/NIH.

### 2378 Impaired Learning and Memory in Rats after Subchronic Inhalation Exposure to an Indoor School Air Mixture of PCBs

H. Wang, A. A. Dodd, R. B. Steines, H. J. Lehmler, and P. S. Thorne. University of Iowa, Iowa City, IA.

Polychlorinated biphenyls (PCBs) are persistent, bioaccumulative, toxic pollutants, which are still present in the ambient environment and indoor buildings despite their production being ceased since the 1970s. Exposure to PCBs, especially during fetal and childhood developmental period, can affect IQ, learning and memory abilities. In this study we exposed female Sprague-Dawley rats to a PCB School air mixture of East City indoor school air in order to evaluate the effects of PCBs on learning and memory. Female Sprague-Dawley rats were exposed simultaneously to either SAM vapor (n = 8) or clean air (n = 8) through a nose-only exposure system. The exposure was 4 h/day, 7 days/week for 4 weeks. Positive control rats (n = 6) for assessing neurotoxic behavior were treated with 1-bromopropane (1-BP, 800 mg/kg bw, by gavage) for 12 days. Sentinel rats (n = 2) were kept in vivarium for health surveillance. Morris Water Maze (MWM) was performed for 6 days to evaluate the learning and memory abilities. Oxidative stress in super-natant of brain homogenates was assessed by determination of reactive oxygen and nitrogen species, detection of 4-hydroxynonenal (HNE) protein adducts and formation of malondialdehyde (MDA). Significantly increased escape latency was found in 1-BP group at 4th and 5th day, compared with control group (p < 0.01, p < 0.01 respectively). In contrast, no significant difference was found between negative for SAM group and control group, but from the learning efficiency, SAM group was slightly lower than control. Additionally, significant decreases of time spent in target quadrant and number of crossing platform were observed in 1-BP group, compared with control group (p < 0.01, p < 0.01, respectively); similar decrease of number of crossing platform was found in SAM exposure group (p = 0.01). None of the oxidative stress tests showed a statisti cal significance when SAM group was compared with controls. Results suggest the impairment of memory and learning after SAM exposure might not result from oxidative stress. Further investigation is needed to uncover the mechanism of the learning and memory deficit caused by PCBs.

### 2379 Low-Dose Perfluorooctane Sulfonate (PFOS) Is Associated with Induction of Fatty Acid Uptake Mechanisms in Diet-Induced Non-Alcoholic Fatty Liver Disease (NAFLD)

M. Pfohl, H. Ma, M. Abustan, E. Martell, N. Seeram, and A. Slitt. University of Rhode Island, Kingston, RI.

Obesity, diabetes, and insulin resistance are all risk factors associated with the development of hepatic steatosis and non-alcoholic fatty liver disease (NAFLD). It is estimated that 20-30% of the population present with NAFLD in the United States alone. The contribution of environmental exposures as risk factors for fatty liver disease has been largely overlooked. Perfluorooctane sulfonate (PFOS) is a widespread environmental toxicant that persists in over 98% of the general population. The aim of this study was to evaluate whether PFOS exposure in combination with a moderately high-fat diet, augmented hepatic lipid content and biomarkers associated with NAFLD. 6-week-old male C57BL/6 mice were co-fed either a 10% kCal low fat diet (LFD) or 45% kcal high fat diet (HFD), with or without 0.0003% PFOS (LFD-PFOS and HFD-PFOS, respectively) for 12 weeks. The HFD increased liver weight by about 30% and body weight by 50% compared to the LFD controls. HFD-PFOS administration increased liver weight by 50% and body weight by 40% when compared to the LFD group. LFD and LFD-PFOS groups had similar body weights and liver weights, with LFD-PFOS trending toward increased liver weight (p < 0.06). The LFD-PFOS and HFD-PFOS groups had higher liver lipid accumulation scores when compared to the LFD controls. Triglycerides increased 50% with HFD and 25% with HFD-PFOS compared to LFD alone. LFD-PFOS decreased liver triglycerides by 35%. Both HFD-PFOS and LFD-PFOS administration trended toward decreased non-esterified free fatty acids (NEFA) compared to the LFD controls, whereas HFD increased NEFA by 35%. A targeted liver gene expression array was conducted to assess the potential mechanism of PFOS induced steatosis within a LFD and HFD diet. Fatty acid uptake
genes, fatty acid translocase (Fat/Ca36) and long-chain fatty acid transport protein 1 (SLC27A1), were significantly induced by PFOS. PFOS treatment also resulted in significantly increased expression of glutathione S-transferase mu 3 (GmSU3) and sterol regulatory element-binding transcription factor 1 (Srebf1). The data suggests that PFOS exposure at an environmentally relevant dose (0.0003%) may have an adverse effect on hepatic lipid accumulation when combined with a LFD. The effect of diet on the distribution and mechanism of PFOS is described herein.

2380 Rat PCB Inhalation Study: Do PCBs Resembling a School Indoor Air Mixture Induce Hematotoxicity in Bone Marrow Cells?

S. Flor1, X. Xin1, H. Wang1, A. Adamcakova-Dodd1, P. Thorne1, W. Watson2, L. Robertson1, and G. Ludewig1. 1University of Iowa, Iowa City, IA; and 2University of Louisville School of Medicine, Louisville, KY.

Polychlorinated biphenyls (PCBs) are ubiquitous in our environment and it is estimated that about 1/3rd of all school buildings in the US have detectable levels of PCBs in indoor air. PCBs are immunotoxic and linked to childhood leukemia, Non-Hodgkin’s lymphoma and hematotoxicity. We previously reported that several PCB congeners and a mixture reduce telomerase activity in cells in culture. We then discovered that a single ip injection of PCB126 significantly reduced telomerase activity and down-regulated TERT gene expression and protein in male Sprague-Dawley rats by 48h/day, 7 days/week by nose-only inhalation to Aroclor 1254 vapor. Subsequent cultivation of these stem cells in soft agar showed an increase in Colony Forming Units (CFU) and a shift of hematopoietic stem/progenitor cells (HSC) differentiation toward the granulocytic direction compared to the untreated control. Our hypothesis is that inhaling a PCB mixture can affect telomerase activity and thereby interfere with proliferation and differentiating of hematopoietic stem/progenitor cells. We exposed female SD rats 4h/day, 7 days/week by nose-only inhalation to Aroclor 1254 vapor which closely resembles a school air mixture from a Chicago school. Then whole blood was drawn and analyzed for GSH/GSSG and Cys/CySS redox homeostasis and DNA damage in form of micronuclei per 1000 immature erythrocytes. Bone marrow nucleated cells were isolated to determine the number of viable and functional progenitor cells, telomerase activity, and TERT expression. No significant differences were seen in the GSH/GSSG, Cys/CySS and micronuclei analysis. However, the PCB inhalation group showed significantly decreased TERT expression and telomerase activity. Also, bone marrow HSC differentiation into the granulocytic and macrophage direction was promoted, as indicated by increased number of CFU-G (granulocytes) and CFU-M (macrophages) colonies. These results suggest that inhalation of PCBs may exhibit hematotoxicity by negatively affecting the immortality activity of telomerase in HSCs and through modification of their differentiation pattern towards the myelocytic pathway. The role of these mechanisms in PCB immunotoxicity needs further investigation. Supported by NIH E01 ES013661.

2381 Characterization of an Immortalized Mouse Pancreatic Stellate Cell Line: Effects of PFOA Exposure

L. M. Kamendulis, J. M. Hocevar, and B. A. Hocevar. Indiana University, Bloomington, IN.

Pancreatic cancer is the fourth leading cause of cancer death in the United States whose etiology remains largely unknown. PFOA is a chemical widely used in consumer and industrial applications that has been shown to induce pancreatic acinar cell tumors in rodents through a yet to be determined mechanism. Pancreatic cancer is characterized by a dense desmoplastic/stromal reaction, which has been attributed to activation of pancreatic stellate cells (PSCs). PSCs are located in the periacinar spaces and become activated in response to pancreatic injury and inflammation. Once activated, PSCs secrete cytokines and excess amounts of extracellular matrix proteins which leads to fibrosis. We have previously shown that the pancreas is targeted in vivo following PFOA exposure, resulting in the expansion of early neoplastic lesions (pancreatic intraepithelial neoplasia; PanIN), concomitant with the induction of oxidative stress. We hypothesize that PFOA-induced oxidative stress leads to activation of stellate cells which in turn leads to expansion of PanIN and promotion of pancreatic cancer. To determine the effects of PFOA exposure on stellate cell activation, we have generated conditionally immortalized mouse pancreatic stellate cell lines derived from the Immortomouse. The Immortomouse harbors a thermolabile mutant of the SV40 large T antigen under the control of the ubiquitous interferon-γ-inducible promoter (H-2Kb-tsAS8) which is rapidly degraded when cells are switched from permissive (33°C; presence of IFNγ) to nonpermissive conditions (37°C; absence of IFNγ). We have successfully established two immortal pancreatic stellate cell lines (ImSt1 and ImSt2) isolated under permissive culture conditions at 33°C in the presence of IFNγ. Nonpermissive culture conditions led to increased expression of α-smooth muscle actin (αSMA) and perisin, both markers of activated PSCs. In addition, exposure of ImSt1 and ImSt2 to PFOA led to increased mRNA production of cytokines which increase extracellular matrix protein production, such as CTGF and TGFβ1, while conditioned media from PFOA-treated ImSt cells displayed increased levels of TNFα, DLK-1, and MMP3, suggesting that cytokines derived from stellate cells may influence pancreatic cancer progression. Collectively, these results demonstrate that ImSt cells provide a useful model system to assess the effects of environmental chemicals on pancreatic injury and disease.
The Pacific Decadal Oscillation and Contaminant Concentrations in Eggs of Thick-Billed Murres (Uria alioana) and Common Murres (Uria aalge) from the Gulf of Alaska and Bering Sea between 1999 and 2010

M. O. Gribble1, V. Kalia1, and S. S. Schuur2. 1 Emory University, Atlanta, GA; and 2 National Institute of Standards and Technology, Charleston, SC.

Persistent organic pollutants (POPs) are ubiquitous in the Arctic food web. The Seabird Tissue Archival and Monitoring Project (STAMP) is an ongoing, long-term effort to track trends in environmental quality along the coast of Alaska. It is a collaboration between the U.S. Fish and Wildlife Service Alaska Maritime National Wildlife Refuge (USFWS-AMWR) and the National Institute of Standards and Technology (NIST). Historical records of sea surface temperature in the Pacific Northeast show that temperature appears to oscillate between cold and warm phases. This pattern has been called the Pacific Decadal Oscillation (PDO). Using contaminant measurements made by NIST and PDO measurements made by the University of Washington, we assessed the relationship between chemical concentration in seabird eggs and average PDO, measured from February-May (egg-laying season). Chemicals were log-transformed for statistical analyses. The association between eggs of thick-billed murres and each of 34 POPs congeners was estimated using linear spline regression to accommodate a non-linear relationship, while that between eggs of common murres and POPs was estimated using linear regression, both adjusted for year of measurement. Models used cluster-robust standard errors to account for clustering by seabird colony. In the negative PDO range, the geometric mean ratio of oxychlordane in thick-billed murre eggs was 2.83 per unit increase in PDO (95% CI: 1.98 to 4.02), while in positive values of PDO, the geometric mean ratio was 0.81 (95% CI: 0.39 to 1.65) per unit increase in PDO. In the same species, the ratio of geometric mean of 4,4-DDD and 2,4-DDT (measured together) was 0.29 (95% CI: 0.08 to 1.11) per unit increase in PDO in the negative range, while in the positive range, it was 0.20 (95% CI: 0.06 to 0.73) per unit increase in PDO. Among common murre eggs, the geometric mean ratio for oxychlordane was 1.40 (95% CI: 0.66 to 2.99) per unit increase in PDO. These results suggest a relationship between sea surface temperature changes and the amount of POPs in the Alaskan food web, which has not yet been fully explored.

Quantitative Analysis of Urinary Organophosphate Insecticide Metabolites in Diapered Children in Japan

Y. Inoue1, T. Ebara1, J. Ueyama2, K. Hikibi1, S. Kato1, T. Oguri1, N. Shoji1, and M. Kamijima1. 1 Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; and 2 Nagoya University Graduate School of Medicine, Nagoya, Japan.

Recently, epidemiological studies to examine the relationship between pesticide exposure and neurodevelopmental effects have drawn more attention. Although central nervous system rapidly develops in early childhood, information about pesticide exposure of children who cannot control urination is limited. In this study, we aimed to clarify the exposure levels of organophosphorous pesticide (OP) in urine extracted from disposable diapers. We recruited diapered children participating in Japan Environment and Children’s Study (JECS) at the Aichi Regional Center of JECS. JECS used disposable diapers from 1,073 children (16-23 months old, 548 males and 529 females) from June in 2015 to August in 2016 (Consent rate was 86%). Urine samples were extracted from the diapers. Six urinary dialkylphosphates (DAPs) were analyzed by ultra-performance liquid chromatography with tandem mass spectrometry. This pattern has been called the Pacific Decadal Oscillation (PDO). Using contaminant measurements made by NIST and PDO measurements made by the University of Washington, we assessed the relationship between chemical concentration in seabird eggs and average PDO, measured from February-May (egg-laying season). Chemicals were log-transformed for statistical analyses. The association between eggs of thick-billed murres and each of 34 POPs congeners was estimated using linear spline regression to accommodate a non-linear relationship, while that between eggs of common murres and POPs was estimated using linear regression, both adjusted for year of measurement. Models used cluster-robust standard errors to account for clustering by seabird colony. In the negative PDO range, the geometric mean ratio of oxychlordane in thick-billed murre eggs was 2.83 per unit increase in PDO (95% CI: 1.98 to 4.02), while in positive values of PDO, the geometric mean ratio was 0.81 (95% CI: 0.39 to 1.65) per unit increase in PDO. In the same species, the ratio of geometric mean of 4,4-DDD and 2,4-DDT (measured together) was 0.29 (95% CI: 0.08 to 1.11) per unit increase in PDO in the negative range, while in the positive range, it was 0.20 (95% CI: 0.06 to 0.73) per unit increase in PDO. Among common murre eggs, the geometric mean ratio for oxychlordane was 1.40 (95% CI: 0.66 to 2.99) per unit increase in PDO. These results suggest a relationship between sea surface temperature changes and the amount of POPs in the Alaskan food web, which has not yet been fully explored.

Aflatoxin Exposure in Children of Eastern Province, Kenya

R. N. Wangia1, D. Githanga2, K. S. Xue1, L. Tang1, and J. S. Wang1. 1 University of Georgia, Athens, GA; and 2 University of Nairobi, Nairobi, Kenya.

Aflatoxins (AFs) are fungal metabolites that commonly contaminate food grains such as peanuts and corn. Contamination of corn by AFs is a recognized public health problem in Kenya, which has resulted in over 600 human deaths. In the rural Kenya, like many other developing nations, most children are weaned on corn or peanut related meals. Dietary exposure to AFs can occur in utero, via maternal milk, through weaning foods and throughout an individual’s lifetime. Consistent dietary exposure to AFs has been implicated to be a contributing factor to micronutrient deficiency, immune-suppression and growth impairment in children. In this cross-sectional study, 433 children aged 1-14 were recruited from the Makuani County, in Eastern Province, Kenya and their serum samples were collected and analyzed to determine the extent of AFs exposure. Aflatoxin B1-lysine (AFB1-lysine) adducts being a reliable biomarker for AFs exposure was measured using High Performance Liquid Chromatography with Fluorescence detection. 100% of the samples had detectable levels of AFB1-lysine adducts (>0.4 pg/mg albumin). The AFB1-lysine adduct level was adjusted for albumin concentration before analysis using SAS v.9.4 (Cary, NC). The minimum, maximum and geometric mean (95% confidence interval) of AFB1-lysine adduct levels were determined as 0.74, 901.15 and 20.40 (18.22-22.85) ng/mg albumin respectively. About 11.32% (43/384) samples had AFB1-lysine adduct levels less than 5.0 pg/mg albumin; 19.71% (73/384) serum samples had AFB1-lysine levels ranging from 5.0-9.9 pg/mg albumin; 19.63% (75/384) had 10.0-19.9 pg/mg albumin; 28.41% (109/384) had ≥ 20 pg/mg albumin. Serum samples with over 50 pg of AFB1-lysine adducts per mg albumin. The AFB1-lysine adducts levels were among the highest found in children populations in the literature, which suggest that prevention and intervention strategies for reducing AFs exposure need to be immediately taken in this high risk area, especially in susceptible children populations.
2388 Impacts of Welding Parameters on Workers’ Exposure to Mn Fumes

P. Sarazin1, B. Bahkhyi2, C. Godin3, and J. Zayed1,2. 1Institut de recherche Robert-Sauvé en santé et en sécurité du travail (IRRSS), Montreal, QC, Canada; 2Université de Montréal, Montreal, QC, Canada; and 3MultiPrévention ASP, Longueuil, QC, Canada.

Welders’ exposure to fumes has been associated with several types of cancer, as well as respiratory tract and nervous system health effects. Among the numerous metals found in welding fumes, manganese (Mn) remains one of the main contaminants. Chronic exposure to Mn may lead to neurological injuries, such as parkinsonism. Reducing exposure to Mn fumes is therefore crucial to protect workers involved in welding activities. Innovative approaches now tend to focus on the adjustment of welding parameters, in addition to source capture, general ventilation and respiratory personal protective equipment. The aim of this study was to assess the impact of adjustments of certain welding parameters on workers’ exposure to Mn fumes. The assessments were conducted in two welding facilities in Québec that were sampled twice, once before and once after modifying current intensity (using electrodes with a smaller diameter, specifically 1.3 mm instead of 1.6 mm, allowing the reduction of the current intensity) and characteristics of the electrodes (0.202% Mn content instead of 1.62%). Mn fumes were sampled from the personal breathing zones of six workers in the first facility and of two workers in the second. Personal breathing zone samples for workers using Flux Cored Arc Welding (FCAW) to perform the same welding tasks were collected in both facilities, before and after changing the welding parameters. The first results showed mean levels of Mn of 0.41 mg/m³ when the highest current intensity was used and 0.61 mg/m³ when the highest electrode Mn content was used. These levels were respectively two and three times higher than the Québec Occupational Exposure Limit (OEL) of 0.2 mg/m³. The second results showed a significant decrease in workers’ exposure to Mn fumes, with a resulting mean level of 0.25 mg/m³ (1.25 times the OEL) when the lowest current intensity or the lowest electrode Mn content was used. Investigations are currently ongoing by our research group regarding all welding parameters in order to assess their effects on workers’ exposure to Mn fumes.

2389 Evaluating Consumer-Relevant Exposure from Articles for Use in Safety Assessment: A Case Study Using Diapers

K. Woeller1, D. Schowanek2, K. Acuff1, K. Krivos3, and S. Felter3. 1Procter & Gamble, Cincinnati, OH; 2Procter & Gamble, Brussels, Belgium; and 3Procter & Gamble, Mason, OH.

Increasingly, both industry and regulatory agencies are challenged to determine relevant exposure to chemicals in consumer products or articles. In the absence of published methods, it is common for articles (e.g., toys, textiles, hygiene products) to be subjected to extreme conditions (solvents, temperature, homogenization, etc.) that destroy the matrix in an effort to determine anything that can possibly be detected (e.g., metals, microplastics). This constant trend of successive puff parameters could be observed. Each participant smoked all cigarettes with the same puff profile, enabling the creation of a personal smoking topography profile. We are the first to show that detailed data of four random cigarettes per individual are enough to create a personal smoking regime for future machine smoking exposure measurements. Interestingly, the participants’ puff profiles exceed the Health Canada intense parameters used in regulatory machine smoking, underlying the need for appropriate cigarette smoke exposure measurements based on human smoking.

2390 Personal Smoking Topography: Smokers Display a Unique Individual Smoking Profile

C. Pauwels1,2, A. Boots1, J. Pennings2, R. Talhout2, A. Opperhuizen1,3, and F. Van Schooten1. 1Maastricht University, Maastricht, Netherlands; 2National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands; and 3Netherlands Food and Consumer Product Safety Authority (NVWA), Utrecht, Netherlands.

To date, little is known about individual smoking behavior and actual exposure to hazardous smoke components. Additionally, there is a lack of consensus concerning the methodology to determine human smoking behavior. The goal of this human study is to characterize natural human smoking topography, for use in future exposure experiments and to optimize current methodology. A prospective observational human pilot study included five healthy males (25-34 years), used to smoking 13-25 Marlboro cigarettes per day. Habitual smoking behavior was observed in a homelike-apartment for 36 hours. For each smoked cigarette, smoking topography (i.e., puff volume, duration, frequency, flow and inter-puff-interval) was recorded with the CreSSmicro, a portable smoking topography measurement device. Puffing profiles were created by linear regression (least-squares method). Participants smoked cigarettes randomly during the day and showed a significantly different puffing profile when compared to each other. Each participant showed only subtle differences between the single puff parameters per cigarette. When comparing all cigarettes of an individual participant, a constant trend of successive puff parameters could be observed. Each participant smoked all cigarettes with the same puff profile, enabling the creation of a personal smoking topography profile. We are the first to show that detailed data of four random cigarettes per individual are enough to create a personal smoking regime for future machine smoking exposure measurements. Interestingly, the participants’ puff profiles exceed the Health Canada intense parameters used in regulatory machine smoking, underlying the need for appropriate cigarette smoke exposure measurements based on human smoking.

2391 A Pilot Study of Gestational Exposure to Environmental Contaminants Related to Unconventional Natural Gas Exploitation in Communities of Northeastern British Columbia

E. Caron-Beaudoin1, J. Chevrier2, P. Ayotte3, M. Bouchard4, M. Bouchard4, K. Frohlich3, and M. Vermet3. 1Université de Montréal, Montreal, QC, Canada; 2McGill University, Montreal, QC, Canada; 3Maastricht University, Maastricht, Netherlands; and 4Centre de Recherche du CHU de Québec - Université Laval, Montreal, QC, Canada.

The Peace River Valley (Northeastern British Columbia, Canada) is an area of intensive hydraulic fracturing for unconventional natural gas exploitation. Concerns have been raised regarding the potential health effects of contaminants like volatile organic compounds and heavy metals emitted by gas exploitation. Indeed, a recent study conducted in Colorado found associations between density and proximity of natural gas wells and birth defects. In our pilot study, we aimed to evaluate exposure to benzene, toluene and a suite of heavy metals in 29 pregnant women from the Peace River Valley. Enrolled participants collected repeated urine samples over five consecutive days. We measured metabolites of benzene (trans,trans muconic acid (tt-MA), S-phenylmercuric acid (S-PMA)) and toluene (S-benzyl-N-acetylcysteine (S-BMAC)), and heavy metals in urine samples. The median urinary tt-MA level was 3.5 times higher (182 µg/g creatinine) than that from the general Canadian population (48 µg/g creatinine); In Indigenous participants, the median level was 6 times higher (319 µg/g creatinine). Moreover, 5 women had urinary tt-MA levels above the safe exposure guideline (500 µg/g creatinine) put forward by the ACGIH. Median urinary manganese (0.49 µg/L) and vanadium (0.17 µg/L) levels were higher in participants than those from the general Canadian population. Our results suggested elevated gestational exposure to contaminants in our study population compared to the general population. Documenting gestational exposure to environmental chemicals in this region is paramount to assess the health risks associated with unconventional natural gas exploitation and develop exposure mitigation strategies.
Biomonitoring of human exposure to estrogens most frequently focuses on environmental and dietary estrogens, and infrequently includes measures of exposure to potent endogenous estrogens present in serum. Pregnancy is a developmentally sensitive period during which “added” serum estrogenicity exceeding normal intra-individual daily variability is of particular concern. Developing non-invasive biomonitoring methods for estrogens would overcome a key barrier to assessing the potential for biologically significant “added” estrogenicity. We collected repeated measures of serum concentrations of estrone (E1), estradiol (E2), estriol (E3), estetrol (E4), daidzein (DDZ), genistein (GEN) and bisphenol A (BPA) in thirty pregnant women using ultra-performance liquid chromatography coupled with tandem mass spectrometry detection (UPLC-MS/MS) and electrospay ionization (ESI). Serum estrone, estradiol and estriol concentrations varied significantly, with broad ranges across the cohort: 1.61-83.1 nM, 0.09-60.7 nM, and 1.5-36.3 nM respectively. BPA, DDZ and GEN concentrations were 1-5 orders of magnitude lower. The median within-individual coefficients of variation were large, 10.3% for estrone, 9.1% for estradiol, and 9.7% for estriol. The median serum estrone concentration was poorly correlated with gestation period but correlation with gestation period (log concentrations) increased with hydroxylation of the estrogens, tau=0.45 (estradiol), tau=0.58 (estriol) with p values < p = 2.2 x 10^-17. 24-hour urinary elimination of the endogenous estrogens were each strongly correlated with their corresponding serum concentrations, with Pearson’s Correlation Coefficients of 0.83 (E1), 0.82 (E2) and 0.84 (E3). A multivariate regression analysis produced equations for estimating serum concentrations of E1, E2, E3, E4, GEN and DDZ from urinary elimination rates and gestation period, an important step towards non-invasive biomonitoring for assessment of added estrogenicity during pregnancy.
Exposure to elevated levels of heavy metals in residential soils can pose a serious risk to human health. Families living near sources of heavy metal contamination (e.g., coal-fired power plants) and children who often engage in frequent hand-to-mouth activity may be highly susceptible to exposure. Quantification of total metals in soils is necessary to aid in assessing whether residential soils are heavily contaminated with toxic metals thereby posing a significant exposure risk. In this study, 42 residential soils were collected from communities in Stokes County, NC, which is also the home of a coal-fired power plant in Belews Creek, NC. Soil samples were digested using microwave-assisted acid digestion. Inductively-coupled plasma - optical emission spectroscopy was subsequently used to detect and quantify the total concentrations of arsenic (As), cadmium (Cd), lead (Pb), and manganese (Mn) in the soils. Arsenic concentrations ranged from 0.1–43.9 mg As/kg soil. Cadmium concentrations ranged from 0.1–1.6 mg Cd/kg soil. Lead concentrations ranged from 6.8-219.0 mg Pb/kg soil. Manganese concentrations ranged from 26.1-885.3 mg Mn/kg soil. Ninety-five percent of the soil samples fell below North Carolina’s non-cancer child hazard concentration for ingestion of As, Cd, Pb, and Mn (39, 78, 1600, and 1900 mg metal/kg soil, respectively). Among the soil samples collected, those closest to the coal ash impoundments (or the remaining 5%) had arsenic concentrations exceeding the non-cancer child hazard concentration. These data suggest families residing closest to coal ash impoundments may have elevated risk of exposure to toxic metals in soils, thus posing a potential risk to human health that merits additional study.

The occurrence and distribution of heavy metals in excess of natural loads is increasingly a global concern due to the potential risk to ecological receptors and humans via food chain transfer. This study assessed the risk associated with the levels of metals (As, Cr, Cd, Cu, Co, Fe, Mn, Ni, Pb, and Zn) in surficial soils from East Chicago, IN and Columbus Junction, IA since 1979. During the study, we assessed concentrations of trace metals in sidewalk surficial soils in proximity to a cohort in the Airborne Exposure to Semivolatile Organic Pollutants (AESOP) Study which has been following mothers and their children in East Chicago, IN and Columbus Junction, IA since 2008. Surficial soil samples (n=200) from sidewalks were collected in accordance with U.S. EPA Soil Sampling Guidelines (Method #SEDSPROC-300-R1, using a soil sampling core which were then analyzed in situ using X-ray fluorescence spectroscopy (XRF) for Ti, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Pb, Sr, Zr, Mo, Ag, Cd, Sn, Sb, Ba, Hg, and Pb. Concentration of lead in East Chicago was found to be significantly greater than Columbus Junction (p<0.01). Furthermore, lead in soil was found to be greater than the EPA maximum contaminant level (MCL) of 400 ppm in 4% of the samples from East Chicago and Columbus Junction, respectively. Trace metals in clotted blood were analyzed using inductively coupled plasma-mass spectrometry (ICP-MS) using an acid digestion protocol from the CDC (Method 8005). Results from analysis of a subset of clotted blood samples indicate the presence of trace metals in blood of AESOP Study participants in East Chicago. These preliminary results indicate the presence of aforementioned pollutants in East Chicago soil environment and blood and in some cases significantly above the regulatory limits. Ongoing work seeks to better understand the mechanisms responsible for synergistic toxicity resulting from co-exposure to PCBs and trace metals.

The Woolfolk Chemical Works, Inc., located in Fort Valley, GA, was a manufacturing facility where pesticides, insecticides, and herbicides that contained organic and inorganic arsenic compounds were produced during World War II for the US Army. The site was placed on the EPA’s National Priorities List in 1990 because of contaminated groundwater and soils resulting from facility operations. The properties, which had soils contaminated with arsenic above 100 mg/kg, were removed for final disposal at an off-site landfill. Soon after the EPA cleanup, residential homes were built on and around old contamination areas. Concerns for perimeter communities have risen because a drainage ditch from the Spiller Street pipe past the railroad to Big Indian Creek was filled with soil that may have contained contaminated runoff from facility operations which may have not been removed. The objective of this study was to determine if significant levels of arsenic are still present along the perimeter of a Fort Valley community surrounding the Woolfolk Chemical Works, Inc. The study began by collecting soil samples from two control sites and four different perimeter locations from the Fort Valley community. The soil samples were brought to the lab to let dry and then analyzed for the presence of aforementioned pollutants. The objective of this study was to assess concentrations of trace metals in soil samples from the perimeter of a Fort Valley community surrounding the Woolfolk Chemical Works, Inc.

The occurrence and distribution of heavy metals in excess of natural loads is increasingly a global concern due to the potential risk to ecological receptors and humans via food chain transfer. This is a health-oriented follow-up to a previously reported biomonitoring study of Vietnamese female electronic waste (e-waste) recyclers for metals and halogenated organics. We review potential health aspects of select elevated metals. Forty female Vietnamese e-waste recyclers and 20 Vietnamese non-recyclers were compared. Lead was higher in recyclers than non-recyclers and higher in the Vietnamese e-waste recyclers.
4.1 Three-compartment model

The three-compartment model was applied to evaluate the distribution of phthalates, dl-PCBs, and PBDEs among different demographic categories.

4.1.1 Distribution of Phthalates, DL-PCBs, and PBDEs among Demographic Categories

G. Merillis, G. Johnson, M. Bourgeois, and R. Harbison, University of South Florida College of Public Health, Tampa, FL.

Phthalates, dioxin-like polychlorinated biphenyls (dl-PCBs) and structurally similar polybrominated diphenyl ethers (PBDEs) are ubiquitous in environments. Additionally, all three compounds are alleged endocrine disrupting compounds. An alleged consequence of endocrine disruption is obesity. Average concentrations of these compounds were compared among age groups, genders and ethnicities using the National Health and Nutrition Examination Survey (NHANES). ANOVA analyses indicate that males had a significantly higher average blood concentration of a sum of 10 PBDEs in comparison to females. Significant differences of mean urinary phthalate and dl-PCB blood concentrations were detected in comparisons of age groups and ethnicities, with 85+ years and Non-Hispanic Whites having the highest mean values of PBDEs, and 19-30 years and Other Hispanics having the highest mean values of phthalates. Logistic regression analyses were conducted to determine whether an increase in background concentrations of PBDEs, dl-PCBs, and phthalates increased the NHANES survey participants’ odds of being obese. Logistic regression analyses indicate that none of these compounds increased the risk of having an obese body mass index. A comparison of the phthalate levels in the highest vs lowest quartile yielded an odds ratio estimate of 1.7 with a 95% confidence interval ranging from 1.1 to 2.7 for obesity. A comparison of the dl-PCB levels in the highest vs lowest quartile yielded an odds ratio estimate of 1.4 with a 95% confidence interval ranging from 0.6 to 3.3 for obesity. A comparison of the sum of 10 PBDE levels in the highest vs lowest quartile yielded an odds ratio estimate of 1.0 with a 95% confidence interval ranging from 0.6 to 1.7 for obesity. As a result, these data do not support the claim of a significant association between these contaminants, as alleged endocrine disruptors, with obesity.

4.1.2 Potential Risk to Environmental and Human Health by Heavy Metals in a Colombian Rain Forest

Y. Palacios-Torres, J. de la Rosa, and J. Olivero-Verbel, University of Cartagena, Cartagena, Colombia; and University of Huelva, Huelva, Spain.

Heavy metals are widespread pollutants in the world. The objective of the present study was to assess the presence of metals in several environmental matrices and its corresponding ecological risk in the Biogeographic Choco at the Colombian Pacific, a rainforest considered one of the most biodiversity-rich areas on the planet, threatened by massive illegal mining. Total mercury (T-Hg) was quantified using a direct Hg analyzer and other 47 elements by ICP-MS. Human exposure to mercury was low, with average and median hair T-Hg levels of 4.9 μg/g and 0.9 μg/g, respectively; although in some gold shops, Hg concentrations were two orders of magnitude greater than those found in reference sites. Mercury concentrations in sediments from Atrato River were moderately low, with minimum variation along the river course. In this compartment, some toxicologically relevant elements such as Ca, Cd, Cr, and Pb had values either respective threshold effect concentration (TEC), whereas Cr and Ni were above their probable effect concentration (PEC). In general, potential ecological risk assessment evidenced most sediment samples from Atrato River are moderately polluted by Cd. Mercury content in fish muscle increased according to the position each species occupies in the food chain. Elements different from Hg were also present in examined fish, with Cs and Rb following a distribution typical of biomagnification processes. However, some species belonging to lower trophic status displayed the greatest concentrations of Co, Ni, Cu, and Sn, in particular Prochilodus magdalenae and Hemiancistrus wilsoni. In conclusion, besides Hg, other metals should be considered in the evaluation of human and environmental health risks in gold mining areas.

4.1.3 Proposition 65 Exposure Assessments of Styrene in Consumer Products

J. Lund, R. Galante, and J. Fleischer, ToxServices LLC, Washington, DC.

Styrene is included on California’s Proposition 65 list of chemicals known to the State to cause cancer or reproductive toxicity; it is used widely in the manufacture of consumer goods, such as packaging materials, insulation, and carpet backing, resulting in consumer exposure. The likelihood of exposure and subsequent health effects is the net result of chemical-specific factors (volatility, emitter factors (material composition, density, surface area), exposure factors (dose, duration, and route), and receptor factors (age, inhalation rate), necessitating a diverse approach to exposure assessment. This project evaluated potential exposure to styrene through use of two different consumer products, carpeting and a bicycle helmet shell liner, to determine if exposure is greater than styrene’s Proposition 65 Safe Harbor levels of 0.5 mg/day. For carpeting, we used ConsExpo modeling to estimate styrene air concentrations in home, office, and school settings using the initial, measured styrene concentration, volatility, diffusion (within-material) transfer rate, material-air partition coefficient, mass transfer coefficient, carpet density and surface area, and EPA’s site-specific air volumes and air change rates, together with a published inhalation uptake value and OEHHA’s age-specific body weight and breathing rate values. Maximum styrene exposure was 0.62 mg/day for children in a residential setting. In contrast to the approach for the carpet, we calculated inhalation and dermal exposure to styrene from use of a bicycle helmet shell liner. For inhalation exposure, we used analytical test results to estimate worst-case styrene concentration in the breathing zone and included published inhalation uptake value, manufacturer information on helmet
2406 Human Exposure to Polyhexamethylene Guanidine Phosphate from Humidifiers in Residential Settings: Cause of Serious Lung Disease

Exposure to the humidifier disinfectant, polyhexamethylene guanidine phosphate (PHMG), PHMG in mists generated from ultrasonic humidifiers was studied in a simulation chamber and apartment rooms. PHMG was suspected as a causative agent of lung disease in Korea residences. In the simulation chamber study, the amount of disinfectant discharged from three different ultrasonic humidifiers was measured. Mists generated at 1, 2 and 4 times the recommended amount of disinfectant were sampled with an impinger, and the effect of relative humidity on airborne disinfectant concentration was studied by changing RH from 40-70% to 90-100%. In addition, particle size distribution in mists was measured by SMPS, APS, and Mastersizer. In the apartment study, mists generated from ultrasonic humidifiers were sampled for 6 hrs in small and large rooms during fall and winter. In the simulation study the humidifiers discharged 205±24.6 ml/hr of mist at maximum capacity. Concentrations of airborne disinfectant increased with increasing concentration of disinfectant. RH affected airborne disinfectant concentration in the chamber, with increasing concentration with increasing RH. Below RH 70% no airborne PHMG was detected. PHMG-containing mists generated from ultrasonic humidifiers showed various sizes ranging from 149-157 nm, 690-740 nm and larger than 5.4 µm by SMPS and APS. Surface area mean diameter measured by Mastersizer was 5.39 to 5.72 µm. In the apartment study conducted during the fall, the geometric mean and standard deviation and arithmetic mean and standard deviation of airborne PHMG concentration were 3.22 ± 5.13 µg/m³ and 8.26 ± 12.18 µg/m³. In the winter, GM = GSD and AM = SD of airborne PHMG concentration was 0.21 ± 2.11 µg/m³ and 0.35 ± 0.62 µg/m³. RH and temperature in the apartment rooms for fall and winter were 22.2 ± 1.7°C, 74.5 ± 15.6% and 22.0 ± 2.2°C, 51.1 ± 12.9%. Different RH’s in the fall and winter resulted in very different airborne concentrations of disinfectant in the apartment rooms. Exposure levels and particle size distribution of mists generated from ultrasonic humidifiers in apartments are not sufficient to conclude that PHMG causes lung disease in Korean residences.

2407 Risk of Mycotoxins in Mold-Infested Consumer Products

Despite the findings of learned bodies, there continues to be misunderstanding about risk from indoor fungal growth. The US Consumer Product Safety Commission (CPSC) indicated 12 consumer products were recalled between 2011 and 2016 due to “risk to health because of mold exposure.” CPSC specified mold on these recalled consumer products posed “a risk” of respiratory or other infections in consumers with compromised immune systems, chronic health problems, damaged lungs, or an allergy to mold. Recall notices did not include exposure route, concentration, or how products were intended for use by immunocompromised individuals. We assessed the risk of mycotoxin exposure in nonsensitized individuals using 3 exposure scenarios including: (1) dermal contact of visible mold on products, (2) ingestion of mold spores, and (3) inhalation of mold spores aerosolized during handling of the product. There are no published data available for mold spores or mycotoxin inhalation exposures resulting from handling or using recalled consumer products. We estimated airborne mold spore exposures from recalled consumer products using measurements obtained during excessive handling of an obviously moldy product in a normal home environment. In considering mycotoxin exposure, maximum possible mycotoxin concentrations from breathing mold spores were estimated using published exposure modeling (Kelman et al. 2004) and compared to known effects levels for several mycotoxins. Corresponding margin of exposures (MOEs) for inhalation scenarios, breathed continuously by infants or adults for 24h/d, ranged from 0.003 to 0.010. In addition, the highest mycotoxin concentrations did not exceed the concentration of no toxicological concern (30 ng/m³) as reported by Hardin et al., 2009. Potential dermal and oral exposure from these consumer products were lower than levels associated with mycotoxicoses (human toxicity from molds). It is unlikely that individuals handling these consumer products with mold growth are at risk of exposure to biologically important numbers of mold spores and mycotoxins. Consumer products identified are unlikely to pose an increased risk of adverse health effects immune-compotent populations.

2408 The Plural Chemical Specific IgG Values of Two Small Plants’ Workers Handling Plastic Resins

M. Tsuji1, Y. Ishiiha2, N. Ikeda-Ishihara3, T. Issue1, R. Tanaka1, and T. Kawamoto1. 1University of Occupational and Environmental Health, Kitakyushu, Japan; 2Hiroshima University, Higashi-Hiroshima, Japan; and 3University of California Davis, Davis, CA.

When considering plastic allergy and exposure status, most surveys focus on a single primary chemical substance which is handled at a specific plant. However, particularly small plants use several plastic resins according to customers’ requests. At this time, we report the plural chemical-specific IgG values of two small plants’ workers who are handling multiple plastic resins. Workers at plant “A” (N=81) are mainly using urethane resin. “B” plant’s workers (N=39) are handling low heat urethane resin and epoxy resin. Control subjects are the general inhabitants surrounding Kagoshima prefecture in Japan (N = 104). Data including working habits were collected using a self-administered questionnaire. Blood serum was collected and chemical-specific IgG values were measured by a dot blotting assay. The target chemicals were toluene disocyanate (TDI): urethane resin raw material, bisphenol A diglycidyl ether (BADGE): epoxy resin raw material, ethylenediamine (ED): epoxy resin curing agent and formaldehyde (FA): urea formaldehyde resin raw material. Plant A: The TDI-specific IgG values were elevated but not significantly higher compared to control subjects. The FA-specific IgG value was significantly higher than control subjects. B plant: BADGE-specific IgG and ED-specific IgG values were higher than control subjects but not significant. In addition to the primary chemical-specific IgG values of resin production, other chemical specific IgG values were higher in workers compared to controls. It is a significant challenge for industrial physicians to monitor multiple resins and chemical substances at small plants compared to big plants. Therefore, when investigating plastic allergy and plastic resin exposure status, it is important to target plural chemical substances especially at small plants. This study was funded by an Industrial Disease Clinical Research Grant.
Pharmaceuticals and personal care products in water in the environment have become a public concern. Angiotensin II receptor blockers (ARBs) are used widely as antihypertensive drugs and have been detected at high frequency at concentrations less than a few μg/L in urban river water and the effluent of sewage treatment plants. To advance environmental risk assessment of ARBs, it is necessary to estimate the behavior of ARBs in the water environment. Degradation by sunlight is one of the important parameters for the prediction of environmental concentration; however, little is known about the degradation of ARBs by irradiation by sunlight in environmental water. The objective of this research was to clarify the degradation of ARBs in water caused by irradiation using artificial sunlight. The ARBs investigated in this study were candesartan, irbesartan, losartan, olmesartan, and valsartan. The ARBs were dissolved in purified water at a concentration of 100 μg/L. To estimate the degradation of the ARBs near the water surface, the depth of the ARBs solution was set to be shallow as follows: 100 ml of the ARBs solution was put into a beaker (85 mm i.d. × 115 mm) made of quartz, and the water surface was irradiated using an XC-100BSS solar lamp (300 nm < λ < 700 nm, UV-A: 108,000 J/m²/h) at a height greater than 1 m. As a control sample, a beaker containing the ARBs solution was shielded from the light by covering the beaker with aluminum foil and the beaker was incubated in the same way as the non-shielded beaker. An aliquot of the ARBs solutions was taken at incubation times of 0, 1, 2, 4, 8, and 24 h and was analyzed by liquid chromatography tandem mass spectrometry. The half-life of each ARB by irradiation with the artificial sunlight was calculated by first order kinetics. The half-lives of candesartan, irbesartan, losartan, olmesartan, and valsartan were 64, >100, 36, >100, and 44 h, respectively, under the present irradiation conditions. The daily UV-A irradiation in Tokyo, Japan, is about 700,000 J/m², and this daily irradiation is equivalent to 6.5 h of irradiation time under the conditions of this experiment. Therefore, the half-lives of the ARBs are estimated to be more than 6 days near the surface of water. These results suggest that the ARBs investigated in this study are relatively persistent.

Breath analyzers are commonly used to estimate the blood alcohol concentration (BAC) at workplaces and among vehicle drivers. Breath analyzers indirectly, based on a stable partitioning of alcohol between blood and breath (ratio = 2100). However, local exposure to ethanol, eg inhalation of vapors, use of mouthwash etc, may increase the breath alcohol concentration without affecting the BAC leading to an overestimation of the true concentration in blood. In this study we investigated the elimination rate of breath ethanol followed by local exposure by inhalation of vapor and mouth wash to see if they pose a potential risk of a faulty estimation of BAC, particularly related to the Swedish statutory limit of 0.20 mg/g blood. The study was approved by the regional ethical committee and performed after informed consent by the volunteers. Eleven healthy subjects (5 men and 6 women) were exposed to inhalation by 1000 mg/m³ ethanol vapor for 15 min in an exposure chamber. After the exposure, breaths were sampled in Tedlar bags. After a break of 45 min, the subjects rinsed their mouth for 30 seconds with a typical mouth-rinse containing 21% ethanol. Post-exposure breaths were again collected in bags. Capillary blood was sampled from the fingertip before and after each exposure. Ethanol in breath and blood was analyzed by gas chromatography. No or negligible levels (less than 2.7x10⁻⁶ mg/g) of ethanol were detected in blood and breath of the subjects. The decline in breath is mono-exponential, however, the half-life of ethanol in breath (7.7±0.6 min) was shorter than the half-life of ethanol in blood (9.4±1.0 min). The study showed that breath ethanol is overestimated when compared to the blood alcohol concentration.
Crumb rubber (CR) used as an infill in artificial turf has brought public health concerns in recent years. The National Toxicology Program (NTP) is conducting research to improve the understanding of potential human health impacts following exposure to CR. As a part of the NTP research program, a lot of CR prepared by combining material from multiple commercial sources was analyzed using a variety of techniques to generate information on chemical and physical characteristics. Optical and scanning electron microscopy demonstrated that the lot consists of a range of particle sizes (0.1 to 4 mm) and types (dark and light rubber, visible inclusions, fibers). Thermogravimetric analysis revealed that the lot contains a minute fraction of volatile organic compounds (VOCs) and ~8% inorganics by weight. Elemental analysis by inductively coupled plasma with atomic emission spectrometry or mass spectrometry (MS) identified zinc, aluminum, cobalt and other metals and metalloids totaling ~2.9% by weight. Analysis for VOCs by gas chromatography (GC) and MS with head space sampling detected a large number of constituents; 33 compounds were identified totaling ~0.0007% by weight in CR. Extraction of CR with multiple solvents covering different polarities indicated that at 0.6% and ~8% inorganics by weight, respective. The extraction with water and methylene chloride, demonstrating that the majority of the extractable material consists of relatively non-polar organics. Analysis of methylene chloride extract by GC/MS identified 42 compounds with high confidence using authentic standards or reference library spectra, 7 of which were also identified in the VOC analysis, and 60 compounds with lower confidence using reference library spectra. 9 of which were also identified in the VOC analysis. An additional ~200 compounds previously reported to be in CR were investigated but were not detected in the extracts of the current lot. Analysis of solvent extracts of CR by liquid chromatography MS did not reveal any new analytes that were not previously detected by GC/MS. These data demonstrate that VOCs and metals constitute a very small fraction of CR lot.

Public health concern for playing on synthetic turf fields with crumb rubber infill has increased in recent years. Crumb rubber (CR) manufactured from recycled tires contains potential carcinogenic and toxic substances and there is potential for widespread exposure with over 12,000 synthetic turf fields in the United States. The National Toxicology Program (NTP) is conducting research to improve the understanding of potential human exposure and health impacts following CR exposure. CR was obtained from multiple commercial sources, combined into a single lot and size fractionated for use in these studies: 37-170μm for oral gavage, and greater than 170μm for feed and bedding studies. NTP conducted 14-day studies in female B6C3F1/N mice (n=10/group) by oral gavage (0 or 1250 mg/kg/day in corn oil), dose-fed (0 or 50,000 ppm) or by housing on CR mixed-bedding (bedding only or 50%/50% by weight). Plasma and urine were collected to determine internal exposure. Hematology, bone marrow cytology and limited histopathology were evaluated as conventional approaches to assess systemic exposure through evidence of biological effect. There were no effects on survival, food consumption, body weight or organ weights following CR exposure. CR was observed to be cytotoxic to human peripheral lung cancer (A549) cells in vitro and in vivo testing of the material used here, this work will contribute to what is known about potential human exposure to CR constituents resulting from contact with CR used in synthetic turf.

Public health concern for playing on synthetic turf fields with crumb rubber (CR) infill has increased in recent years. CR manufactured from recycled tires contains potential carcinogenic and toxic substances and there is potential for widespread exposure with over 12,000 synthetic turf fields in the United States. The National Toxicology Program (NTP) is conducting research to improve the understanding of potential human exposure and health impacts following CR exposure. The objectives of this study were to determine the leachability and cytotoxicity of CR in vitro using human peripheral lung (HPL-1D) cells and keratinocytes (HaCaT cells) to establish both aqueous and dermal routes of exposure. CR (100 mg/ml) was mixed and incubated in cell type-specific culture media for 3 h, 1, 4 or 7 d at room temperature, 37°C or 60°C. CR-conditioned media was then sterile-filtered and serially-diluted to 50, 25, 12.5 and 6.25 mg/ml for cell exposures. HPL-1D or HaCaT cells were exposed to CR-conditioned media for 24 h or 72 h and cell viability was measured via MTS cell proliferation assay. Cytotoxicity was observed for both cell lines in a concentration-dependent manner following incubation of CR at multiple temperatures and durations. For HPL-1D cells, 100, 50 and 25 mg/ml CR-conditioned media were cytotoxic at 24 and 72 h for all incubation times at 60°C. For HaCaT cells, 100 and 50 mg/ml CR-conditioned media were cytotoxic at 24 and 72 h for CR incubation times of 1, 4 or 7 d (100 mg/ml) and 4 or 7 d (50 mg/ml) at 60°C. For both cell types, cytotoxicity was also observed following CR incubation at 37°C but was most pronounced at 60°C. Untargeted LC-MS was used to characterize the chemical composition of CR-conditioned media. Compounds found to be elevated included 2-mercaptopentanoic acid, which is a known rodent carcinogen used in the vulcanization of rubber. Other compounds of interest included N,N'-diphenylguanidine, 1,2-benzisothiazolone-3-one and multiple phthalates. Studies are in-progress to address the in vitro cytotoxicity of CR using human small
intestinal cells, to reflect oral exposure, and the effects of CR incubation in more physiologically-relevant biofluids. In conjunction with chemical characterization and in vivo testing of CR, this study will contribute to what is known about potential human health effects of playing on synthetic turf fields made from recycled tires.

2417 Benchtop Testing Supporting Feasibility to Conduct In Vivo Studies of Synthetic Turf/Recycled Tire Crumb Rubber

J. Richey1, H. Toy1, K. Elsassy1, D. Fallacara1, G. Roberts2, M. Stout2, and B. Sparrow1. Battelle, Columbus, OH; and 1NIEM, Research Triangle Park, NC.

Over 12,000 synthetic turf fields exist in the US, with up to 1200 added annually. A primary component of synthetic turf is crumb rubber (CR) infill, synthesized from recycled automotive potential carcinogenic and toxic substances. However, the potential for human exposure from playing on these fields is not well understood. As such, likely exposure scenarios in humans that could be translated into exposure routes for in vivo testing were evaluated. Benchtop trials were conducted to evaluate various CR formulations for bedding (indirect contact), feed (indirect ingestion), oral gavage (direct consumption), and dermal (direct contact) exposures. Due to the physical characteristics of CR (irregular sized particles of ground tires that encompass a large size range and composition), physical manipulation methods were performed prior to testing. Milling was not feasible due to the characteristics of rubber (elasticity and thermal properties) and the additional additives employed during the grinding process; therefore, CR was sieved into various particle sizes for evaluation in each exposure scenario. Bedding and feed formulations were prepared at 50:50 (wt:wt) CR:bedding and at 50,000 ppm in feed with various sieved fractions of CR (greater than 170 µm). The formulations were rotated on an orbital shaker for four days to evaluate uniformity and potential for vapor off-gassing (bedding only). Uniformity of the feed formulations was maintained over four days of shaking. While larger CR particles maintained uniformity with the bedding, smaller particles settled to the bottom of the cage. No vapor off-gassing was observed for the bedding. Corn oil gavage formulations were prepared as homogenous suspensions at concentrations up to 200 mg/mL using CR with a particle size no greater than 170 µm. Particle sizes and concentrations greater than 170 µm resulted in blockage of the gavage needle during dispensing. Dermal administration of CR suspensions was determined to not be feasible due to clumping of CR in the vehicle, preventing homogeneous formulations. From this study, three potential human exposure scenarios (incidental exposure, indirect ingestion, and direct consumption) were identified as feasible exposure regimens for in vivo testing.

2418 Cumulative Assessment of Steroid Hormone Receptor-Mediated Activity of Contaminants in Water Samples Using In Vitro Bioassays

Cell-based assays could serve as a useful tool in the regulatory screening toolbox due to their high sensitivity and the ability to assess complex mixtures in which unknown compounds may be present. We have completed three major projects in collaboration with USGS: 1) Chemical Mixtures (surface water), 2) Source and Treated Drinking Water, and 3) Water Reuse. In each study, samples were extracted and assessed using T47D-KBLuc and MDA-kb2 transactivation assays for estrogen receptor (ER) and androgen receptor (AR) activation, respectively. Glucocorticoid (GR) activation was detected using CV-1 cells transduced with hGR and a luciferase reporter construct. In the first two studies, ER-mediated activity was the most frequently detected and was primarily explained by concentrations of estrone. There was limited detection of AR- or GR-mediated activity. For the Water Reuse project we examined the fate and transport of complex mixtures as they travel from a wastewater treatment plant (WWTP) to a drinking water treatment plant (DWTP) across the local drinking water supply (fall, spring, summer). Grab samples were collected upstream of the WWTP, at the WWTP effluent pipe, effluent mixing zone, downstream, DWTP intake, and treated drinking water. Polar organic chemical integrative samplers (POCIS) were deployed for 30 days each season at all locations except WWTP effluent and treated drinking water. The activity was detected at low levels (<0.3 ng E2EQ/L) in most grab samples, but was highest (1.4-28.6 ng E2EQ/L) at the effluent pipe in all seasons. AR and GR activity was only detected in the effluent grab samples (2ng DHTEq/L, 20ng DexEq/L, respectively) and was significantly lower in summer than fall and spring. ER activity in the POCIS samples was highest in the spring at the upstream and mixing zone sites. Importantly, ER activity was below quantifiable limits in the treated drinking water in grab and POCIS samples. No GR activity was detected in the POCIS samples. Overall, cell-based assays and analytical chemistry are complements that allow us to gather more robust data on the possible effects of contaminants in various water sources. This abstract does not necessarily reflect US EPA policy.

2419 Fluctuating Emissions and Availability of Health Reference Values: Implications for Estimating Acute Exposure and Health Risk

Assessing the potential for non-cancer health risks following inhalation of chemicals is important to informing air pollution risk management. Health risks from air pollutants are calculated by comparing exposure estimates from chronic (i.e., an average over one year or greater) or acute (typically 1-hour) durations to chemical- and duration-specific reference values or standards when available. However, modeled estimates of acute chemical exposure concentrations based on emissions data can be uncertain for many air pollutants. This uncertainty is largely due to a lack of hourly emissions data being reported from most industrial sources, compared to the availability of long-term data (e.g., annual emissions). In this study, we analyze some of the rare hourly air pollutant emissions information reported from industrial sources. We examine and discuss differences between these reported hourly emission rates and average hourly emission rates (calculated from annual emission rates) for reduced sulfur compounds from kraft pulp mill operations, and sulfur dioxide and oxides of nitrogen from a large U.S. power plant. We then discuss the additional challenge of assessing health risks based on hourly exposures, particularly the lack of acute reference values for many air pollutants applicable to the general population. The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the US EPA.

2420 US EPA’s Non-Targeted Analysis Research Program: Expanding Public Data Resources in Support of Exposure Science

Suspect screening (SSA) and non-targeted analysis (NTA) methods using high-resolution mass spectrometry (HRMS) offer new approaches to efficiently generate exposure data for chemicals in a variety of environmental and biological media. These techniques aid characterization of the exposome and provide critical information on thousands of chemicals in commerce for which exposure data are lacking. EPA is advancing such techniques with workflows (feature extraction, formula generation, structure prediction, spectral matching, chemical confirmation), and tools (databases; models for predicting retention time, functional use, media occurrence, and media concentration; and schemes for ranking features and chemicals) to rapidly identify, prioritize, and quantify novel compounds in high-interest environmental and biological samples. EPA is also leading a Non-Targeted Analysis Collaborative Trial (ENTACT) to evaluate a range of SSA and NTA approaches. Four categories of experiments are underway, with analyses focused on: 1) ten standard chemical mixtures from the EPA’s ToxCast library; 2) extracts of standardized sample matrices (including house dust, human serum, and environmentally deployed silicone paint samples); 3) extracts of standardized sample matrices spiked with known chemical mixtures; and 4) approximately 4600 single chemicals from the ToxCast library. More than 20 laboratories worldwide from academia, government, and private (i.e., vendor) organizations are participating. Each laboratory is using their own SSA/NTA methods, and will submit results to EPA for performance evaluation and public release. A project goal is to produce benchmark methods for sample and data analysis, as well as results reporting, and to identify areas of future research. A further outcome of this work will be to identify which analytical methods are more suitable to detecting specific classes of chemicals in environmental media. Current progress on these varied NTA/SSA projects and initial results will be presented. This abstract does not reflect US EPA policy.
Bioavailability is a crucially important factor for estimating oral inorganic arsenic exposure in human subjects where exposure-response relationships can be better understood. Many studies have been conducted to quantify the potential for human health risk assessment. In the recently published Arsenic in Rice and Rice Products Risk Assessment Report, FDA used an estimate of 70% ~ 90% to quantify a distribution of the bioavailability of inorganic arsenic in rice. Furthermore, some newly published studies with revised design and expanded sample size, including both in vivo and in vitro experiments reported different outcomes from the previous studies considered by FDA. In this study, we conducted a systematic review together with meta-analysis to qualitatively identify the important factors that can significantly impact bioavailability and quantitatively characterize the distribution of bioavailability. A thorough literature search in the PubMed database identified 111 peer-reviewed journal articles using the key words of “arsenic” and “bioavailability” or “bioaccessibility”. 38 out of the 111 papers were selected by removing other irrelevant articles, such as those focused on arsenic bioavailability from soil to crops, and 8 among these 38 included papers provided adequate data for meta-analysis. A preliminary review suggests that, the bioavailability is likely to be correlated with arsenic species, whether its trivalent or pentavalent, and the actual dose of exposure, indicating a higher amount of intake might lead to greater bioavailability, which can range from 50% to 100%. Thus, the more reliably derived distributional estimate of the bioavailability of inorganic arsenic would remarkably improve the exposure assessment in support of human health risk assessment of inorganic arsenic and decision making.

Development of a Bisphenol A (BPA) Exposure Risk Questionnaire and Food Packaging Assessment Tool

J. C. Hartle, and M. Freedman. San Jose State University, San Jose, CA.

Sponsor: M. Holsapple

Bisphenol A (BPA), an endocrine-disrupting chemical, is widely used in consumer products. The main exposure pathway for BPA is from ingestion of foods contaminated by BPA leaching from polycarbonate plastic food storage containers and epoxy resin-lined cans. Current methods of identifying BPA exposure fail to recognize all sources, with some estimates indicating that only half of the sources are identified. Dietary exposure assessment methods often rely on dietary recalls to identify ingestion sources although dietary recall methods are designed to assess nutrient intake, not to identify environmental chemical exposures. This research aimed to develop and test a) a risk-based questionnaire to identify behaviors that increase the potential for dietary BPA exposure, and b) a food packaging assessment tool (FPAT). The risk-based questionnaire and FPAT methods were developed based on the literature describing the main BPA dietary exposure pathways. The tools were tested with 33 students enrolled in a university-level nutrition science course. Students were instructed on how and when to complete each assessment tool. The risk-based questionnaire, composed of 9 questions designed to identify eating behaviors known to increase BPA exposure, was administered at the same time as the FPAT and a 24-hour dietary recall. 36% of students (n=12) were identified as being at high risk for exposure to BPA according to the risk-based questionnaire scoring matrix. Internal consistency of the questionnaire, tested with Cronbach’s alpha, was 0.57. The FPAT captured potential BPA ingestion exposures by documenting details regarding how food was packaged, stored, prepared, and served. The risk-based questionnaire provided a strong foundation for identifying dietary behavioral patterns and gaps in exposure knowledge. Forty-five percent of students (15/33) did not know that BPA was labeled BPA-free, and 30% of students (10/33) did not know that their plastic bottles for water were BPA-free. The FPAT documented details about potential food exposures currently missed by dietary recalls. The researchers plan to modify the tool based on feedback from students. Planned future applications of the risk-based questionnaire and FPAT are to compare these tools to urinary BPA concentrations to assess their accuracy in identifying exposures.

Environmental pollutants are increasing at an exponential rate and many of them pose a potential health risk. Among these contaminants, pesticides are one hazardous class of contaminants used around the world. Pesticides exposure has been found to be associated with a range of human health problems like immune suppression, hormone disruption, adverse reproductive outcomes, etc. Owing to their xenobiotic nature, Organochlorine pesticides (OCPs) disturb the normal estrogen-progesterone balance, which is important in the maintenance of pregnancy. Preterm delivery (PTD) is the largest cause of perinatal death, neonatal morbidity and mortality and adult illness. Exposure to environmental chemicals and their improper metabolism is one of the factors causing excessive oxidative stress, DNA damage and cytokines imbalance during pregnancy. The root cause of many adverse pregnancy outcomes are not well understood but there is growing evidence that many of them might arise from the complex interaction between genes and environment. Hence, the present was designed to assess the risk of PTD by analyzing blood OCPs level, gene environment interaction between OCPs levels, DNA damage and mRNA expression of inflammatory and antioxidant genes in PTD cases, n=150) and term delivery (controls, n=150). Significantly higher levels of α-HCH, β-HCH and p’p’ DDE were observed in maternal blood and o’p’ DDT and p’p’ DDE in cord blood of PTD cases. The levels of HCH isomers, αHCH, βHCH, γHCH, p’p’ isomer, p’p’ DDE and o’p’ DDT were detected in maternal and cord blood indicating the placental transference of OCPs. The extent of DNA damage was also significantly higher in maternal, and cord blood of PTD cases as compared to controls. It was found that mRNA expression of IL-6 gene is higher and SOD gene was 7.5 folds and CAT gene was 6.95 folds lower in maternal blood of PTD cases as compared to controls. A positive significant linear correlation between the birth weight (kg), period of gestation (POG) and IL-6 ΔCt was found in all subjects. A negative correlation between birth weight, POG and ΔCt of SOD and CAT gene in all subjects were observed. The study concludes that gene-environment interaction is one of the potent risk factor for the etiology of PTD.
Conventional calculations of oral reference doses include uncertainty factors to account for extrapolation uncertainties associated with estimating a human equivalent dose from animal toxicity studies that measure administered dose. Increasingly, internal dose metrics are being used as an alternative method of quantifying the relationship between exposure and health risk. Specifically, changes in concentrations in serum and in target organ tissues are keys to understanding human health toxicity. However, internal dosimetry presents its own uncertainties and requires a careful evaluation of empirical data to support assumptions. In the case of long-chain perfluoroalkyl acids, the relatively long half-life in humans compared with mice has prompted some regulatory agencies to rely on internal dose as a preferred metric for dose-response analysis. Using perfluorooctanoic acid (PFOA) as a case study, we provide a side-by-side assessment of the use of internal and external dose metrics as the basis for calculating the RfD. We reassess some of the key studies for which PFOA kinetic models are based and highlight examples of how evolving understanding of species-specific kinetics and exposure sources impact interpretation of the underlying data. We extend the findings of Worley, Yang, and Fisher (2017) who demonstrated the relevance of non-drinking water exposures in understanding the inter-individual variability in PFOA serum concentrations by showing how this concept is extended to both the serum-to-water ratio and relative source contribution (RSC) assumptions used in derivations of drinking water standards. Using data reported by Emmett et al. (2006) on populations exposed to PFOA in drinking water and populations who were not exposed to this source, we demonstrate how the serum-to-water ratio relevant to quantifying PFOA exposures via the drinking water pathway is approximately 20:1 rather than the frequently cited ratio of 105:1. This approximately five-fold difference coupled with a closer examination of the RSC term has important implications for risk assessment and risk communication for PFOA and other perfluoralkyl acids that are compared with PFOA.

Application of Internal Dosimetry for Perfluoroalkyl Acids and Methods to Assess Uncertainty Factors Used in Risk Assessment

P. Goodrum1, and J. Anderson2. 1Integral Consulting Inc., Fayetteville, NY; and 2Integral Consulting Inc., San Antonio, TX.

Biomonitoring data such as concentrations of chemicals in human blood have routinely been used to assess national trends in exposure and to identify communities for which exposures are consistently elevated compared to national averages. Measured concentrations in people are often viewed as more informative exposure metrics than estimates based on exposure, uptake, and kinetic models; however, from a risk assessment perspective, for most chemicals, challenges remain in linking biomonitoring data with statements about the magnitude and likelihood of adverse health effects. Traditionally, reference doses (RfD) and associated human health drinking water threshold levels are calculated from and compared with administered or oral ingestion dose rather than internal dose. However, internal dose measurements and human biomonitoring data are being used more frequently to derive RfDs and drinking water threshold levels. The use of human serum data from biomonitoring studies to calculate a threshold level requires chemical-specific or default assumptions about how a chemical is absorbed, metabolized, distributed, and eliminated. A shift in calculating RfDs towards a focus on internal dosimetry is accompanied by an expectation that we will have greater confidence in the internal dose-response relationship. It is not clear that this is always the case. This presentation will propose a decision making framework for assessing relative uncertainties in dosimetric approaches. Key factors and important data needs will be highlighted, including chemical persistence (biological half-life); frequency, duration, and magnitude of exposure; availability of animal toxicology data that includes internal dose metrics; and an understanding of interspecies differences in metabolic and physiologic processes that affect both dose and route and resultant exposure compounds in drinking water will be presented for which approaches using compartmental models and biokinetic slope factors can be compared with traditional methods based on administered dose.

Detection of Ethylene Glycol in Aqueous Solutions through the Use of Gas Chromatography

J. Cedillo, and R. Bright, Fort Valley State University, Fort Valley, GA.

Ethylene glycol is a poisonous compound found in nearly pure form at any auto parts department in the country. Upon ingestion, ethylene glycol can cause death or serious health effects within 24 hours. Liquid foods such as milk and orange juice are a particular safety concern because of transportation of those products in unsecured vehicles. A detection method needs to be developed that will allow milk plants to test for the presence and concentration of ethylene glycol prior to introduction of the milk into the plant environment. The purpose of this study was to determine if cyclohexanol can be used to quantitatively and reliably extract ethylene glycol from aqueous solutions. If successful, this extraction to method could be utilized in liquid foods. Liquid-liquid extraction and quantification through the use of gas chromatography was employed. A set of ethylene glycol standards in water was used to determine the calibration curve for the extraction of ethylene glycol. It was determined that the distribution constant of the extracted ethylene glycol between organic and aqueous solvents was not consistent, because of this, it can be said that cyclohexanol is not a good fit for the extraction of ethylene glycol. The ideal extraction solvent should have a boiling point below 200°C, be immiscible in water, and interact with the hydroxide groups of the ethylene glycol for extraction.

Comparative Estrogenicity of Endogenous, Environmental, and Dietary Estrogens in Pregnant Women II: Accounting for Receptor Competition and Ligand Potency

P. Pandel1, S. Fleck2, N. Twaddle3, M. Churchwell4, D. Doerge5, and J. Taequard6. 1Pacific Northwest National Lab, Richland, WA; and 2US FDA/NCTR, Jefferson, AR.

The potential for cumulative effects of exposure to multiple exogenous estrogens is a commonly raised concern. The potency for estrogen receptor based mechanisms can be described as comprising two factors: (i) affinity of ligand binding to the receptor, determined by the dissociation constants, and (ii) affinity of the co-activator recruitment to the estrogen receptor-ligand complex, determined by the relative coactiv-
vator affinity (RCA), eventually leading to downstream processes culmi-

nating in an estrogenic response. This goal of this study was to assess

and compare the estrogenicity of a group of seven estrogens, com-

prising endogenous (E1, E2, E3, E4), environmental (BPA), and dietary

(Genistein (GEN), Daidzein (DDZ)). Two related metrics of estrogenicity,
called the fractional receptor occupancy (FRO), and the relative response

(RR), were designed to reflect the above two dimensions of estrogen

potency. FRO is a measure of the effectiveness of an estrogen to bind
to an estrogen receptor (ER), whereas, the RR metric aims to capture the
potency of an estrogen in terms of not only its effectiveness of binding
to an ER but also recruiting a coactivator. To compute these metrics, we
utilized measured total ligand concentrations and available data on ER-α
and ER-β receptor affinity and the corresponding RCAs. The FRO based
estrogenicity was dominated by E1, E2 and E3, which together repre-

sented 84.1-99.9% (median: 99.2%) and 79.9-99.9% (median: 99.3%) of
the total receptor occupancy for ER-α and ER-β receptors, respectively.
The median fraction of receptors occupied by BPA was five orders of
magnitude lower than E1, E2 and E3, and three orders of magnitude
lower than the fetal derived E4 and GEN and DDZ. Likewise, based on
the RR values, E3 was the most potent serum estrogen (median RR
values of 0.746 and 0.794 for ERα and ERβ receptors, respectively. The
median RR values for E2 were 0.243 for ERα and 0.167, for ERβ receptors.
The RR values for the remaining estrogens were consistently less than
0.01 across the two scenarios examined. Moreover, RR values for the
dietary and synthetic estrogens GEN, DDZ and BPA were remarkably
lower. The overall approach proposed in this study represents a general
framework for calculating estrogenicity in serum, which is extendable to
other similar ligand-receptor systems.

Targeted and Non-Targeted Analysis of Serum Pools to Provide Chemical Exposure Data for Exposure Modeling and Chemical Prioritization

B. A. Wetmore1, J. F. Wambach1, K. Favela2, A. Yau2, S. M. Hayes2, R. Church3, A. Rice3, S. Garantiottis3, and L. L. Aylward4 1-US EPA, Research Triangle Park, NC; 2-Southwest Research Institute, San Antonio, TX; 3-Summit Toxicology, LLP, Boynton, MT; 4-NIEHS, Research Triangle Park, NC; and 5-Summit Toxicology, LLP, Falls Church, VA.

Biomonitoring data can help inform the development and calibration of high-throughput exposure modeling for use in chemical prioritization and
guiding regulation. This project was conducted to evaluate the feasibility of using pooled banked blood samples to generate initial data
on population blood concentrations for compounds not to date routinely
analyzed in biomonitoring efforts such as the National Health and Nutrition Examination Survey (NHANES). Serum samples were obtained from the NIEHS Clinical Research Unit. Serum pools were constructed from 25 individual 1 ml aliquots. Four pools each were constructed
based on samples stratified by age (<45 vs 45 and greater) and male vs. female, for a total of 16 pools. Samples were analyzed in triplicate using GCxGC-TOFMS and LC-qTOFMS analysis (positive and negative mode). An exposure- and risk-based prioritization scheme was used to identify approximately 130 chemicals of interest subjected to additional
processing and evaluation. Targeted GCxGC was used to assess seven
chemicals: triclosan, bisphenol A, dibutyl phthalate (DBP), dimethyl
phthalate (DMP), diethyl phthalate (DEP), di-n-octyl phthalate (DNOP). Although these chemicals are rapidly metabolized, levels exceeding those
in method blanks were detected in most samples tested but not
in method blanks. Among the gender and age stratifications, only DEP showed a significant (p < 0.05) difference between groups, with age ≥45 having a mean of 0.24 (sd 0.06) and age ≤45 having mean 0.17 (0.04). Concentrations of DEP and triclosan in serum were similar to those previously reported in other studies. Non-targeted GC analysis found an average of 355 detections per sample. Females had a significantly higher (p-value 0.00018) number of detections (mean 440, sd 89) than males (mean 270, sd 26). These data can be used to inform development of high-throughput exposure models and design of further explorations of human chemical exposure through analysis of human serum samples. This abstract may not reflect US EPA policy.

Use of Lichens to Evaluate Predictions of Spatial Distribution of Metals by AERMOD in the Ohio River Valley

J. Ste Marie, K. Lerch, and D. J. Brown. Marietta College, Marietta, OH; Sponsor: M. Denison

Computer models, such as AERMOD, have been used to predict spatial distribution of airborne pollutants from point sources. However, it can be difficult to test these computer models to make sure that they are accurately predicting distribution. In an attempt to test AERMOD, endogenous lichens have been used as biomonitors to map airborne metal deposition in the Mid-Ohio River Valley and compare the results to predictions made by AERMOD for a ferromanganese alloy factory located in Washington County, Ohio. Mapping the lichen data has indicated that the plumes of manganese and chromium released by this point source have a northeast orientation, while AERMOD calculations for the same time period predicted that the plume would have a more northern and lichen dominated trajectory. Transplanted lichens (hypogymnic conditions from a control site were also used in an effort to better understand the rates at which lichens accumulate metals and the impact of wind direction, and precipitation on the spatial deposition of metals from this source. F. caperata collected at a control location was rinsed and placed in plastic mesh packets and transplanted at various distances lasting from one to 6 months, and by 5 months the transplanted lichens were reaching steady state in regards to metal concentrations. By 5 months the metal levels in transplanted lichens were also approximately the same as lichens found at those locations. Lichen samples were acid digested, and metal concentrations (Cr, Cu, Fe, Mn, and Ni) were determined using atomic absorption spectroscopy. Distance from the point source was strongly correlated with accumulation, with the closest transplant site having the highest concentration of Mn (286 µg/g dry weight). Exposures were also conducted each month for a year to compare accumulation of metals in lichens transplanted one kilometer to the north, south, east and west of the point source and relate those levels to wind direction and precipitation during the exposure period. Weather data for the area was obtained from a NOAA weather station located just outside of the Ohio River Valley. Based on prevailing winds from the southwest, we expected the highest metal concentrations to be observed to the north and east of the point source. However, for more than half of the months the highest metal levels were found at the western transplant site. We are currently working to optimize the ability of AERMOD to predict the monthly results that were obtained from the transplanted lichens.

Determining the Health Protective Capability of Analytical Detection Methods for Short Duration Exposures

J. C. Lipscomb1, S. Willison1, E. Parry1, S. Chattopadhyay2, E. Silvestri3, and E. Snyder2 1-US EPA, Cincinnati, OH; and 2-US EPA, Research Triangle Park, NC.

Emergency-response decisions require integrating exposure and risk information. Chemical exposure guidelines may be available, and are optimal when based on dose-response data for the relevant duration and address multiple levels of severity. US EPA’s National Homeland Security Research Center (NHSRC) has tools to characterize exposures and risk during temporary reutilization of previously contaminated infrastructure: Provisional Advisory Levels (PALs) and Selected Analytical Methods for Environmental Remediation and Recovery (SAM). Oral and inhalation PALs characterize three tiers of severity (minimal and reversible; more severe, irreversible or escape-impairing; and lethal) for durations of up to 24 hours, 30 days, 90 days and two years. PALs decrease with time and increase with effect severity. SAM recommends optimal analytical methods for a matrix-analyte pair and describes performance. Using SAM, the sufficiency of analytical capability for acrylonitrile, a widely used industrial chemical, relative to the PALs values was evaluated. Oral PALs (expressed as drinking water equivalents for children) ranged as low as 0.064 mg/L. SAM identified EPA Method 524.2 (run time ~ 30 minutes) as the optimal method for acrylonitrile in drinking water (by GC/MS). This method provides a detection limit of 0.00022 mg/L and a limit of quantitation of 0.0009 mg/L, representing sufficient analytical sensitivity to detect concentrations capable of producing even minimal, reversible effects, following a two-year exposure. Inhalation PALs ranged as low as 0.030 mg/m3. SAM identified OSHA Method PV2004 for acrylamide (HPLC/UV) as potentially applicable to acrylonitrile, with a possible detection limit of 0.001 mg/m3. Confidence will be increased when this method can be verified for acrylonitrile and a limit of quantitation is established. When the consequences of exposure to acrylonitrile are needed for exposure durations less than those required to procure, transport and analyze environmental samples (most relevant to the 24-hour exposure duration), field detection capabilities should be evaluated. This process will be applied to other priority chemicals. This abstract may not represent the views and policies of the US EPA/ORD/NHSRC.
**2433 Determination of Temephos and Its Metabolites in Biological Samples**
F. A. Verdin-Betancourt1, M. L. López-González, M. A. Figueroa2, E. Gómez3, and A. Sierra-Santoyo1, 1CINESTAV-IPN, Mexico City, Mexico; 2Facultad de Química, UNAM, Mexico City, Mexico; and 3Instituto de Química, UNAM, Mexico City, Mexico.

Temephos (Tem) is a broad spectrum organophosphorus insecticide mainly used as a larvicide to control mosquitos. Tem is added to drinking water at a dose not exceeding 1 mg/mL. It is an unstable compound in chlorinated water and undergoes oxidation to its respective oxons and other oxidized metabolites. Based on its acute toxicity, Tem is classified in category U. The information about its toxicokinetics and chronic toxicity is very limited. There is no available a routine analytical method to determine oxidized metabolites of Tem in biological samples. The aim of this study was to develop and to validate an analytical method for analyzing metabolites of Tem in biological samples. An HPLC/DAD method to determine at least Tem and six metabolites was developed. The aqueous phase consisted of a 12 mmol/L linear gradient of acetonitrile, and water at a flow of 1 ml/min, a C18 column, and metabolites were monitored at 254 nm. Four metabolites were synthesized and characterized, and two more were commercially obtained, plus the parent compound. Adult male Wistar rats were orally administered for 3 d at a dose of 300 mg/kg/d. Two h after the last dose, animals were sacrificed by cardiac puncture under CO2-induced anesthesia. Serum was obtained from blood and organs removed. Serum and liver samples of non-treated animals were spiked with Tem and metabolites. Tem and its metabolites were extracted with a mix of ethyl acetate:acetonitrile:water at a flow of 1 ml/min, a C18 column, and metabolites ranging from 90 to 120%. The main metabolites detected in serum were Tem-sulfoxide and Tem-dioxo-sulfoxide, in addition to four non-identified metabolites. In liver, the main metabolites were Tem-sulfoxide, thiophenol and thiophenol-sulfoxide. This analytical method may be useful for future analysis of Tem in biological samples and would help in the development of physiologically-based pharmacokinetic models of this pesticide.

**2434 Measurement of Oxidative Stress Biomarker in Saliva: 8-Hydroxyguanine**

Oxidative stress leads to many kinds of diseases. Information about the oxidative status in the body is useful for the prevention of diseases and the mitigation of aging brought on by oxidative stress. To prevent diseases potentiated by oxidative stress, a method for the appropriate assessment of the oxidative stress status is needed. Currently, urinary 8-hydroxydeoxyguanosine (8-OHdG) is widely measured as an oxidative stress biomarker. It would be advantageous if saliva could be used as the sample to measure this oxidative stress biomarker, because saliva is much easier to collect than urine. However, urinary 8-OHdG is hardly detectable as a single peak, even after solid-phase extraction and concentration pretreatments. Salivary 8-OHGua may be a useful biomarker in the human population, in relation to the assessment of the oxidative stress induced by various factors in daily life. Ethics approval: The study was approved by the Ethics Committee of Medical Research, University of Occupational and Environmental Health, Japan.

**2435 Identification of a Sulfur Adduct of 1,4-Naphthoquinone during Reaction with a Polysulfide**
R. Hirose, Y. Shinkai, Y. Abiko, and Y. Kumagai. University of Tsukuba, Tsukuba, Japan.

Atmospheric quinones such as 1,4-naphthoquinone (1,4-NQ) interact readily with protein thiols, resulting in formation of protein adducts involved in cytotoxicity. Reactive sulfur species (e.g., hydrogen sulfide, persulfides and polysulfides) exhibit high nucleophilic property and thus capture electrophiles such as 1,4-NQ. We found that preincubation with sodium tetrasulfide (Na2S4) for 10 min at room temperature, the reaction mixture was applied to an ODS column. While a couple of reaction products were formed, UPLC-MS, FT-ICR-MS and ESI-MS analyses revealed that a sulfur adduct of 1,4-NQ has high purity exhibited a m/z of 361, corresponding to an elemental composition of C20H10O5S. 1H NMR and 1H-1H COZY NMR analysis indicated that the sulfur adduct was identical to 1-[2-(1,4-dioxonaphthalene-2-yl)sulfanyl]-3-hydroxynaphthalene-1,4-dione (1,4-NQ-S-1,4-NQ-OH).

**2436 Mice Lacking the NAD(P)H Quinone Reductase (NQO1) or NQO2 Gene Are More Susceptible than Wild Type Mice to Hyperoxic Lung Injury In Vivo: Protection by β-Naphthoflavone (BNF) Administration**
B. Moorthy, L. Wang, X. Couroucli, K. Lingappan, and W. Jiang. Baylor College of Medicine, Houston, TX.

Supplemental oxygen administration is frequently encountered in the treatment of infants and adults with pulmonary insufficiency. However, hyperoxia contributes to biological damage. NQO1 and NQO2 are phase II detoxifying enzymes that NQO1- and NQO2-null mice are more susceptible to hyperoxic lung injury in vivo, compared to wild-type (WT) mice, and that pretreatment of these mice with the cytochrome P450 inducer β-naphthoflavone (BNF) will rescue this phenotype. Ten- to twelve-week-old wild-type (WT) mice, C57BL/6J strain, NQO1-null, or NQO2-null mice were treated i.p. with vehicle CO or BNF (40 mg/kg), once daily for 4 days, and the animals were either maintained in room air or exposed to hyperoxia for 24-72 h. Lung injury and inflammation was assessed by measuring lung weight/body weight (LW/BW) ratios, histology, and neutrophil recruitment by immunochemistry. Gene expression of CYP1A1, Nrf2 and NQO1/2 genes was determined in lung by real-time RT-PCR. The NQO1-null and NQO2-null mice were more susceptible to oxygen-mediated lung damage and inflammation as evidenced by increased lung weight/BW ratios, lung injury, neutrophil recruitment, and augmented expression of IL-6 and TNF-α, in these animals compared with those in WT mice. There was no significant difference in the extent of lung injury between NQO1- and NQO2-null mice. Pretreatment of WT, NQO1-null, as well as NQO2-null mice with BNF, followed by hyperoxia for 24-72 h, led to significant attenuation of lung injury. BNF treatment led to increased expression of CYP1A1 gene expression in lungs and liver, and of CYP1A2 gene in liver in each of the genotypes. The fact that NQO1- and NQO2-null mice are more susceptible to hyperoxic lung injury suggests that these enzymes are protective against oxygen injury. That BNF-pretreated mice show attenuation of hyperoxic lung injury in WT, NQO1-null, and NQO2-null mice, and the fact that these mice display augmentation of pulmonary CYP1A1 and hepatic CYP1A1/1A2 support the hypothesis the BNF protected against lung injury by the expression of CYP1A enzymes... Future research could lead to the development of novel strategies for prevention and/or treatment of BPD and ALI/ARDS.

**2437 Polysulfide Na2S4 Regulates the 1,4-NQ-Mediated Activation of PTEN/Akt/CREB Signaling in Primary Mouse Hepatocytes**
Y. Abiko1, Y. Shinkai1, T. Unoki1, R. Hirose1, T. Uehara1, and Y. Kumagai1. 1University of Tsukuba, Tsukuba, Japan; and 2Okayama University, Okayama, Japan.

Electrophiles can activate redox signal transduction pathways, through actions of effector molecules (e.g., kinases and transcription factors) and sensor proteins with low pKa thiols that are covalently modified. In this study, we investigated whether 1,4-naphthoquinone (1,4-NQ) could affect the phosphatase and tensin homolog (PTEN)-Akt signaling pathway and persulfides/polysulfides could modulate this adaptive response. Simultaneous exposure of primary mouse hepatocytes to sodium tetrasulfide (Na2S4) and 1,4-NQ markedly decreased 1,4-NQ-mediated cell death and S- and cysteinyl- proteins. Modification of cellular PTEN during exposure to 1,4-NQ was also blocked in the presence of Na2S4. 1,4-NQ, at up to 10 µM, increased phosphorylation of Akt and cAMP response element binding protein (CREB) in a concentration dependent manner. However, at higher con-
IL22 Mediates Environmentally Persistent Free Radical Exposure-Exacerbated Influenza Infection

V. S. Patel, J. Harding, D. You, and S. A. Cormier. University of Tennessee Health Science Center, Memphis, TN.

Particulate matter containing environmentally persistent free radicals (EPFRs) are formed during various combustion processes including thermal remediation of hazardous wastes. Exposure to EPFRs adversely affects respiratory health in infants and is associated with increased morbidity and mortality due to acute lower respiratory tract infections. We reported previously that early-life exposure to EPFRs (1,2-dichlorobenzene adsorbed on CuO/Silica particles at 230 °C; DCB230) damages lung epithelium and suppresses immune responses to influenza (Flu) infection thereby enhancing Flu severity. Interleukin (IL) 22 is important in resolving lung injury following Flu infection in adult mice. In the current study, we determined the effects of EPFR exposure on pulmonary IL22 responses using our neonatal mouse model of Flu infection. RNA expression, protein concentration and immune cells were assessed using RT-qPCR, multiplex assay and flow cytometry, respectively. Exposure to EPFRs resulted in an immediate (0.5-1 day post-exposure; dpe) increase in IL22 expression in the lungs of C57BL/6 neonatal mice; however, IL22 expression was not maintained and failed to increase with subsequent EPFR exposures or Flu infection. This was associated with transiently increased and persistently decreased expression of the inhibitory cytokines IL10 and IL17A, which were earlier shown to activate and induce proliferation of group 3 innate lymphoid cells (ILC3). Because ILC3 are one of the major sources of IL22 and thus play a crucial role in the maintenance of lung epithelium, we also investigated the effects of EPFR exposure on lung ILC3. In congruence with IL22 levels, there was an initial increase in ILC3 frequencies in the lungs of EPFR-exposed neonatal mice that declined to baseline after 1 dpe. Together, these data suggest that exposure to EPFRs results in failure to sustain IL22 levels and an inability to induce IL22 upon Flu infection. Insufficient levels of IL22 may be responsible for aberrant epithelial repair and immune responses, leading to increased Flu severity.

Zinc-Deficient Diet Exacerbates Testicular and Epididymal Damage by Increasing Oxidative Stress and Altering Zinc, Insulin, Testosterone Signaling in Type 2 Diabetic Rat

Proper and planned dietary supplementation can cure or reverse the metabolic syndromes like diabetes. Zinc (Zn) is one of the most important trace elements in the body and is required for insulin secretion and release. Alteration in the Zn levels can cause moderate to severe damage to various organs. Most of the type 2 diabetic patients have altered insulin signaling. Type 2 diabetes induces irreversible damage, which can subsequently pass on to the next generation causing metabolic syndromes in the children. On the other hand Zn is required for proper development and function of the gonads, so the obvious role of Zn in type 2 diabetes-induced germ cell damage requires further exploration. Type 2 diabetes was induced by the combination of high fat diet and a single low dose of streptozotocin (35 mg/kg, i.p.). Animals were confirmed type 2 diabetic by assessing blood glucose, cholesterol and triglyceride levels. Control animals were on normal pellet diet throughout the study, while Zn-deficient diet was given for four consecutive weeks to the diabetic rats which were further kept on high fat diet for 16 weeks. Zn-deficient diet given to diabetic rats further decreased the serum Zn, plasma insulin and serum testosterone levels and increased cholesterol, triglycerides, BUN, %HbA1c and the oxidative stress in testes by decreasing glutathione, catalase and SOD1 levels. It also decreased the levels of GPX5, which is an epididymal secretory protein present in the caput. Further, Zn-deficient diet to diabetic animals decreased Metal response element (MRE)-binding Transcription Factor-1 (MTF-1) levels and SOD1 levels in the caput epididymis. Several of the histopathological alterations in testes, epididymis and sperm head defects were noted in the Zn-deficient group. Apart from these, organs rich in Zn levels like prostate, kidney and liver were also severely affected by the intake of Zn-deficient diet. The present results demonstrated that, any imbalance in the dietary Zn levels can exacerbate the type 2 diabetes induced germ cell and other organ damages.

Role of Cytochrome P450 (CYP) 1A2 in Neonatal Hyperoxic Lung Injury and Its Modulation by the CYP1A Inducer B-Naphthoflavone (BNF)

X. I. Couroucli, K. Lingappan, Y. Wei-Liang, P. Maturu, W. Jiang, and B. Moorthy. Baylor College of Medicine, Houston, TX.

Exposure to hyperoxia leads to bronchopulmonary dysplasia (BPD), one of the most common pulmonary morbidities in preterm neonates, which is more prevalent in males than females. We reported recently that adult mice lacking genes for Cyp1a1 or 1a2, and neonatal mice lacking Cyp1a2 are more susceptible to hyperoxic lung injury than wild type mice. In this investigation, we tested the hypothesis that neonatal mice lacking the Cyp1a2 gene will be more sensitive to oxygen-mediated lung injury, and that beta-naphthoflavone (BNF) treatment will rescue this phenotype. Newborn WT or Cyp1a2/-/- mice were treated with BNF (10 mg/kg) or the vehicle corn oil (CO) i.p, from postnatal day (PND) 2 to 8 once every other day, while being maintained in room air or hyperoxia (85% O2) for 14 days. Hyperoxia exposure led to alveolar simplification and arrest in angiogenesis in both genotypes. No significant differences were observed between WT and Cyp1a2/-/- mice. Cyp1a2/-/- female mice had better preservation of pulmonary angiogenesis at PND15 compared to similarly exposed males. BNF treatment attenuated lung injury and inflammation in both genotypes, and this was accompanied by a significant induction of hepatic and maternal CYP1A1 expression in WT but not in Cyp1a2/-/- mice. Under hyperoxic conditions, BNF treatment induced Nqo1 mRNA levels in WT and Cyp1a2/-/- mice compared to corn oil-treated mice. Newborn mice lacking the gene for Cyp1a2 did not have increased susceptibility to hyperoxic lung injury compared to the WT. Nevertheless, the ISCs of lung from Cyp1a2-/ females lacking the gene for Cyp1a2 were more susceptible to hyperoxia-induced lung injury than WT mice. Under normal breathing conditions, BNF treatment attenuated the expression of several pro-inflammatory genes in both genotypes.

Pro-Oxidant and Antioxidant Properties of Polycyclic Aromatic Hydrocarbons and Extractable Organic Matter from Particulate Matter <2.5 μM

We investigated the kinetics of reactive oxygen species (ROS) production and its link to antioxidant response in human embryonic lung fibroblasts (HEL) and human alveolar basal epithelial cells (A549) treated with extractable organic matter (EOM) from PM2.5 and polycyclic aromatic hydrocarbons (benzo[a]pyrene, BaP; 3-nitrobenzanthrone, 3-NBA). We analyzed ROS levels, total antioxidant capacity (TAC), lipid peroxidation (15-F2t-IsoP) and total protein carbonyls (15-F2t-IsoP) in HEL and A549 cells exposed to EOMs. Exposure to EOMs increased ROS levels, total antioxidant capacity (TAC), lipid peroxidation (15-F2t-IsoP) and total protein carbonyls (15-F2t-IsoP) in HEL and A549 cells exposed to EOMs. Exposure to EOMs increased ROS levels, total antioxidant capacity (TAC), lipid peroxidation (15-F2t-IsoP) and total protein carbonyls (15-F2t-IsoP) in HEL and A549 cells exposed to EOMs. Exposure to EOMs increased ROS levels, total antioxidant capacity (TAC), lipid peroxidation (15-F2t-IsoP) and total protein carbonyls (15-F2t-IsoP) in HEL and A549 cells exposed to EOMs. Exposure to EOMs increased ROS levels, total antioxidant capacity (TAC), lipid peroxidation (15-F2t-IsoP) and total protein carbonyls (15-F2t-IsoP) in HEL and A549 cells exposed to EOMs.
after 24h exposure of HEL and 4h treatment of A549. In summary, our data suggest the ability of individual PAHs and EOMs to impact ROS generation, induce antioxidant mechanisms, and affect lipid peroxidation levels. However, the extent of these effects depends on the cell line used for the tests. Supported by Czech Science Foundation (16-14631S).

2442 Air Pollutant 1,2-Naphthoquinone Inhibits Glycolysis through Peroxide-Mediated Protein Inactivation in Human Bronchial Epithelial Cells

K. S. Lavrich, E. D. Hickman1, and J. M. Samet1. 1University of North Carolina at Chapel Hill, Chapel Hill, NC; and 2US EPA, Research Triangle Park, NC.

Ambient particulate matter (PM) exposure is a leading cause of morbidity and mortality worldwide. PM-linked health outcomes are thought to be mediated by oxidative stress mechanisms, but the specific redox events involved have not been well-characterized. PM-associated quinones, such as 1,2-naphthoquinone (1,2-NQ), can contribute to cellular oxidative stress through reactive oxygen species (ROS) generation by redox cycling and by direct addition to proteins. We have previously shown that 1,2-NQ induces production of the ROS hydrogen peroxide (H2O2), a potent signaling molecule that oxidizes proteins to regulate their function. We specifically identified the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) as a target of H2O2 oxidation induced by 1,2-NQ. GAPDH inactivation in human bronchial epithelial cells has been hypothesized that this modification could cause a functional inactivation of the enzyme. Glycolysis is essential for many key cellular functions such as ATP production. GAPDH inactivation by 1,2-NQ leading to inhibition of glycolysis would therefore greatly impair cellular function and growth. Here, we examined the functional effects of 1,2-NQ on glycolysis in the human bronchial epithelial cell line, BEAS-2B. We found that environmentally-relevant doses of 1,2-NQ rapidly inhibited glycolytic function as measured using extracellular flux analyses. Overexpression of catalase, an enzyme that scavenges H2O2, reversed the glycolytic inhibition caused by 1,2-NQ, suggesting an underlying H2O2-dependent mechanism to inactivate glycolytic proteins rather than addition. To our knowledge, this is the first report that exposure to low doses of an environmental toxicant results in a functional inhibition in glycolysis through peroxide-dependent mechanisms. These results suggest novel approaches to cancer therapies, as cancer cells are highly reliant on glycolysis for energy production. This study informs our mechanistic understanding of PM-induced human health effects. This abstract of a proposed presentation does not necessarily reflect US EPA policy.

2443 Mammalian Target of Rapamycin (mTOR) Regulates Mitochondrial Metabolism and Redox Homeostasis in Astrocytes

C. Garza-Lombo1, J. Rose1, M. E. Gonsebatt2, and R. Franco1. 1University of Nebraska-Lincoln, Lincoln, NE; and 2Instituto de Investigaciones Biomedicas, Mexico City, Mexico.

Astrocytes play an essential role in the brain as they regulate both neuronal excitability and homeostasis. Glutathione (GSH) efflux from astrocytes provides precursors for neurons to synthesize GSH. However the mechanisms and signaling pathways by which astrocytes maintain GSH homeostasis are unknown. In this work, we report the role of the mammalian target of rapamycin (mTOR) in the regulation in GSH homeostasis in primary cultures of rat cortical astrocytes. Inhibition of de novo GSH synthesis with buthionine sulfoximine (BSO; 500 µM) induces GSH depletion. Interestingly, GSH depletion was not paralleled by oxidative stress suggesting an active flux of GSH. GSH depletion was independent from the activity of the multidrug resistance-associated protein 1 (MRP1/ABCC1) as evidenced by the lack of effect of the MRP1 inhibitor MK571 (50 µM). GSH-depletion induced by BSO was reversible after 12 h of BSO withdrawal. Inhibition of mTOR (Torin 250 nM) and phosphatidylinositol 3-kinase (LY294002, 10µM) signaling, as well as mitochondrial pyruvate transport (UK5099, 5 µM) and free fatty acid oxidation (Etomoxir, 200 µM) depleted GSH content in astrocytes, and prevented the recovery of the intracellular GSH pool after BSO withdrawal. Our results suggest that mTOR/PKB signaling and mitochondrial central carbon metabolism (pyruvate and free fatty acid oxidation) regulate GSH homeostasis in astrocytes.

2444 A Sensitive and Cost-Effective Fluorescence-Based Pyrogallol Red Assay for H2O2: Applied to Detect H2O2 Mobility Between Culture Wells

A novel fluorescence-based assay to quantify hydrogen peroxide levels in biological samples was developed with the relatively inexpensive and non-toxic reagents pyrogallol red (PGR) and horseradish peroxidase (HRP). These characteristics of PGR, as well as its ability to be readily oxidized by various species and its absorbance maxima at 540 nm at physiological pH, have led to its use in a number of assays to quantitate levels of small molecule oxidants and antioxidants, metal ions, and catalase. When the reaction is catalyzed, such as by HRP, PGR is oxidized by H2O2. We find that the linear range of H2O2 detection by this method is limited to the low µM range. Given its structural similarity to other anionic xanthene dyes, such as fluorescein, we hypothesized PGR would also have fluorescent properties, which might extend its linear range of H2O2 detection. We find that the reduced and oxidized forms of PGR both fluoresce, with distinct excitation and emission spectra, depending on pH. The linear range of H2O2 detection is significantly extended by fluorescence detection. A rapid 96-well plate assay was developed. Controls are included for 1) specifically detecting H2O2 by subtracting out any changes observed after treating samples with catalase and 2) accounting for any nucleophilic quenching of H2O2 (such as by glutathione) by pretreatment with the electrophile N-ethylmaleimide. This assay was then utilized to determine whether and to what extent H2O2 released in neighboring wells in a multi-well cell culture plate, due to volatilization from a treated well. We find that detectable amounts of H2O2 are found in wells that neighbor a treated well.

2445 Age-Dependent Oxidation of Cysteine/Cystine Redox State (Eh[Cys/CySS]) Is Mediated by Decreased SLC7A11 Expression in Mouse Lung Fibroblasts

Progressive oxidation is associated with aging and may contribute to increased susceptibility to environmental insults. The redox state of human plasma, defined by the concentrations of cysteine (Cys) and cystine (CySS), becomes more oxidized as we age. Recently, we showed that fibroblasts isolated from the lungs of young and old mice retained this differential phenotype; old cells produced and maintained a more oxidizing extracellular redox potential (Eh[Cys/CySS]) than young cells. Microarray analysis identified down-regulation of SLC7A11, the light subunit of the CySS/glutamate transporter, as a potential mediator of age-related oxidation in these cells. The purpose of the present study was to investigate the mechanistic link between Slc7a11 expression and extracellular Eh[Cys/CySS]. Sulforaphane treatment or transient transfection with a plasmid encoding Slc7a11 was used to increase expression levels of Slc7a11 in old fibroblasts, and sulforaphane treatment or siRNA-mediated knock down was used to decrease activity and expression of Slc7a11 in young fibroblasts. L-buthionine-sulfoximine (BSO) was used to inhibit cellular GSH synthesis. Slc7a11 mRNA levels were measured by qPCR, concentrations of Cys, CySS, GSH, GSSG and CySSG were measured by HPLC, and their redox potentials were calculated from the Nernst equation. The results showed that both extracellular Eh[Cys/CySS] and Eh[GSH/GSSG] were more oxidized in old cells than in young cells. Up-regulation of Slc7a11 resulted in a more reducing extracellular Eh[Cys/CySS], whereas down-regulation produced a more oxidizing Eh[Cys/CySS]. Up-regulation via sulforaphane increased total GSH and restored Eh[GSH/GSSG], whereas up-regulation via overexpression plasmid had no effect on these parameters. Neither siRNA-mediated knock down of Slc7a11 nor sulforaphane inhibition of Slc7a11 activity influenced total GSH. Inhibition of GSH synthesis with BSO had no effect on the ability of cells to restore their extracellular redox potential in response to an oxidative challenge. In conclusion, our study reveals Slc7a11 is the key regulator of extracellular Eh[Cys/CySS], and its effects are not dependent on intracellular GSH synthesis.
Bioenergetic Determinants of Cellular Resistance to Ozone-Induced Intracellular Redox Changes

E. A. Gibbs-Flourney, and J. M. Samet. US EPA, Chapel Hill, NC.

Exposure to air pollution is a persistent and widespread global public health problem. As a principal component of air pollution, ozone (O<sub>3</sub>) is a highly reactive oxidant gas known to induce adverse health outcomes such as pulmonary inflammation and functional decrements in the lungs of exposed individuals. Importantly, oxidative injury is commonly cited as a key mechanistic feature in the toxic action of O<sub>3</sub>. We have previously demonstrated O<sub>3</sub> to significantly alter the ratio of oxidized to reduced glutathione (glutathione redox potential, E<sub>redox</sub>) of human aortic endothelial cells (HAEC) exposed to 0.15-0.5 ppm O<sub>3</sub>, thus linking O<sub>3</sub> exposure to a specific intracellular redox outcome. Maintenance of the reducing potential for redox active biomolecules such as glutathione is critical for cellular health in an antioxidant defense against oxidative stress, and depends on the availability of reducing equivalents produced through bioenergetic processes. In the present study, we used a live-cell imaging approach to assess cellular susceptibility to oxidative stress by examining the bioenergetic role of glucose availability on intracellular E<sub>redox</sub> recovery following O<sub>3</sub> exposure. Glucose-deprived BEAS-2B cells expressing the E<sub>redox</sub> sensor roGFP2 were monitored in real time during exposure to 0.5 ppm O<sub>3</sub> in a glucose-free exposure medium. As with previous exposures, O<sub>3</sub> induced a substantial increase in the E<sub>redox</sub>. The addition of glucose to the exposure medium during a recovery period following the O<sub>3</sub> exposure resulted in a rapid restoration of the E<sub>redox</sub> to levels near those observed in the established pre-exposure period. A glutaredoxin1-linked version of roGFP2 showed the same pattern of responsiveness to O<sub>3</sub> and glucose-induced recovery with enhanced rate kinetics across the entire exposure period. These results suggest that the availability of reducing equivalents produced from glucose metabolism, as measured by E<sub>redox</sub>, is critical to the maintenance of redox homeostasis and antioxidant defense. Together, these findings provide insight into the mechanisms through which HAEC mitigate environmental oxidative stress. This abstract of a proposed presentation does not necessarily reflect US EPA policy.

Nrf2-Dependent Antioxidative Action of an Anti-Arthritic Drug, Auranofin: The Possible Repositioning for Oxidative Stress-Related Diseases

Y. Fuse, V. T. Nguyen, Y. Endo, and M. Kobayashi. University of Tsukuba, Tsukuba, Japan. Sponsor: H. Terakoa

The Nrf2 pathway confers biological defense against oxidative stress and redox-reactive xenobiotics. It is anticipated that the activation of the pathway will have applications in therapies and prevention for oxidative stress-related diseases. However, it is not easy to activate this pathway safely, because Nrf2-activating compounds themselves are highly reactive and toxic, and the toxicity may be enhanced under specific conditions. For example, we previously found that sulforaphane, a plant-derived Nrf2 activator, exerted Nrf2-independent toxic effects in combination with sodium arsenite. To circumvent the toxicity problems that have been disturbing smooth commercialization of this therapeutic strategy, we herein aimed to find a safe Nrf2 activator from the lineups of already-approved drugs. For this purpose, we used a zebrafish model, taking advantage of its usefulness in the in vivo assessment of biological actions of chemicals. Protective actions of two Nrf2 activators were evaluated: auranofin and dimethyl fumarate, which are approved therapies for rheumatoid arthritis and multiple sclerosis, respectively. After 12-hour pretreatment with these drugs, zebrafish larvae (4 days post fertilization) were exposed to oxidative stressors and subsequent survival rates were investigated. Although the protection by dimethyl fumarate was unclear, auranofin conferred strong protection against oxidative stress. Only 5.0% of zebrafish larvae survived 24-hour exposure to 2 µM auranofin. Survival rates were 71.6% when 2 µM auranofin was pre-treated. This protective effect was diminished in Nrf2 mutant strain, confirming that the action of auranofin was dependent on the activation of the Nrf2 pathway. In addition, auranofin pre-treatment attenuated toxicity of arsenite. Survival after 24-hour exposure to 1.5 mM sodium arsenite was 14.8%, while 2 µM auranofin pre-treatment raised the rate to 53.8%. This protective effect was also shown to be Nrf2-dependent by the genetic analysis. Importantly, auranofin did not show any combinatorial toxicity with arsenite, at least during 120-hour test period. These results clearly demonstrate that auranofin activates the Nrf2 pathway and confers strong protection against oxidative stress in a relatively safe manner.

Repositioning of this drug for oxidative stress-related diseases will provide a promising therapy.

Cinnamic Aldehyde as a Potential Therapeutic for Preventing Neointimal Hyperplasia in Diabetes

Diabetes Mellitus (DM) accelerates the rate of atherosclerosis. Balloon angioplasty is a common surgical intervention for treating athero-sclerotic disease. However, angioplasty often fails from vessel re-occlusion (restenosis) secondary to neointimal hyperplasia. Neointimal hyperplasia is the result of vascular smooth muscle cells (VSMC) proliferation and migration into the intima, a process driven by reactive species. Systemic redox dysfunction in DM leads to higher restenosis rates. Activation of the Nrf2-KEAP1 antioxidant defense pathway inhibits neointimal hyperplasia in animal models of vascular disease. Therefore, we hypothesize that a Nrf2 activator, cinnamic aldehyde (CA), will prevent neointimal hyperplasia by inhibiting VSMC migration and proliferation. VSMC were isolated and propagated from the aorta of male Zucker Diabetic Fatty (ZDF) rats. Cell viability was measured by MTT assay and flow cytometry. Migration was analyzed using the scratch assay. Nrf2 pathway activation was assessed by western blot and confocal microscopy. The balloon carotid injury model was performed in male ZDF rats after onset of DM. CA (100 µM) in Pluronic F127 (100 µl) or vehicle alone was applied to the perivascular surface of the carotid after injury. Arteries were harvested after 2 weeks for neointimal hyperplasia assessment, or after 3 days for BrdU incorporation and Nrf2 localization. CA inhibited VSMC proliferation by MTT (EC<sub>50</sub> = 23.9±19.5 µM). By flow cytometry, CA caused a 42% decrease in total cell number without changing percent viability (95.7%) or inducing apoptosis. CA inhibited platelet derived growth factor-induced migration by 42%. CA induced Nrf2 translocation to the nucleus and pathway activation both in vitro and in vivo. CA inhibited proliferation in vivo with a 47% reduction in the vessel proliferative index. Most importantly, CA inhibited neointimal hyperplasia with a 47% reduction in intimal area (P<0.025) compared to injury alone. CA effectively inhibited neointimal hyperplasia in our rat model of DM. Therefore, localized Nrf2 activation may provide a novel therapeutic target for inhibiting restenosis and improving surgery outcomes.

Ethanol Induces the Generation of Reactive Oxygen Species through NAPDH Oxidases (NOXs) and Mitochondria to Suppress Early Murine Osteoblast Differentiation In Vitro

J. Watt, K. Meredith, and M. Ronis. Louisiana State University Health Sciences Center, New Orleans, LA.

Bone marrow mesenchymal stromal cells (BM-MSCs) can differentiate into osteoblasts and adipocytes. Maturation of osteoblasts is associated with increased expression of factors such as alkaline phosphatase and osteopontin. NADPH oxidase (NOX) enzymes (e.g. NOX4 and NOX2), are expressed at different phases of osteoblast differentiation and produce reactive oxygen species (ROS). Both NOX4 and NOX2 are up-regulated by ethanol and are hypothesized to increase oxidative stress and suppress osteoblast maturation while upregulating bone-resorbing osteoclast differentiation. Mitochondria provide a significant source of ROS but the role of ethanol in mitochondria-induced oxidative stress in bone is not well established. These studies herein used BM-MSCs to model osteoblast and adipocyte differentiation in vitro to address the role of varied ROS sources in response to ethanol. BM-MSCs from WT and NOX4<sup>-/-</sup> C57Bl/6J mice were cultured in the presence of 50 µM l-asorbate phosphate to stimulate osteoblast differentiation, and treated with 0 or 50 mM ethanol. BM-MSCs from WT and NOX4<sup>-/-</sup> mice were exposed to ethanol and the mitochondrial antioxidant mitoTEMPO. At 14 days, fibroblast colonies and osteoblast differentiation were evaluated using hematoxylin and alkaline phosphatase staining, respectively. NOX4 deletion and mitoTEMPO co-treatment, but not NOX2 suppression (via deletion of p47phox), protected against ethanol's suppression of alkaline phosphatase-expression and Nrf2 localization. CA inhibited VSMC proliferation by MTT co-treatment, but not NOX2 suppression (via deletion of p47phox), protected against ethanol's suppression of alkaline phosphatase-expression and Nrf2 localization. CA inhibited VSMC proliferation by MTT and flow cytometry. Migration was analyzed using the scratch assay. Nrf2 pathway activation was assessed by western blot and confocal microscopy. The balloon carotid injury model was performed in male ZDF rats after onset of DM. CA (100 µM) in Pluronic F127 (100 µl) or vehicle alone was applied to the perivascular surface of the carotid after injury. Arteries were harvested after 2 weeks for neointimal hyperplasia assessment, or after 3 days for BrdU incorporation and Nrf2 localization. CA inhibited VSMC proliferation by MTT (EC<sub>50</sub> = 23.9±19.5 µM). By flow cytometry, CA caused a 42% decrease in total cell number without changing percent viability (95.7%) or inducing apoptosis. CA inhibited platelet derived growth factor-induced migration by 42%. CA induced Nrf2 translocation to the nucleus and pathway activation both in vitro and in vivo. CA inhibited proliferation in vivo with a 47% reduction in the vessel proliferative index. Most importantly, CA inhibited neointimal hyperplasia with a 47% reduction in intimal area (P<0.025) compared to injury alone. CA effectively inhibited neointimal hyperplasia in our rat model of DM. Therefore, localized Nrf2 activation may provide a novel therapeutic target for inhibiting restenosis and improving surgery outcomes.

Chronic ethanol abuse increases susceptibility to acute lung injury. Previous studies suggested that ethanol acts through one or more nicotinic acetylcholine receptor (nAChR) subtypes to induce expression of fibronectin, an extracellular matrix protein implicated in lung injury and disrepair. Culturing fibroblasts in media with an oxidized cysteine/cystine redox potential (Eₜ-Cys/CySS mimics the effect of ethanol, suggesting a potential mechanism by which ethanol activates these receptors. The purpose of the present studies was to investigate redox regulation of the α4 nAChR subtype in response to ethanol. Primary lung fibroblasts were isolated from α4 nAChR knock out and wild type mice. NIH 3T3 fibroblasts in which wild type or α4 nAChR was stably knocked down were used to express mutants of α4 nAChR. Fibronectin and CySS metabolizing genes were measured by real time-PCR. Intracellular and extracellular Cys, CySS, glutathione (GSH) and glutathione disulfide (GSSG) were measured by HPLC. Redox potentials (Eₜ) were calculated from the Nerst equation. Fibronectin mRNA levels were increased by 60 mM ethanol or 0 mM oxidized redox media. Lung fibroblasts from α4 nAChR knock out mice also had defects in CySS metabolism and distribution. Expression of the CySS transporter Slc7a11 was low, extracellular CySS accumulated, intracellular GSH levels dropped, and lower amounts of Cys and GSH were exported in cultures of α4 nAChR knock fibroblasts. Extracellular Eₜ-Cys/CySS of knock out fibroblast cultures was more oxidized than wild types, and total GSH concentrations in the conditioned media were lower. These results showed Cys residues on the extracellular surface of α4 nAChR mediated cellular responses to ethanol in primary mouse lung fibroblasts. Furthermore, these studies provide evidence for a feedback loop, wherein activation of α4 nAChR by extracellular oxidation up-regulates intracellular production and export of Cys and GSH, providing a means to restore the redox state of α4 nAChR and limit signaling.

2451 Evaluation of Positive Controls for In Vitro Assays of Oxidative Stress

P. Dunlap, J. Rice, S. Ramaiahgari, S. Ferguson, and M. DeVito. NIEMS, Research Triangle Park, NC.

Increases in oxidative stress plays a critical role in the carcinogenic process as well as many other toxicities. The evaluation of this study compared the dose-response relationship and time course for effects on cell viability, mitochondrial membrane potential, and oxidative stress in in HepaRG and HaCaT cells. Diquat, antimycin, menadione, tert-butyl hydroperoxide (TBHP) and etoposide were evaluated as positive controls in these assays. Potassium chloride and sucrose were used as negative controls. Cells were exposed for 1 or 24 hours, after which CellTiterGlo, ROSGlo, and JC-10 assays were performed and dose-response curves generated. These chemicals displayed unique dose- and time-response relationships. There was little difference in the response of the HepaRG and HaCaT cells to the test chemicals for all assays. Both antimycin and etoposide induced oxidative stress at one hour, but not at 24 hours of exposure. Induction of ROS by menadione was similar between the two-time points. Both diquat and TBHP induced greater ROS at 24 hours and at lower concentrations compared to one hour exposures. Decreases in cell viability, as measured by CellTiter-Glo occurred at one hour for antimycin and menadione but not with the other test chemicals. At 24 hours of exposure decreases in cell viability were observed for all chemicals except etoposide, KCl, and sucrose. At 1 and 24 hours antimycin, menadione, and diquat altered the MMP assay in both cell types, while it took 24 hours for TBHP to alter the MMP assay. While antimycin induced ROS, decreases in cell viability and alterations in MMP occurred at lower concentrations. Changes in viability, MMP, and ROS occurred at similar concentrations for menadione and diquat; however for diquat, the ROS and viability changes required 24 hours of exposure. These studies suggest that when evaluating ROS using in vitro assays, multiple time points and positive controls may be necessary due to the differences in potential mechanisms of oxidative stress induced by the chemicals under evaluation.

2452 Effects of Oxidants on Human Superoxide Dismutase (SOD)

J. J. Tao, and V. Mishin. Rutgers University School of Public Health, Piscataway, NJ.

Amyotrophic lateral sclerosis (ALS) is a progressive neurological disease, characterized by the gradual degeneration and death of motor neurons. In some dominant familial amyotrophic lateral sclerosis (FALS) pedigrees, mutations have been linked to a genetic defect for Cu, Zn-binding in superoxide dismutase (SOD). SOD catalyzes the dismutation of superoxide radical anion to hydrogen peroxide (H₂O₂) and oxygen (O₂). The modern view is that mutations in SOD1, the gene for Cu, Zn superoxide dismutase (CuZn-SOD), may be implicated in FALS. It is thought that the free radical generating activity by CuZn-SOD in the FALS mutant is enhanced relative wild-type human SOD possibly due to a decrease in the Kₘ value for H₂O₂. Previous reports also indicate that CuZn-SOD is capable of using high concentrations of H₂O₂ as a substrate to form hydroxyl radicals. In the present studies, we determined the treatment of human SOD with low concentrations of H₂O₂ (1-100 µM) in the absence of superoxide anion, SOD catalyzes the formation of hydroxyl radicals from H₂O₂. For these studies, we used a highly sensitive probe, diodeoxytrephephosphate (TPT), as a hydroxyl radical trap to quantify the formation of the free radical. TPT reacts with hydroxyl radicals to form 2-hydroxyterephthlate (2-OHTA)-H₂O₂ in a 1:1 ratio. 2-OHTA can be detected and quantified using a microplate reader with fluorescence detection (excitation and emission wavelengths, 310 and 425 nm). We found that SOD readily generates hydroxyl radicals from H₂O₂. Hydroxyl radical formation was time and concentration-dependent, concentrations of H₂O₂ used ranged from 1-100 µM. Hydroxyl radical formation was inhibited by the antioxidant, dimethyl sulfide. Based on these results, we conclude that human SOD is capable of catalyzing the formation of hydroxyl radicals from H₂O₂. In future experiments, we will use high performance liquid chromatography to determine if treatment of human SOD with lower, physiologically relevant concentrations of H₂O₂ also catalyzes the formation of hydroxyl radicals. This may be an area of further study to better understand the progressive nature of FALS and how SOD may be implicated in the disease process.

2453 Fracking Sand Dust Elicits ROS and Pro-Inflammatory Cytokines from Murine Macrophage Cells

A. Morris, N. Olguin, K. Russ, J. Fedan, and S. Leonard. NIOSH, Morgantown, WV.

Hydraulic fracturing is used in the majority of natural gas wells across the United States. Water, sand, and chemicals are delivered at high pressure to drilled wells to cause fractures in the shale formations, allowing for the release of natural gas. Fracking sand, comprised mainly of silica dioxide (SiO₂), along with water and chemicals, is used to keep these fissures open. Silicosis is a pulmonary disease that affects workers exposed to inhaled silica and is characterized by inflammation and fibrosis, causing a decrease in lung capacity. Fracking sand dust (FSD) is generated during preparation of fracting fluid for injection. In this study, murine macrophage cells (RAW 264.7) were used to investigate whether pro-inflammatory signals are associated with inhaled FSD (<10 µm). We hypothesized that soluble and insoluble components in the FSD would each play a unique role in initiating pro-inflammatory responses and cytotoxicity. FSD was washed in PBS two separate times, 5 d each time, allowing for any soluble material to be released. On the 10th day of washing, sand that was twice washed was re-suspended in PBS (10 mg/ml) so that comparisons could be made to a freshly prepared, unwashed mixture. Production of the hydroxyl radical (OH), measured with electron paramagnetic resonance (EPR), was the highest in unwashed sand, followed by PBS from the 5 d and 10 d washes. Unwashed FSD sand also generated the most intracellular reactive oxygen species and the response was significantly larger than that obtained from FSD re-suspended after two consecutive washes. Cells were treated with a 1.2 and 1:10 dilution of stock solution. Compared to PBS controls, the viability of RAW 264.7 cells decreased by 40% following exposure to FSD that was washed and re-suspended after 10 days, whereas unwashed sand decreased viability by 30% over a 24 h period. Finally, production of the pro-inflammatory cytokines TNFα, IL-1β, and IL-6 were measured using ELISA. While IL-1β and IL-6 production decreased with washing, TNFα production remained elevated. Our results indicate that FSD is cytotoxic to RAW 264.7 cells, as evidenced by decreases in viability, and stimulates intracellular ROS and OH production. The substantial differences in the production of cytokines stimulated by the soluble and insoluble components of FSD warrants future studies of the pro-inflammatory effects of the dust.
Diarhoea is one of the most common health conditions affecting people globally. However, less developed countries are most susceptible. Therefore, identification of new source of antidiarrhea drugs becomes one of the most prominent focuses in modern research. This study was aimed at evaluating the antidiarrhoea activity of methanol stem extract and solvent fractions of Terminalia catappa using two different animal models. Phytochemical screening was qualitatively performed on the methanol extract using standard method, followed by partitioning to get the chloroform and aqueous fractions. Antidiarrhoea effect was evaluated by stooling test using castor oil-induced mice and charcoal transit assay using rats. 100mg/kg, 200mg/kg, and 400mg/kg of the methanol extract and 80mg/kg and 50mg/kg of solvent fractions were used for both antidiarrhoea studies, while loperamide (10mg/kg) and atropine (0.6mg/kg) were administered as positive control, distilled water (2ml/kg) and normal saline (2ml/kg) were administered as negative control, respectively, for both animal models. However, the presence of phenol, alkaloid, flavonoid, tannins, terpenoids, steroids, and cardiac glycoside was observed. The plant extracts (methanol, aqueous, and chloroform) showed pronounced and dose-dependent antidiarrhoeal activity. Oral doses of 100, 200, and 400mg/kg of methanol extract showed percentage inhibition of 37.9%, 46%, and 100%, respectively. 80 and 50mg/kg of aqueous and chloroform fractions showed percentage inhibition of 14.7% and 9.3%, respectively, and were comparable to that of the reference drug, loperamide (10mg/kg). The methanol extract (100 and 200mg/kg) produced a decrease in intestinal transit (28.5% and 35.3%, respectively); the aqueous and chloroform fractions (80 and 50mg/kg) also showed decrease in intestinal transit (24.6% and 29.5%) and were comparable to atropine (0.6mg/kg). The results showed that the extract and fractions of T. catappa has a significant antidiarrhoeal activity, which supports its use in traditional herbal medicine practice.

Thiol-Containing Compounds Attenuate Oxidative Stress and Neuronal Hyperexcitability In Vitro

A. Sri Hari1, L. Liang1, D. Yang2, B. J. Day3,1, and M. Patel1.
1 University of Colorado, Aurora, CO; 2 The University of Hong Kong, Hong Kong, China; and 3 National Jewish Health, Denver, CO.

Chemical agents such as industrial chemicals, pesticides, and chemical warfare agents can induce uncontrolled seizure activity (neuronal hyperexcitability). Oxidative stress has been implicated as a pathogenic factor in the etiology of seizures and epilepsy. However, whether and how cellular redox status modulates neuronal hyperexcitability is unclear. We hypothesized that the modulation of cell redox status with thiol-containing compounds would decrease oxidative stress, and attenuate neuronal hyperexcitability in vitro. 3,3-dimercaptopropionic acid (DMP), a thiol-containing compound showed percentage inhibition of 14.7% and 9.3%, respectively, and were comparable to that of the reference drug, loperamide (10mg/kg). The methanol extract (100 and 200mg/kg) produced a decrease in intestinal transit (28.5% and 35.3%, respectively); the aqueous and chloroform fractions (80 and 50mg/kg) also showed decrease in intestinal transit (24.6% and 29.5%) and were comparable to atropine (0.6mg/kg). The results showed that the extract and fractions of T. catappa has a significant antidiarrhoeal activity, which supports its use in traditional herbal medicine practice.

Mechanistic Role of Human NQO1 Promoter Polymorphisms in Oxygen-Mediated Toxicity to Human Lung Cells

R. J. Burke, C. Chu, and B. Moothy. Baylor College of Medicine, Houston, TX.

Oxidative stress following exposure to high concentrations of inspired oxygen is a known risk factor in the pathogenesis of acute lung injury and bronchopulmonary dysplasia (BPD). NAD(P)H quinone oxidoreductase 1 (NQO1) is a phase II/antioxidant enzyme involved in the formation of reactive oxygen species. Previous reports have demonstrated that the A/C single nucleotide polymorphism (SNP) at -1221 of the NQO1 promoter resulted in decreased in vitro transcription of luciferase in room air, and following exposure to hyperoxic conditions. However, little is known regarding the functionality or role of SNPs in oxygen toxicity. In this investigation, we tested the hypothesis that H441 human lung cells transfected with plasmids containing the A/C SNP at -1221 in the NQO1 promoter will demonstrate less protection against oxidative stress, and attenuate neuronal hyperexcitability compared to cells transfected with wild type promoter constructs. Human NQO1 with a CMV, wild type (WT) or -1221 SNP-containing promoter was subcloned into the pcDNA3.1 plasmid and confirmed by DNA sequencing. Overexpression of NQO1 protein was confirmed by western blotting using H441 human lung cells transfected with NQO1-containing plasmids. Cell viability assays and cellular apoptosis assays were performed following incubation of control and NQO1 transfected lung cells in room air or 80% oxygen conditions for 24 hours. In another set of experiments human lung cells transfected with plasmids containing NQO1 were pretreated with BNF or sulforaphane prior to exposure to hyperoxia. Our results showed that cell viability was enhanced by transfection of cells containing the WT NQO1 promoter compared to the SNP-containing NQO1 promoter under hyperoxic conditions. Transfection with the WT NQO1 promoter, but not the SNP-containing NQO1 promoter was protective against hyperoxia-induced cell death. Additionally, Pretreatment with BNF or sulforaphane decreased cell death under hyperoxic conditions in cells transfected with the WT NQO1 or the SNP-containing promoter, but the extent of protection was lesser in cells treated with the latter. These results suggest that NQO1 expression driven by the -1221 C NQO1 promoter decreases cell oxygen toxicity compared to the WT promoter. Further studies could lead to development of rational strategies for the prevention and/or treatment of BPD in premature infants.

Suppression of Nonsense-Mediated MiRNA Decay under Environmental Stresses

F. Usuki1, M. Fujimura1, and A. Yamashita2. 1 National Institute for Minamata Disease, Minamata, Japan; and 2 Yokohama City University School of Medicine, Yokohama, Japan.

Nonsense-mediated mRNA decay (NMD) is a cellular mechanism eliminating mRNAs that harbor premature translation termination codons (PTCs). It is known that several stress-induced genes are NMD targets because of upstream open reading frame (uORF), alternative mRNA splicing that introduces nonsense codons, or uncharacterized mechanisms. The inhibition of NMD stabilizes these mRNAs and aug-
ments the cellular stress responses. Here we investigated the effect of environmental stresses such as methylmercury (MeHg) exposure and endoplasmic reticulum (ER) stress (thapsigargin (TPTG)) on the activity of NMD using mouse myogenic cells, rat cerebral cortical neuronal cells (CNC) and astroglial cells (AGC). NMD suppression, evidenced by upregulation of SlincR1 or GASS mRNA harboring PTC and phosphorylation of UPF1, was observed in MeHg treated myogenic cells and CNC whereas NMD suppression was weak in MeHg-treated AGC. In order to know the causative factor of stress-induced NMD suppression, the role of phospho-eIF2α/ATF4 pathway, a key pathway involved in adaptation to stresses, was investigated. Knockdown studies demonstrated that phosphorylation of eIF2α/ATF4 was an upstream factor of NMD suppression used under mild ER stress whereas ATF4 expression was not, suggesting that phosphorylation of eIF2α plays a role in the induction of NMD suppression. Further we investigated the effect of NMD suppression on cellular MeHg content. MeHg can be transported to cells as MeHg-cysteine complex via an anti-cystic transporter or transported through an ATP-binding cassette (ABC) transporter such as ABCC4 which functions the efflux of glutathione conjugates. We previously reported that integrated stress responses change the expression of these membrane transporters. Here we demonstrate that NMD suppression and ATF4 expression under mild ER stress affect the intracellular mercury content using synthetic siRNA-mediated knockdown study.

2458 Phosphorylation of eIF2α Promotes Cell Survival in Response to Benzo(a)pyrene Exposure

E. Smit, J. C. Kleinjans, and T. van den Beucken. Maasstricht University Medical Center, Maastricht, Netherlands. Sponsor: H. van Loeveren

Translational control is a mechanism which allows quick cellular adjustments promoting cell survival during stress situations such as hypoxia, starvation, and irradiation. Currently, the relationship between translational control and xenobiotic stress is poorly understood. In this study, the importance of the unfolded protein response (UPR) for cellular adaptation to the environmental carcinogen benzo(a)pyrene (BaP) was determined. Activation of the UPR results in phosphorylation of eukaryotic translation initiation factor 2 alpha (eIF2α) via the kinase PERK and subsequently affects global and gene specific mRNA translation. Mouse embryonic fibroblasts (MEFs) carrying the wild-type (WT) eIF2α allele or a severe to alanine mutant allele (SSA) were used in this study. SSA- MEFs cannot phosphorylate eIF2α and are therefore impaired in regulating mRNA translation upon UPR activation. We found that SSA- MEFs are 2.8 fold more sensitive to 10 μM BaP treatment compared with WT-MEFs in clonogenic assays. Furthermore, BaP exposure reduced cell proliferation to a larger extent in SSA-MEFs compared to WT-MEFs. To explain the differences in cell survival between SSA- and WT-MEFs DNA damage after BaP exposure was measured with the COMET assay. DNA damage in SSA-MEFs was increased after BaP exposure compared to WT-MEFs, suggesting that SSA-MEFs either accumulate more DNA damage or are impaired in DNA damage response upon exposure. We found no evidence of ROS formation after BaP exposure, nor did co-treatment with antioxidants rescue SSA-MEFs from BaP-induced toxicity. Overall, our study demonstrates the importance of signaling through eIF2α in the response to the classical chemical carcinogen BaP and suggests a connection between eIF2α signaling and the DNA damage response.

2459 The Role of a Novel Long Noncoding RNA in the Regulation of Sox9b and Its Contribution to TCDD-Induced Toxicity Endpoints

In zebrafish, sox9b has been determined to be one of the most-reduced transcripts upon activation of the aryl hydrocarbon receptor (AHR) by 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). We identified a novel long noncoding RNA named sox9b long intergenic non-coding RNA (slincR) located adjacent to sox9b, and previously demonstrated that slincR expression increases in an AHR2-dependent manner in response to multiple strong AHR ligands. SlincR is required for proper expression of sox9b and its known downstream targets, and reduced slincR expression significantly affects some aspects (i.e., neuromuscular and somitogenesis of elongation) of development. In the current study, we performed a comprehensive capture hybridization analysis of RNA targets (CHART) RT-qPCR to determine if slincR binds to the sox9b promoter, and found that slincR is enriched at the 5' untranslated region (UTR) of the sox9b locus in 48hpf DMSO and TCDD-exposed zebrafish. To understand slincR’s role in the TCDD-induced toxicity pathway, we performed RNA sequencing and clustered gene ontology enrichment analysis on 48hpf control and slincR morphants exposed to 0.1% DMSO or 1ng/mL TCDD. We identified significant enrichment in processes related to skeletal and cartilage development unique to TCDD-exposed control morphants, and angiogenesis and vasculature development unique to TCDD-exposed slincR morphants. To further investigate slincR’s role in TCDD-induced toxicity phenotypes, we evaluated the cartilage of TCDD-exposed 72hpf zebrafish, and found a significant difference in the structure of the craniofacial cartilage in slincR morphants compared to control morphants. Additionally, a blood hemorrhage screen showed that TCDD-exposed slincR morphants at 48hpf had a lower proportion of hemorrhaging compared to TCDD-exposed control morphants. We also mined unpublished and published data from 16 PAHs, and found 6 PAHs caused a significant increase in both cyt1a and slincR expression, of which 3 are from the EPA’s priority PAH list. Collectively, our results suggest that slincR regulates sox9b expression by binding to the 5'UTR of the sox9b locus, regulates cartilage development, contributes significantly to TCDD-induced angiogenesis, and is upregulated by multiple environmentally relevant PAHs. This study was supported by the SRF Grant P42 ES016465, NIEHS Core Center Grant P30 E000210, and NIHES Training Grant T32 ES007060.

2460 Hepatocyte-Specific Deletion of Tiparp Increases Sensitivity to Dioxin-Induced Hepatotoxicity and Lethality

D. Hutin1, G. Grimaldi1, H. Sööding1, A. Gomez1, S. Ahmed1, C. Lucas2, H. Nebbi2, D. M. Grant1, J. Matthews2, and S. Taether2. 1University of Toronto, Toronto, ON, Canada; and 2University of Oslo, Oslo, Norway.

The aryl hydrocarbon receptor (AHR) mediates diverse cellular responses to numerous phytochemicals, metabolites and environmental contaminants, such as dioxin (2,3,7,8-tetrachlorodibenzo-p-dioxin; TCDD). Dioxin causes a range of toxic responses in laboratory rodents, including thymic atrophy, hepatotoxicity and a lethal wasting syndrome. Although the mechanisms of dioxin-toxicity remain unknown, AHR signaling in hepatocytes is necessary for dioxin-induced liver toxicity. We have previously reported that loss of Tiparp, an ATP-dependent poly(ADP-ribose) polymerase (TIPARP/PARP7/ARTD14), an AHR target gene and mono-ADP-ribosyltransferase, increases the sensitivity of mice to dioxin-induced toxicities. To test the hypothesis that Tiparp is a negative regulator of AHR signaling in hepatocytes, we generated Tiparpfl/fl mice where exon 3 of Tiparp was flanked by loxP sites. Using Cre-lox technology, we created hepatocyte-specific Tiparp (Tiparpfl/flCreα/α) and full knockout mice (Tiparpfl/flCreα/α; referred to as Tiparp1/1) by crossing with mice expressing Albumin Cre or CMV Cre, respectively. Tiparpfl/1 mice given a single injection of 10 μg/kg dioxin did not survive beyond day 7 and 9, respectively, whereas Tiparp null mice treated with 100 μg/kg did not survive beyond day 3. All Tiparp1/1 mice survived the 30-day treatment. Tiparpfl/1Creα/α or Tiparp1/1 mice treated with 10 μg/kg dioxin displayed increased hepatotoxicity and hepatotoxicity as indicated by increased alanine aminotransferase activity compared with similarly treated wildtype mice. Tiparpfl/1Creα/α or Tiparp1/1Creα/α mice exhibited increased Ahr signaling denoted by increased expression of dioxin-induced gene expression. The ability of Tiparp to mono-ADP-ribosylate and repress AHR activity was also found to be conserved among dioxin-sensitive and insensitive species. Taken together, these data illustrate that Tiparp is a key negative regulator or repressor of AHR activity and its specific loss in hepatocytes is sufficient to increase the sensitivity to dioxin-induced hepatotoxicity and lethality. The data also reveal that the AHR-Tiparp axis is conserved among species.

2461 Nrf2 Regulates Redox-Responsive Transcription of HIF1A

S. Freeman1, S. Lachec2, and M. Slattery1. 1University of Minnesota Duluth, Duluth, MN; and 2University of Minnesota Medical School Duluth, Duluth, MN.

Reactive oxygen species (ROS) are important signaling molecules for the cell, however, if left unchecked, ROS can lead to sustained damage of cellular macromolecules and cell death. Fortunately, cells have evolved mechanisms to combat this potentially harmful condition. Nrf2 is a transcription factor that regulates the cellular response to oxidative stress. Once activated by ROS, NRF2 translocates to the nucleus and upregulates the transcription of dozens of potential target genes. Recently we found evidence that Hypoxia Inducible Factor 1α (encoded by HIF1α) transcription is controlled by NRF2 and ROS. Like NRF2, HIF1α is also a redox-responsive transcription factor, only it controls expression of an arsenal of proteins in response to hypoxia. We found that treatment with ROS inducing compounds (menadione and tert-butyl hydroperoxide) leads to significant increases in HIF1α expression in three cell types (HEPG, MCF7, and MDA-MB-231). For all three cell types, MDA-MB-231 cells treated with the EC50 of menadione had significantly increased rel-
The polymorphic nature of the human 3'IGHRR is polymorphic due to an invariant sequence (IS) mouse studies these enhancers are thought to collectively play a role. Each 3'IGHRR contains three enhancers (hs3, hs1.2, hs4). Based on production of immunoglobulins (Ig) is partially controlled by the Ig heavy chain gene (IgH). The IgH gene consists of two regulatory regions or transcription units. Each 3'IGHRR contains three enhancers (hs3, hs1.2, hs4). Based on mouse studies these enhancers are thought to collectively play a role in the regulation of IgH expression and class switch recombination to different Ig isotypes (IgG1-4, IgA1-2, IgM, IgE). The hs1.2 enhancer within the human 3'IGHRR is polymorphic due to an invariant sequence (IS) that is repeated one to four times in tandem. The polymorphic nature of the hs1.2 enhancer is of interest due to its association with human autoimmune disorders and its sensitivity to xenobogenous chemicals, including 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). Previous work in mouse models has shown TCDD-induced inhibition of the hs1.2 enhancer and 3'IgHRR, correlating with inhibition of secreted Ig. However, TCDD has been shown to activate the human hs1.2 enhancer and produce different effects on Ig secretion; i.e., decreased IgG and increased IgE. These results highlight the potential species differences in hs1.2 activity and 3'IgHRR function. Our objective is to understand the role of the hs1.2 polymorphism in the expression and production of different Ig isotypes and sensitivity to TCDD. Using CRISPR/Cas9 gene editing with an altered hs1.2 genotype that corresponded to changes in basal and stimulated IgM and IgG secretion, as well as changes in the different Ig isotypes with corresponding increases or decreases were determined utilizing new nanopore sequencing technology by which large intact amplicons (8-kb) can be sequenced without fragmentation. Implementation of this new sequencing technique has been vital for providing long-range sequencing data that is impossible to achieve with standard sequencing due to the redundant sequences within and flanking the hs1.2 enhancer. Ongoing efforts are focused on utilizing the hs1.2-edited clones to determine the role of the hs1.2 genotype in the sensitivity of each Ig isotype to TCDD. Connection of the functional effects to a specific genotype of the hs1.2 enhancer may influence the sensitivity of Ig expression to TCDD in humans.
cell culture screening model identified novel genes that are relevant for neuronal and astrocyte homeostatic adjustment to cellular energy loss. The established cellular screening model is also applicable for testing genetic variability outcome paradigms under various environmental or chemical exposure settings.

2466 LncRNA MALAT1 Regulates Xenobiotics-Induced Toxicity in Pancreatic Islets and Insulin Resistance

J Chen1, S Ke1, B Morpurgo2, A Golovka2, and Y Tian1. 1 Texas A&M University, College Station, TX; and 2Texas Institute of Genomic Medicine, College Station, TX.

The metasis-associated lung adenocarcinoma transcript 1 (MALAT1) is a long noncoding RNA and its overexpression is associated with the development of many types of malignancy. MALAT1 null mice show no overt phenotype. However, in transcriptome analysis of MALAT1 null hepatocytes and pancreatic islets we found significant upregulation of antioxidant related genes including nuclear factor-erythroid 2 p45-related factor 2 (Nrf2), Nqo1, Sod1, Nos2 with significant reduction in reactive oxygen species (ROS) as indicated by the suppression of carbonylation level in proteins from hepatocyte and islets. Nrf2 is a master regulator of the antioxidant genes and we performed LncRNA pulldown assay using biotinylated antisense oligonucleotides against MALAT1 and found MALAT1 interacted with Nrf2, suggesting Nrf2 is transcriptionally regulated by MALAT1. Exposure to excessive ROS has been shown to cause insulin resistance through activation of c-Jun N-terminal kinase (JNK) which leads to inhibition of insulin receptor substrate 1 (IRS-1) and insulin-induced phosphorylation of Akt. We found MALAT1 ablation suppressed JNK activity with concomitant insulin-induced activation of IRS-1 and phosphorylation of Akt suggesting MALAT1 regulate insulin responses. MALAT1 null mice exhibited favorable insulin-sensing response to fast-refeeding and glucose/insulin challenges and significant increases in insulin secretion in response to glucose challenge in isolated MALAT1 null islets, suggesting an increased insulin sensitivity. Based on the role of ROS in the development of T2DM, we developed a pancreatic islet cell-based assay for screening diabetogenic environmental chemicals. Using this method, we found that bisphenol A (BPA), Benzo[a]pyrene (Bap), and polychlorinated biphenyls (PCBs), could induce high level of ROS suggesting that they may potentially induce damage in pancreatic cells. In summary, we demonstrate that MALAT1 plays an important role in regulating insulin sensitivity and has the potential as a therapeutic target for the treatment of diabetes as well as other diseases caused by excessive exposure to ROS.

2467 Nuclear Receptor 4A1 (NR4A1) Ligands Exhibit Antidiabetic Activity in Pancreatic β-Cells

J Lee, Y Sun, and S Safe. Texas A&M University, College Station, TX.

Pancreatic β-cells play a key role in maintaining cellular homeostasis by sensing glucose levels and secreting insulin to maintain normoglycemia but in type 2 diabetes the β-cell function is compromised. In this study we used INS-1 rat β-pancreatic cells to investigate the antidiabetic activity of NR4A1 ligands. Real-time PCR and western blot analysis of INS-1 β-cells lysates show that NR4A1, NR4A2, and NR4A3 are expressed in these cells at the mRNA and protein level. RNA interference (RNAi) experiments show that knockdown of NR4A1 in INS-1 β-cells resulted in a >35% decrease in proliferation; whereas knockdown of NR4A2 (Nurr1) or NR4A3 (NurI) resulted in a 20% and <5% decrease in proliferation of INS-1 β-cells. In previous studies we identified 1,1-bis(3’-indolyl)-1-(p-hydroxyphenyl) methane (C-DIM8/DIM-C-pPhOH) as an NR4A1 ligand that exhibit selective NR4A1 modulator activities in cancer and non-cancer cell lines. C-DIM8 and related NR4A1 ligands decreased proliferation of INS-1 β-cells and thus resembled the responses observed after knockdown of the receptor. Incubation of INS-1 β-cells in low (3.3mM) and high (22.2mM) glucose resulted in an increase in secretion of insulin from these cells and co-treatments with C-DIM8 and related compounds further increased insulin secretion only in the cells maintained on high glucose. The role of NR4A1 and its ligands in modulation of stress-induced responses, mitochondrial respiration, and insulin secretion in INS-1 β-cells and other β-cell lines, the applications of bis-indole-derived NR4A1 ligands as a novel class of antidiabetic drugs will be discussed.

2468 Benzo(a)pyrene Regulates Gene Expression by Modifying mRNA Translation

Controlling mRNA translation initiation is an important mechanism for modulating protein expression, especially under stressful conditions that require rapid responses. Still, the relevance of translational control for the response to xenobiotics has been poorly addressed. Therefore, the goal of this study was to analyze the contributions of changes in mRNA translation to differential gene expression on a genome-wide scale. Primary rat hepatocytes were exposed to 1 and 10 μM benzo(a)pyrene for 1 and 24 hours. At each time point, mRNAs were isolated using sucrose gradients to obtain 4 fractions with increasing translation rates. Next, RNA sequencing was performed on these 4 fractions as well as on the total mRNA for each time point to determine gene-specific changes in mRNA translation. From these data, we determined both transcriptional changes (mRNA abundance) and translational changes (translated mRNA) in response to BaP. Surprisingly, 1h exposure to 10 μM BaP only resulted in differential gene expression for 4 genes due to changes in mRNA abundance and for 6 genes due to differential translation. While after 24h exposure to BaP, 190 genes were altered with respect to mRNA abundance (FDR<0.05) and +2000 genes were differentially translated. Based on this analysis we were able to distinguish 3 categories of genes; (i) genes with concordant changes in mRNA abundance and mRNA translation, (ii) genes with altered mRNA abundance only and (iii) genes with changes in mRNA translation only. GO term analysis showed that genes in the “mRNA translation only” category were involved in specific biological processes including translation, apoptosis and oxidation-reduction process. Genes from the “concordant” group were mainly associated with BaP metabolism and anti-oxidant response. To test the robustness of these findings we validated 3 genes from each category by means of qPCR. All 9 genes tested revealed similar expression changes. We are currently investigating the basis for this selective translation after BaP exposure. This includes the presence of upstream open reading frames within the 5’translated region of these genes. In conclusion, our data reveal that gene expression changes in response to BaP occur more on the levels of mRNA translational than on the level of mRNA abundance.

2469 Identifying Mitochondria Cell Signaling Networks by Functional Profiling

R. Zeidan1, H. Rapier1, A. Sobh1, M. Proctor1, J. Aris1, and C. Vulpe1.
1University of Florida, Gainesville, Fl; and 2University of California Berkeley, Berkeley, CA.

In order to maintain homeostasis and safeguard cellular fitness, permanent communication between the mitochondria and the nucleus, through tightly regulated signaling pathways, is indispensible. This ensures synchronizing the mitochondrial function with the ever-changing cellular requirements. Mitochondrial biogenesis is influenced by a myriad of intrinsic and extrinsic factors, where a complex network of pathways dictates the response. Such pathways include the anterograde, nucleus to mitochondria, and the retrograde, mitochondria to nucleus, communications. While the anterograde communications are more studied, little is known about the retrograde pathways. In our study we aim to explore mitochondrial-nuclear signaling centers using functional profiling on Saccharomyces cerevisiae, in an attempt to identify key components involved in responding to certain mitochondrial stressors. We individually targeted the mitochondrial electron transport chain complexes III, IV, and V by using complex-specific inhibitors, formic acid, and oligomycin, respectively. We screened a pool of ~4,600 different yeast mutants using the 20% inhibitory concentration (IC20s) of the mentioned compounds in YPL (2% lactate) media for three time points (5, 10, and 15 generations). Each yeast mutant is tagged with a unique barcode sequence that can be used to identify and quantify the abundance of the mutant by next-generation sequencing. By comparing barcode reads of vehicle controls to treated samples, we identified genes involved in the biological response to the mitochondrial dysfunction that play a major role in the capability of the yeast cell to survive the stress. Based on the results we speculate that the retrograde pathways are involved in the response to the stress produced by oligomycin since knockouts of genes involved in these pathways show increased sensitivity to oligomycin. On the other hand, deleting components of the EGO complex leads to oligomycin resistance while increasing sensitivity to formic acid. We also observed that the RIM pathway is involved in response to complex III inhibition but additional work should be done to confirm this link and understand how it works. Our work revealed stressor-specific differences in signaling requirements, suggesting a nuanced response to mitochondrial dysfunction and communication between the mitochondria and the nuclear genome.
2470 Circadian Regulation of AhR Induced Cyp1a1 Gene Expression Is Dependent upon P53 Binding Activity

E. E. Schmitt, R. Barhoumi, C. McQueen, and W. Porter. Texas A&M University, College Station, TX.

The circadian clock plays a key role in coordinating many biological processes including physiological processes and cellular metabolism and mitosis. Despite the fact that circadian rhythms are associated with critical biological processes, very little is known about their mechanism in carcinogen metabolism, endocrine disruptor activity and mammary carcinogenesis. Furthermore, recent studies have linked disruption of circadian rhythms in breast cancer cell lines to increased breast cancer risk, suggesting that, when working alternative shifts may have a higher risk of breast cancer. We have found that time of day, as well as individual circadian clock components, uniquely regulate processes governing polyaromatic hydrocarbon (PAH) metabolism in the mouse mammary gland and breast cancer cell lines. We have shown in vitro and in vivo that the pattern of PER1, BMAL1, and AhR-induced Cyp1a1 gene expression and PAH metabolism is similar to BaP-induced Cyp1a1 and Cyp1b1 gene expression. Despite time dependent regulation of Cyp1a1 gene expression, we found no change in AhR binding over time. Here we show that circadian regulation of p53 binding activity is responsible for time-dependent differences in Cyp1a1 and/or AhR induced target genes. Therefore, we hypothesize that a link between the circadian clock, specifically PER2 and p53, plays an essential role in PAH metabolism.

2471 Finding the Source of AhRR Expression in Whole Blood

J. Yee. University of Wisconsin-Madison, Madison, WI. Sponsor: C. Bradfield

The responsome is the collection of all physiological responses that can be influenced by the multitude of chemical and environmental stimuli to which humans are exposed. Understanding the responsome can be used to identify chemical exposures and determine their effects on human health. MiRNA can be used in this manner to serve as a biomarker of chemical exposure in human populations. We had previously proposed to define the human responsome though changes in gene expression caused by activation of the aryl hydrocarbon receptor (AhR) pathway in the blood of cigarette smokers, who chronically expose themselves to high levels of polycyclic aromatic hydrocarbons. We found that the aryl hydrocarbon receptor repressor (AhRR) gene was significantly upregulated in the two independent populations of cigarette smokers. In order to improve the sensitivity of the assay, we set out to determine if there was a specific cell type in the whole blood that was responding to the chemical insult. We created a model of AhRR induction in the mouse using beta-naphthoflavone (BNF), a nontoxic AhR agonist that more closely imitates PAHs than the classic AhR agonist 2,3,7,8-tetrachlorodibenzo-p-dioxin. Using our model of AhRR induction by BNF and magnetic cell separation and other techniques, we have determined that the AhRR induction occurs in a subset of the leukocyte fraction of the whole blood.

2472 Activation of PXR Modulates the Expression of Long Noncoding RNAs in Mouse Liver

J. L. Dempsey, and J. Y. Cui. University of Washington, Seattle, WA.

Long non-coding RNAs (lncRNAs) are novel regulators of cell physiology, including gene transcription and translation. Dysregulation of lncRNAs by environmental chemicals, such as heavy metals, solvents, and polycyclic aromatic hydrocarbons, modulate the expression of xenobiotic biotransformation related genes and may serve as novel biomarkers for exposure. However, little is known regarding the transcriptional regulation of lncRNAs. The pregnane X receptor (PXR/NR1I2) is a critical regulator of p53 binding activity, and may serve as important biomarkers for oxidative stress. Therefore, lncRNAs regulated by PXR activation and that they may be important regulators of xenobiotic metabolism.

PXR-DNA binding. Surprisingly, the most frequent PXR-DNA binding motif was direct repeat with a 1bp spacer (DR-1), but not DR-4 as was previously reported. Among lncRNAs induced by PCN, PXR was predicted to co-localize with hepatocyte nuclear factor 4 alpha (Hnf4α), nuclear receptor subfamily 2 group member 2 (Nr2z2/Tak1), Nr2f1 (Coup-Tf1), Nr2f6 (Coup-Tf3), peroxisome proliferator activated receptor gamma, and retinoid X receptors. There was limited overlap of PXR binding with the epigenetic mark for transcriptional activation (histone-H3K4-di-methylation, H3K4Me2), but no overlap with the epigenetic marks for transcriptional silencing (H3K27Me3 and DNA methylation). Among differentially expressed lncRNAs, 264 were in proximity of PCGS, and gene ontology and differentiation analysis using STRING showed an enrichment for response to oxygen-containing compounds. This study was among the first to demonstrate that lncRNAs are regulated by PXR activation and that they may be important regulators of xenobiotic metabolism.

2473 Myomir Regulation of Pulmonary Response to Smoking and Diet-Induced Obesity

M. Walcott1, K. L. Halvorson2, L. K. Siddens2, and S. C. Tilton2. Vassar College, Poughkeepsie, NY; and 2Oregon State University, Corvallis, OR.

Smoking and obesity are two of the most prevalent risk factors for human morbidity and mortality. We previously observed a combined effect of mainstream cigarette smoke and diet-induced obesity on markers of inflammation and oxidative stress in the lung of exposed mice. Recent literature suggests an important role for miRNAs in regulating acute inflammation in the lung associated with toxicity and chronic inflammation associated with lung disease and obesity. To better understand the specific role of miRNAs in response to both risk factors (individually and in combination), the expression levels of miRNAs in the lung of regular weight and diet-induced obese mice exposed to mainstream cigarette smoke were evaluated by RNA sequencing. A family of miRNAs, known as myomirs, was significantly lower (p<0.05) elevated in obese mice compared to regular weight mice and was subsequently repressed (q<0.05) in obese mice after exposure to cigarette smoke. Differential expression of myomir miR-133a/b, miR-1a, miR-206 by obesity and smoke was confirmed by quantitative PCR. Predicted gene targets of significantly altered miRNAs were integrated with expressed and quantitatively expressed mRNA gene expression to determine the functional consequences of miRNA regulation in mouse lung. Myomir regulation was associated with significant (p<0.05) alteration of inflammatory and immune response pathways in mouse lung suggesting they are important regulators of inflammation in the lung in response to environmental insult. Previously, myomirs have been associated with inflammatory myopathies and adipogenesis and were measured in plasma of COPD patients. These studies are the first to identify the role of miRNAs are regulators of inflammation and oxidative stress mechanisms in obese mice that may make them more vulnerable to environmental lung toxicants.

2474 Akt Involvement in p21 Activation Induced by Mitomycin C and Its Analog

Cancer with normal p53 activity is commonly treated with Mitomycin C (MC), an anti-tumor drug that treats a specific type of cancer, whose pharmacological mechanism has been studied thoroughly. MC is a well-known DNA alkylating agent, where alkylation occurs both monofunctionally and bifunctionally. When cells are treated with MC, the main DNA inter-strand crosslink (ICL) is generated. However, little is known regarding the transcriptional regulation of ICL. The pregnant X receptor (PXR/NR1I2) is a critical xenobiotic-sensing nuclear receptor that regulates the expression of many drug-processing genes. To test our hypothesis that ICLs are regulated by PXR in concert with PXR-targeted protein-coding genes (PCGs), adult male C57BL/6 mice were treated with corn oil or the PXR agonist PCN (n=3), and RNA from the livers were subjected to RNA-Seq using poly-A tail and TruSeq v3 chemistry (Illumina HiSeq2000). Data analysis and visualization was performed using R and the edgeR package. This p21 activation triggered by MC and DMC is p53 independent. The purpose of this study is to elucidate the signaling pathway that facilitates p21 activation in MCF-7 and K562 cells. The Akt signaling pathway plays an important role on p21 regulation by phosphorylating p21 at threonine 145 (T145), resulting in the cytoplasmic localization of p21 and its degradation. This study focused on revealing how Akt is involved in MC- and DMC- triggered p21 activation. The results exhibited that MC and DMC inhibited Akt activation in MCF-7 cells, but not in K562 cells. When the p53 expression of MCF-7 cells was knocked down by p53 shRNA, the inhibition of the Akt activation in MCF-7 cells was alleviated. This implied that the deactivation of Akt caused by MC and DMC was p53 dependent. When MCF-7 cells were pre-treated with the Akt acti-
High throughput in vitro toxicity testing of multitudinous chemicals across any number of biological endpoints allows for rapidly assessing human and ecosystem health impacts, thus reducing resources associated with traditional animal testing. For application in risk assessment, it is necessary to compare chemical concentrations sufficient to produce bioactivity in vitro with those capable of perturbing a relevant in vivo target, as determined by exposure factors and pharmacokinetic (PK) properties. This work presents a variety of computational approaches demonstrating how uncertainty in exposure and PK properties can influence application of in vitro dose-response data in risk assessment. First, qualitative screening of chemicals with in vitro acetylcholinesterase inhibition activity was achieved through in silico prediction of ADMET properties to assess potential for reaching the target enzyme. This analysis resulted in a 33% reduction in the number of candidates, and the remaining compounds were further ranked based on quantitative estimates of in vivo bioactivities derived using a PK/pharmacodynamic (PD) model. Next, with sufficient exposure and PK data, external points of departure were predicted for six thyroid peroxidase inhibitors using a physiologically based PK/PD model. It was found that investigating exposure, potency, or PK individually is insufficient for evaluating chemical risk. Finally, potential metabolites were predicted for chemicals shown to be inactive across eighteen estrogenic assays and validated in vitro assays, and ER binding activity for these potential metabolites was predicted using a quantitative structure activity relationship model. Of the 1,400 inactive parents investigated, 20% were found to have at least one metabolite predicted to be active. The integration of in vitro testing with computational approaches will help to improve confidence in evaluation of chemical risk by identifying those chemicals requiring no further testing and those inactive parents capable of producing potentially active metabolites. Novel Typing System of Bacteria by Their Intrinsic Ability to Utilize Amino Acids

C. Chou, C. Sung, and W. Hsu. National Chung Hsing University, Taichung, Taiwan.

Amino acids (AAs) are critical substances for nitrogen and carbon metabolism in bacteria. Different bacteria may have distinctive abilities in utilizing amino acids, depending on their genetic and biochemical differences. Therefore, the intrinsic ability for AAs consumption presents a novel mechanism to distinguish bacteria species by characteristic AAs consumption pattern. More than 50 bacterial strains, including isolates of Pasteurella multocida and Escherichia coli, Pasteurella multocida, Salmonella enterica and Pseudomonas aeruginosa, were evaluated for their intrinsic ability to consume 20 essential AA individually. The bacteria were cultured in minimum-nutritional media containing 3 mM of each AA for 18 hours and the supernatant was analyzed for the remaining AA concentration by flow-injection analysis. In a first phase, a subset of in vivo assays statistically associated with a specific in vivo outcome was selected and curated. Results of these assays were then used as descriptors of a machine learning model predicting the outcome of interest. In a second phase, QSR models were developed to predict each in vivo assay selected. Finally, the two types of models were linked to predict the in vivo outcome for a new chemical structure. QSR models allowed the prediction of in vivo bioactivities and these predictions were then used as input of the in vivo outcome predictive model. In general, each in vivo outcome of interest led to its own predictive model since the in vivo assays were chosen according to this outcome. This global approach relies on different choices for several key aspects (machine learning algorithms, bioassays selection methods, qualitative vs quantitative data, biological interpretation, etc.), which were assessed based on the first results obtained using public data. The evaluation of the approach was done using a reference dataset consisting of 418 compounds for which bioactivity data and chemical structures were available to predict hepatotoxicity observed in rat carcinogenicity studies.
Differentiation and subtyping of bacteria can be done by many approaches. In the present study, we demonstrated a novel bacterial differentiation system solely based on their amino acid (AA) consumption characteristics. The bacteria were cultured in minimum-nutritional medium containing single AA and a flow-injection analysis system emploting electrochemical detection was used to quantitate the AA consumption by bacteria. The results suggested that differential AA utilization profile presents a new approach to differentiate between (1) toxigenic vs non-toxigenic strains of Pasteurella multocida, (2) type A vs type D P. multocida, (3) different serovars of Salmonella enterica subsp. enterica, and (4) methicillin-resistant Staphylococcus aureus (MSSA) vs methicillin-resistant S. aureus (MRSA). The consumption of valine and methionine showed striking contrast between P. multocida toxin-producing and non-producing strains. P. multocida type A and type D strains utilized isoleucine, tryptophan, tyrosine, arginine and histidine in the opposite manner. Furthermore, five serotypes of Salmonella serovars and MSSA and MRSA as well, exhibited different AAs consumption preferences. In summary, different bacteria subtypes/groups may consume AAs differently and these characteristics were significant enough to afford the method as a new bacteria subtyping system. Further studies are warranted and may prove that the AA utilization profile has a great potential to be an alternative tool for subtyping/grouping of bacteria that are not conveniently identified with traditional methods.

Measurements of In Vitro Neural Network Activity Are Influenced by the Number of Electrodes in Micro-Electrode Arrays

B. S. Lynch, C. M. Grant, C. M. Mack, and T. J. Shafer. New York University, Brooklyn, NY; North Carolina State University, Raleigh, NC; and US EPA, Durham, NC.

Multi-well micro-electrode array (mwMEA) recordings are used to screen compounds for the potential to disrupt neural network function. Conventional MEA formats use 60-64 electrodes to detect and record activity within a neural network, but mwMEA plates have different well configurations containing varying numbers of electrodes (i.e., 12-well = 64 electrodes/well, 48-well = 16 electrodes/well, 96-well = 8 electrodes/well). It is unclear how measures of neural network activity may be influenced by the number of electrodes used to collect the data. Therefore, the goal of this study was to determine how network activity parameters changed depending on the number of electrodes used to measure network function. The present study used 12-well mwMEA plates (n=2) to measure two network parameters: mean firing rate (MFR) and network spikes (NwSpk). Rat primary cortical cells express stable spontaneous electrical activity after 12-15 days in vitro (DIV) in the form of individual spikes and bursts. On DIV 14 or 34 initial baseline (BL) data were recorded and MFR and NwSpk, number of electrodes (#AE), and concentration were calculated and analyzed using an in-house analysis program. Next, BL recordings were further analyzed by using an R-script to randomly eliminate data from 4 to 60 electrodes, in sets of 4. This R-script analysis was repeated 10 times, in efforts to increase accuracy of the computational analysis. For BL recordings, MFR was not influenced by the number of electrodes used to determine network parameters. By contrast, although NwSpk was also constant across different numbers of electrodes, it become inconsistent once data from more than 48 electrodes were eliminated. Post BL, cortical cells received either lindane (1μM) or verapamil (10μM) to determine if fewer electrodes alters the detection of chemically induced network changes. Although lindane increased and verapamil decreased MFR as expected, there was no correlation with numbers of electrodes. However, NwSpk showed a similar response as untreated cultures. These results indicate that investigators should carefully consider the mwMEA format selected when designing experiments, particularly if network parameters will be evaluated. Computational Integration of Human Genetic and Toxicological Data to Evaluate Adverse Outcome Pathway-Specific Susceptibility

H. Mortensen, and S. Euling. US EPA, Research Triangle Park, NC.

There is a need for approaches to define human variability and susceptibility in response to environmental chemical exposure. Direct estimation of the genetic contribution to variability in susceptibility to environmental chemicals is only possible in special cases where there is an observed association between exposure and effect (e.g., genotype and phenotype information). The availability of genetic and toxicological data sources makes it possible to indirectly estimate the relative contribution of genetic variability to differential human susceptibility. We developed a computational workflow that integrates genetic and toxicological resources. This approach implements the adverse outcome pathway (AOP) framework in order to integrate molecular targets associated with AOPs with functional genomic annotations and population allele frequencies. Resources include the EPA internal Adverse Outcome Database (AOP-DB), and publicly available resources, such as the AOP-wiki, Ensembl genomic annotations, expression quantitative trait loci identified by the GTEx consortium, and 1000 Genomes Project. With this information it is possible to formulate predictions of genetic susceptibility built upon established toxicological and genetic knowledge that are specific to an adverse outcome. The computational workflow was developed in R and built around the Ensembl database interfaces (REST API and biomaRt R package). It downloads, integrates, and analyzes the data from different data sources using a computational pipeline that is based on the AOP framework. The computational workflow integrates both genetic and toxicological information, from which predictions of genetic susceptibility are derived. The tool is available as an online portal at https://www.epa.gov/toxtools/aopdb. The tool provides predictions of genetic susceptibility that are specific to an adverse outcome. Applying a Tiered Risk-Based Approach to Prioritizing Thousands of Chemicals for Further Evaluation: A Comparison of Current High-Throughput Computational Approaches

C. L. Nicolas1, K. Mansouri1, P. D. McMullen1, B. A. Clewell1, M. Yoon1, M. B. Phillips1, G. Patlewicz2, and H. J. Clewell1.
1SciToVation, LLC, Research Triangle Park, NC; and 2US EPA, Research Triangle Park, NC.

Current computational technologies offer novel opportunities to help in the prioritization of chemicals for toxicity testing. Here, we present a tiered risk-based approach using an initial triage based on the ratio between high-throughput exposure estimates and thresholds of toxicological concern (TOCs), followed by automated read-across to identify suitable analogues for identifying potential endpoints and potency estimates. To demonstrate the applicability of TTCs for the initial triage, 300+ ToxCast chemicals were processed as follows: 1) oral equivalent doses (OEDs) were calculated based on ToxCast bioactivity measurements and available metabolism data for estimating in vivo clearance, 2) TTC values were determined using the Cramer classification system, 3) OEDs and TTCs were then compared with available ExpoCast exposure estimates to determine their respective activity/exposure ratios (AERs). This evaluation demonstrated that TTCs could serve as a reasonable basis for further prioritizing compounds. The TTC approach was then applied to the Collaborative Estrogen Receptor Activity Prediction Project (CERAPP) database, a set of ~45,000 chemicals. An in-house read-across tool was used to identify suitable analogues for the top prioritized chemicals based on available experimental and predicted data. Potential analogue identification was guided by categorizing the CERAPP compounds into structural classes (e.g., carbamates) using SMARTS. This resulted in 17 structural classes with at least 13 chemicals for which predicted and measured bioactivity data were publicly available. We also identified an optimal combination of chemical descriptors that were predictive of bioactivity across specific endpoints (e.g., estrogen receptor, skin sensitization). We then interrogated the impact that various combinations of descriptors may have on identifying regions of chemical space that might be amenable to read-across. Our endpoint specific read-across approach employed supervised machine learning for optimal analogue selection for AER-ranked compounds. This study demonstrated the utility of exploiting computational approaches as part of a tiered risk-based approach to prioritize thousands of chemicals. Automated Analyses of Dendritic Morphology in Rodent Primary Neuronal Cell Cultures

Altered dendritic morphology is associated with neurodevelopmental disorders (NDDs); thus, primary neuronal cell cultures are a useful in vitro model for studying NDD pathogenesis. However, analyzing dendritic morphology is challenging due to the structural complexity of dendrites, particularly when grown at high density. Low-efficiency transfection for microtubule-associated-protein-2B to label a small percentage of neurons overcomes some difficulties; however, image analysis remains challenging as it involves manually tracing processes. Alternatively, dendritic morphology is assessed using Sholl analysis where the user chooses individual neurons, defines a center point and thresholds manually. Automated software superimposes concentric rings around the center point, determines the number of dendritic intersections at each ring, and generates a distribution plot. Both methods are time-intensive and suffer from thresholding bias. Therefore, we developed new software, which has been added to the previously published Omnisphero software, for automated identification and thresholding of neurons, analysis of neurite mass, total neurite length, number of primary processes, average neurite length, number of branching points, number of terminal tips, and Sholl analysis. First, neurons are identified and binarized, at which point the researcher is able to manually annotate neurons of interest or delete identified neurons. This allows analysis of specific neuronal subpopulations, like pyramidal neurons, which will be a valuable asset for machine learning approaches. Second, only selected objects are analyzed. This method eliminates bias associated with tracing and thresholding, decreases evaluation time and provides an interactive user interface, allowing the user to manually judge and refine the analysis. The increased rate of analysis also enables an increased number of neurons to be analyzed, thereby increasing statistical power. Manual vs. automated analysis of sex differences in murine neurons results in the same statistical effects in Sholl analysis. Automated analysis additionally identified significant effects in number of branching points and neurite length. These data suggest the potential for this software to increase sensitivity and decrease bias in morphometric analyses of dendritic arborization. Supported by NIEHS (RO1 ES014901; PJL, T32 ES007059-55), NICHD (F32 HD088016; KPK).

Structural Changes of Androgen Receptor Ligand-Binding Domain Due to Antagonist Binding Elucidated by Long-Time Molecular Dynamic Simulations

H. Hong. US FDA/NCTR, Jefferson, AR. Sponsor: W. Tong

Androgen receptor (AR) is one of the important receptors for assessing endocrine-disrupting potential of chemicals. Ligands binding to AR induces conformational changes in AR-LBD (ligand-binding domain) that affect the binding of co-regulator proteins and DNA to AR. Three-dimensional (3D) structures of AR-antagonist complexes are helpful to understanding of androgenic activity of chemicals using various computational techniques. Unfortunately, wild-type(WT)-AR-LBD complex with an antagonist is not available in the protein data bank. Hence, we applied molecular docking and MD simulations to identify the important residues involved in the structural changes due to antagonist binding. Molecular docking was carried out to find a suitable binding orientation of the antagonist (bicalutamide) in the ligand-binding pocket (LBP) of AR-LBD. The complexes of WT-AR-LBD with bicalutamide, WT-AR-LBD with agonist (R1881), and mutant-AR-LBD with bicalutamide obtained from molecular docking were optimized through long time, 1 micro-seconds (μs), MD simulations to identify the conformational changes in LBP and activation function 2 (AF2) site of AR. The results revealed that the binding of WT-AR-antagonist in WT-AR-LBD moved residues in H12 (Phe222, Met226, and Ile230) and Arg726 outward when compared with WT-AR-LBD-agonist. This displacement of residues in H12 moved the helix outward and Arg726 and distorted AF2 site which plays a major role in binding of co-regulators. The structural changes elucidated in our study could be helpful to gain a structural insight of WT-AR-LBD-antagonist and are expected to facilitate development of in silico predictive models for assessment of endocrine-disrupting potential of chemicals. A Targeted Approach toward Enhancing Salmonella Mutagenicity QSAR Models for Regulatory Use

C. Mayer-Bacon, M. T. Kim, N. Kruhlak, and L. Stavitskaya. US FDA, Silver Spring, MD.

The International Conference on Harmonisation (ICH) M7 guidelines describe the use of (quantitative) structure-activity relationship (q(2)SAR) models to assess the mutagenic potential of drugs in the early stages of drug discovery and development. As the number of new and generic drug products increases, there is a need for optimal predictive performance and utility, models need to be continually updated with new data to ensure coverage for new drug substances entering the regulatory pipeline. Additionally, limitations in predictive performance caused by inadequate structural representation in selected areas of chemical space should be addressed. A targeted approach to enhancing a training set ensures that the existing performance of a model is maintained for well-represented areas of chemical space, while areas with few or no structural examples are improved upon. To this end, data were harvested from published literature (n=326), FDA approval packages for drugs approved between 2009 and 2017 (n=159), Center for Food Safety and Applied Nutrition databases (n=111), the Japanese Ministry of Health, Labor and Welfare databases (n=501), and through data sharing efforts (n=53). After removing duplicates, mixtures, salts, and inadequately tested chemicals, 521 compounds were selected to support the current FDA Center for Drug Evaluation and Research training set. Through real-time application of the Salmonella mutagenicity models for internal assessments, 17 sub-structural features were identified as un- or underrepresented and 315 compounds containing functional groups such as internal iminal dialdehydes and hindered epoxides were added to the training set from the harvested dataset. Additionally, an external validation set of 442 drug impurities representing proprietary pharmaceutical space was constructed from FDA submissions. This dataset was used in conjunction with other benchmark datasets (n=6,040) to confirm that data gaps were filled while high predictive performance was retained by the model. This effort represents a major enhancement to (QSAR) models that are recommended for use under ICH M7, leading to improved patient safety through greater predictive accuracy and applicability when assessing the mutagenic potential of drug impurities.
2492 A Machine Learning Model for Prediction of Compound Mode-of-Action from Toxicogenomics

Genome-wide gene expression (transcriptomics) studies provide an attractive means of evaluating chemical toxicity because of the rapidity with which they can depict the profiles of genes affected by a compound, transcriptomic studies can yield essential information on mode of action. Furthermore, transcriptional responses are predictive of the dose that will lead to cell and tissue toxicity; chemicals that cause positive responses in classical apical endpoints in vivo (i.e., the two-year rodent bioassay) evoke gene expression changes at corresponding exposure levels. Here, we present a computational model for relating chemical modes of action based on the expression responses they evoke in primary rat hepatocytes. The model is trained using a subset of the 170 compounds tested in the TG-GATEs library, many of which are “reference” agents with well-defined modes of action. In some cases, compounds with similar modes of action demonstrated shared patterns of enriched transcriptomic pathways in Gene Ontology. For example, the similarity index (here, a modified Jaccard index) is 0.56 between PPARalpha agonists fenofibrate and Wy-14,643. In contrast, the average similarity index was 0.20 between randomly chosen compounds. To understand whether artificial intelligence could aid in the classification of compound mode of action, we trained seven distinct machine learning models on compounds representing four modes of action: PPARalpha agonism, CAR agonism, estrogen receptor binding, and genotoxicity. Samples with different exposure times and concentrations were treated as independent. As inputs, we used quantitative gene expression changes and enriched Gene Ontology pathways. Model performance was evaluated using 10-fold cross validation. The two top performing models were Logistic Regression (mean accuracy: 0.96) and Gaussian Naive Bayes (mean accuracy: 0.89). In nearly every case, models based on continuous gene expression changes outperformed models based on Gene Ontology pathways. We are currently evaluating the utility of these predictive models with independent validation data sets from 2D and 3D in vitro models and in vivo liver studies. By leveraging recent developments in computational and bioinformatic tools, we expect this approach to improve early decision-making about chemical safety.

2494 Pathway Analysis and Mode-of-Action Prediction Based on Computational Modeling of High-Throughput Toxicogenomics

S. Haider, K. Mansouri, M. B. Black, and P. D. McMullen, ScitoVation, LLC, Research Triangle Park, NC.

The utility of transcriptomic data for interpreting cellular modes-of-action (MOA) after exposure to chemicals has been established for over a decade. It is conventionally performed by whole transcriptome gene expression tools such as microarray and next-generation sequencing (RNA-seq). However, for the toxicity assessment and testing prioritization of chemicals, there is a pressing need for efficient alternatives such as high-throughput transcriptomics (HTT). The goal of this study was to develop suitable HTT computational models for evaluating the diverse cellular modes of action of environmental, pathological, and agricultural chemicals. As a proof of concept, we used Genometry’s L1000 platform to demonstrate the possibility for establishing statistical relationships between genes and to infer whole genome transcriptional profiles. Then we developed a qualitative MOA-oriented strategy to predict relevant cellular pathway information and applied it to Affymetrix array data collected from three human cell lines HepG2, MCF7, and A549 exposed to three aromatic amides (misonidazole, fenbucouznole, and 2,4-dichlorophenoxoxacyclic acid) over nine concentrations. To avoid commonly encountered pitfalls from comparing different technologies and to increase prediction accuracy, we built three-class categorical models predicting up-regulated, down-regulated and unchanged genes essential to the cellular MOA. This work was then extended to predict gene expression changes resulting from exposure to heterogeneous chemicals from a wide range of classes. The models were developed using the Open TG-GATEs database providing toxicogenomics data of multiple cell lines for over 900 samples covering 170 compounds. Different machine learning techniques were used to identify a set of landmark genes which can predict differential expression changes of the genomic profile. A 10-fold cross validation balanced accuracy of ~65% was reached compared to a correlation coefficient of 42% with continuous models. The predicted and actual Affymetrix pathway enrichment profiles for HepG2 cell line in response to 0.01 μM Fenbucouznole showed the 22 (out of 39) highest enriched pathways in common. Such models can be used for MOA prediction and pathway analysis to prioritize large libraries of chemicals starting from gene expression data of representative genes.
A Non-Parametric Approach for Selecting Benchmark Responses for In Vitro or Alternative Animal Model Data

J. Hsieh1, J. Lin1, A. Sedykh2, F. Parham3, A. Shapiro4, N. S. Sipes4, K. Ryan4, M. Behl4, R. S. Paulus4, and S. S. Auerbach4. 1Kelly Government Solutions, Research Triangle Park, NC; 2US FDA, Silver Spring, MD; 3Scime LLC, Research Triangle Park, NC; and 4NIETHS, Research Triangle Park, NC.

Benchmarks provide a way to compare alternative data to validate standard benchmarks. It is well known that the toxicity response of the genotoxicity endpoint is highly variable. Common approaches to evaluate drug toxicity, such as genotoxicity, are expensive and time-consuming. In this study, we present a comprehensive set of QSAR models built using a previously-reported downsampling method to improve sensitivity while maintaining structural coverage. The set of models consists of effects on male and female fertility in mice and rats, sperm toxicity in mice and rats, newborn behavioral toxicity in mice and rats, rat keratination, and rat and rabbit reproductive toxicity. For this work, an enhanced, high-throughput method for predicting DART endpoints based on chemicals based on chemical structure.

In Europe, increased requirements for pesticide registration and the drive to reduce animal use have increased the use of in silico tools to predict potential genotoxicity of impurities and metabolites. Today, at least one rule-based and one statistical system are required, and emphasis is put on reliability of predictions. In order to choose the most reliable in silico systems, Bayer agrochemical substances were entered into the genotoxicity models in Derek Nexus, Toxtree, TopKat, Leadscope, and Vega, to compare the in silico prediction to the experimental outcomes for each substance. In this study, we present a comprehensive set of QSAR models for DART endpoints based on predominantly negative data are limited or unavailable. An earlier generation of QSAR models was developed for DART endpoints based on predominantly negative training data. The datasets contained only 10-30% positives, yielding models with high specificity and negative predictivity, but low sensitivity. In this study, we present a comprehensive set of QSAR models built using a previously-reported downsampling method to improve sensitivity while maintaining structural coverage. The set of models consists of effects on male and female fertility in mice and rats, sperm toxicity in mice and rats, newborn behavioral toxicity in mice and rats, rat keratination, and rat and rabbit reproductive toxicity. For this work, an enhanced, high-throughput method for predicting DART endpoints based on chemicals based on chemical structure.

Reliability of In Silico Genotoxicity Predictive Software for Bayer CropScience Chemistry

E. B. Shipp1, and A. Hueser2. 1Bayer SAS, Sophia Antipolis Cedex, France; and 2Bayer CropScience, Monheim am Rhein, Germany. Sponsor: A. Blacker

In Europe, increased requirements for pesticide registration and the drive to reduce animal use have increased the use of in silico tools to predict potential genotoxicity of impurities and metabolites. Today, at least one rule-based and one statistical system are required, and emphasis is put on reliability of predictions. In order to choose the most reliable in silico systems, Bayer agrochemical substances were entered into the genotoxicity models in Derek Nexus, Toxtree, TopKat, Leadscope, and Vega, to compare the in silico prediction to the experimental outcomes for each substance. In this study, we present a comprehensive set of QSAR models built using a previously-reported downsampling method to improve sensitivity while maintaining structural coverage. The set of models consists of effects on male and female fertility in mice and rats, sperm toxicity in mice and rats, newborn behavioral toxicity in mice and rats, rat keratination, and rat and rabbit reproductive toxicity. For this work, an enhanced, high-throughput method for predicting DART endpoints based on chemicals based on chemical structure.

New QSAR Models for Developmental and Reproductive Toxicity with Enhanced Sensitivity

D. P. Russo1, 2497 K. Zorn1, A. M. Clark1, A. Korotcov4, V. Tkachenko6, H. Zhu2, and S. Ekins1. 1Collaborations Pharmaceuticals, Inc., Raleigh, NC; 2Rutgers, The State University of New Jersey, Camden, NJ; 3Molecular Materials Informatics, Inc., Montreal, QC, Canada; and 4Science Data Software, LLC, Rockville, MD.

Drugs entering the regulatory pipeline may require non-clinical evaluation of their potential to cause developmental and reproductive toxicity (DART), which is performed through a standard battery of in vivo assays described in International Conference on Harmonisation (ICH) guidance. These in vivo assays include the assessment of male and female reproductive toxicity in rodents and behavioral abnormalities and fetal dysmorphogenesis in teratology studies. They are intended to provide an assessment of the potential effects on human fertility, reproductive viability, as well as effects on the fetus in female patients exposed to the drug through clinical use. Quantitative structure-activity relationship (QSAR) models may be used as early screening tools during drug development and to support regulatory safety decisions. As QSAR data are limited or unavailable. An earlier generation of QSAR models was developed for DART endpoints based on predominantly negative training data. The datasets contained only 10-30% positives, yielding models with high specificity and negative predictivity, but low sensitivity. In this study, we present a comprehensive set of QSAR models built using a previously-reported downsampling method to improve sensitivity while maintaining structural coverage. The set of models consists of effects on male and female fertility in mice and rats, sperm toxicity in mice and rats, newborn behavioral toxicity in mice and rats, rat keratination, and rat and rabbit reproductive toxicity.
In recent years, transcriptomics has become a powerful tool in predictive toxicology and contributed much to our understanding of the molecular and cellular mechanisms of chemical toxicities. However, even with the modern highly parallel assay systems, large-scale experimental acquisition of transcriptomic data is still costly. Thus, it is an appropriate target for the development of a computational structure-activity relationship (QSAR) modeling that has been used to predict a wide range of chemical-induced biological responses. However, QSAR has not been utilized to model chemical-induced genome-wide gene expression changes until very recently, owing to the complexity of training and evaluating a very large number of models. To address this issue, we examined the performance of variable nearest neighbor (v-NN) method that uses information of near neighbors conforming to the principle that similar structures have similar activities. Using a dataset of gene expression signatures of 13,150 compounds derived from cell-based measurements in the NIH Library of Integrated Network-based Cellular Signatures program, we were able to make predictions for 62% of the compounds in a 10-fold cross validation test, with a correlation coefficient of 0.61 between the predicted and experimentally derived signatures—a reproducibility rivaling that of high-throughput gene expression measurements. To evaluate the utility of the predictions, we compared them with experimentally derived signatures in their ability to flag drugs known to cause specific human organ injuries. Overall, the predicted and experimentally derived signatures had similar receiver operating characteristics across three human organ injury models. Detailed analyses of enrichment curves indicate that the gene expression signatures predict toxicological mechanisms by which environmental exposures affect human health. Our results demonstrate that the v-NN method can serve as a practical approach for modeling large-scale, genome-wide, chemical-induced gene expression changes.

The Comparative Toxigenomics Database (CTD; http://ctdbase.org) is a premier public resource that helps illuminate the molecular mechanisms by which environmental exposures affect human health. CTD’s literature-based content is derived from four manually curated modules: toxicogenomic core (chemical-gene interactions), disease core (chemical-gene associations and human andlevant gene-disease associations), experiment (environmental stressor-receptor-event-outcome statements), and our new phenotype module (chemical-induced modulations of cellular and physiological traits). At CTD, we distinguish between phenotypes and diseases, wherein a phenotype refers to a non-disease-term biological event: e.g., decreased cell cycle arrest (phenotype) vs. lung cancer (disease), increased fat cell proliferation (phenotype) vs. obesity (disease), decreased spermatocyte division (phenotype) vs. male infertility (disease), etc. All CTD chemical-phenotype interactions are noted in a structured format using controlled terms for chemicals, phenotypic processes (Gene Ontology), taxon, and anatomical descriptors. These terms are from established and experimentally validated resources that include synonyms and accession identifiers (allowing terms to be computationally processed and mapped to additional vocabularies for database interoperability). To date, we have manually curated over 18,500 scientific articles for this module, producing 105,000 interactions that associate 6,260 chemicals to 1,700 phenotypes for 680 anatomical terms in more than 200 comparative species. Integrating this information with CTD’s extensive chemical-disease content allows novel connections to be inferred between phenotypes and diseases, yielding potential insight into the biological processes of a pre-disease state, before the clinical manifestation of a toxicogenomic disorder. As well, integrating all four CTD modules furnishes unique opportunities to generate computationally predictive adverse outcome pathways (AOPs), linking chemical-gene molecular initiating events, phenotypic key events, diseases, and population-level health outcomes. To our knowledge, this is the first comprehensive set of manually curated, literature-based, contextualized chemical-phenotype data provided to the public.

Image-based phenotypic profiling is a high-throughput screening method which combines automated microscopy and image analysis workflows to measure a large variety of features at the single-cell level. Such methods have been used for functional genomics studies and in the pharmaceutical industry for compound efficacy and toxicity screening. Here, we describe the initial steps in optimization, miniaturization, and application of a microfluidics-based laboratory workflow and image-based phenotypic profiling assay for use as a bioactivity screen for environmental chemicals. MCF7 cells were plated in 384-well plates (2,500 cells / well) using a MultiFlo FX tool. After 24 h, cells were treated with 7 concentrations (0.02-100 μM, n = 3/plate) of 16 reference compounds in a randomized pattern using an Echo 550 acoustic dispenser. After 48 h of treatment, cells were live-stained with MitoTracker (mitochondria), fixed, permeabilized and stained with Hoechst-33342 (nuclei), SYTO14 (nucleoli) and fluorescent conjugates of phalloidin (actin cytoskeleton), wheat germ agglutinin (Go1gi / plasma membrane) and concanavalin A (ER). Images were acquired using a Cellomics ArrayScan XTI and analyzed using CellProfiler software, yielding >1,000 features per cell. Cell level data were MAD normalized using DMSO controls. A screening threshold for effects was established as median +/- 2 units from control. A multiplexed cell viability and apoptosis assay was run in parallel. Examples of effects observed at non-cytotoxic concentrations included: berberine chloride affecting intensity and texture measurements in the mitochondria channel, fenbendazole altering intensity measurements in the DNA channel and tetrabenazine affecting intensity, radial distribution and texture measurements in the mitochondria and Golgi/membrane channel. The measured changes were confirmed by visual inspection of the images. In summary, the described protocol was successfully applied to MCF7 cells using automated liquid handling tools. Testing of diverse compounds yielded distinct patterns of affected parameters below the threshold for cytotoxicity, indicating that the assay can detect toxicant-specific effects and may be used to group (fingerprint) toxicants with similar profiles. Future efforts will include screening of additional chemicals and cell lines. This abstract does not necessarily reflect US EPA policy.

The past decade has seen significant research and regulatory initiatives devoted to the ultimate objective of supplanting in vivo toxicity studies with less extensive in vitro and computational alternatives, especially within the pharmaceutical industry for compound efficacy and toxicity screening. Here, we describe the initial steps in optimization, miniaturization, and application of a microfluidics-based laboratory workflow and image-based phenotypic profiling assay for use as a bioactivity screen for environmental chemicals. MCF7 cells were plated in 384-well plates (2,500 cells / well) using a MultiFlo FX tool. After 24 h, cells were treated with 7 concentrations (0.02-100 μM, n = 3/plate) of 16 reference compounds in a randomized pattern using an Echo 550 acoustic dispenser. After 48 h of treatment, cells were live-stained with MitoTracker (mitochondria), fixed, permeabilized and stained with Hoechst-33342 (nuclei), SYTO14 (nucleoli) and fluorescent conjugates of phalloidin (actin cytoskeleton), wheat germ agglutinin (Go1gi / plasma membrane) and concanavalin A (ER). Images were acquired using a Cellomics ArrayScan XTI and analyzed using CellProfiler software, yielding >1,000 features per cell. Cell level data were MAD normalized using DMSO controls. Examples of effects observed at non-cytotoxic concentrations included: berberine chloride affecting intensity and texture measurements in the mitochondria channel, fenbendazole altering intensity measurements in the DNA channel and tetrabenazine affecting intensity, radial distribution and texture measurements in the mitochondria and Golgi/membrane channel. The measured changes were confirmed by visual inspection of the images. In summary, the described protocol was successfully applied to MCF7 cells using automated liquid handling tools. Testing of diverse compounds yielded distinct patterns of affected parameters below the threshold for cytotoxicity, indicating that the assay can detect toxicant-specific effects and may be used to group (fingerprint) toxicants with similar profiles. Future efforts will include screening of additional chemicals and cell lines. This abstract does not necessarily reflect US EPA policy.
Perchloroethylene organ-specific toxicity has been associated with both oxidative and conjugative metabolism pathways. Previous perc PBPK modeling could accurately predict oxidation but we suggested the need to better characterize glutathione (GSH) conjugation as well as toxicokinetic uncertainty and variability. We updated the previously published “harmonized” perc PBPK model for mice to characterize the uncertainty and variability of perc toxicokinetics, with particular emphasis on modeling GSH conjugation metabolites. The updated PBPK model includes physiologically based sub-models for conjugation metabolites trichlorovinyl glutathione (TCVG), trichlorovinyl cysteine (TCCV), and N-acetyl trichlorovinyl cysteine (NACTCV), and added a brain compartment for perc and GSH conjugates. In vivo perfusion data were used to calibrate these pathways for both oxidative and conjugative metabolites. We successfully predicted across the three strains of mice, with estimated residuals errors of two-fold for the majority of data. Inter-strain variability across the three strains was evident for oxidative metabolism; GSH conjugation data were only available for one strain. Updated PBPK model fills a critical data gap in quantifying the oxidative and conjugative metabolism of perc. Previously compiled mouse kinetic data on perc and TCA in B6C3F1 and Swiss mice was augmented to include data from a recent study in male C57Bl/6J mice that measured perc, TCA, and GSH conjugation metabolites in serum and multiple tissues. A hierarchical Bayesian population approach was used to estimate model parameters and characterize the uncertainty and interstrain variability, implemented using Markov chain Monte Carlo (MCMC) simulation. All convergence criteria were satisfied with four MCMC chains, each 100,000 iterations long. The updated model performed as well or better than the previously published model. This approach allows both oxidative and conjugative metabolites to be clearly applied to multiple key characteristics. Only a few could not be assigned to any pathway. The majority of pathways were assigned to the 9th key characteristic representing the 10th key characteristic of human carcinogens. Since both are also known to be genotoxic from routine toxicological testing, the gene expression data support the conclusion that these classic carcinogens express most of the key characteristics. We propose to extend the current findings to additional chemical agents.
of developing and curating MIE knowledge, discovery toxicology using omics and model species, target-based in vitro assays, SAR model generation, understanding of the quantitative trigger conditions can be used to develop integrated testing strategies to quantitatively predict DART effects.

### 2507 Predicting Chemical Mechanisms-of-Action Using High-Throughput Transcriptional Data

The EPA ToxCast effort has screened thousands of chemicals across hundreds of high-throughput in vitro assays. Now, the project is leveraging high-throughput transcriptomic (HTTr) technologies to substantially expand its coverage of biological pathways by measuring the expression of 19,290 genes across multiple cell types. Our objective is to deploy HTTr as an initial screen to prioritize the existing suite of high-throughput assays for additional testing. To accomplish this goal, we must elucidate the potential mechanisms of action (MoA) for each chemical using the transcriptomic profiles. Thus far, HTTr data have been generated for 2,200 chemicals in concentration response format in MCF7 cells at 6 h time point. We have also developed a computational pipeline in Python/R to streamline data processing and analysis as follows: (a) translating raw RNA-Seq data to normalized transcriptional profiles, (b) identifying statistically significant transcriptional perturbations using DESeq2, (c) finding concentration-responsive transcripts using benchmark dose modeling (BMD), and (d) predicting chemical mechanism of action (MoA). We used “connectivity mapping” to infer the 35% of a chemical based on similarity with a database of HTTr profiles from the Connectivity Map (CMap) project (Lamb et al, 2006). The CMap transcriptomic database contains 3,334 Affymetrix transcriptomic profiles (13,029 genes) for 1,176 chemicals and 482 chemicals annotated with >90% from classes curated from KEGG and DrugBank. Analyzing HTTr profiles for genistein (10μM), sirolimus (0.1μM) and trichostatin A (1μM) from MCF7 cells using connectivity mapping correctly identified their known targets as estrogen receptor (ESR), mechanistic target of rapamycin (mTOR) and, histone deacytelase (HDAC), respectively. However, connectivity mapping also produced high-scoring database matches that were not consistent with the known MoA for these chemicals. We are exploring machine learning techniques to mine higher-order dependences between genes in order to make MoA predictions that are biologically meaningful, sensitive and specific. We will present MoA predictions for 2,200 chemicals using concentration-response HTTr data and show their utility as an initial screen for high-throughput toxicity testing. This abstract does not reflect US EPA policy.

### 2508 Confidence in Fitting and Hitting Concentration-Response Data: Tox21 10k Library Pipeline Comparison

The Tox21 program has generated high-throughput screening data on thousands of chemicals. While the data are publicly available through partner websites, PubChem, and publications, the analyses are different. We developed a pipeline consensus to identify higher-confidence chemical-assy calls and are developing a public web application. Tox21 chemical-assay pair activity calls (active, inactive, and, in some cases, inconclusive) were compared among the four hit-call methods: CurveP and 35% of a chemical based on similarity with a database of HTTr profiles from the Connectivity Map (CMap) project (Lamb et al, 2006). The CMap transcriptomic database contains 3,334 Affymetrix transcriptomic profiles (13,029 genes) for 1,176 chemicals and 482 chemicals annotated with >90% from classes curated from KEGG and DrugBank. Analyzing HTTr profiles for genistein (10μM), sirolimus (0.1μM) and trichostatin A (1μM) from MCF7 cells using connectivity mapping correctly identified their known targets as estrogen receptor (ESR), mechanistic target of rapamycin (mTOR) and, histone deacytelase (HDAC), respectively. However, connectivity mapping also produced high-scoring database matches that were not consistent with the known MoA for these chemicals. We are exploring machine learning techniques to mine higher-order dependences between genes in order to make MoA predictions that are biologically meaningful, sensitive and specific. We will present MoA predictions for 2,200 chemicals using concentration-response HTTr data and show their utility as an initial screen for high-throughput toxicity testing. This abstract does not reflect US EPA policy.

### 2509 Use of In Silico Models for Compound Property Prediction to Reduce the In Vitro Screening Burden

In order to maximize the return on investment for early ADMET screening assays, a way to prioritize testing of novel compounds was developed to remove compounds from the automated submission system when the outcome of the assay could be predicted with high confidence. To demonstrate feasibility, a pilot experiment was initiated to apply such an in silico model filter for the human protein binding (hPPB) assay. Human protein binding is an important piece of data in the assessment of safety margins when considering toxicological data. An in silico support vector machine model incorporating the conformal prediction framework was developed for hPPB and its utility in selecting compounds for which no measurement was required initially was evaluated. Compounds where the predictions had a low confidence (< 80%) were submitted to automated testing, for the remaining compounds predicted hPPB data were stored in the internal database accessible to scientists. During the first quarter of 2017 more than 35% of all project compounds to be removed from automated testing, thus, saving unnecessary testing and expense. Moving forward we have investigated how confidence predictions can be applied to ADMET assay panels rather than individual assays. Since there are cost advantages in running these assays as one panel the ability to predict all assays with high confidence will be essential but may be challenging to achieve.

### 2510 Integrated Analysis of Transcriptomics Data and the Adverse Outcome Pathway Framework for Risk Assessment of Chemicals: An Exploratory Case Study Using Piperonyl Butoxide and Liver Models

The integration of existing knowledge to support the risk assessment of chemicals is still a challenge for scientists, risk assessors, and managers. International initiatives like the Adverse Outcome Pathways (AOP) programme have a role in supporting the integration of information from various sources and building collaboratory platforms enabling the scientific community to address risk assessment issues. In this exploratory case study, gene expression data from HepaRG and HepG2 liver cell lines for piperonyl butoxide (PBO) housed in the Data Infrastructure for Chemical Safety (diXa) database were used. The differentially expressed genes were used in pathway enrichment analysis, chemical similarity associations (similar mode of action (MOA) as PBO), and disease associations using tools from the LINCS Consortium, and the Comparative Toxicogenomics Database (CTD). The resulting pathways, chemical analogs, and disease associations were combined with specific liver AOPs and key events from the AOP knowledge base to show evidence supporting a case for PBO as a liver toxicant. There was an 8% overlap in pathways between the two cell lines in response to treatment, and a 6.1% overlap of chemicals with similar MOA to PBO across both lines 146 and 133 known chemicals for HepaRG and HepG2, respectively. Overall, there were fewer associations for the HepaRG cells compared to the HepG2 line, highlighting the mechanistic differences that exist between the different liver models as illustrated by the low overlap in association results. The results also highlight the reference bias that may be introduced by the computational tools used in analysis and the reference data they depend on. This work shows that human in vitro transcriptomics data and modeling tools can identify potential toxicity
by highlighting the biological pathways, diseases, and related chemicals based on the biological signatures. When mapped to existing AOPs, this information can be used to identify relevant AOPs for a chemical, highlighting knowledge gaps where new AOPs could be defined, and assemble AOP networks relevant for the chemical. This approach could support the evidence-based risk assessment of individuals or groups of compounds by using the transcriptomic profiles to identify data gaps and eventually propose additional testing.

2510a Structure-Based QSAR Models to Predict Systemic Toxicity Points of Departure

P. Pradeep1,2, and R. Judson1. 1Oak Ridge Institute for Science and Education, Oak Ridge, TN; and 2US EPA, Durham, NC.

Human health risk assessment associated with environmental chemical exposure is limited by the tens of thousands of chemicals with little or no experimental in vivo toxicity data. Data gap-filling techniques, such as quantitative structure activity relationship (QSAR) models based on chemical structure information, are commonly used to predict hazard in the absence of experimental data. This study presents a set of QSAR models developed for chronic or subchronic in vivo points of departure (POD, the point on the dose response that marks the beginning of a low-dose extrapolation). The in vivo data are taken from the EPA’s ToxValDB, a compilation of information on ~3,000 chemicals from a variety of public data sources. Using PubChem fingerprints and Chemistry Development Kit (CDK) descriptors as physchem descriptors (with feature selection), and support vector machines, random forests, K-nearest neighbor, and gradient boosting regressor as machine learning algorithms (with hyper-parameter tuning), models were developed and evaluated using five-fold internal cross-validation and external test validation. Quantitative POD models were developed for mouse (538 chemicals) and rat (811 chemicals), using point estimates for the experimental POD values. The best mouse model had an external test root mean square error (RMSE) = 0.86 and R² = 0.36. The best rat model had an external test RMSE = 0.18. Since the training data for both mouse and rat models was skewed, they were reconstructed by creating bootstrap samples with 10% duplicate data (randomly selected from the long tail), and the models were rebuilt. Reconstructing the datasets to reduce the skewness in original data did not result in significantly improved models. A second set of models was built that accounted for both lab to lab variability in the POD values. To do this, a POD distribution was constructed for each chemical using mean = median experimental POD value and standard deviation = 0.5 log-units, based on the typical lab-to-lab variability. Bootstrap models were built with random sampling of values from the pre-generated POD distribution to derive point estimates of POD values and confidence intervals for each prediction. The best mouse model had an average external test RMSE = 0.96 and R² = 0.31. The best rat model had an average external test RMSE = 1.15 and R² = 0.02. All units are log10 mg/kg/day. These models will inform chemical screening and prioritization efforts. This abstract does not necessarily represent US EPA policy.

2511 Uncovering Drug-Drug Associations by Data Mining of Drug Adverse Event Database

W. Zou1, W. Zhao1, H. J. Hung2, J. M. Tonning1, Y. Wang1, H. J. Duggirala1, and J. J. Chen1. 1US FDA/NCTR, Jefferson, AR; 2US FDA, Silver Spring, MD; and 3US FDA, Rockville, MD.

The FDA centers receive reports from consumers, healthcare professionals, manufacturers, and others regarding the safety of various regulated products, such as drugs, vaccines, artificial hearts, surgical lasers, and nutritional supplements. FDA Adverse Event Reporting System (FAERS) is a database that contains spontaneously reported adverse events submitted to the FDA. It is a challenge to extract the information in these reports for better assessment of product safety and rapid detection of adverse event signals. A total of 63,082 drug adverse event pairs were identified as the significant association between 936 drugs and 10,316 adverse events. Report ratio (RR) values and p-values of chi square test of drug adverse event pairs indicated that the identified signals were significant. New safety signals were identified when comparing with the currently available information in various sources. After applying random network algorithm to DDI network, 14 drug groups were obtained. Some groups were dominated by drugs with the same first-level Anatomical Therapeutic Chemical (ATC) classification system code, indicating the high purity of identified drug groups. It was distinguished that similar side effects could infer similar target of drugs. The outcome of this study is expected to enhance information input to the decision-making process for drug safety detection and postmarketing surveillance.

2512 Bioinformatics Resource Manager: Web Tool for Data Integration and Systems Toxicology

S. C. Tilton1,2, J. Brown3, M. D. Mans1, A. R. Phillips1, E. S. Peterson3, and K. M. Waters3,4. 1Oregon State University, Corvallis, OR; 2Superfund Research Center, Corvallis, OR; and 3Pacific Northwest National Laboratory, Richland, WA.

The Bioinformatics Resource Manager (BRM) is a web-based application that provides computational tools for biologists to assist with analysis and integration of high-throughput (HTP) or high-content omics data sets. BRM allows users to cross-reference gene identifiers within data sets or to integrate across datasets, including integration of multi-omic platforms (e.g., proteomics and transcriptomics) or integration across different model organisms with simple to follow workflows. In this study, we identified the functional consequences of miRNA regulation in human airway epithelium organotypic 3D culture model after exposure to polycyclic aromatic hydrocarbons, benzo(a)pyrene (BAP) and dibenz[o(def)]chrysene (DBC), through integration of global miRNA and mRNA. The BRM miRNA workflow provides the ability to identity conserved miRNA gene targets from multiple public databases or identify potential regulatory miRNAs for genes of interest. BRM allows users to not only identify predicted targets of miRNAs from both computational and experimentally validated sources, but also to integrate predicted gene targets with experimental miRNA in a single step for human, mouse, and zebrafish data. Cells were exposed to 500 µg/ml BAP and 10 µg/ml DBC for 48 hrs and samples were collected for parallel analysis of miRNA and mRNA by RNA sequencing using Illumina HiSeq 3000. Differentially expressed targets for mRNA and miRNA were integrated using the BRM miRNA workflow. The output from BRM can easily be imported into other commercial or public data analysis software and visual analytic tools. Comparison of miRNA networks for BAP and DBC showed common regulation of genes predominantly affecting extracellular matrix remodeling, cell adhesion, oxidative stress and inflammation. BRM was developed using Java™ and other open-source technologies and is freely available to users (http://ccb.pnnl.gov/brm/). This study was supported by P42 ES016465.
Our aim is to apply mechanistic and clinical understanding to develop a next-generation risk assessment (NGRA) approach for skin allergy that doesn’t require new animal test data, addresses novel exposure scenarios, and better characterizes our uncertainty. Our NGRA approach for skin allergy involves a comprehensive multi-omics approach that integrates predictive chemistry expertise, historical in vivo data, and existing or new in vitro data using two model-based, defined approaches (DAs) to predict the probability of human skin sensitization occurring following a given product exposure, with explicit uncertainty. The first computational model is a probabilistic, weight-of-evidence (WoE) approach that predicts the outcome of a hypothetical in vivo (HRIPT and mouse local lymph node assay [LLNA]), in vitro (direct peptide reactivity assay [DPRA]), human cell line activation test (hCLAT), KeratinoSens, SENS-IS and U-SENS or in silico (DEREK-NEXUS) hazard information. The WoE model output can be expressed as the probability of observing one or more incidences of inducing skin allergy following exposure to a chemical under the conditions of exposure, with hazard information. The WoE clinical potency model is a high-dimensional probability distribution constructed using skin sensitization-relevant in vivo (HRIPT and mouse local lymph node assay [LLNA]), in vitro (direct peptide reactivity assay [DPRA]), human cell line activation test (hCLAT), KeratinoSens, SENS-IS and U-SENS or in silico (DEREK-NEXUS) hazard information. The WoE model output can be expressed as the probability of observing one or more incidences of inducing skin allergy following exposure to a chemical under the conditions of the HRIPT and can therefore be used for risk assessment decision-making. Depending on initial WoE model prediction, a second model-based approach can be used for risk extrapolation from a HRIPT exposure to a product exposure scenario by applying skin exposure and toxicokinetic models that use consumer exposure, skin penetration, and protein reactivity data. Our NGRA for skin allergy has been evaluated using six cases: (2,4-dinitrochlorobenzene DNCB), eugenol, lactic acid, propyl paraben, 1,4-toluenediamine (PTD), and resorcinol used at case study ingredients (2,4-dinitrochlorobenzene DNCB), eugenol, lactic acid, propyl paraben, 1,4-toluenediamine (PTD), and resorcinol used at 0.2% in two hypothetical product exposure scenarios (face cream and acid, propyl paraben, 1,4-toluenediamine (PTD), and resorcinol used at case study ingredients (2,4-dinitrochlorobenzene DNCB), eugenol, lactic acid, propyl paraben, 1,4-toluenediamine (PTD), and resorcinol used at 0.2% in two hypothetical product exposure scenarios (face cream and shampoo); 2% from this analysis will be described alongside conclusions and next steps.

Targeted gene panels have been used in clinical settings to specify breast tumor type and to predict breast cancer prognosis and response to treatment. Separately, panels have also been curated to predict systemic toxicity and xenobiotic activity as a part of chemical screening strategies. However, currently available panels do not specifically target the biological processes relevant to breast development and carcinogenesis. We have curated a gene panel called the Breast Cancer Screen (BC Screen) as a tool to identify potential mammary carcinogens and characterize mechanisms of toxicity. First, we used seminal papers and reviews to identify 14 key characteristics of carcinogenesis and breast cancer development. Next, we applied a hybrid data and knowledge-driven gene selection system to identify combinations of information from publicly available whole transcriptome data, reported chemical-gene interactions, and primary literature review to generate a panel of 500 genes representing these key characteristics. We found that BC Screen partially overlaps with existing gene lists used in breast cancer prognosis, and with lists currently used in chemical toxicity screening. For example, 47% of BC Screen genes are included in the Tox21 S1500+ gene list, although representation is not uniform within each characteristic. Overlap with S1500+ ranged from 16% for the growth hormone characteristic to 76% for xenobiotic metabolism. One third or fewer BC Screen genes selected to represent effects on epigenetics, genotoxicity or immunotoxicity were included in the S1500+ list. Enrichment analysis showed that BC Screen includes genes involved in cell cycle signaling pathways, responses to steroid hormones, and nuclear receptor activation, as well as genes associated with breast cancer and reproductive diseases. BC Screen has the potential to highlight the key molecular initiating events and pathways that are involved in chemically-induced rodent mammary carcinogenesis for a diverse set of chemicals, and to serve as a tool in high-throughput chemical screening to identify potential breast carcinogens. Furthermore, our biologically-based systematic approach to gene prioritization for breast carcinogenesis can be extended to develop gene panels for other endpoints in order to support discovery related to etiology and strengthen toxicological screening.
The U.S. Environmental Protection Agency (EPA) Computational Toxicology (CompTox) research effort helps prioritize chemicals for research based on potential human health risks by integrating advances in biology, chemistry, and computer science. As an outcome of these efforts, the National Center for Computational Toxicology (NCCT) has generated an enormous quantity and diversity of data for the environmental sciences including high-throughput in vitro screening data, in vivo and functional use data, exposure models and physicochemical databases. EPA CompTox research is publicly accessible through a series of software applications. The CompTox Chemistry Dashboard web application is the most recent of these tools and is based on a software architecture that provides a web-based data integration hub associated with ~760,000 chemicals. These data include experimental and predicted physicochemical property data, bioassay screening data associated with the ToxCast and Tox21 programs, product and functional use information and a myriad of related data of value to environmental scientists. This presentation will provide an overview of the CompTox Chemistry Dashboard, its capabilities for delivering data to the environmental toxicology community and how the architecture provides a foundation for the development of additional applications to support chemical risk assessment. This abstract does not reflect US EPA policy.

CompTox Chemistry Dashboard: A Web-Based Data Integration Hub for Environmental Chemistry Data

Data Sharing and Linking Across the Entire Drug Development Continuum

I. J. Tripodi1, M. Boguslav2, N. Hailu2, and L. E. Hunter2. 1 University of Colorado Boulder, Boulder, CO; and 2 University of Colorado Denver, Denver, CO.

Prior knowledge about how a chemical interacts with genes or proteins is valuable in predictive computational toxicology. Many relationships between chemicals and proteins (or genes) have been catalogued in various databases. However, these databases are incomplete; some information can be found only in the literature. Here, we describe a text-mining approach that leverages information in databases to improve the quality of text mining with the goal of identifying relationships missing from those databases. Automated relation extraction from text is difficulty due to the many ambiguities in natural language. The current state of the art consists of selecting features such as words, word stems and syntactic information, and using them as inputs to a machine learning classifier. Here, we demonstrate that automatic identification of relationships between chemicals and proteins found in existing databases to the features used in machine learning. We integrate knowledge from many different databases using the KaBOB [1] knowledge base, to automatically identify a set of five possible relations ("upregulation," "downregulation," "agonist," "agonist," and "substrate of") between a chemical and a protein mentioned in PubMed abstracts. The knowledge base incorporates information about the chemicals and proteins (i.e., "participates in kinase activity," "has N aromatic rings," "it’s lipoxygenase activating," etc). We tested our approach on an extensive manually annotated set of relations from the ChemProt [2] database (including therapeutics), using this prior knowledge in conjunction with text-derived features. Feature selection algorithms and post-hoc analysis of the machine learning results identifies the aspects of the prior knowledge that were most helpful. Furthermore, these results can now be used to estimate the probability of each of these relationships between any chemical-protein pair, based on their attributes in the knowledge base.

Knowledge-Based Chemical Relation Extraction

Applying Bioinformatics to Unravel Mechanism of Toxic Effects of E-Cigarette Aerosol Exposure

T. Krsmanovic1, D. Mitic Potkrajcic1, R. B. Russell1, and G. Apic1. Metisox Ltd., Cambridge, United Kingdom; and 1 University of Heidelberg, Heidelberg, Germany.

Multi-billion dollar ECIG industry continues to grow as more people use ECIGs, out of curiosity, a desire to quit smoking, or a safer way to continue a nicotine addiction. However, there is still little evidence regarding the physiological effects of exposure to ECIG aerosol and the aim of this study was to investigate toxicities induced by electronic cigarette aerosol. We analyzed gene expression data of primary human bronchial epithelial cells grown at Air Liquid Interface exposed to four different ECIG aerosols. Two different flavors and presence or absence of nicotine in ECIGs were compared. From the whole genome analysis, 204 signature genes (p<0.05, FC>1.5) were detected as significantly deregulated after exposure to any ECIG aerosols. We created a computational model of biological pathways describing cellular processes in human bronchial epithelium by manually annotating and processing molecular information from the publicly available data (PubMed articles and FDA reports) and made the information computable. ECIG exposure induced genes involved in oxidative stress pathways and decreased expression of genes involved in cilia assembly and movement. These changes were more pronounced in ECIG products containing nicotine than those without nicotine. Furthermore, we generated a comprehensive database of known side effects. By applying bioinformatics analysis tools to this data, we have identified a number of adverse effects associated with cardiovascular, nervous and hepatic system, and generated the mechanistic hypothesis describing the involvement of ECIG products in development of those toxicities.

BioCelerate Toxicology Data Sharing Initiative: Development of a Centralized, Searchable, Preclinical Data Repository for the Biopharmaceutical Industry

T. Page, Eli Lilly and Company, Indianapolis, IN.

BioCelerate, a subsidiary of TransCelerate, was formed in 2015 as a preclinical industry consortium that could identify and implement initiatives to drive efficiency and productivity in early stage R&D. Toxicology Data Sharing (TDS) is the first initiative launched under BioCelerate and involves creation of a centralized, searchable toxicology data repository that will enable participants to make more informed decisions on compound progression based on increased understanding of on-target and off-target toxicity. The project has also been extended to include a repository of background control data. Moreover, the initiative has implemented a framework for successful and secure collaboration and data sharing within a biopharmaceutical industry consortium. Motivated in part by the FDA’s 2011 Strategic Plan for Regulatory Science and Innovation, the TDS Initiative partnered with a technology vendor to design, develop, host, and maintain a cloud-based data lake to facilitate sharing and analysis of deidentified unstructured (e.g. PDF) and structured (e.g. SEND) data sets. The platform was designed for flexibility and modularity, built in line with our future-state vision - to enable voluntary data sharing and linking across the entire drug development continuum, from preclinical discovery through late phase clinical studies. Presented here are the core capabilities, use cases and value story driving the TDS Initiative, the processes and system architecture for the core data sharing platform, and the principles guiding data sharing and collaboration amongst BioCelerate participants.

Development of a Computerized Workflow to Predict Nicotinic Acetylcholine Receptor-Mediated Acute Mammalian Toxicity

A. Andrus, S. Wijeysakere, D. Wilson, T. Auernheimer, A. Parks, and S. Marty. The Dow Chemical Company, Midland, MI.

While techniques such as sub-structure scaffolding and ligand-docking are well-established in the field of computational drug discovery, their utility in predicting the toxicity of xenobiotics via receptor-mediated interaction is unclear. To this end, we aimed to develop automated in silico workflows to predict the acute toxicity of compounds based on their interactions with known biological targets. As an initial proof-of-concept effort, we investigated the nicotinic acetylcholine receptor (nAChR) as a model target receptor. The nAChR is a cholinergic cys-loop receptor that functions as a ligand-gated cation channel that responds to its endogenous ligand (acetylcholine; ACh) as well as numerous xenobiotics (e.g. nicotine), representing an important therapeutic target and a potential off-target of toxicity. We curated a database of over 4,400 nAChR agents using a combination of automated and semi-automated data-mining approaches. Using a cluster-based chemical scaffolding algorithm coupled with machine-learning techniques, we identified 92 unique scaffolds that describe the chemical space of nearly all known nAChR agents with high sensitivity (96.4%) and specificity (82.4%) when iteratively tested against a challenge set comprising 10% of the known nAChR non-binders from a public ToxCast and in vitro database. Using high-throughput molecular docking, we evaluated the ability of compounds within various scaffolds to interact with the nAChR at its ACh binding site, peripheral allosteric binding site and receptor channel. Based on the docking results, we developed a set of regression models to predict the intravenous LD50 or in vitro EC50 values for several classes of nAChR agents with reason-
2523 Applying a High-Throughput PBTK Model for IVIVE

G. S. Honda1,2, R. G. Pearce1,2, L. L. Pham1,2, B. A. Wetmore1, N. S. Sipes3, R. W. Setzer1, R. S. Thomas1, and J. F. Wambaugh1. 1US EPA, Research Triangle Park, NC; 2Oak Ridge Institute for Science and Education, Oak Ridge, TN; and 3NIEMS, Research Triangle Park, NC.

The ability to link in vitro and in vivo toxicity enables the use of high-throughput in vitro assays as an alternative to resource intensive animal studies. Toxicokinetics (TK) should help describe this link, but prior work found weak correlation when using a TK model for in vitro–in vivo extrapolation (IVIVE) (Wetmore et al., 2013). In this work, we evaluated the assumptions in the use of a high-throughput, physiologically based (PBTK) model to relate in vitro and in vivo toxicity data. The generic, high-throughput PBTK model in this study used rat in vitro measured values of fraction unbound in plasma (fu) and intrinsic hepatic clearance for 92 chemicals. In vivo doses (endpoint-specific low effect levels for rat, EPA’s ToxRefDB) were transformed to concentrations (cPBTK) via the PBTK model, and compared with in vitro AC50 (EPA’s ToxCast program, 394 assays) relative to a randomized parameterized result (rand) and untransformed dose (xasso). For each pair of in vitro assay and in vivo response, simple regressions were performed of standardized AC50 vs the three separate predictors: PBTK, xasso, and fu. Different combinations of assumptions in the use of the PBTK model were then evaluated based on how frequently PBTK, xasso, fu, and xasso 8 predictor had the largest absolute slope. The best result for the PBTK model was achieved by using maximum plasma concentration and assuming metabolism independent of fu (PBTK = 82 %, xasso = 7 %, and fu = 11 %). Using in vitro free vs cell culture also improved results for cell-based assays (PBTK = 87 % vs 78 %). Results demonstrate that use of the PBTK model improves the correlation between the in vitro and in vivo toxicity data relative to the untransformed dose and the randomized result in the rat. This suggests that incorporating TK may enhance human IVIVE. This abstract may not reflect US EPA policy.

2524 Virtual Screening of Chemicals for Estrogen and Androgen Activities

K. Mansouri1, N. Kleinstreuer2, C. Grulke1, A. M. Richardson1, L. Shah3, A. J. Williams2, and R. S. Judson2. 1ScitoVation, Research Triangle Park, NC; 2US EPA, Research Triangle Park, NC; and 3NIEMS, Research Triangle Park, NC.

Toxicity assessments of chemical substances, only using their structures, can cause damage to the respiratory organs and organism as a whole. While regulatory bodies, e.g., European Union, require inhalation toxicity evaluation to be performed for high-volume production chemicals, the use of animals is not permitted in such evaluations. In place of animal testing, it is often recommended to use data, identification of structural alerts to judge toxicity, grouping of chemicals for read-across analysis, and the development and use of quantitative structure-activity models. However, the volume of experimental data and number of reliable QSAR models, concerning the acute inhalation toxicity is limited which hinders all in silico approaches. In this study, we developed a set of QSAR models built using publically available acute inhalation toxicity data in rat. The set consists of four categorical models, designed to predict one of the four GHS categories available acute inhalation toxicity data in rat. The set has assign the correct GHS category to 75% of the external validation compounds. Coverage was maintained in the range of 71-84%. Identified alerts are discussed along with the advantages and disadvantages of using the categorical versus the default model. Overall, this approach provides a reliable QSAR method for predicting acute inhalation toxicity of chemical substances, only using their structures.
Gaps in the database of points of departure (PODs) constitute a major hurdle in public health chemical risk assessment. Methods of computation and selection of high-throughput screening are often viewed as an adjunct to laboratory mammalian toxicology that can help filling the gaps. In the present work, statistical relationships between oral health guidance values (HGVs) for different exposure durations and associated PODs were examined. The endpoints specific to acute, intermediate, and chronic exposure durations were extracted from the ATSDR MRL and US EPA RFD databases; these sources represent a unique data collection concerning adverse health effects due to low-dose chemical exposures. The strength of association between the acute, intermediate, and chronic oral endpoints were investigated using the correlation and regression analyses. The correlation coefficients for acute, intermediate (AI), acute-chronic (AC), and intermediate-chronic (IC) log-HGV pairs in molar units were all similar at about 0.93. Both type I and II regression approaches were explored. Because the relationships were log-linear with slopes statistically equal to 1, simple linear regression with ordinary least squares was applied. The derived relationships suggested the possibility of cross-extrapolation between HGVs for different exposure durations within the limits of statistical uncertainty. The estimated extrapolation factors between HGVs for AI, AC, and IC durations were 5, 5, and 2, respectively. Because of remarkable strength of correlation, in the future, the statistical uncertainty is expected to decrease as the number of HGVs available for regression analyses increases. The proposed relationships are consistent with recent US EPA conclusions (Thomas R.S. et al, Toxicol Sci 134:180-194) concerning “temporal concordance between apical and transcriptional points of departure for chemical risk assessment.” Disclosure: The findings and conclusions in this presentation have not been formally disseminated by the CDC/ATSDR and should not be construed to represent any agency determination or policy.

The potential for neurotoxicity in adults and children following exposure to environmental chemicals remains a high public priority due to concerns that recent increases in the prevalence of neurological disorders may in part be due to chemical effects. Thus, the need for reliable and efficient screening tools to identify, prioritize, and evaluate chemicals for their potential to induce developmental neurotoxicity (DNT) is well recognized. To address this, the National Toxicology Program (NTP) created a library comprising a set of reference compounds (e.g., developmental neurotoxicants, flame retardants, PAH compounds, and so forth) that were not available for regression analyses. The findings and conclusions in this presentation have not been formally disseminated by the CDC/ATSDR and should not be construed to represent any agency determination or policy.

The scientific community.

OpenRiskNet is an EU funded infrastructure project with the main objective to develop an open e-infrastructure providing resources and services to a variety of industries requiring risk assessment, including chemicals, cosmetic ingredients, drugs and nanomaterials. The OpenRiskNet approach is to work on different case studies to test and evaluate requirements to overcome the fragmentation of data and tools and to provide solutions improving the harmonization of data, usability and interoperability of application programming interfaces (APIs) and the deployment into virtual infrastructure. The cases present real-world settings such as systems biology approaches for grouping compounds, read-across applications using chemical and biological similarity, and identifying areas of concern based only on alternative methods approaches. We discuss our progress on the OpenRiskNet goal of harmonizing data and metadata within APIs that can be added to already existing analysis and modeling services and data warehouses. We also demonstrate how these APIs can be easily be used towards the generation of full risk assessment workflows either using scripting languages or workflow managers. Finally, we show the first approaches to make these APIs semantically rich by annotating data with human- and computer-readable data schemata. OpenRiskNet has initiated the Associated Partners Programme strengthening the working ties between the OpenRiskNet members and other organizations within the scientific community.

Pharmacogenomics: A Genomics-Based Toxicity Screening Platform

Elucidating the in vivo molecular actions of drugs can provide insights into drug toxicity. However, systematic efforts in examining the molecular pathways influenced by individual chemicals in in vivo systems remain limited. Previous efforts, e.g., the Connectivity Map, have focused on genomic footprints of drug compounds based on in vitro cell lines mostly applicable to oncology studies, which may not cover a broad spectrum of toxicity. On the other hand, curated toxicity databases like the comparative toxicogenomics database (CTD), are largely based on previously published literatures and in vitro assays and may not provide a complete picture of toxicity in in vivo systems. Here, we present a framework to construct a comprehensive drug-toxicity knowledgebase, Pharmomics, using genomic footprints in a species- and tissue-specific manner, aggregating and meta-analyzing microarray and sequencing data relevant to drugs/substances from tissues and primary cell populations derived from human, mouse, and rat samples. Using multi-tissue/cell gene expression signatures as intermediate modulators, we can infer the perturbed molecular pathways and associate drugs with various potential toxicity endpoints and diseases that share similar gene expression signatures. We will first validate the platform using a training set of known drug toxicities and apply the platform to make novel predictions, followed by experimental validation in animal/cell models. We have established a prototype of the Pharmomics platform and constructed species- and tissue-specific gene signatures of select cardiovascular drugs. We envision this informatics-platform based on big data will offer species- and tissue-specific insights into the in vivo drug activities and can be broadly applicable to toxicity prediction.
2531 Deriving Pathways of Toxicity from Omics Data: Endocrine Disruption as a Case Study

A. Maertens, A. Kleensang, and T. Hartung. Johns Hopkins University, Baltimore, MD.

Systems toxicology has transformed toxicology from a reductionist approach to a more holistic viewpoint that takes advantage of the newer, high-content and high-throughput technologies. From a hazard assessment perspective, it offers an opportunity to move away from the limited mechanistic information provided by a traditional "blackbox" animal tests to a pathway based approach that can provide a detailed mechanistic understanding at a cellular level. Endocrine disruptors have proven very difficult to understand using animal models, as they have subtle effects over a long-term exposure and not necessarily with a monotonic dose response curve. Here, we show how using a network based approach to an in vitro microarray dataset of endocrine disruptors and a time course can derive a basic Pathway of Toxicity and better elucidate the complexity of cellular responses to estrogenic substances such as BPA, can identify thresholds, and elucidate target receptors with better accuracy than other approaches. Moreover, a network approach can reveal several important genes in humans that may not have analogs in other model systems and would also be likely be invisible in an annotation based approach to transcriptomic data.

2532 New Features in ToxRefDB to Improve Modeling Applications and Data Integration

S. Watford1, L. L. Pham2, J. Wignall3, R. Shin4, M. Martin2, and K. Paul Friedman2. IORAU, Contractor to USEPA, Research Triangle Park, NC; US Army Engineer Research and Development Center, Vicksburg, MS; ICF, Burlington, VT; ICF, Fairfax, VA; Pfizer, Inc., Groton, CT; and US EPA, Research Triangle Park, NC.

The Toxicity Reference Database (ToxRefDB) contains publicly available in vivo toxicity studies conducted largely to Environmental Protection Agency (EPA) guidelines, with information for >1,000 chemicals and >5,000 studies. ToxRefDB has been utilized for training and testing of alternative models yet a "positives"-only resource, i.e., only effects significantly different from controls were included. The lack of "true negatives" limited available balanced datasets for modeling. Other impediments to modeling may include a lack of quantitative dose-response information and controlled vocabulary for in vivo effects. The objective of this work was to address these challenges to improve ToxRefDB as a predictive modeling resource. First, endpoints were annotated as either required, triggered, recommended, or not required/mentioned based. The new annotations included "true negatives" to be lin- dignished from "not tested" endpoints. Next, quantitative data were extracted for subchronic and chronic studies, enabling statistical modeling on nearly 400 endpoints. In this process, units were standardized to enable comparisons, decreasing the total unit number from >800 to <400. Finally, the lack of controlled vocabulary for in vivo effects led to challenges in continued data extraction, QA/QC, and integration with other resources. As a solution, ToxRefDB vocabulary was standardized to reflect the language used in corresponding EPA 870 series guidelines and cross-referenced to the National Cancer Institute Thesaurus (NCIt). These cross-references are based on Clinical Data Interchange Standards Board (CDISC), an international effort to describe clinical and non-clinical data. NCIt cross-references enable mapping of in vivo pathological effects from ToxRefDB to PubMed (via MeSH terms) and subsequent genes (and other information) that may be relevant for toxicological research. The new annotations to ToxRefDB increase the potential for connections between ToxRefDB and other resources and enhance utility for toxicology modeling applications. This abstract does not necessarily reflect USEPA policy.

2533 In Silico Identification of Molecular Targets for Three Optical Brighteners

Optical brighteners (OB) are fluorescent white dyes that absorb ultraviolet light and produce fluorescence in the blue region, creating a false sense of whiteness and cleanliness. These chemicals have been massively used in laundry detergents, although few studies have been carried out on their toxic effects, implying a lack of knowledge regarding potential risks to environmental and human health. The goal of this study was to employ molecular docking to identify possible target proteins and signaling pathways modulated by three OBs (DAST, DASC-4 and FWA-1). Protein target identification was carried out using PharmMapper web server, selecting those human proteins contained in PharmTargetDB that generated the best 50 complexes with each OB. The proteins were subsequently downloaded from the Protein Data Bank database, prepared using Sybyl-X and then employed to dock the optimized OB structures. The best docking affinity values, lower than ~9.0 kcal/mol, were found in complexes formed between OBs and nuclear receptors, ERbeta, RAR gamma, PPAR, as well as for proteins involved in the metabolism of glutathione and phospholipids, apoptosis and glucose tolerance, among other processes. FWA-1 was the chemical that produced the greatest number of AOPs. Results suggested OBs may have the capacity to act as endocrine disruptors and alter mechanisms involved in oxidative stress and cell death. In short, OBs are potentially active chemicals that should be subjected to greater toxicological scrutiny to minimize adverse effects from current exposure. Unicartagena (2016-2017), Colciencias, 647-2014.

2534 ICE Tools for Aligning Assay Endpoints to Adverse Outcome Pathways

S. M. Bell1, L. D. Burgoon2, J. Phillips3, P. Cogger1, A. Karmas1, D. Allen1, W. Casey4, and N. Kleinstreuer4. 1ILS, Research Triangle Park, NC; 2 US Army Engineer Research and Development Center, Vicksburg, MS; 3 Sciome LLC, Research Triangle Park, NC; and 4 NIEHS, Research Triangle Park, NC.

A critical challenge to the implementation of non-animal approaches in chemical safety testing is linking endpoints measured in these approaches to adverse physiological responses in vivo. The adverse outcome pathway (AOP) framework allows these molecular, cellular, and tissue-level endpoints to be placed in a biologically relevant context. The National Toxicology Program's Integrated Chemical Environment (ICE) web resource houses curated data from in vivo, in vitro, and in silico assays and models. Many of these non-animal data sources measuring different key events in an AOP can be integrated to form defined approaches to testing and assessment for particular toxicology endpoints. The ICE ontology maps assay endpoints to key events within AOPs and enables use of ICE data with AOPxplorer, a Cytoscape plugin that allows visualization of data in AOP networks. The ability to map ICE data to AOPs can be used to identify data gaps and build confidence in the mechanistic plausibility and relevance of a proposed defined approach. This work is also relevant to understanding the respective role of active ingredients in mixtures, such as pesticide formulation products. ICE includes data on over 300 active ingredients in over 800 formulations, and provides the ability to highlight key events perturbed by the active ingredients, and compare that to formulation toxicity data. We demonstrate the utility of this workflow using an accepted AOP for skin sensitization and putative AOPs for acute toxicity pathways. This was funded with US federal funds from the NIEHS/NIH/NIH under Contract HHSN273201500010C.

2535 Use of ToxCast High-Throughput In Vitro Data to Develop a Computational Model to Identify Compounds That Interact with Neurological Receptors

The ability to predict the neurotoxicity of xenobiotics is a major goal of predictive toxicology. ToxCast data presents an important repository of structurally diverse compounds with high-throughput in vitro assessment of their activity against a number of toxicologically relevant targets. We sought to understand the utility of this resource by using it as the basis for developing two-dimensional structural schematic-based prediction models to screen compounds for their ability to interact with neurological receptors. We modeled the ToxCast database for compounds that interacted with the nicotinic and muscarinic acetylcholine receptors, acetylcholinesterase, the GABA receptors as well as the serotonin and glycine receptors. For each target, the active compounds were clustered and common structural motifs (scaffolds) identified using an automated in-house KNIME workflow. For targets with a sufficient number of active compounds, we were able to build accurate prediction models with sensitivities in the range of 80-96% and associated negative prediction values >93%. Using a similar workflow to analyze the 264 compounds that were active against any of the 21 neuronal targets in ToxCast, we identified 153 unique scaffolds and developed a prediction model that can identify the likelihood of a compound inter-
The PubChem database contains highly curated information "on the biological activity of small molecules". It can be used to get a high-level overview of available information about chemicals. Toxicologists seek to gain an understanding of the effects of chemicals by grouping them into classes based on their structure and toxicological effects. Researchers can discover chemicals which are novel or relatively unstudied in the same class as highly studied chemicals by seeing the density of public information on toxicologically and structurally related chemicals. By noting perturbed biological pathways or toxicological effects of highly researched chemicals, researchers can make informed decisions as to what evaluations they should run on novel compounds. 

PubChem-heatmap is written in Shiny, an R web framework. Users input compounds using chemical identifiers and view the data density (or word count) of sections of PubChem. The heatmap clusters chemicals using various similarity tests. By default, similarity is calculated by converting the "CACTVS Substructure Key Fingerprint" contained in the "Chemical and Physical Properties" section of PubChem into 880-bit descriptors which are used to calculate Tanimoto similarity scores. Individual chemicals and sections can be selected to see a word cloud or curated 'hit call matrix', identifying highly discussed organs, biological systems, cell types, and assays related to a chemical. Perfluorinated chemicals of interest to the NTP were surveyed using the tool. Out of 20 chemicals had little to no information in sections such as 'Toxicity' and 'Pharmacology and Biochemistry'. Perfluorohexanesulfonic acid, the compound with the most information in the 'Toxicity' section of those surveyed, has been linked to developmental neurotoxicity and endocrine signaling disruption. This information can be used to guide exploration of the additional chemicals in the class. Since the tool is written in R, it can be adapted to work with similar databases and extended to provide additional functionality. Future directions for the tool are to integrate it with other established software and services like SWIFT-Review to gain a broader view of the body of research related to a compound.

Digital PCR has been promoted as a method for obtaining absolute measures of the amount of nucleic acid in a sample and has gained widespread use since the first instruments were introduced approximately 10 years ago, but still lacks standardization in data reporting. In many cases, concentrations of target have been represented only on a per volume basis, making comparisons between data from different sets of assays and especially different platforms difficult. We considered that a more useful approach would be to normalize the measured copies to the amount of nucleic acid present in the assay. Since many factors can affect the actual concentration of nucleic acid in the final digital PCR assay, our goal was to develop a method which would account for as many of these factors as possible. Using droplet digital PCR as our platform and previously validated reference genes duplexed with the target genes, we have developed a method of normalization which can be used to estimate the amount of input nucleic acid in the individual assay, and have subsequently reported the number of copies of a target gene relative to this amount. Correcting for the actual amount of nucleic acid present demonstrated a much higher correlation between various dilutions of sample mRNA compared to that obtained by using the theoretical amount and allowed us to make more widespread comparisons of digital PCR results. Supported by the Intramural Research Program at NCI/NIHES.

Alternative splicing is a gene regulatory process that splices out introns (a segment of DNA that consist of noncoding material) and chooses specific exons (a segment of DNA that is intended to be included in the final mRNA product which can result in different protein products). Alternative splicing is important to the regulation of normal physiological functions and is dysregulated in pathologies. To analyze alternative splicing, researchers use software such as JuncBASE, MISO, and MapSplice. However, through reviewing RNA sequencing (RNA-Seq) of tumor samples, we found a previously uncharacterized and complex splicing event in CTNNB1, a gene known to be mutated in many cancers that software like JuncBASE cannot detect. The issue of not detecting these events could cause some genes with splicing changes to be unaccounted for in the analysis of RNA-Seq data. We present our new approach called MESA: Mutually Exclusive Splicing Analysis, that will be able to detect these complex splicing events in RNA sequencing data. The user will input junction coordinates (location where intron was spliced out) and as output will receive mutual exclusive junctions, and a calculated Percent Spliced In (PSI) of those mutually exclusive junctions. The program will allow researchers to identify all possible splicing events and identify new ways that genes can be alternatively spliced.

The EPA Adverse Outcome Pathway Database (AOP-DB) is a database resource that aggregates association relationships between AOPs, genes, chemicals, diseases, pathways, species, orthology information, and ontologies. The AOP-DB front end is a simple yet powerful AOP-DB user interface in the form of a web application. By replacing applications like MySQL Workbench and the MySQL command line interface (MySQL CLI), it allows users to interact with the SQL database conveniently within their preferred web browser on any operating system. This approach includes all information that the AOP-DB has to offer without the need of excess applications or knowledge of creating SQL queries. The front end itself is built using pure-JavaScript frameworks Node.js and AngularJS. These modern frameworks allow for increased modularity, responsiveness, and robust page features without impacting development time. Currently, the AOP-DB front end is to be utilized for exclusive in-house EPA use (intranet); though this is the case, the front end is being built with eventual public external (internet) use in mind by taking appropriate measures for administration and security. Alongside these considerations, the application will also serve as a framework for other databases housed at the EPA. One database integrating the front end framework is the EPA Nanomaterials Research Database (NaKnowBase), a database responsible for organizing physical and chemical parameters of nanomaterials and their potential actions on environmental and biological systems. The workflow described here includes a finished mockup for the AOP-DB, a prototype that includes essential features such as database navigation, and site administration. This abstract does not reflect US EPA Policy.

COSMOS Database, maintained through the COSMOS DataSharePoint, is part of a suite of tools for managing and storing toxicity and chemical data to assist in the early assessment of cosmetics-related substances under the paradigm of non-animal testing strategies. This public resource comprises a total of 102,285 substance records spanning 31 toxicity endpoints searchable within COSMOS DB. Also included in the database is the US EPA’s most extensive and openly accessible database compiled from 15 sources, including regulatory inventories such as Cosling, Korean Cosmetics Industry Institute, US Personal Care Products Council,
and Cosmetics Ingredient Review, as well as the European Food Safety Authority (EFSA). In order to assure data quality, the COSMOS project established a robust data quality evaluation process through application of the COSMOS MINIS criteria. These were developed from toxicity data, including the oRepeatToxDB and used to derive a quantitative data reliability metric, which in turn is essential for estimating uncertainties in information used for Read-Across. Assessment of the uncertainties based on multiple sources of data includes consistent comparisons of data quality, which depends on the reliability and relevance of the data. Reliability scores define five categories, ranging from “meeting all COSMOS MINIS criteria (score=5)” to “meeting none of the major criteria (score=1)”. In addition, COSMOS DB allows for convenient research reproducibility, significant challenges persist with data sharing in toxicity and environmental health sciences. This study provides an initial look into the state of data sharing in environmental health sciences with the goal of informing the additional resources and infrastructure that are needed to increase the discovery, accessibility, and reuse of NIH-funded data. A sample of NIH-funded journal articles that were published over a two-month period in 2015 (N = 357) were analyzed for evidence of data sharing. In total, 20% of NIH-funded supported publications exhibited some level of data sharing. Of these articles, more than half (11.4%) cited human subject data, while few articles with human subject data had evidence of sharing. Further, impacts of publisher data sharing requirements were examined. Journals were classified using a published rubric for strength of their data sharing policy, and publications in journals with strong data sharing policies exhibited a greater proportion of data sharing (30.3%) that those with a weak (15.5%) or unclear (15.5%) sharing policy. Overall, these findings provide a representation of the current landscape of data sharing in environmental health sciences, which are largely consistent with previous analyses of data sharing in journal articles funded across all NIH institutes, and suggest that additional efforts to increase data sharing are warranted.

2541 Digging for Data: Understanding Data Sharing in Environmental Health Sciences

Environmental health research is becoming increasingly data-centric. Data sharing is essential for maximizing the utility and impact of the rich and diverse datasets being generated by the environmental health research community. Despite many known benefits of sharing data, including enhanced research reproducibility, significant challenges persist with data sharing in toxicology and environmental health sciences. This study provides an initial look into the state of data sharing in environmental health sciences with the goal of informing the additional resources and infrastructure that are needed to increase the discovery, accessibility, and reuse of NIH-funded data. A sample of NIH-funded journal articles that were published over a two-month period in 2015 (N = 357) were analyzed for evidence of data sharing. In total, 20% of NIH-funded supported publications exhibited some level of data sharing. Of these articles, more than half (11.4%) cited human subject data, while few articles with human subject data had evidence of sharing. Further, impacts of publisher data sharing requirements were examined. Journals were classified using a published rubric for strength of their data sharing policy, and publications in journals with strong data sharing policies exhibited a greater proportion of data sharing (30.3%) that those with a weak (15.5%) or unclear (15.5%) sharing policy. Overall, these findings provide a representation of the current landscape of data sharing in environmental health sciences, which are largely consistent with previous analyses of data sharing in journal articles funded across all NIH institutes, and suggest that additional efforts to increase data sharing are warranted.

2542 Use of ToxPrint Chemotypes for Exploring Chemical Feature Enrichments across the ToxCast Chemical-Assay Landscape

A. M. Richard1, R. Lougee2, C. Grulke2, K. Connors2, K. Paul-Friedman1, T. J. Shafer1, J. Rathman1, C. Yang3, and A. J. Williams1.

1US EPA, Research Triangle Park, NC; 2Oak Ridge Institute for Science and Education, Research Triangle Park, NC; 3Altamira LLC, Columbus, OH; and 4 Molecular Networks GmbH, Erlangen, Germany.

EPA’s ToxCast library spans diverse chemical uses, functionalities, structures and features potentially relevant to toxicity and environmental exposure. This diversity, along with assay noise and low average hit rates across the high-throughput screening (HTS) technologies used in sets, poses challenges to traditional, global structure-activity relationship (SAR) modeling approaches. A publicly available set of 729 ToxPrint chemotypes (CTs), representing a diverse set of chemical features spanning toxicity alerts, common scaffolds, and varied ring, bond, and atom types, is being used to explore the dimensionality of the ToxCast inventory and codify local chemistry domains to amplify structure-activity signals within those domains. An automated CT-enrichment workflow (CTEW) has been developed, with preliminary functionality released via the EPA Chemistry Dashboard (https://comptox.epa.gov/). ToxPrints were computed for the entire DSSTox database (>700K structures), and CT-enrichment results were generated for >800 ToxCast/Tox21 HTS assays. Over 460 CTs are statistically enriched (Odds Ratio >3, Fisher’s Exact p-value <0.05) in ≥ 1 assay, with 191 of these CTs enriched in ≥ 40 assays; 600 assays are enriched with ≥ 3 CTs, with 140 of these assays enriched in ≥ 40 or more CTs. These results offer a rich vein of chemical inferences to mine, such as CTs associated with promiscuous HTS activity. The CTEW has been applied to a variety of datasets, including ToxCast assays grouped by target type (e.g., nuclear receptors) and by common detection technologies (e.g., autofluorescence); analytical QC “failed” Tox21 chemical samples; microelectrode array (MEA) neurotoxicity assay results where enriched CTs support mechanistic linkages to ToxCast ion channel assays enriched with the same CTs; and various activity subsets within the ToxRef vivo dataset. The approach offers an intuitive, flexible complement to traditional SAR methods, with results that are easily interpreted, anchored to visualizable chemical features, and that can productively guide more targeted SAR investigations. Abstract does not reflect US EPA policy.

2543 Novel Approaches to Safer Chemical Identification for the US EPA’s Safer Chemical Ingredients List

Candidate chemicals for the US EPA’s Safer Chemical Ingredients List (SCIL) are routinely obtained via product formulation submissions to the Safer Choice program (SCP). Chemicals used in Safer Choice-certified products are published on the SCIL and represent a palette of commercial chemicals that meet specific functional use criteria. These criteria include comprehensive review analyses for human health, ecotoxicity, and environmental fate. Efforts to further expand EPA’s SCIL were conducted with the goal to provide stakeholders, such as product formulators and manufacturers, with a dynamic and informative tool that can be used to formulate new products and support the development of Safer Choice-certified products in new product sectors. This presentation will describe how the current universe of commercial chemicals was screened and prioritized to identify candidates for the SCIL. Two novel approaches were developed using publicly available datasets and tools. Multiple chemical inventories containing functional use information were employed in this study, including the EPA’s Chemical and Product categories (ChemCat) database, the ECHA’s Candidate List (CL) database, the Environmental Working Group (EWG’s) Skin Deep® database and the National Institute of Health (NIH)’s Household Products Database. In the first new approach, the functional use chemical inventories were combined and duplicate entries and known PBT and CMR chemicals were removed. Chemical structures were obtained for the chemicals in the combined data set, using SRC internal databases of chemical structure information. The structures for the chemicals in the combined dataset were clustered using EPA’s ChemACE software. Clusters containing substances that were structurally similar to those chemicals already meeting SCIL criteria were chosen for further SCP review as SCIL candidate chemicals. In the second approach, the REACH and the Danish QSAR toxicological data sets were queried to identify chemicals with reported experimental or estimated toxicity values that would likely pass SCP criteria. The chemicals with known toxicological uses were identified as candidate chemicals for further SCP review which included a comprehensive hazard screening assessment. Over 40 chemicals have been added to the SCIL as result of these screening and prioritization methodologies.

2544 Identifying Attributes That Influence In Vitro-to-In Vivo Concordance by Comparing Tox21 Bioactivity versus DrugMatrix Transcriptional Responses to 130 Chemicals

1Texas A&M University, College Station, TX; 2ToxStrategies, Austin, TX; 3ToxStrategies, Houston, TX; 4ToxStrategies, Cary, NC; and 5NIHES, Research Triangle Park, NC.

The concordance between chemical-induced responses observed in vitro high-throughput screening (HTS) vs. in vivo models represents a critical research area, as the integration of HTS data in chemical toxicity assessments is increasing in prevalence. This investigation set out to (i) measure concordance between chemical-induced responses observed in vitro and in vivo across many diverse classes of compounds, including pharmaceuticals and environmental/industrial chemicals, were compared between in vitro data produced in the Tox21
suit of bioassays and transcriptomic data from the liver of rats exposed to a chemical for ≤5 days, available through the DrugMatrix database. A comparison of pathway-level responses showed both similar and different signaling profiles between datasets. A global comparative analysis (i.e., in vitro vs. in vivo) resulted in a Cohen's kappa concordance statistic of 0.02 and a percent agreement of 79%, with results ranging on a per-chemical basis between -0.25-0.76 and 41-100% for the Cohen's kappa statistic and percent agreement, respectively. Three attribute categories were then analyzed for their potential to influence response concordance. First, experimental design attributes were found to influence concordance, including cell type and target pathway. Second, in silico-derived drug similarity was shown to influence concordance by filtering DrugMatrix data to only include experimental doses administered to rats that were within a 10-fold factor of those related to likely bioactivity, derived previously using ToxCast/Tox21 data and high-throughput toxicokinetic modeling. Third, chemical-specific attributes were evaluated by modeling physicochemical properties and structure fingerprints, and the partition coefficient (logP) and a subset of structural attributes were predicted to influence response concordance. Together, findings suggest that experimental design, dose applicability, and chemical-specific attributes should be considered when using in vitro HTS data to predict or inform in vivo toxicological responses.

2545 Development, Validation, and Integration of QSAR Models to Identify Androgen-Active Chemicals within CoMPARA Project

S. Manganelli1, A. Manganaro1,2, A. Roncaglioni1, K. Mansouri3, E. Benfenati4, and P. Ruiz5. 1 of animals that potentially could be used for testing. This roundtable discussions will explore the opportunities and challenges in utilizing in vitro and other alternative toxicology testing methods for the assessment of e-cigarettes. The panel members, representing a wide range of viewpoints, including academia, industry, and government, will discuss: 1) how global regulations are impacting research; 2) what innovations are necessary to make the science ready for regulatory decision making; 3) how to foster collaboration to ensure standardization of approaches; 4) what lessons can be taken from other industries and agencies adopting alternative approaches; 5) what role industry and other stakeholders can play; and 6) how progress can be accelerated.

2547 Arsenic, a Gift and Malice: From Discovery to Detrimental Effects, a Historical Perspective

B. Mahadevan, Abbott Laboratories, Mumbai, India.

From natural/industrial toxin to chemical warfare, murder to crime fiction, healer to poison, arsenic remains a powerful force in modern life. Arsenic toxicity is a global health problem affecting millions of people. Apart from the limit on levels of arsenic (10 parts per billion (ppb)) in drinking water established by the US Environmental Protection Agency, the US Food and Drug Administration (FDA) has been measuring total arsenic concentration in foods through its Total Diet Study and has come up with limit levels. In order to better understand the toxicity of arsenic, one needs to consider its toxicokinetic and toxicodynamic interactions. This session will elaborate on our understanding of the interactions of arsenic (As III, As V, and total), as well as the role of arsenic metabolites (dimethylarsinic acid and monomethylarsonic acid). The US FDA found that inorganic arsenic exposure in infants and pregnant women can result in a child's decreased performance on certain developmental tests that measure learning based on epidemiological evidence about arsenic, including dietary exposure. More recently, the US FDA has proposed an action level of 10 ppb for inorganic arsenic in apple juice. The objectives of this symposium are to provide: 1) historical and scientific understanding of arsenic from toxicology and therapeutic perspective; 2) safety policies; 3) recent updates on mechanism of arsenic toxicity and carcinogenesis; and 4) the thought process on arsenic exposure through food.

2548 In It to Win It: How to Negotiate During the Interview Process

K. Sant, University of Massachusetts, Amherst, MA.

After years of professional training, early-career toxicologists are eager to start interviewing to finally secure their dream job. While nailing the interview is important, navigating the delicate process of negotiations is critical to successfully sealing the deal. However, negotiations are often kept private, giving trainees little knowledge of negotiation logistics and etiquette. Further, negotiating procedure and tactics can vary widely between academia, industry, and government. This session is designed to provide trainees with tips and strategies that will help them successfully navigate the negotiation process. Speakers, representing successful toxicologists from academia, industry, and government, will: 1) provide an overview of the negotiation process; 2) give advice on specific items that are included in recruitment packages; and 3) present practical examples of negotiating skills and techniques. The presentations will be interactive and will engage the audience through live polling technology, role playing, and mock negotiations. These discussions will be highly relevant to all student and postdoctoral attendees, as well as senior toxicologists considering a transition across the professional sectors. This career development session will stimulate an active discussion about how negotiations proceed and provide trainees with strategies, tips, and the confidence to navigate this daunting process and secure their dream job.

2546 Alternative Toxicology Approaches to Evaluate Next-Generation Nicotine Products

J. Fowle III. Science to Inform, LLC, Pittsboro, NC.

The development and uptake of novel nicotine products, including e-cigarettes, has grown rapidly around the world in the last decade, creating a need to evaluate the potential health risks associated with the use of these products. The US Food and Drug Administration Center for Tobacco Products and the European Union Tobacco Products Directive have made recommendations and issued guidance documents outlining the criteria for assessing the risks of these novel products. As part of these proposed frameworks, significant nonclinical testing is required. A wide variety of stakeholders are concerned about the large number of animals that potentially could be used for testing. This roundtable discussion will explore the opportunities and challenges in utilizing in vitro and other alternative toxicology testing methods for the assessment of e-cigarettes. The panel members, representing a wide range of viewpoints, including academia, industry, and government, will discuss: 1) how global regulations are impacting research; 2) what innovations are necessary to make the science ready for regulatory decision making; 3) how to foster collaboration to ensure standardization of approaches; 4) what lessons can be taken from other industries and agencies adopting alternative approaches; 5) what role industry and other stakeholders can play; and 6) how progress can be accelerated.

2549 Application of Data from New Approaches in Regulatory and Product Safety Decisions

R. Thomas, US EPA, Research Triangle Park, NC.

Following more than 10 years of evolution in applied toxicology from the release of the seminal National Research Council report, Toxicty Testing in the 21st Century: A Vision and a Strategy, and the progress to date highlighted in the 2017 report, Using 21st Century Science to Improve Risk-Related Evaluations, there is now broad recognition of the problem to be targeted with innovations in applied toxicology: Hazard and exposure assessments are needed for thousands of chemicals, and the data gaps present cannot be filled using solely traditional methods in toxicology and exposure science due to time and resources. High-throughput predictions for bioactivity and exposure are beginning to inform both
regulatory and product safety decisions, including prioritization, screening-level assessments for emerging contaminants, read-across, and product development and safety assessment decisions. Critical to the use of high-throughput and alternative methods for decisions informed by toxicology is definition of the qualitative and quantitative uncertainty of these methods to ensure conservative protection of human and ecological health. The purpose of this symposium is to provide details on successful first implementations using high-throughput toxicology tools in specific types of decisions and how the associated uncertainty with these tools was understood and accounted for within the decision. Importantly, the lessons learned from these early applications of high-throughput methods to regulatory and product safety decisions will provide the context for modification of high-throughput tools and data interpretation to meet the ongoing challenges of more rapid and efficient safety assessments.

2550 Application to Prioritization for Health Canada’s CMP
T. Barton-MacLaren. Health Canada, Toronto, ON, Canada. Sponsor: R. Thomas

Following advancements in toxicology and risk assessment, Health Canada has been working toward the development of strategic tools for the prioritization of existing chemicals in the Canadian marketplace under the Chemicals Management Plan (CMP). The next goal for the CMP is consideration of the remaining 1,550 priority chemicals out of the original 4,300 chemicals identified as priorities by 2020. To meet this goal, Health Canada’s current approaches for identifying priorities and conducting screening level assessments are being further developed to make use of new approach methodologies including QSAR, adverse outcome pathways, integrated approaches to testing and assessment, and other approaches to support regulatory decision-making, including the use of high-throughput toxicokinetic data to support incorporation of in vitro bioactivity with appropriate consideration of uncertainty.

2551 GenRA: From Research and Implementation to Practical Application

Read-across is a data gap-filling technique in chemical category and analogue approaches that has been used in various regulatory programs. There are a number of steps in the category/analog workflow, though the two critical steps in the process are analog identification and analog evaluation. Source analogs are typically identified on the basis of their structural similarity whereas analog evaluation relies upon mechanistic similarity. One way that mechanistic information can be packaged to justify a read-across is by using an approach known as generalized read-across (GenRA). The read-across prediction is a similarity weighted activity of nearest neighbors characterized by chemical and mechanistic similarity. Here we present several examples where GenRA has been practically applied to identify source analogs, evaluate their validity, and make read-across predictions for specific chemicals of interest. We draw specific examples from PFAS and Superfund chemicals and highlight the insights gained from being able to make reproducible predictions with quantitative measures of uncertainty. The views expressed are those of the authors and do not necessarily reflect the views or policies of the US EPA.

2552 Utilizing Novel Data Streams to Characterize Emerging Contaminants in the Superfund Program
A. Frame. US EPA, Arlington, VA.

The Comprehensive Environmental Response, Compensation, and Liability Act, as amended, (CERCLA; also known as Superfund), authorizes the President to respond to chemical releases or threatened releases of chemicals into the environment. A significant challenge facing the Superfund program is proactively identifying novel substances of concern, understanding their health effects, and providing robust, consistent evaluations of potential chemical properties and toxicity. To address this problem, US EPA’s Superfund Program has part-nered with the Office of Research and Development’s National Center for Computational Toxicology to develop a program specific dashboard to aggregate data on over 740,000 chemicals. These data include experimental and predicted physicochemical property data, bioassay screening data associated with the ToxCast and Tox21 efforts, product and functional use information, predictive toxicity models, analytical methods, and a myriad of related data of value to environmental scientists. Specific to the Superfund program, this dashboard incorporates “screening levels” (SLs) for chemicals using standard Superfund approaches. These screening levels are risk-based concentrations derived from standardized equations incorporating physicochemical properties, toxicity, and assumptions about human exposure to calculate medium specific concentrations which are considered by the agency to be protective for humans over a lifetime of exposure. This dashboard enables users to quickly access information on novel compounds and provides estimates of human health risks, along with SLs, to facilitate site-specific risk assessments. The data in the dashboard are intended to assist risk assessors, project managers, and the public to identify emerging contaminants and facilitating access to available in vitro, in vivo, and in silico data. The views expressed are those of the authors and do not necessarily represent the views or policies of the US EPA.

2553 Utilization of High-Throughput Data for Product Safety Assessment
R. J. Rasoulipour, Dow AgroSciences, Indianapolis, IN.

Technological developments for in silico and in vitro screening assays have created the opportunity to perform 21st century product safety assessment that does not necessarily rely on anchoring to animal-intensive in vivo studies to derive all of the endpoints to perform human health risk assessment. In this talk, the high-level challenges and opportunities posed by discovering and developing novel agricultural plant protection products will be discussed, followed by a deeper dive into many of the predictive in silico and in vitro assays that are currently being utilized to design molecules of the future with more favorable human health and environmental safety profiles.

2554 Application to Risk Assessment: Can Bioactivity Predictions Be Used as a Conservative Point-of-Departure?
K. Paul Friedman, and R. Thomas. US EPA, Research Triangle Park, NC.

Use of high-throughput, in vitro bioactivity data in setting a conservative point-of-departure (POD) has the potential to accelerate the pace of human health risk assessments. Advancement toward this goal requires greater confidence that in vitro bioactivity data, in concert with high-throughput toxicokinetic and reverse dosimetry, can be used to estimate administered dose equivalents at or below the PODs derived from traditional animal studies. The primary goal of this work is to elucidate whether a “region of safety,” i.e., a threshold below which no bioactivity or toxicity would be anticipated, can be identified for nearly 400 chemicals. Using human health evaluations as well as high-throughput predictions of bioactivity, reverse dosimetry, and exposure. PODs were compiled from in vivo guideline study data available to the US EPA, Health Canada, ECHA, and EFSA, and were compared to a distribution of administered dose equivalents calculated for ToxCast bioactivity and predicted exposure (ExpoCast). This work demonstrates more broadly the feasibility, and challenges, of using high-throughput predictions of bioactivity as a conservative POD in screening level assessments. The views expressed are those of the authors and do not necessarily represent the views or policies of the US EPA.

2555 Effectively Leveraging Cellular Functional Genomics Strategies for Elucidating Chemical Mechanisms of Action
A. Bone. US EPA, Research Triangle Park, NC.

High-throughput toxicity testing has become increasingly important in the field of toxicology, as evidenced by the advent of programs such as ToxCast and Tox21. However, these programs cover a fairly limited amount of biological space and are constrained by current knowledge of biological pathways of toxicity. In order to comprehensively assess the potential for chemical hazard without the bias of only investigating known pathways, more wide-ranging screening techniques are needed. In recent years, new technologies have been developed that broadly can be referred to as functional genomics (or proteomics), which are capable of globally determining genes/gene products that are criti-
cally involved in chemical interactions. Techniques include, but are not limited, to: 1) yeast knockout collection with haploinsufficiency profiling/homozygous deletion profiling (HIP/HOP) technology and the like, which uses chemical tolerance or intolerance to identify toxicity targets; 2) CRISPR-Cas9 knock-out screening in human cells, which functions similarly to the HIP/HOP screen; 3) proteomics methods that identify specific chemical-protein interactions in the context of the environment or milieu; and 4) transcriptomics methods which use the technologies of next-generation sequencing (NGS) to study the cellular state of healthy, chemically perturbed, and/or diseased tissue. These techniques cover more comprehensive biological space that may provide data leading to discovery of new biological targets and pathways of toxicity. In addition, since these techniques provide some measure of cell health as a result of gene manipulation linked to chemical insult, the role of each gene in either chemical tolerance or intolerance can be functionally ascertained. The purpose of this session is to provide an overview of the cell-based techniques that are currently in use or being developed to demonstrate powerful new ways of determining mechanisms of toxicity for environmental and other chemicals. One of the co-chairs will provide an introductory overview of functional genomics and describe how these technologies could be applied in 21st-century toxicology. The first speaker will describe the use of a large diversity of cell lines including cell lines, iPSC and primary cells, with critical gene targets modified using CRISPR-Cas9 technology to identify critical chemical targets. Validation of results using both CRISPRi (inactivation) and CRISPRa (activation) of targets identified also will be demonstrated and use of these approaches in understanding off-target effects of drugs. The second speaker will discuss the use of CRISPR technology to identify genes following arsenic exposure that promote the endoplasmic reticulum stress response and apoptosis in human cells. Experimental data presented will include novel validated gene hits, in particular, those of the classical repressive complex and microRNAs. The third speaker will continue the discussion of the use of CRISPR technology in human cells for functional genomics by presenting work done in human erythroleukemic K562 cells exposed to arsenic trioxide or acetaldehyde. The speaker will present data that demonstrates not only the utility of this approach for identifying novel toxicity pathways, as he will show in the case of arsenic trioxide, but also the capability to assign potential roles to uncharacterized proteins based on known toxicity pathways, as he will show in the case of acetaldehyde and DNA repair. The fourth speaker will compare use of gain of function and loss of function genomic screens using CRISPR-Cas9 to deliver an open reading frame library into human cells to characterize mechanisms of action of drugs in cancer cell lines and compare this approach to CRISPR-Cas9 methods. The final speaker will discuss an unbiased chemical proteomics platform that identifies chemical-protein interactions in intact cells by a variety of techniques including cell lines, iPSC and primary cells, with critical gene targets modified using CRISPR-Cas9 technology to identify critical chemical targets. Validation of results using both CRISPRi (inactivation) and CRISPRa (activation) of targets identified also will be demonstrated and use of these approaches in understanding off-target effects of drugs.

**2558 CRISPR Genetic Screens on Cellular Stress Response to Proteotoxins**

Q. Lu. Harvard T.H. Chan School of Public Health, Boston, MA. Sponsor: A. Bone

We report the identification and characterization of multiple cellular suppressors of ER stress response and the associated apoptosis that is induced by environmental proteotoxins such as arsenic. Using a genome-wide CRISPR library targeting both protein coding genes and microRNAs, we screen for genes whose inactivation further increased ER stress-induced upregulation of C/EBP homologous protein 10 (CHOP)-the transcription factor central to ER stress-associated apoptosis. Among the top validated hits are components of the polycomb repressive complex and microRNAs. Our study reveals previously unrecognized mechanisms by which cells suppress the ER stress response and its associated cell death, and may lead to the development of new therapeutic strategies aimed at restoring cellular homeostasis. This approach showcases how CRISPR-mediated inactivation of genes and microRNAs can identify novel mechanisms of toxicity that may be broadly shared by many proteotoxics.

**2559 Genome-Wide CRISPR-Cas9 Screens in Human Cell Lines Provide Novel Mechanistic Insights into Toxic Responses to Arsenic and Acetaldehyde**

A. Sobh. University of California Berkeley, Berkeley, CA.

Comprehensive identification of pathways involved in cellular response to a toxic substance has recently become more feasible due to the emergence of novel genomic approaches. The CRISPR (clustered regularly interspaced short palindromic repeats)-Cas9 (CRISPR associated protein 9) gene knockout system enables genome-wide functional screening, a powerful tool to study mechanisms affecting cellular sensitivity to a toxic substance. We utilized the CRISPR-Cas9 system to perform genome-scale loss-of-function screens in human K562 erythroleukemic cells. Using this approach, we investigated mechanisms affecting cellular response to acetaldehyde, the primary product of alcohol metabolism, and arsenic trioxide (ATO), a potent anti-leukemic agent. Our acetaldehyde screen revealed 18 candidate genes whose disruption increased resistance to acetaldehyde exposure and 21 candidate genes whose inactivation exacerbated acetaldehyde toxicity. Consistent with the reported role of aldehydes in DNA damage, multiple candidate gene products that we identified as components reducing acetaldehyde toxicity were DNA repair enzymes. The screen further revealed functionally uncharacterized genes whose role in acetaldehyde toxicity was validated by individual gene knockout. Our primary arsenic trioxide screen identified 74 genes whose inactivation decreased sensitivity and 26 genes whose disruption increased sensitivity to ATO. Using a secondary screening approach, we validated the relevance of the vast majority of the identified candidates to ATO toxicity. Pathway analysis on validated genes showed a predominant role of reactive oxygen species (ROS) in ATO toxicity and revealed a novel link between YO1/TO loss-of-function and nucleocytoplasmic biosynthesis/incorporation into selenoproteins. Our work further demonstrates the strength of functional screening using the CRISPR-Cas9 system in deciphering mechanisms of toxicity.

**2557 The Use of CRISPR-Cas9 Technology for Validation and De-Validation of Targets from Functional Genomics**

L. Mayr. AstraZeneca, Cambridge, United Kingdom. Sponsor: A. Bone

This presentation will cover recent advances in the field of Precise Genome Editing (PGE), CRISPR-Cas9, and other RNA/DNA-guided endonucleases, which enable identification and validation of drug targets and off-targets at unprecedented ease, speed and precision. It is believed that CRISPR-Cas9 has the potential to substitute the currently used technologies for target validation which are mostly based around RNA-interference (RNAi), such as siRNA, shRNA, and their variations. The presentation will give examples about target validation and de-validation in vitro and in vivo models, and will show the advances and limitations of this novel technology over existing technologies.
High-throughput genetic screening is a powerful tool for target discovery in cancer, it can be used to systematically identify genes that support cancer cell viability and regulate cancer drug. The latest development of CRISPR-Cas9 and ORF technologies enables us to knock out, activate, and introduce precise mutations in genes, and makes possible to perform loss-of-function and gain-of-function studies at genome scale to interrogate mechanisms of action of drugs or toxicants. Novel genetic screens offers improvements in speed and scale compared to arrayed-based screening. Negative selection proliferation screens can be used to detect genes that affect sensitivity of cancer cells to drug treatment. Synthetic lethal phenotypes can be detected using negative selection proliferation wide screens, where thousands of genes can be simultaneously disrupted and tested in presence of a small molecule to find genes that are synthetically lethal with the compound. However, the power of pooled genetic screens is particularly evident in the setting of positive selection, such as identifying genes that mediate resistance to cytotoxic or targeted chemotherapy agents. A subset of drug targets/ cancers, representing a diverse range of cancers chemotherapy and targeted therapies, were screened for causal drug resistance perturbations using genome-scale ORF and CRISPRa lentiviral libraries. Our screens identified classical genes involved in resistance mechanisms as well as novel and potentially drugable genes. The identification of resistance mechanisms to targeted and traditional cytotoxic therapies can be used to evaluate the most effective path forward for resistance studies to new therapies, and it helps the understanding of the biology of tumor responsiveness to inhibition of specific targets or cytotoxic drugs. Loss-of-function genome-wide screens are powerful sets of unbiased tools that allow the identification of critical genes involved in susceptibility or resistance to environmental toxicants and provide novel mechanistic insights in the field of toxicology.

Unbiased high-throughput methods are urgently needed to monitor the spectrum of protein-compound interactions since the toxic modes of actions remain unclear for most bioactive environmental chemicals. Yet while chemical-genomics methods have been developed to assess the impact of chemicals on biological pathways, most existing approaches do not pinpoint the actual proteins physically bound by bioactive compounds. Here we developed a hybrid platform by incorporating complementary chemical proteomics assays to identify physical protein targets of environmental chemicals. Specifically, target identification by chromatographic co-elution (TICC), target identification by ligand stabilization (TILS), activity based protein profiling (ABPP), and affinity pull-down system combined with untargeted chemical analysis (PUCA with ~6000 His-tagged protein library) methods will be incorporated into the platform, and the broad applicability of the platform was validated by identifying both known and unexpected protein targets of bioactive molecules. For example, enoyl-acyl carrier protein reductase (FabI) was identified to be the bacterial target of 6-OH-BDE-47 in Escherichia coli. The physical interaction was further confirmed by PUCA assay with recombinant protein. Overexpression of FabI rescued the growth inhibition of Escherichia coli by 6-OH-BDE-47, validating it as the primary in vivo antibacterial target. Our study demonstrates the strength of chemical proteomics platform in unbiased identification of protein targets of environmental chemicals. The work presented here will highlight the value of identifying the physical protein targets of environmental chemicals, which is a key part of understanding their pathways to adverse outcomes.

Air pollution research has traditionally focused on exploring the mechanisms linking acute and chronic exposure to lung injury/inflammation and, ultimately, the development and exacerbation of airway diseases. More recently, evidence has emerged linking air pollution to adverse cardiovascular health effects, neurological diseases, systemic inflammation, diabetes, obesity, steatohepatitis, and poor reproductive and developmental outcomes. A novel paradigm has been proposed involving the role of central nervous system activation to explain pulmonary and extra-pulmonary effects of inhaled pollutants. The new evidence in general brings forth a compelling common mechanism involving sympathetic-adrenomedullary and hypothalamos-pituitary-hypothalamic axis-mediated biological homeostatic processes that can explain the widespread multi-organ metabolic and immune effects of air pollution. The role of these neuroendocrine axes in mediating systemic effects of pollutants has been overlooked in the past. This mechanism emphasizes the importance of considering a systems biology approach for inhaled pollutants and other stressors and proposes a common mechanistic pathway for chemical and non-chemical stressors. The unifying hypothesis involving the neuroendocrine axes will be presented and supported by each speaker to specifically explore: 1) the basic understanding of how acute physical and psychological stresses (good stress) through neuroendocrine activation modulate the cell egress and extravasation and other homeostatic changes and, in the long term, contribute to chronic inflammatory diseases (bad stress); 2) epidemiological evidence linking environmental stressors, specifically air pollutants, to the neuroendocrine pathway leading to exacerbation of inflammatory conditions of asthma and chronic obstructive pulmonary disease (COPD), which will include looking at the interactive effects of psychological and environmental stressors during development and susceptibility to chronic respiratory diseases; 3) how irritant pollutants likely activate neuroendocrine stress response through nociception by stimulation of sensory nerves, including vagal C-fibers, and integrate sensory signals to the brain to stimulate stress-responsive centers including hypothalamus, which is involved in a flight-or-flight response upon physical stress encounter; 4) experimental studies examining how exposure to inhaled pollutants through neuroendocrine stress response pathways activate adrenergic and steroid mechanisms and alter systemic metabolic homeostasis to affect liver, muscle, and adipose tissue lipid and glucose metabolism and influence lung injury/inflammation; and 5) the development of a glucocorticoid receptor antagonist adverse outcome pathway to integrate the new mechanistic information on environmental and sensory irritant and metabolic and immune function through neuroendocrine stress axes activation and tissue-specific activation of stress hormone receptors. The goal of this session is to synthesize and discuss these emerging findings in order to build a consensus that neuroendocrine stress axes play a major role in air pollutant and environmental health effects and disease susceptibility. The topics covered also will highlight areas where redirection of research efforts might better address the most critical knowledge gaps in the understanding of air pollutant-induced modulation of neuroendocrine pathways and disease susceptibility and improve health risk assessment.
Widespread metabolic changes observed after air pollution exposure, how the release of stress hormones through the activation of sympathetic challenges an accepted mechanistic paradigm of how irritant air pollutants induce systemic metabolic impairment and lung injury.

New experimental evidence involving the role of neuroendocrine activation demonstrates that, in addition to the traditional effects of both chemical and non-chemical stressors on respiratory outcomes. Exposure to air pollutants, including ambient particulate matter has been associated with asthma development and exacerbation in children in sex-specific manner. The evolving research provide insights in to how these complex interactions may more accurately identify vulnerable human populations and to more fully characterize health risks due to common airborne pollutants. Adverse effects of stressors (psychological or environmental) during development are postulated to interactively increase the susceptibility of children to subsequent air pollution exposures. Exposure to environmental stressors can modify lung development, especially in susceptible sub-populations. Because fetal development occurs through a complex orchestration of developmental events, toxins that disrupt these processes can have variable impact depending on the nature of the pollutant as well as timing and/or dose of exposure. The air pollution epidemiology and clinical evidence linking neuroendocrine stress response to respiratory diseases such as COPD and asthma provides mechanistic insights for potential therapeutic interventions.

The airways are densely innervated by sensory nerves from the trigeminal and vagal ganglia. Airway sensory nerves are heterogeneous with respect to their receptor and neurotransmitter expression and anatomical distribution, and thus different subpopulations serve different functions. The two major functions of airway sensory nerves are the homeostatic regulation of breathing and the defense of the airways. The latter is regulated by sensory nerves that sense noxious stimuli, thus are termed 'nociceptors'. Airway nociceptors express the ion channels TRPA1 and TRPV1, which are activated by a host of inhaled pollutants including ozone, acrolein, particulate matter, aldehydes and disocyanates. Acute inhalation of these pollutants triggers airway nociceptive responses including cough, bronchospasm, mucus secretion, dyspnea and changes in blood pressure and heart rate via the recruitment of nociceptor-associated CNS and autonomic networks, including neuroendocrine stress axes. Furthermore, neuronal protein expression is not static, and plasticity in receptor or neurotransmitter expression can lead to altered sensory functionality in both respiratory and cardiovascular disease. For example, activation of airway nociceptors via inhalation of TRPA1 agonists evokes parasympathetic-mediated reflex bradycardia in normotensive rats, but in spontaneously hypertensive rats the same sensory stimulus evokes a complex combination of parasympathetic-mediated reflex bradycardia and sympathetic-mediated tachycardia. Inhibition of pollution-induced sensory nerve activation will likely decrease the impact of air pollution on respiratory and cardiovascular disease.

New experimental evidence involving the role of neuroendocrine activation challenges an accepted mechanistic paradigm of how irritant air pollutants induce systemic metabolic impairment and lung injury. We focus on recent air pollution studies highlighting how the release of stress hormones through the activation of sympathoadrenal-medullary and hypothalamic-pituitary-adrenal axes lead to downstream systemic metabolic imbalance and stimulation of an innate immune response, two fundamental survival mechanisms. Widespread metabolic changes observed after air pollution exposure, typical of a flight-or-fight response, are characterized by adipose lipolysis, muscle protein catabolism, inhibition of pancreatic insulin secretion and increased glucogenogenesis as determined using metabolic assessment in rodents and humans. There is also evidence of a major metabolic shift in the liver associated with transcriptional depression of lipid catabolism and increased mitochondrial stress. Furthermore, the oxygen-induced innate immune response involves extravasation of immune cells to the lung and is associated with changes in stress hormones. The roles of circulating epinephrine and cortisol/corticosterone are examined using interventional approaches involving pharmacological agents specific for adrenergic and glucocorticoid receptors with or without the surgical removal of the whole adrenal glands or adrenal medullas. These studies emphasize that the presence of circulating stress hormones is necessary in mediating irritant air pollutants-induced metabolic and lung inflammatory effects and demonstrate selective modulation based on the differences in the tissue distribution of specific adrenergic and glucocorticoid receptors. Changes in induced alterations in homeostatic mechanisms and dysregulated stress response pathways are postulated to contribute to diabetes, obesity and cardiovascular disease susceptibility. This abstract does not reflect US EPA policy.

The Adverse Outcome Pathway (AOP) framework represents an ideal tool for integrating diverse data relating chemical exposures to adverse outcomes. Glucocorticoid signaling is tightly controlled and numerous adverse health outcomes have been associated with either elevation or suppression of these glucocorticoids including cardiovascular health, diabetes, growth, gonadal function, osteoporosis, myopathy, and increased disease susceptibility. The requirement for tight regulation of hormone levels leaves this system vulnerable to chronic elevation or depression associated with exposure to environmental stressors. Recently, impacts of air pollutants on glucocorticoid signaling have been identified. A network of AOPs describing glucocorticoid signaling have been developed based on the wealth of mechanistic and clinical data resulting from the long-term use of glucocorticoids as therapeutic agents. This framework has been used to integrate data from chemical structure-based predictions, in vitro toxicity tests, animal toxicology, and human clinical data to evaluate the potential impact of environmental exposures on glucocorticoid dysregulation. The broad range of clinical applications for this class of compounds has resulted in clinical information in humans at a wide variety of doses. In addition, there are both acute and chronic indications for these compounds including diverse such as congenital adrenal hyperplasia, where lifelong hormone replacement is sometimes required. When considered in the context of the AOP framework, this information can be used to predict the potential impacts of environmental stressors from air, food, and water considering pre-existing disease and the treatment thereof. These studies highlight the value of the AOP framework for integrating information from chemical and non-chemical stressors to provide a holistic view of the etiology of complex diseases. This is an abstract of a proposed presentation and does not necessarily represent US EPA policy.

You have performed your experiment or analysis, generated or used toxicological big data, want to publish it, and need it to be transparent and reproducible. What do you do? This is one of the challenges faced when using or generating toxicological big data (high-throughput screening, high-content analysis, or omics technologies). Data analyses have become more complex, with increasing scrutiny being placed on the computational methods to ensure analyses are clearly communicated (transparency) and easily reproducible. Supplementary data files may be insufficient to adequately relay the necessary detail or metadata, nor meet the data quality needs and minimum information criteria required for risk assessors to utilize such data/analyses. This session seeks to address these challenges facing toxicologists highlighting platforms for data sharing, how to cite alternative data sources, and the minimum information required for reproducibility and transparency that will help lead toward regulatory acceptance of big data. Furthermore, in order for complex models to be broadly utilized and reproducible, and
clear methodologies, as well as developing fit-for-purpose models that address specific needs, are required. This session will encompass various viewpoints—from the research perspective to that of regulators and industry—providing suggestions and resources for establishing reliable and useful models, as well as promoting transparent communication regarding the use of big data and computational approaches in the toxicological sciences. An aim of the session is to promote awareness regarding the dissemination and use of big data in toxicology, and it will conclude with a panel discussion including all speakers.

2569 Challenges Focusing Publication and Transparency for Big Data in Toxicology

L. Burgoon, US Army Engineer Research and Development Center, Research Triangle Park, NC.

Toxicology is coming of age: The Big Data age. Since the birth of toxicogenomics, the amount of toxicological data has increased exponentially. Today, the wealth of data goes beyond ‘omics, as large databases of curated “classical toxicological data” come online, and more and more chemical entities are screened in high-throughput screening assays. As data size increases, so does analysis complexity. This is not the first time we faced these challenges. In the early days of transcriptomics, the Minimum Information About A Microarray Experiment (MIAME) standard and its associated tools sought to address many of these same challenges: How do we share data in a way that anyone can use it; how do we share analysis details; can we standardize information to facilitate interpretation; how do we make our research results reproducible? Although a MIAME for big data in toxicology may or may not be warranted, we can learn important lessons from that time period regarding data sharing and availability, clearly communicating protocols, providing sufficient meta data, sharing analysis code, and the ethics of citation when using alternative data sources in a new publication. This talk will briefly touch on our current challenges specifically faced by toxicologists with data sharing, data discovery, and ethical use of data. Furthermore, minimum information required for regulatory use/acceptance will be discussed, as criteria for meeting needs of the risk assessment workflow can present unique challenges for the use of big data in toxicology.

2570 Big Data in Toxicology: Remodeling the Publishing Landscape

G. Miller, Emory University, Atlanta, GA.

The classical model of scientific publishing was developed at a time when datasets were manageable and supplemental data were a rarity. The past decades have witnessed a transformation in toxicology research with a rapid expansion of data volume and complexity. Although there have been significant improvements with the ‘omic revolution, publication models still struggle to deal with the ever-growing data. Investigators and funders need tools and resources to make complex data accessible and useful. This talk will discuss some of these challenges and provide examples of how journals and publishers can assist with the handling of big data. Many journals, including Toxicological Sciences, are partnering with data repositories to make the data and code underlying the scientific findings available to the larger scientific community, but to date these resources have been underutilized. These efforts parallel those in the area of open access publishing that are designed to disseminate research findings to as large an audience as possible. Strategies to improve the use of these tools will be discussed with a goal of optimizing the storage, access, and use of complex toxicological data.

2571 Resources and Alternative Publication Streams for Big Data

A. Williams, US EPA, Research Triangle Park, NC.

The volume of data and associated myriad of data analyses conducted to support toxicological research studies has been expanding for years, and there is little indication that it will be slowing. Traditional publication methods offer, at best, a summary of the data underlying a research publication, and in general are not sufficient for meeting the needs of data sharing and transparency. Datasets can be too large to be supplied as supplementary files in peer reviewed publications, commonly cannot be distilled into a PDF file (the publishers preferred format for data distribution), and this sometimes necessitates release in the form of large file downloads of complex databases. Analyses are commonly conducted using custom-written computational codes, unique to the study, which are currently not commonly published alongside the results. There are many resources available to toxicologists that can be utilized to effectively share data and methodology in the toxicology community. Such approaches can deliver data in a more readily available format for public use when supplied in a computable format and using standards amenable to integration into other systems. This presentation will address some of the challenges associated with data sharing and highlight options and tools available to publish toxicological data and analysis methods to facilitate reproducibility and transparency. This abstract does not reflect US EPA policy.

2572 Utility of Big Data: Developing Reliable Fit-for-Purpose Data Models

M. Martin, Pfizer, Inc., Groton, CT.

Big, complex data and models are most frequently compiled for hypothesis generating and data exploration. Such bottom-up approaches to knowledge discovery present unique challenges; follow-up hypothesis testing experimentation is often applied, which can confirm whether data are good enough and of sufficient quality (reliable), results are generalizable (repeatable), and are of value (relatable). While knowledge discovery efforts should continue to be developed and explored bottom up, evaluation and communication of evolving big data approaches generally requires a top-down approach. Data models should be evaluated by their inherent accuracy in the context of how such models will be used, i.e., fit for purpose. This permits clearly defining what is good enough for a specified purpose, how repeatable it needs to be, and ensures the models are described in non-statistical terms from the perspective of the potential user. If deemed "good enough," a snapshot of the data and model can be extracted, further ensuring reproducibility. From an industry perspective, establishing a clear use case and evaluating big data and models through the lens of the user are critical to ensure adoption, and effectively communicate utility, of any alternative toxicological data and models.

2573 Establishing Confidence in Prediction Models

Increased availability of data has greatly influenced the development of predictive modeling technologies, as well as methods to increase predictivity, interpretation, and confidence in the results. Computational approaches such as using conformal prediction can be used on both small and large datasets, and are suitable for a variety of applications such as prioritizing compounds for experimental testing and chemical risk assessment. These methods are honest in the sense that they display model utility when the user is making predictions. We will look at cases from AstraZeneca such as prioritizing compounds for experimental testing, and chemical risk assessment, to highlight the benefits of these methods, including how data quality influences interpretation of results and decision-making, and quantification of the risk associated in various situations. Further examples from AstraZeneca on how results are shared will be presented. Ultimately, these examples will focus model development to address specific needs, requiring effective sharing of data and methods to effectively communicate results and maximize utility.

2574 Mitochondria: Critical Targets in Pharmaceutical and Environmental Toxicity

B. van de Water, Leiden University, Leiden, Netherlands.

Mitochondria are essential for cellular metabolism, and mitochondrial damage is a key event in adverse outcome pathways. Toxic insults causing mitochondrial dysfunction can lead to cellular necrosis due to loss of adenine triphosphate production, to apoptosis through cytochrome-C leakage, and to many other adverse events, including reactive oxygen species production. Speakers from academia and industry will discuss several aspects of mitochondrial toxicity in the context of pharmaceutical and environmental toxicity. The goal is to present current insights into the central role of mitochondria in distinct toxicity pathways and state-of-the-art approaches to investigating mitochondrial toxicity. The latest technologies, including transcriptomic, proteomic, and metabolomic, as well as fluorescent protein reporters in combination with high-resolution microscopy, provide time-resolved mechanistic insight into cause and consequences of chemical-induced mitochondrial injury. The session will start with cutting edge work that centers on the mechanisms by which mitochondrial quality is maintained and how damaged mitochondria are removed from the cell. This
will be followed by new findings obtained through metabolomic characterization of isolated human mitochondria and definition of the mitochondrial exposome. The next presentation will feature exciting work showing how off-target adverse drug effects on mitochondrial energetics cause muscle dysfunction. The following presenter will discuss innovative approaches to unraveling mitochondrial toxicity pathways as developed in the EU-ToxRisk project. The final presenter will address how changes in mitochondrial biogenesis serve as a cellular adaptive mechanism counteracting drug-induced liver toxicity. This session will be of general interest to scientists interested in cellular and tissue-level mechanisms of toxicity. In addition, attendees with an interest in state-of-the-art approaches to unraveling pathways of toxicity in a time- and concentration-resolved manner will benefit from the session. Finally, this session will be of interest to regulatory scientists incorporating information from in vitro assays in the decision-making process.

### W 2575 New Insights in Mitochondrial Quality Control and Mitophagy

**A. Gustafsson. University of California San Diego, San Diego, CA.**

**Sponsor: B. van de Water**

Damaged mitochondria pose a lethal threat to cells that necessitates their prompt removal. Recent findings from our lab have shed new insights into mitochondrial quality control and removal of damaged mitochondria. It was found that NF-kB on the one hand activates inflammation but on the other hand restricts inflammasome activation through elimination of damaged mitochondria. The latter involves parkin-mediated mitochondrial ubiquitylation and subsequent mitophagy via the autophagy receptor p62/SQSTM1. Moreover, an alternative pathway for mitochondrial elimination was discovered, in which mitochondria are sequestered into Rab5-positive early endosomes and subsequently delivered to lysosomes for degradation. Endo-lysosomal clearance of mitochondria and mitophagy are activated by the same stressors and share regulation by Beclin1, suggesting cross-talk between these two pathways. These findings reveal novel mechanisms for mitochondrial quality control and mitophagy. The work reveals mechanisms that are highly relevant to our understanding of mechanisms of mitochondrial toxicity. Recent progress of this work will be presented.

### W 2576 The Mitochondrial Exposome

**D. Walker. Emory University, Atlanta, GA.**

Over the course of a lifetime, humans are subjected to a diverse chemical experience that varies spatially, temporally, and in magnitude. While it is well recognized that environmental factors have the potential to contribute to disease, relationships between exposures and human health are largely unknown. Thus, the cumulative measure of exposures and associated biological response, defined as the human exposome, is a critical component of understanding how environmental factors contribute to disease. To date, exposure assessment in human populations has largely focused on circulating biomarkers of exposure; in vivo mitochondrial exposure and accumulation in humans is unknown. In this presentation, research efforts at the Emory University HERCULES Exposome Research Center to delineate the mitochondrial exposome in human tissue will be presented. Mitochondrial phenotyping using powerful untargeted chemical profiling platforms and integrated ‘omic approaches provide new insight into the burden of environmental chemicals in humans. Application to mitochondria from human adrenal glands, which provide critical endocrine and hypothalamic-pituitary-adrenal (HPA) axis function, shows the presence of a diverse range of exposure-related chemicals. Identified compounds were consistent with NRF-1 and 2 mechanisms, and herbicides, endocrine disrupting chemicals were also detected, including Bisphenol A, di-n-hexylphthalate, styrene, and piperonyl butoxide. These results represent the first characterization of the human mitochondrial exposome. Efforts are ongoing to further define the presence of environmental chemicals accumulated in human mitochondria and identify blood-based biomarkers that can be used to assess the mitochondrial exposome. This work will be discussed.

### W 2577 Drug-Induced Myopathy through Adverse Effects on Mitochondrial Energetics

**F. Russel. RIMLS, Amsterdam, Netherlands.**

Mitochondrial dysfunction is a common outcome of drug-induced toxicity. Understanding the mechanisms by which drugs perturb mitochondrial function is of significant importance to identify patients at risk, and assist in the development of more effective and safer drug therapies. Many of these adverse mitochondrial effects are not predictable consequences of the known mechanism of a drug, but result from off-target pathways. The studies have applied a systems medicine approach to identify the long-sought mechanism of statin-induced muscle toxicity, by integrating molecular, cellular, chemical, and clinical data on the mitochondrial off-target effects of these drugs. *in vitro* determination of muscle cell viability and characterization of mitochondrial energetics (e.g., oxygen consumption, ATP production, and individual respiratory chain complex activities) were combined with *in silico* protein-binding pocket similarity predictions to select potential off-targets. A strong inhibition, up to 84%, of the third complex of the respiratory chain by statins in their lactone form, was found. The inhibitory effect was associated with muscle complaints, as confirmed in patients suffering from these clinically cumbersome adverse effects. This approach appeared also successful to reveal the mitochondrial ATP/ADP exchanger as off-target of the anti-obesity drug ibipinabant, which explained its previously observed muscle toxicity in a preclinical safety study in dogs. To conclude, the developed strategy will be discussed, demonstrates to be a powerful tool to explore mitochondrial off-targets, and has the potential to unravel the molecular mechanisms underlying drug-induced adverse effects on mitochondrial energetics.

### W 2578 EU-ToxRisk: Advances in High-Content Microscopy Analysis for Mitochondrial Toxicity

**E. Danen. Universiteit Leiden, Leiden, Netherlands.**

**Sponsor: B. van de Water**

An integrated network-based approach has been developed to help unravel adverse outcome pathways. Data generated for this approach include RNA interference screens, global transcriptomics, phospho-protein and metabolomics. Recently, a panel of generally encoded reporters has been generated for key signaling pathways to complement these approaches with real-time high-content microscopy analysis. Data will be presented of the EUToxRisk “mitochondrial toxicity” case study, where this integrated approach was used in the context of a set of compounds representing different mitochondrial toxicant classes, including uncouplers, complex I inhibitors, complex II inhibitors, and complex III inhibitors. For mitochondrial toxicity, the studies included tools to quantify changes in mitochondrial membrane potential, mitochondrial ROS formation, and mitochondrial morphology. The time and concentration-resolved high-content microscopy parameters in relation to changes in mitochondrial functionality and cell fate outcome, provides the information required to connect a series of events to points of departure for adversity. This approach is applied in a single-exposure and repeated-dose setting. The obtained information will serve as input for the establishment of quantitative adverse outcome pathways (qAOPs) specific for compound-induced mitochondrial toxicity and ultimately, these AOPs could contribute to the improvement of toxicity prediction, both for known and unknown chemical classes. This ongoing work will be presented.

### W 2579 Increased Mitochondrial Biogenesis as a Cellular Adaptive Mechanism Counteracting Drug-Induced Liver Toxicity

**P. Carmichael. Unilever, Sharnbrook, United Kingdom.**

Mitochondrial dysfunction has been implicated in acute, severe liver injury caused by overdose of acetaminophen. A recent collaboration between the Chinese Academy of Military Medical Sciences and Unilever points to an important role for altered mitochondrial biogenesis in this process. Low, non-cytotoxic concentrations of acetaminophen triggered increased mitochondrial biogenesis in liver cells in vitro. In parallel, expression of key transcriptional regulators of mitochondrial biogenesis, such as PGC-1α, NRF-1 and TFAM, as well as expression of antioxidants including glutathione, MnSOD, HO-1, NQO1, and Nrf2, was upregulated. In contrast, exposure to high, cytotoxic concentrations of acetaminophen did not trigger this response but, instead, led to inhibition of mitochondrial biogenesis and reduced expression of these regulatory proteins and antioxidants. A computational model was for-
Color plays a significant role in food choice by influencing consumer preference, taste perception, and acceptability. With an increasing number of consumers looking for foods with “clean labels,” the market demand for “natural” colors has recently been rising significantly. There have been a growing number of food manufacturers turning away from synthetic colors and towards extracts from plant sources, primarily because of the increasing public interest in “natural” products. Currently, global regulatory agencies do not have a harmonized viewpoint as to the definition of color additives from botanical sources and their use requirements. In the United States, any unapproved color additive from a natural source is subject to premarket safety review by the US Food and Drug Administration (USFDA) with the same safety standard as for synthetic color additives. For plant-based color additives, considerations include chemical identity and composition, manufacturing process, source plant material, heat, pH, light stability, and pesticide and toxic element contamination. In the European Union, a decision tree is used to help determine when an ingredient can be considered a coloring food versus a coloring additive, with the latter being subject to scientific safety assessment. Failure to be aware of the regulatory review requirements can lead to compliance and labeling challenges and possibly charges of adulteration and misbranding upon importation of finished food items. Dialogues and collaborations among stakeholders, including color manufacturers, industrial end users, researchers, and regulatory scientists, are needed. They should work together to harmonize and optimize the safety evaluation of plant-based color additives. This workshop brings together food color experts from these stakeholder groups to share their experiences and perspectives on this topic. Following an introduction that will summarize the use pattern of food colors, speakers will discuss wide-ranging topics related to the safety evaluation of plant-based color additives used in foods, including: (1) the differences between synthetic and natural color with regard to manufacturing and practical applications; (2) issues related to adulteration and contamination that impact the safety of these colors; (3) issues with product quality related to adulteration and contamination that compromise the safety; (4) United States Pharmacopeia (USP)’s experiences in establishing identity and specification standards for plant extracts; (5) the US FDA review processes and special considerations; and (6) highlights of the most recent developments by global regulatory authorities. Examples of data packages sent to the US FDA, European Food Safety Authority (EFSA), and the Joint Food and Agriculture Organization of the United Nations (FAO)/World Health Organization (WHO) Expert Committee on Food Additives for support to safety will be presented.
safety evaluation of an article to determine whether or not it is qualified for admittance to the USP monograph development process. Using an example of a USP botanical monograph article, this talk will illustrate how the USP admission evaluation and quality monograph together can serve in ensuring the quality and safety of natural extracts. Similar principles could be applied in assessing the safety of natural colors.

2585 Assessing the Safety of Plant-Based Food Colors in a Regulatory Setting

Y. Zang. US FDA, College Park, MD.

Color additives are extensively used in food. In the United States, they are under the regulatory oversight of the US FDA. All new color additives, synthetic and naturally-sourced, are subject to premarket safety review by the US FDA, and there is no “generally recognized as safe” (GRAS) exemption applicable to color additives. Once approved, a color additive will be listed in the regulations as either subject to or exempt from US FDA batch certification, the latter historically includes those that are not synthetic (e.g., plant, animal, and mineral sources). Though the safety standard for synthetic or natural color additives is the same, the source materials inform the assessments. The toxicology data package required to establish safety for plant-based color additive is judged on a case-by-case basis. In addition, special consideration is given to the chemical identity and characterization, heat and light stability, pesticide and toxic element contamination, etc. The speaker will delineate US FDA’s review process of color additives used in foods, with examples of both synthetic and plant-based color additives. Typical safety testing submitted to US FDA in support of the safe use and common deficiencies will be discussed.

2586 Global Regulations for Plant-Based Food Colors

S. McAvoy. Sensient Colors LLC, St. Louis, MO. Sponsor: M. Bastaki

Consumers globally are demanding clean label and colorants which are plant-based. Consumer products companies (CPG) are responding to this demand with 75% of new product launches in the United States containing “ exempt from certification” colors in 2016. This shift will likely continue in the subsequent years, and will expand to other regions. With this shift away from the traditional synthetic dyes, there are new challenges for the color suppliers and the CPG. International regulations, with non-synthetic color additives are not harmonized. This talk focusing on plant-based color additives, provides comparison on the current regulations in the United States and the EU, criteria that differentiate food colors and coloring foods under the regulation of the EU, and safety assessment monographs from different regulatory bodies including EFSA and JECFA. Failure to be aware of these differences can lead to compliance and labeling challenges, and charges of adulteration and misbranding upon importation of finished food items into countries outside of the manufacturing country.

2587 Communicating Science: Unconventional Oil and Gas Operations as a Case Study

E. Bruce. Baylor University, Waco, TX.

Ten years ago, there was a rapid increase in oil and natural gas development activities (OGD) in various unconventional resource basins around the country. The increase was the result of an innovative use of existing technologies (horizontal drilling and hydraulic fracturing). The transformation also led to a rapid increase in the build out of the infrastructure required to deliver the product to the markets (i.e., pipelines, compressor stations) and facilities for processing the product (i.e., natural gas process facilities, liquefaction facilities). While the increase was a boon to the economy, it also generated scrutiny from policymakers, researchers, and advocates who commonly cited health concerns. As the decade mark of the nationwide ramp up in industry development activities, Texas has a rich history of OGD going back to the early 20th century and is home to some of the largest shale basins. The publication of the group’s work in 2015 (PLoS One. 2015 Jul 15;10(7):e0131093. doi: 10.1371/journal.pone.0131093. eCollection 2015) led to extensive multimedia interest (the study has been downloaded more than 22,000 times). This level of interest is likely a reflection of a deficit of health information related to UGOD. The presentation will discuss the experience of CEET in disseminating the findings to interested parties that have included testimony to state legislators, the Marcellus Shale Documentary Project, through international, national and local news media, presentation at national conferences, and discussion with community organizations. The talk will address the need to provide accurate and understandable risk assessment to audiences when gaps in hazard identification and hazard characterization exist and how to communicate this uncertainty. The presentation will address how this lack of knowledge leads to gaps in health information and how these gaps frame the risk discussion to audiences that have a preconceived risk perception of UGOD.
2590 Perspectives from the Texas Commission on Environmental Quality (TCEQ) Related to Risk Communication and Unconventional Oil and Gas Operations in Texas

T. Bredfelt, Texas Commission on Environmental Quality, Austin, TX.

The TCEQ utilizes data to evaluate potential risks associated with the development and production of shale gas via hydraulic fracturing. The data includes air monitoring data, the use of infrared cameras either by hand or helicopter mounted to assess potential sources of emissions, and hand held Jerome units to detect reduced sulfur compounds. This data are made publicly available, and the use of these devices and the subsequent data output are often demonstrated at public open house meetings wherein the public can directly see these tools used and the types of data that they produce. The Agency has worked with the public and with the media to communicate observed risk sources and potential management strategies. In addition, the TCEQ has worked collaboratively with industrial entities to identify potential sources of air emissions or groundwater contaminants, and produced an inventory of risk sources. This effort has led to the genesis of programs that enable industry to fix problems before they pose a risk through the “Find it and Fix it” Program. This experience has enabled the public to understand how transparent communication of information with the public has provided us with policies, rules, and guidelines that mitigate risks associated with unconventional shale gas facilities. These programs offer a microcosm of greater programs that can be implemented for risk communication.

2591 Perspectives from a Risk Communication Expert: Focus on Unconventional Oil and Gas Operations

While it is essential to convey facts clearly, that alone is often insufficient to quell public concerns. Research shows that public concerns typically are based 95 percent on perceptions, and only five percent on facts. People’s behavior usually is predicated on perceptions - often misperceptions - that differ from reality. Concerns and question raised by stakeholders typically fall into two groups: 1) Information concerns and questions typically related to concerns and questions focused on the following six questions: who, what, where, when, why, and how; and; 2) challenge concerns and questions that relate to trust, credibility and consistency of the message. This presentation discusses how utilizing proven science-based collaborative techniques, key issues can be identified. Also discussed is how tailored risk communication tools can be adapted to build trust and foster informed support among stakeholders. A panel discussion to encourage audience interaction will follow this presentation.

2592 Communication of Scientific Findings and Risk Perception Associated with Unconventional Oil and Natural Gas Development

E. Craft. Environmental Defense Fund, Austin, TX.

Public concern around the development of unconventional natural gas resources continues to be a challenge in communicating health risks associated with development of the sector. Many studies have relied on exposure estimates based on proximity to drilling activity rather than actual pollution measurements, and the increasing influence of citizen science reports has complicated explanation of peer reviewed findings. Nonetheless, evidence of associations between drilling activity and adverse health outcomes continues to grow, especially with regard to birth outcomes and respiratory disease. How the findings in the literature are presented is critically important in communicating health risks to the public. In addition, special consideration of the risks to communities that may be burdened by both chemical and non-chemical stressors (e.g., neighborhoods of recognized low socio-demographic status located close to drilling activity) is a difficult task because of the multiple facets of risk present and challenges in measuring and controlling for them. New efforts in evaluating cumulative risks of chemical and non-chemical stressors are underway to assess exposure risks posed to vulnerable communities. This presentation will focus on a few of these initiatives as part of the effort to secure vital environmental and health protections for communities that may experience an increased burden as a result of pollution from unconventional oil and natural gas development.

2593 Radiation Toxicity: Historical Perspective on Epidemiological and Experimental Evidence Informing Standards

R. McClellan. Toxicology and Risk Analysis, Albuquerque, NM.

The literature on the health effects of external radiation exposures and internally-deposited radionuclides, most of which was developed post-World War II, is extraordinarily voluminous and robust. This literature includes information on the sources of radiation and radionuclides, environmental and occupational exposures, substantial epidemiological findings, and complementary findings from controlled exposures of molecules, cells, tissues, and populations of multiple species of laboratory animals. The substantial scientific literature has been used to inform the settings of radiation exposure standards for workers and the general population. The radiation protection scheme takes account of radiation quality and dose projection. The presentations in this session will briefly review the history of key discoveries in the radiation field and the development of radiation protection standards, as well as the historical development of knowledge on radiation effects discovered using both epidemiological and experimental approaches. Mutations and cancer, which have traditionally been primary endpoints in radiation protection standards, will be highlighted. Various models describing radiation dose-response relationships, including the use of the linear no-threshold model, will be covered. Uncertainties and controversies in the knowledge base will be discussed, including the extent to which the setting of radiation protection standards has subsequently influenced the standard setting for chemical exposures. Further, in light of the thousands of nuclear weapons tests conducted since World War II, this session will also put into perspective the human and environmental consequences of ionizing radiation that could ensue from their potential use.

2594 Skeletal Toxicity Resulting from Exposure of Growing Male Rats to Coplanar PCB126 Is Associated with Disruption of Calcium Homeostasis and the GH-IGF-1 Axis

M. Ronis1, C. F. Pulliam1, J. Watt1, G. Gadupundi2, and L. Robertson2. 1Louisiana State University Health Sciences Center, New Orleans, LA; 2University of Iowa, Iowa City, IA.

Polychlorinated biphenyls (PCBs) are ubiquitous persistent environmental pollutants. Several studies have described skeletal toxicity following exposure to PCB mixtures, and coplanar PCBs. However, molecular mechanisms remain poorly understood. We exposed groups of N = 6 male Sprague-Dawley rats age 4-5 weeks to PCB126, a pentachloro-substituted, dioxin-like PCB congener by a single i.p. injection of 5 μmol/kg in soy oil vehicle or vehicle alone. After 4 weeks rats were sacrificed and serum, liver, kidney, bone (tibia and vertebrae) were collected. PCB exposure resulted in hypocalcemia (P<0.05) and significant increases in serum PTH without changes in serum phosphorous. Hyperparathyroidism was accompanied by increased expression of mRNAs encoding vitamin D3-metabolizing cytochrome P450 enzymes CYP27B1 and CYP24 in the kidney (P<0.05). PCB exposure also reduced serum IGF-1 and hepatic expression of mRNAs encoding the male-specific GH-pattern-regulated cytochrome P450 enzymes CYP2C11 and CYP3A2 relative to controls (P<0.05). PCB exposure also reduced serum CYP3A2 relative to controls (P<0.05). In addition, microCT analysis revealed that PCB exposure resulted in smaller long bones with reduced diameter and surface area but increased trabecular thickness and volume (P<0.05). This was accompanied by a reduction in serum osteocalcin, a marker of bone formation (P<0.05) but no effect on the bone resorption marker, RatLaps. These data suggest that skeletal toxicity after exposure to PCB126 is a result of disruption of calcium homeostasis and the GH-IGF-1 axis and may also involve direct effects on bone formation. Funded in part by the Iowa NIEHS Superfund Center P42 ES013661 (L.R.) and R37 AA18282 (M.J.R.).

2595 Environmental PCBs in the Serum and Breast Milk of Lactating North Carolina Women

E. P. Hines1, G. Kissling2, and S. E. Fenton1. 1US EPA, Research Triangle Park, NC; and 2NIEHS, Research Triangle Park, NC.

PCBs, are ubiquitous, persistent organic compounds that form a family of 209 structurally-related congeners. PCBs are lipophilic compounds that bioconcentrate in the food chain and are present in detectable amounts in human populations. There is a paucity of data about recent human exposures through breast milk to the PCBs, especially in US studies and even fewer studies with repeated measures over time from the same individual. The goal of the US EPA Methods Advancement
for Milk Analysis (MAMA). Study was to develop or adapt methods to measure PCBs, and other environmental chemicals in milk and serum twice during lactation (at 2-7 weeks and 3-4 months postpartum) in 34 North Carolina women. Milk and serum were quantified for 35 PCB congeners. A majority of the milk congeners were measured at concentrations above LOD, including PCBs 132, 137, 138, 140, 158, 170, 209, 178, 189, 194, 196, 197, 199, 206, 207, 208, 213, 218, and 226. In descending order of concentration with mean concentration ranges of 19.6 to 0.8 ng/g lipid. Similar trends were measured in serum (mean concentrations ranged from 13.3 to 0.86 ng/g lipid). There was no evidence of depuration between visits. These data suggest that breastfeeding North Carolina mothers are exposed to these environmental PCBs and that the PCBs can partition to breast milk. This abstract is the opinion of the authors and does not represent US EPA or NIEHS policy.

2596 Polyaromatic Hydrocarbons and Their Oxygenated Metabolites Directly Alter Ion Channels and Alter Eye Development in Zebrafish Embryos

E. B. Holland1, G. Xu2, D. C. Volz2, and D. Schlenck1. 1California State University of Long Beach, Long Beach, CA; and 2University of California Riverside, Riverside, CA.

Polyaromatic hydrocarbons (PAH) present in crude oil may alter the movement of ions across the membrane of cardiomyocytes contributing to impaired excitation-contraction coupling, possibly resulting in diminished cardiac function and changes in morphogenesis. Alterations are proposed to occur through the ether go go related K+ channels (ERG), L-type Voltage-Gated Calcium Channels (CaV), ryanodine receptors (RyR) or sarco/endoplasmic reticulum calcium ATPase (SERCA) but direct binding of PAHs or oxygenated metabolites with these channels has not been demonstrated. We utilized the ryanodine receptor ligand binding assay (RRLBA) to assess whether PAH parent compounds, and several oxygenated metabolites, interact with these ion channels in zebrafish. We also evaluated the potential of PAHs and their metabolites that cause ion channel disruption to contribute to other forms of developmental toxicity; namely eye development. Zebrafish embryos were treated with 0.5, 5 and 10 µM of PAHs from 2 hours post fertilization (hpf) to 72hpf. In vitro assays demonstrated that, of the 14 compounds assessed, anthraquione-1 and 1-hydroxyquione caused greater than a 200% overactivation and 2-hydroxyfluorene caused an 80% reduction in the activity of the RyR in zebrafish skeletal muscle homogenates. Channel disruption was concentration dependent and altered activity occurred 10 µm or below. In zebrafish embryos exposed to 0.5 µM of phenanthrene-dione, pyrene and phenanthrene showed significantly decreased eye size, and 5 µM of phenanthrene and anthraquinone caused a greater than 30% reduction in eye area than control groups. These results support the direct interaction of PAH or PAH metabolites with ion channels with important implications on various forms of developmental toxicity.

2597 Exposure to BDE-99 Leads to Vascular Toxicity and Disruption of Gene Expression Related to Angiogenesis and Barrier Function in Endothelial Cells

Y. Wei1,2, J. Gong3, and X. Xing1. 1School of Public Health, Sun Yat-Sen University, Guangzhou, China; and 2Johns Hopkins University School of Medicine, Baltimore, MD.

Perfluorinated compounds (PFCs) are widely used in industry as surfactants and in the production of plastic, electronics, textile, and clothing. Due to their stability, persistence in the environment, and their propensity to bioaccumulate, PFCs are of significant toxicological concern. PFCs have been detected ubiquitously in bodies of water, human serum, cord blood, and human breastmilk, worldwide. These chemicals have also been associated with developmental, hepatic and carcinogenic effects in animal studies. Furthermore, there are many PFCs that have yet to be characterized for potential health effects. The objective of this study was to assess the cell viability of the HepaRG cell line, a dual lineage, hepatocyte/cholangiocyte human cell line, when exposed to a set of 22 PFCs. This cell line was chosen because it is known to have metabolic capability, and the liver has been reported as a sensitive tissue to the effects of legacy PFCs in previous work. Assessment of cytotoxicity was performed using a CellTiter-Glo luminescence assay and a JC-10 mitochondrial membrane potential assay. HepaRG cells were dosed with these PFCs at half-log concentrations, in a range of about 1 µM to 100 µM. Three modes of impaired cell viability were evident and some of the PFCs demonstrated EC50 within human exposure range; no effect, moderate and dramatic impairment were evident with increasing con-
centrations of PFCs. Interestingly, the JC-10 assay revealed either mildly decreased, increased at high doses (between 1-100 μM), or no effect on mitochondrial activity. These data suggest that structural information on the varied PFCs tested may help identify events leading to a decline in cell viability. Further analysis of mitochondrial events, such as oxygen consumption rate, extracellular acidification rate, and mtDNA quantification may more accurately determine the magnitude and direction of mitochondrial effects occurring as a result of PFC exposure.

2600 Paradoxical Protective Effect of PFOA and PFOS against High-Fat Diet-Induced Hepatic Steatosis in Mice

I. Huck, K. Begg, and U. Apte. University of Kansas Medical Center, Kansas City, KS.

Perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) are persistent organic pollutants (POP) exhibiting worldwide bioaccumulation because of prolonged half-life. In liver, PFOA and PFOS toxicity presents as fat accumulation (steatosis) and hepatomegaly. It has been suspected that PFOA and PFOS may exacerbate existing liver diseases. The objective of this study was to determine effect of PFOA and PFOS on high fat diet induced hepatic steatosis and metabolic disruption. Eight week old male C57BL/6J mice were fed either normal Chow diet (ND) or a high fat diet (HFD) ad libitum with or without 0.0001% w/w (1 mg/kg) of either PFOA or PFOS for 6 weeks. Interestingly, PFOA/S induced hepatomegaly in ND fed mice but failed to exacerbate hepatomegaly induced by HFD feeding. Immunohistochemical analysis of PCNA positive cells indicated no proliferation across all treatment groups. Oil Red O staining revealed increased hepatic steatosis in ND fed mice treated with PFOA/S. However, PFOA and PFOS treatment protected HFD fed mice from hepatic steatosis. Quantitative analysis of hepatic lipid content confirmed this result. None of the treatment groups exhibited changes in serum triglycerides or cholesterol. Serum glucose levels were not affected in ND fed mice after PFOA treatment, but were elevated in the PFOA treated group and were not affected by PFOA/S plus HFD feeding. We further explored the mechanisms of apparent protection offered by PFOA/S against HFD feeding by qPCR analysis of metabolism related genes. Expression of triglyceride synthesis genes and that of CD36, involved in hepatocyte lipid uptake were not affected by PFOA/S treatment in ND fed mice but was decreased by PFOA/S treatment in HFD fed mice. Fatty acid oxidation genes did not change or were decreased in ND fed mice treated with PFOA/S. PFOA and PFOS treatment inhibited fatty acid oxidation genes in HFD conditions. Together, our data indicate that PFOA/S induce hepatomegaly by altering hepatic lipid storage rather than inducing hepatocyte proliferation. Gene expression analysis suggested that PFOA/S inhibit triglyceride synthesis and fatty acid oxidation in HFD fed conditions. These studies have revealed a potential potometric effects of PFOA and PFOS on hepatic steatosis. Further studies to determine underlying molecular mechanisms and effects on metabolically important organs such as adipose tissue and muscle are warranted.

2601 Temporal Trends in Perfluoroalkyl Substances in Bottlenose Dolphins (Tursiops truncatus) of Indian River Lagoon, Florida, and Charleston, South Carolina

K. Lynch1, M. Gribble1, P. A. Fair2, and S. Bartell3. 1Emory University, Rollins School of Public Health, Atlanta, GA; 2Medical University of South Carolina, Charleston, SC; and 3University of California Irvine, Irvine, CA.

Perfluoroalkyl substances (PFASs), are fluorinated chemicals that are persistent and globally distributed. We performed a temporal trends analysis of serum concentrations of PFASs in bottlenose dolphins (Tursiops truncatus) inhabiting the Indian River Lagoon, FL (IRL) and the waters surrounding Charleston, SC (CHS). Samples were collected during capture-release sessions from free ranging bottlenose dolphins, from June-July of years 2003-2006, 2010-2012, and 2015 for IRL dolphins (n=146), and August of years 2003-2005, and 2013 for CHS dolphins (n=101). We analyzed the data using parametric quantile regression assuming log-normal distribution with robust standard errors to estimate the ratios of median PFAS concentrations per increasing year. We analyzed the nine PFASs that were detected in enough dolphins (<30% below level of detection), and had an adequate range of sample years from both locations. For PFASs with values reported below the level of detection (LOD), we replaced the values with LOD/√2. We performed analysis by sex, and of adult dolphins separately (≥10 years for males, ≥ 6 years for females). The strata were too small to analyze the trends in juvenile dolphins. Median concentrations for all PFASs were higher in CHS dolphins than IRL dolphins. For both CHS and IRL dolphins, the median perfluoro-octane sulfonate (PFOS) concentrations, collapsing over time, were the highest compared to other PFASs, with medians (25th percentile, 75th percentile) of 690.0 (569.7, 1554.3) for CHS dolphins and 389.8 (246.5, 966.4) for IRL dolphins. The ratios suggested similar trends between the two locations for most PFASs. Among CHS and IRL dolphins, perfluorodecane sulfonic acid (PFDS) seemed to have the greatest decrease over time, with a median ratio (95% CI) of 0.79 (0.74, 0.85) for CHS dolphins and 0.84 (0.78, 0.89) for IRL dolphins, considering all ages and both male and female dolphins. In general, the PFASs had median ratios below or close to 1, suggesting decreasing or mostly stable levels over time. Among CHS dolphins, perfluorohexanoic acid (PFHxPA) had a median ratio of 1.12 (1.01, 1.25), which could indicate a slight increasing trend.

2602 Perfecting Your “Elevator” Speech

J. Cichocki. Alnylam Pharmaceuticals, Cambridge, MA.

Effectively communicating science to the general public and to experts in the field is a skill that must be mastered in order to build your career. For most individuals, and especially most trainees, orally presenting a seminar or formalized science speech is much easier than giving a brief, two-to-three minute talk about one’s science and its impact on the general public. This “elevator speech,” however, is often the most important talk one will ever give, as you often have to communicate your science in a brief, succinct, and clear fashion in order to convey your message to lay individuals and experts alike. Further, during job interviews, you will not have one hour to talk to every interviewer individually, but, rather, will have to quickly summarize your work in a couple of minutes. This session will provide tips and tricks to deliver your “elevator speech,” which will be useful for your future presentations, in SOT Annual Meeting and ToxExpo, but also in your daily professional (and maybe personal) life. Following a brief introduction, a panel of experts and early-career scientists will provide examples and advice on how to quickly summarize a scientific project into a brief two-to-three minute speech. Following the short panel discussion, a 35-minute “hands-on” session will follow in which the session chairs will facilitate attendees as they perform their two- to three-minute “elevator speeches” in small groups. Five minutes will be allocated to wrap-up the session following the hands-on activity.

2603 Cardiovascular Adverse Effects Are Still Causing Late Attrition of Novel Therapeutics: Developing Solutions to Detect and Avoid Cardiovascular Toxicity in the Clinic

J. Kremer. Covance, Madison, WI.

Cardiovascular (CV) liabilities continue to be a leading cause of drug attrition in late-stage clinical trials and post-market approval. Aspects of the current paradigm have adequately characterized (e.g., benefit vs. risk) compounds for hERG blockade and QT interval prolongation, but a method to detect arrhythmogenesis directly, rather than using surrogates, still needs to be defined. Even so, the rate of attrition due to CV liability has remained intrinsically high, primarily driven by non-QTc-related liabilities (e.g., blood pressure, contractility). This session will start by highlighting several high-profile drug withdrawals due to unexpected CV liability to establish the problem statement. Specific examples will include Terfenidine (QT prolongation, Torsades de Pointes); Vioxx/COX-2 inhibitors (myocardial infarction, stroke); and Torcetrapib (increased cardiac events, hypertension). The individual speakers will address this problem by describing new scientific and strategic approaches to detect and characterize potential liabilities, culminating in a panel discussion with the audience. Specifically, the first presentation will describe the current state of CV liabilities and the most common mechanisms responsible for drug-induced arrhythmia or structural cardiotoxicity. The second and third presentations will focus on the use of rodent and large animal models, respectively, in safety profile safety and potential mechanisms for drug-induced arrhythmia or structural cardiotoxicity. The second and third presentations will focus on the use of rodent and large animal models, respectively, in safety profile safety and potential mechanisms for drug-induced arrhythmia or structural cardiotoxicity.
how researchers across multiple disciplines and organizations can share approaches and data to improve the testing paradigm. The goal of the session is to provide a data-driven, comprehensive discussion on how to revise CV safety assessments to improve patient safety and reduce the rate of late-stage compound failures.

### 2604 Use of hiPSC-Derived Cardiomyocytes for Cardiac Safety Evaluation

#### L. Guo, Frederick National Laboratory for Cancer Research, Frederick, MD.

Mechanism-based in vitro safety profiling of compounds early in the drug discovery pipeline holds a promise to mitigate safety-related attrition in the late-stage development. This presentation will discuss the potential role of human-induced pluripotent stem cell (hiPSC)-derived cardiomyocytes in shaping the current testing paradigm toward a more comprehensive and translational assessment of both functional and structural cardiotoxicity. Data obtained from studies on cardiomyocyte characterization and model validation as part of CIPA initiative and beyond by siRNA knockdown and small molecule inhibitors are presented. hiPSC cardiomyocytes continue to develop a more mature and adult-like phenotype with increased time in culture, and remarkable changes in responses to selective modulators of major cardiac ion channels, were observed in older cells (cultured for 6 months) compared to those with a short (two weeks) culture, therefore, maturation status of hiPSC-cardiomyocytes may need to be taken into account for study design and data extrapolation. To explore apoptosis as a cellular mechanism responsible for drug-induced cardiotoxicity, expression of apoptosis-related proteins were analyzed at gene and protein level, their functions in maintaining cell viability were characterized by siRNA knockdown and small molecule inhibitors. The results demonstrate that thorough characterization and “fit-for-purpose” validation, hiPSC-cardiomyocytes may be utilized as a valuable tool to improve safety evaluation of both drug-induced arrhythmia and on-target cardiotoxicity of anti-cancer drugs such as ErbB2 and Mcl-1 inhibitors.

### 2605 Incorporation of Cardiovascular Assessment in Early Efficacy or Safety Studies in Rodents

#### R. Macia, Covance Labs, Madison, WI. Sponsor: J. Kremer

This presentation will focus on the use of rodents in early screening and efficacy studies to improve outcomes or assist in the development of early strategies for drug candidate selection and development. Latin-square cross-over and parallel design studies with or without clinical pathology, toxicokinetics, and pathology can be used to assess short term effects on the cardiovascular system and to provide an outlook for possible complications in the development of test articles. Rodent models including blood pressure, left ventricular pressure, body temperature and activity can be used for assessment. Specific data from these models will accompany this discussion and demonstrate the ability to routinely screen candidates for development. Study design considerations and data evaluation from these studies is critical to the success of potential candidates assist in the initial evaluation of potential CV issues, which still remain a major hurdle in bringing compounds to market. Examples comparing CV changes associated with various CV-active agents (aminorin and atenolol (contractility and lusitropy), phenotlamine (hypotensive/increased HR), methoxamine (hypertensive) and amphetamine (increased activity)) will be discussed in comparison to the standard large animal models that are discussed in later presentations. Also described will be the use of rodents to evaluate secondary CV effects as complications from human disease states (e.g. diet-induced obese mice, diabetic and spontaneous hypertensive rats).

### 2606 Clinically-Relevant Large Animal Models of Heart Failure: Model Selection, Limitations, and Optimization

#### K. Hoagland, Amgen, Thousand Oaks, CA. Sponsor: J. Kremer

Large animal disease models have been developed to investigate heart failure (HF) mechanisms and the goal of providing insight that translates to the clinical situation from a pathophysiological perspective. This presentation will focus on the use of large animal heart failure models to study efficacy of new drug candidates, and will include a discussion of model selection considerations (tachypacing, versus ischemic-induction; species selection; anesthetized versus conscious state), and best practices for validation and benchmarking. Additionally, a discussion of what clinically relevant parameters to monitor in HF with the use of telemetry and echocardiography will be included. Both dog and pig models can be valuable to evaluate efficacy of cardioactive agents and be relevant for evaluating safety endpoints, especially proarrhythmia in the HF setting. Our investigations show that ejection fraction (EF) decreases dramatically in tachypaced beagle dogs after 4 weeks of pacing at 240 bpm. Decreases in EF were modest in the ischemia - reperfusion Yucatan minipig model of HF, with individual animal EF values correlating with the ischemic scar area produced by 90-minute occlusion of the left anterior descending artery. Blood pressure and ECG intervals were notably not affected by induction of heart failure, although pigs tended to exhibit more instances of arrhythmia after heart failure induction than dogs. In the tachypaced beagle and ischemia-reperfusion Yucatan minipig models, cardiac functional reserve was blunted, as demonstrated by reduced heart rate and contractility responses to dobutamine (relative to the normal healthy state), consistent with what is observed in clinical heart failure. Collectively, these observations demonstrate the importance of designing and using appropriate model validation protocols with the goal of achieving clinically relevant data sets with test compounds from high-confidence preclinical animal models.

### 2607 Translation from Nonclinical to Clinical Cardiovascular Safety: What Constitutes a Safety Risk?

#### M. Holbrook, VASTA Pharma Solutions, Harrogate, United Kingdom. Sponsor: J. Kremer

In a healthy individual, routine daily activities such as sleeping, walking, eating, and exercise result in marked changes in cardiovascular (CV) parameters such as QT interval, heart rate and blood pressure without any detriment or concern. Whereas in the disease situation or through drug intervention, even modest increases in these parameters are associated with an increased risk of serious adverse CV events such as torsades de pointes, stroke, and ischaemic heart disease (Sager et al., 2013). Hence, it is important to consider the situation and the degree of change in a CV parameter when assessing drug induced cardiac toxicity. In this clinical situation, the challenge is to identify a potential hazard and assess the safety risk preclinically before progressing into clinical studies and eventually the intended patient population. Drug attrition data indicates that, for some CV outcomes our ability to manage this risk has been suboptimal (Redfern et al., 2017). This has brought focus onto translation including the relevant of preclinical models and their statistical and predictive powers (Valentin et al., 2009, Bhatt et al., 2016). This presentation will examine our ability to manage CV safety using nonclinical studies to predict outcome in healthy volunteers and patients. Testing paradigms employing in vitro, ex vivo, in silico, and in vivo techniques will be described along with a discussion of their sensitivity, specificity, and predictive power to the clinical situation. Specifically, the ongoing development of models using human stem cell-derived cardiomyocytes and biophysical in silico models will be described. Importantly, these model systems support the study of structure and function to investigate the content screening to the dissection of pathways and determination of the mechanism of action. There are reports of good translational value with high sensitivity and specificity (e.g. 74% and 74%, Pointon et al 2015) offering promise of improved risk identification. Questions such as What is a “positive” CV finding and how does this affect the novel clinical safety pharmacology evaluations of heart rate and blood pressure pose a risk of falls and injury. Evaluation of drug-induced effects on heart rate and blood pressure is included in the “core battery” of in vivo nonclinical safety pharmacology evaluations specified in the ICH S7A guidance document, Safety Pharmacology Studies for Human Pharmaceuticals. However, the sensitivity of the nonclinical safety pharmacology evaluations of heart rate and blood pressure that are reported to regulatory agencies is poorly understood. This presentation will report a retrospective analysis of the statistical power of the nonclinical heart rate and blood pressure data reported in recent IND submissions to the US FDA’s Center for Drug Evaluation and Research. Results will be reported for “stand-alone” in vivo cardiovascular safety pharmacology studies, for studies that evaluated heart rate and blood pressure during repeat-dose toxicity
studies instead of during stand-alone safety pharmacology studies, and for studies that evaluated heart rate and blood pressure during repeat-dose toxicity studies in addition to stand-alone safety pharmacology studies. As a complement to other presentations during this session, this presentation will also discuss the use of alternative in vivo models for cardiovascular safety pharmacology studies.

W 2609 Environmental Chemical-Microbiome Interactions in Disease Susceptibility

M. Nagarkatti, University of South Carolina, Columbia, SC.

The human body harbors trillions of microbes, and there exists a symbiotic association between humans and microbes. Such an interaction plays a critical role in maintaining homeostasis. Because the microbial ecosystem is found throughout the body, it is constantly exposed to environmental chemicals. Thus, there is a constant crosstalk between the environmental chemicals and microbiota, leading to altered bioavailability of chemicals and/or microbial dysbiosis that could trigger disease processes. It is critical to better understand the mechanisms of these complex interactions between environmental chemicals and microbiota. Such studies may help in understanding why certain individuals are more susceptible to certain diseases when compared to others. This session will explore recent findings that provide conclusive answers, demonstrating that certain environmental insults cause microbial dysbiosis and consequently trigger various diseases. This session will start with introduction to the field, followed by a presentation of data on how bacterially-generated and xenogenous chemicals alter the bacterial composition and metabolism within the gut, leading to altered host homeostasis by activating the Ah receptor (AhR). The session will provide evidence that inhalation of Staphylococcal enterotoxin-B (SEB) triggers acute lung injury (ALI) in mice that can be effectively blocked by resveratrol, an AhR ligand. Interestingly, SEB triggered dysbiosis in the lung and gut microbiota, thereby suggesting gut-lung axis. Moreover, resveratrol treatment reversed the dysbiosis, thereby suggesting that AhR activation may prevent SEB-induced inflammation through alterations in the microbiome. Presenters will provide evidence that specific microbial genotoxic activities originating from various microbial strains, such as Escherichia coli, Atoxoplasma parvulum, and Campylobacter jejuni, promote development of colorectal cancer (CRC). Also, it will be demonstrated that CRC development could be modulated using genetic and pharmacological intervention aimed at the microbiota. These studies represent the first step toward validating the microbiota as a potential therapeutic target for prevention/treatment of CRC. Presenters will discuss obesogenic chemicals and describe how they interact with gut microbiota and promote adiposity in animals. Talks will focus on obesogenic activity of tributyltin. Together, the presentations will be organized in such a way that they will transition from introducing the topic on how crosstalk between environmental chemicals and microbiota plays a critical role in health and disease to addressing, in the second talk, more specific questions, such as the gut-lung axis in regulating the inflammatory disease. The third and fourth presenters will focus on specific disorders, such as cancer and obesity, with the third talk also highlighting how altering the microbiota would serve as a therapeutic tool to prevent/treat colon cancer. Together, this workshop will provide an exciting opportunity for all participants to gain new knowledge of the complexity of the interactions between the environmental chemicals to which people are constantly exposed and the microbiota, as well as novel insights into how they regulate the pathogenesis of a variety of clinical disorders.

W 2610 Modulation of the AhR within the Gastrointestinal Tract Mediates Both Protective and Adverse Outcomes

G. Perdue, and A. D. Patterson, Pennsylvania State University, University Park, PA.

The gastrointestinal tract is exposed to dietary, bacterially generated, and environmental chemicals capable of activating the Ah receptor (AhR). Previous studies have suggested that the level of AhR activation and the class of ligands dictate whether the effects observed are beneficial or lead to toxicity. To explore this further, we have developed two distinct avenues of investigation. First, we investigate the beneficial effects of low dose dietary anthocyanins exposure through the broccoli consuming animal model. In order to assess whether AhR activation is a key chemoprotective effect of broccoli consumption, we administered isocaloric diets, with or without supplementation of whole broccoli (15% w/w), to mice expressing the high-affinity AhRb/b or low-affinity AhRd/d alleles, for 24 days. We then examined the effects of AhR activation on intestinal microecological structure, inflammatory status, and response to DSS-induced colitis. Cecal microbial community structure and metabolic potential were segregated according to host dietary and AhR status. Dietary broccoli that led to heightened intestinal AhR activity resulted in decreased microbial abundance of the family Erysipelotrichaceae, attenuation of colitis and inflammatory signaling. In our second approach, we examined the impact of low dose 2,3,7,8-tetrachlorodibenzofuran (TCDF), to alter intestinal homeostasis in mice. Dietary TCDF exposure (24 μg/kg for 5 days) induced significant changes in the microbiome community structure and metabolism in an AhR-dependent manner. TCDF exposure resulted in an elevation of hepatic lipid, triglyceride, and unsaturated fatty acids in conventionally-raised mice, which was associated with an up-regulation of hepatic SREBP-1C protein and related triglyceride biosynthesis and lipogenic genes. However, no significant changes in the level of lipid and triglyceride-related mRNA or protein expression were found in the livers of germ free (GF) mice or AhR-null mice after TCDF exposure. TCDF-treated GF-mice exhibited more severe inflammation and oxidative stress in the liver. These findings demonstrate that the intestinal microbiota significantly impact the host response to dietary TCDF with a significant role for AhR activation via a diverse set of ligands can lead to changes in the overall microbiome composition and metabolism within the gut, leading to altered host homeostasis.

W 2611 Staphylococcus Enterotoxin B (SEB) Triggers Acute Lung Injury (ALI) through Dysbiosis in Gut-Lung Axis and AhR Ligands Protect the Lungs through Reversal of Microbiome

M. Nagarkatti, University of South Carolina, Columbia, SC.

Staphylococcus Enterotoxin B (SEB), produced by Staphylococcus aureus, is a superantigen that triggers cytokine storm, and inhalation of SEB leads to toxic shock syndrome, respiratory failure, and often death. The gut microbiome plays an important role in the development and functions of immune system in different parts of the body, including respiratory and digestive systems. Also, crosstalk between microbiota in mucosal tissue of gut and lung through Gut-Lung Axis (GLA) can influence immune and respiratory functions of the lungs. The presentation will focus on intranasal exposure of SEB to induce acute lung injury (ALI) in mice and address the role of microbiota. For this purpose, 16S rRNA metagenomics sequencing was performed to investigate the nature of alterations in gut and lung microbiome after induction of ALI by SEB when compared to controls. Analysis of microbiome revealed that SEB inhalation caused a decrease in some species such as Ruminococcus gravis in the lung and gut while increasing Akkermansia muciniphila, which is responsible for degrading mucin barrier of the colon. This correlated with increased permeability and decrease in tight junction proteins in epithelial cell barrier in the lungs and intestines. There was also a decrease at the genus level in the beneficial microbiota in SEB group when compared to control group. Interestingly AhR agonists that suppressed ALI also caused reversal of microbial dysbiosis. Collectively, these data suggested that exposure to SEB that triggers ALI, is associated with similar alterations in the composition of microbiome in the lungs and gut, which promoted inflammation thereby regulating the pathogenesis in the lungs.

W 2612 Tributyltin Exposure Alters Post-Embryonic Growth, Adiposity, and Intestinal Microbiota Assembly in Zebrafish

J. Rawls, S. Gomez De La Torre Canny, and O. Mueller, Duke University School of Medicine, Durham, NC. Sponsor: M. Nagarkatti

Obesity is a ubiquitous public health problem that warrants the study of environmental factors that, by regulating energy balance, promote the storage of excess energy in adipose tissue. Two important environmental factors that promote adipose tissue accumulation are microbial communities residing in the intestine, and environmental chemicals that may act as obesogens. We developed an in vivo model to test the obesogenic effect of chronic tributyltin (TBT) exposure in post-embryonic zebrafish and to study the effect that this chemical has on intestinal microbiota. We have shown that zebrafish develop multiple adipose tissue depots, which consist of white adipocytes that display morphological and molecular homologies with those of mammals. Using fluorescent lipophilic dyes to measure adipose tissues together with nutritional factors that promote adipose tissue accumulation in zebrafish as it does in mice. Also, we show that 21-day exposure to TBT at a nominal dose of 1 μg/L was sufficient to increase the growth of adipose tissue in zebrafish compared to control animals. Unexpectedly, TBT exposure also inhibited somatic growth as early as 14 days post-exposure and at a dose as low as 0.1 μg/L. High-throughput sequencing of 16S rRNA genes revealed specific effects of TBT on intestinal bacterial community assembly including significant increases in Chitinibacter spp. abundance. Together, our
results indicate that TBT exposure promotes adipose tissue deposition even in the absence of a high fat diet, and affects other distinct aspects of post-embryonic growth and intestinal microbiota assembly. This work provides the first comprehensive analysis of the effect of a chemical onzebrafish somatic growth, adipose tissue accumulation, and intestinal microbiota composition, providing a critical frame of reference for future studies to test for mechanistic interactions between environmental toxicins, microbiota, and animal hosts.

2613 Cancer: Mining the Microbiota for Answers

C. Jobin, University of Florida, Gainesville, FL; Sponsor: M. Nagarkaraki

Gene-environment interaction plays a key role in disease susceptibility including colorectal cancer. Microbiota, particularly the intestinal microbiota, plays a central role in host physiology and the composition and activity of this consortium of microorganisms is directly influenced by known cancer risk factors such as lifestyle, diet, and inflammation. Accurately quantifying microbial contributions to a wide range of conditions is important. The mechanism by which microbiota impact cancer development is still unclear, but cancer risk factors such as inflammation and diet are known to influence environmental components that modulate microbiota. Specifically, inflammation represents a powerful condition by which microbial composition and biological activities are altered. Using gnotobiotic technology, microbial genetic manipulation, and genetically engineered mice (Apomucin+/-; IL10-/-), we investigated the role of specific bacterial consortium of bacteria in the development of colitis-associated colorectal cancer. Based on our data, the presentation will provide evidence that specific microbial toxic activities originating from various strains such as Escherichia coli, Atpobium parvulum, and Campylobacter jejuni promote development of CRC. For example, presence of DNA damaging toxins such as colicin from adherent invasive Escherichia coli or cytotoxic distending toxins (cdt) from Campylobacter jejuni are critical for development of colorectal cancer. In addition, we recently observed a correlation between presence of hydrogen sulfide (H2S)-producing bacteria (HSPB) and severity of new onset Crohn’s Disease (CD) in a pediatric population, with strain Atpobium parvulum able to promote development of colorectal cancer in Apomucin+/-; IL10-/- mice. Although single organism promotes development of colitis-associated colorectal cancer (CRC) in preclinical models, an ecologically complex microbial interaction is implicated in human pathology, including inflammatory bowel disease (IBD). This talk will provide evidence that consortia of bacteria obtained from human CRC tissues promote colorectal cancer in gnotobiotic Apomucin+/-; IL10-/- mice. These studies represent the first step in understanding mechanisms by which microbiota influence development of colorectal cancer, and identify new potential therapeutic target for prevention/treatment of cancer.

2614 Matching Analytical Methods to Markets: Balancing Regulatory Expectations and Technical Challenges

B. Henry, W.L. Gore & Associates Inc., Elkton, MD.

Today, regulators, supply chain partners, and customers want to know what is in the products they buy that might harm them. From a risk assessment perspective, the absence of clear consensus and regulatory guidance for chemical characterization of medical devices, drug-device combination products, and their components delays commercialization of life-saving technology, leads to increased animal testing as a clearly-defined path to market, and is expensive. This session will seek to open the dialogue on the challenges and potential paths forward for manufacturers of medical devices, drug-device combination products, and their components. An emerging area of focus is the use of new technologies and the roles they may play in streamlining product development, including new approaches to qualitatively, semi-quantitatively, and quantitatively measure chemical substances in biological matrices. The first presenter will briefly compare several extractables and leachables (E&L) approaches, including ISO 10993 and those by the United States Pharmacopeia, Product Quality Research Institute, the US FDA Container Closure Guidance, the US Pharmacopeia, and the Bio-Process Systems Alliance. (TTC) for a permanently-implanted medical device and a drug-device combination product. Now, that the opening presentations have shared a collaborative plan of attack for E&L, does it matter which lab does the analysis? Inter-laboratory variability related to compound identification and quantitation, including equipment sensitivity and the available chemical library, will be discussed by the next presenter. Diversity in the number of reported compounds among four test laboratories for the same test articles, despite the same extraction solvents, conditions, and analytical techniques, will be shared. Considerable quantitative and qualitative differences potentially impacting the risk assessment will be discussed. The final presentation will provide a high-level complex and complicated tunnel by sharing US FDA expectations of E&L studies for medical devices and combination products. The presentation will include LODs, LOQs, sensitivity, extraction methods, and the interpretation of qualitative, semi-quantitative, and quantitative data, as well as issues frequently encountered. To close out the session, the panel will answer audience questions regarding lab selection, unknowns, use of the TTC, Cramer Classes, and in silico approaches. This session will feature information and provocative discussions that will be transferable to other E&L applications and should be of interest to contract labs and manufacturers of parts intended for use in medical devices, pharmaceutical processing, or single-use systems, as well as regulators.

2615 Which Guidance to Follow for Which Market?

B. J. Henry, W.L. Gore & Associates Inc., Elkton, MD.

Framework: Lacking specific extractable and leachable (E&L) expectations from regulatory authorities, E&L testing is complicated and confuses for manufacturers of medical devices, combination products, and their components. A very brief comparison of several E&L approaches will be presented, including the US Pharmacopeia, ISO 10993-1, Product Quality Research Institute (PQRI), the US FDA Container Closure Guidance, the Extractables Work Group of the BioPhorum Operations Group (BPOG), and the Bio-Process Systems Alliance (BPSA).

2616 Extractables and Leachables Testing for Medical Devices: What About ISO 10993 Series?

A. Poth, Dr. Knoell Consult GmbH, Mannheim, Germany.

Regulatory authorities require the consideration of chemical characterization of Extractables and Leachables (E&L) with the corresponding toxicological risk assessment to ensure safety and successful submissions. For medical devices and combination products, the major standards, ISO 10993-1, -17 and -18 parts, acknowledge the importance of chemical characterization. The information provided in the current standards is not sufficiently detailed to plan extraction, analysis and interpretation for risk assessment. The preparation of sample extracts is a challenge as the conditions and extractions defined in ISO 10993-12, may not be relevant for the identification of E&L. This presentation will address the revisions currently in progress for these three standards. For ISO 10993-1 changes have been discussed to the flow-chart (describing the systematic approach to the biological evaluation of medical devices) to strongly focus on chemical characterization and the importance of in vitro and in vivo testing. Another change considered is to require chemical characterization while all other toxicological endpoints will be evaluated within a toxicological risk assessment. A major revision will be made on ISO 10993-18 to incorporate the technical and scientific experience developed during the last several years since its publication, including addition of several new annexes, and the description of experimental requirements for the investigation of E&L and a revision of the stepwise chemical characterization process, including the setting of the analytical evaluation thresholds (AETs) in alignment with the Threshold of Toxicological Concern (TTC) concept, already established and guidance on toxic pharmaceutical imputities. A major revision of ISO 10993-17 on allowable limits for leachable substances is in progress, though still early in the process. At the present in discussion are risk assessment approaches to use the concept of TTC, and, if it can be shown that an impurity is below the TTC, then the chemical substance is assumed to be of no significant risk. More work is necessary to
Variation in Chemical Characterization Results from Four Test Laboratories

M. Posgai, Johnson & Johnson, Cincinnati, OH.

Chemical characterization is commonly conducted in the biological evaluation of medical devices. These test results may be impacted by laboratory-specific variables, including equipment sensitivity and the available chemical library. An investigation was conducted to evaluate inter-laboratory variations related to compound identification and quantitation. The test articles, two materials (polyurethane and polisoprene) and a medical device, are each known to generate many extractable chemicals. Test articles were extracted in water and isopropyl alcohol under exaggerated extraction conditions (50°C, 72 hours) and analyzed at four test laboratories in a battery of analytical tests per ISO 10993-18. Disparity in the number of reported compounds was observed among the four test laboratories. For example, the reported number of elements in the polyurethane water extract ranged between 0 and 12 for the four labs. For the polisoprene isopropyl alcohol extract, the reported number of gas chromatography-mass spectrometry compounds ranged between 12 and 156 for the four labs. For the polyurethane isopropyl alcohol extract, the reported number of liquid chromatography-mass spectrometry compounds ranged between 3 and 143 for the four labs. In addition, as much as a 10-fold difference in the amount of non-volatile residue was reported. The similarities between the reported compounds varied greatly depending on the test extract. Differences can be partially attributed to the granularity of compound identification and grouping of derivative compounds could improve similarities between test laboratories. Confidence in compound identification also varied, depending on the test laboratory. Comparison of results and the conduct of a risk assessment is further complicated by the reporting of unknown and non-descriptive chemical compounds. This study into inter-laboratory comparisons revealed considerable quantitative and qualitative differences among chemical characterization results, which can potentially impact the outcome of a risk assessment. These results highlight the importance of consistency in test laboratory selection in the identification of design- or process-related changes for individual materials or devices, as well as in the evaluation of potentially equivalent materials.
Corneal Injury Progression

Sulfur Mustard Exposure: A New Model of Corneal Injury Progression

P. McNutt, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.

The eye is the most sensitive organ to sulfur mustard (SM) injury and greater than 90% of SM casualties present with ocular morbidities. While mild and moderate ocular exposures typically resolve without long-term complications, severe exposures involve a prolonged rehabilitation period during which victims are visually disabled. Persistent corneal manifestations subsequently develop in 35-90% of survivors, ranging from chronic ocular discomfort, to advanced corneal disease characterized by progressive corneal degeneration and loss vision. These persistent manifestations are collectively referred to as mustard gas keratopathy (MGK). While mild forms of MGK can be treated symptomatically, severe forms of MGK are progressive and difficult to clinically manage. Despite a century of research, the etiogenesis of corneal SM pathologies is poorly understood, and thus treatment strategies are limited to palliative measures. SM reactivity within biological tissues is rapid and irreversible, and consequently current treatment strategies are focused on mitigating pathological host responses and promoting healing. However, treatments to preserve the epithelium and reduce inflammation have been ineffective in preventing MGK. Hypothesizing that SM toxicity to the non-regenerative corneal endothelium may present a novel injury modality that could explicate ocular SM injury progression, our studies characterized corneal endothelial injury using a well-described vapor SM injury model in rabbits. Convergent functional and ultrastructural methods demonstrated that ocular SM exposure causes acute endothelial toxicity and disruption of endothelial barrier function. MGK eyes exhibit long-term endothelial pathologies, including endothelial cell cytotoxicity and deposition of a retrocorneal fibrous membrane, consistent with an endothelial-to-mesenchymal transition that is associated with endothelial failure. These features were absent in SM-exposed eyes that healed from the acute lesion. The association of endothelial pathologies with MGK suggests that SM damage to corneal endothelial cells provides a novel mechanistic basis for ocular injury progression. Based on these findings, studies hypothesize that (a) the severity of acute SM injury is determined by the degree of endothelial damage, and (b) the efficiency of endothelial repair influences whether corneas resolve or develop MGK.
**2624 Reaching Hazard Conclusions for Endocrine-Disrupting Chemicals: Adapting Systematic Review Methods**

J. Rochester, The Endocrine Disruption Exchange (TEDX), Grand Junction, CO.

Reviews of environmental chemicals, such as endocrine-disrupting chemicals (EDCs), are essential for identifying hazards to the health of humans and wildlife, yet they often lead to inconclusive results that can stall the regulatory process. Attempts to review this literature to arrive at hazard conclusions are often unstandardized, including weight-of-evidence reports or narrative reviews that lack transparency and reproducibility. To address the systematic review methodology has been developed to evaluate environmental health questions. These methods include the Office of Health and Translation (OHAT) Approach for Systematic Review, the University of California San Francisco (UCSF) Navigation Guide, and the systematic review and integrated assessment (SYRNA) of the National Academy of Sciences (NAS). SYRNA increases the objectivity and transparency in an evaluation by using a predefined, multistep process to identify, critically assess, and synthesize evidence. They also contain specific methods to address study quality, among other factors. When appropriate, systematic reviews employ meta-analytical techniques that allow in the interpretation of conflicting results and provide a clearer picture summarizing the overall body of evidence. These methodologies are adapted from the medical field, which has developed, used, and empirically tested systematic review methods to evaluate medical research and reach evidence-based clinical decisions about patient care and interventions. Recognition of the value of systematic review methods has increased among the environmental health community over the last five years. In fact, the US National Academy of Sciences (NAS) recently convened a panel to evaluate how systematic review procedures can be used as part of an overall strategy to evaluate potential low-dose “endocrine-mediated effects for environmental chemicals. The NAS panel, consisting of experts from academia, non-government organizations, government, and industry, developed systematic reviews of two EDCs to illustrate the utility of systematic reviews in decision-making. The resulting report will use the systematic review methodology. In this study, we conducted a systematic review of the literature on the neurological effects of polybrominated diphenyl ethers (PBDEs), as an example of non-reproductive health effects associated with EDCs. The last two speakers are members of the NAS committee and will provide an overview of the timely, cutting-edge evidence and insight from the NAS panel’s report of systematic review use in low-dose environmental toxicology, including its role in regulatory toxicity practices. The NAS strategy and recommendations for evaluating low-dose adverse effects that act through endocrine-mediated pathway will be outlined. The NAS report developed case studies that examined low-dose adverse effects of two EDCs: PBDEs and phthalates. These case studies will be used to illustrate how systematic review methods can be used to evaluate human and animal evidence of adverse effects of EDCs, considerations for health effects evidence and dose-response concordance in integrating the human and animal evidence, and how a published systematic review can be critically evaluated and used when the focus is appropriate for the research question under consideration. They also illustrate an evidence integration process to consider the observed adverse effect and the endocrine-disrupting activity. Now, as we begin to use this tool, we have identified the strengths and weaknesses of systematic review methodologies in the identification and assessment of EDCs. The recent NAS panel report will also be discussed, and their approach considered in the context of SYRNA.

**2626 PDBEs and Neurodevelopment: A Systematic Review Using the Navigation Guide**

J. Lam, University of California San Francisco, San Francisco, CA, Sponsor: J. Rochester

The presentation will provide a brief overview of the Navigation Guide framework as an example of an environmental health systematic review methodology. In this study, we conducted a systematic review exploring developmental exposure to PBDEs and intelligence or Attention Deficit/Hyperactivity Disorder (ADHD) and attention-related behavioral conditions in humans. The Navigation Guide systematic review approach to search articles published up to September 26, 2016 was applied, and included original studies that quantified exposures to PBDEs incurred any time in pregnancy or during in utero, perinatal, or childhood time periods. Fifteen studies met the inclusion criteria; 10 for intelligence and 9 for ADHD-related problems. The studies were reviewed individually with low to probably low-risk of bias. The meta-analysis of four studies estimated a 10-fold increase in PBDE exposure associated with a decrement of 3.70 Intelligence Quotient (IQ) points (95% CI: -6.56, -0.83). It was concluded the body of evidence was of "moderate" quality for ADHD with "limited" evidence for an association with PBDEs, based on the heterogeneity of association estimates reported by a small number of studies and the fact that chance, bias, and confounding could not be ruled out with reasonable confidence.

The first systematic review on this topic and the largest meta-analysis to date, covering over 3,000 mother-child pairs. However, a recurring limitation for systematic reviews remains the inability to combine more relevant studies in a meta-analysis due to the lack of or heterogeneity in reporting study details and measures of association in study publications. To advance the capacity to conduct robust systematic reviews in environmental health, more attention to reporting details and standardized effect estimates should be undertaken. Several high-impact journals have adopted checklists for the reporting of elements necessary to describe studies comprehensively and transparently, which can help to ensure that these details are available for incorporation into future reviews.

**2627 Developmental Neurotoxicity of PBDEs: Integrating Evidence and Consideration of Published Reviews in the NAS Case Study Systematic Review**

A. A. Rooney, NIEHS, Research Triangle Park, NC.

The National Academy of Sciences committee on low-dose toxicity outlined a strategy for evaluating and discussing the evidence for low-dose exposure to environmental chemicals that act through an endocrine-mediated pathway in a July 2017 report. The report includes two systematic review case studies developed to illustrate how these methods can be used to assess the evidence of low-dose effects of EDCs for human and experimental animal literature of polybrominated diphenyl ethers (PBDEs) on neurodevelopment, and (2) evidence that phthalates affect male reproductive-tract development. They also illustrate an evidence integration process to consider use of the health effects and dose-response data from the human and animal evidence streams in reaching hazard conclusions on low-dose effects of EDCs. The approach to evaluating the evidence that PBDEs effect neurodevelopment will be presented. A recent systematic review of the human PBDE epidemiological data was available. The case study developed a new systematic review of the experimental animal data and outlined a procedure to critically assess the published reviews of the human studies. The was moderate level of evidence for PBDEs and effects on learning in rodents based on studies of BDE-47, -99, and -209, with low or inadequate level of evidence to be able to evaluate effects on memory or attention. The Lam et al. systematic review concluded there was a decrease in 3.70 IQ points in children per 10-fold increase in PBDEs, and NAS review considered the human studies provided a moderate level of evidence that exposure to PBDEs is associated...
with a decrease in IQ. During evidence integration, the animal data on learning and memory were considered with the human IQ data to reach the conclusion that developmental exposure to PBDEs is presumed to pose a hazard to intelligence in humans, and that it was not possible to reach a conclusion on potential hazards for attention-related effects based on the available evidence. The lower human exposure levels, both intake and plasma concentrations, associated with effects suggests that animal toxicity testing may detect hazard, but might not be accurately predicting doses at which effects occur in humans. The PBDE case study also illustrates how a published systematic review can be critically evaluated and used for a research question under consideration.

**2628 Phthalate Male Reproductive Toxicity: Comparison of Hazard Conclusions and Dose Responses from the NAS Systematic Review and Traditional Toxicity Testing Studies**

K. J. Johnson, The Dow Chemical Company, Midland, MI.

This presentation will continue addressing the National Academy of Sciences (NAS) committee report on using systematic review to examine human hazard potential following low-dose exposure. One of the case studies developed in the NAS report was an evaluation of the evidence that phthalate exposure effects male reproductive tract development. The data for multiple phthalates were examined, with diethylhexyl phthalate (DEHP) composing a more comprehensive dataset. Upstreaming DEHP case study, systematic reviews of the human and animal data will be outlined, including the steps used to integrate the human and animal datasets, the utility and impact of available mechanistic data at the evidence integration stage, and the dose-response concordance between human and animal data. The DEHP systematic review concluded that in utero DEHP exposure was presumed to be a reproductive hazard in humans. This hazard conclusion will be compared to that obtained from traditional (i.e., guideline) reproductive toxicity studies with DEHP. In addition, the DEHP dose-response concordance between the NAS systematic review and traditional toxicity testing studies will be evaluated in order to highlight the NAS report conclusion that traditional toxicity testing methods “might not accurately predict exposures at which humans are affected.” Finally, key learnings from the NAS report gleaned from both the PBDE and phthalate systematic reviews will be presented, as well as the strengths and weaknesses of systematic review and traditional toxicity testing practices for evaluating human toxicity potential.

**2629 Reducing the Uncertainty of Read-Across Predictions by New Approach Methodologies: Application in Regulatory Human Risk Assessments**

I. Rusyn, Texas A&M University, Texas, TX.

A paradigm shift is ongoing in human risk assessment, away from the traditional in vivo animal studies toward new approach methodologies (NAM). NAM include in vitro, ex vivo, or ’omic technologies, as well as in silico and toxicokinetic modeling. Currently, hazard assessment and derivation of point-of-departure values are based on the apical toxicity findings in animal studies. These apical endpoints seldom provide detailed mechanistic information to inform extrapolation of these findings to humans. NAM have the potential to provide a deeper understanding of key and intermediate steps leading to a certain apical finding, a concept known as adverse outcome pathways (AOP). However, the integration of NAM data into risk assessments is challenging, in particular, for complex endpoints, such as repeated dose or reproductive toxicity. This session will provide an in-depth overview of the use of NAM in regulatory and investigative toxicology, starting with a regulatory perspective, followed by industry examples, and then broadening the scope to cover the most up-to-date developments from the EU-ToxRisk and US academic and government research programs. A focus will be on read-across case studies, by which the use of NAM and mechanistic data are demonstrated. Learnings from the proof-of-concept read-across approaches and case examples will help to develop new mechanism-based chemical safety testing strategies. This session will include a discussion on the limitations and advances of such approaches and the path forward to substantiate and support a paradigm shift in regulatory risk assessment practices.

**2630 Use of Read-Across under the REACH Regulation**

M. Rasenberg, European Chemicals Agency (ECHA), Helsinki, Finland. Sponsor: I. Rusyn

REACH is a regulation of the European Union, adopted to improve the protection of human health and the environment from the risks that can be posed by chemicals. Under this regulation, industry is obliged to assess and document the hazard, exposure, and consequent risk of the chemicals they manufacture or import. Minimum information requirements are defined for the hazard and risk assessment, including for classification and labeling of the substance. Under REACH, animal testing is the last resort, and the use of alternative ways of assessing the hazard of chemicals is highly encouraged. Considerable efforts in developing new approaches and methodologies (NAM) for investigating properties of substances have been made over the past years. Grouping of substances and read-across is one of the most common using alternative approaches for filling data gaps in registrations under REACH. If grouping and read-across are applied correctly, experimental testing can be reduced. The European Chemicals Agency (ECHA), which evaluates dossiers submitted under REACH, developed and published the Read-Across Assessment Framework (RAAF). In registration dossiers, ECHA has evidence for read-across assessment that can be based on theoretical considerations or expert systems, to results from in vivo or in vitro studies. (Q)SARs, alert-based mechanistic profiles, or in vitro assays (e.g., metabolism investigations in cells or cell homogenates) are submitted by registrants. Quantitative toxicokinetics information is unfortunately not so frequently available. Results obtained with ’omics techniques or high-throughput screening are also yet to be used in registration dossiers. This presentation will set out the context of read-across under REACH, describe the RAAF, and will discuss the learnings and paths forward for increased use of NAM-derived data in REACH submissions in the future. The viewers will be presented with a comparison of the hazard conclusions and paths forward for increased use of NAM-derived data in REACH submissions in the future. The viewers will be presented with a comparison of the hazard conclusions and paths forward for increased use of NAM-derived data in REACH submissions in the future. The viewers will be presented with a comparison of the hazard conclusions and paths forward for increased use of NAM-derived data in REACH registrations.
the concept of biological read-across. Each case study has specific scientific questions as well as technical and modeling challenges. Differences in toxicokinetics from in vivo and in vitro investigations are one key aspect of the integrated approach for testing and assessment of EUToxRisk. PBPK models informed by in vitro methods and reverse dosimetry are also used to determine toxicologically relevant test conditions. Overall, the case-study approach is aimed at developing demonstration blueprints on how NAM data may be used in regulatory submissions.

2633 Categorization of UVCBs Using Chemical-Biological Read-Across

I. Rusyn, Texas A&M University, College Station, TX.

Chemicals of unknown or variable composition, complex reaction products, and biological materials (UVCBs) present a major challenge for registrations under the REACH and US High Production Volume regulatory programs. In addition to frequent variations in their chemical composition, many gaps in available toxicity data preclude confident groupings of these substances for read-across applications. Here, we present a comprehensive experimental and computational approach to categorize UVCBs according to global similarities in (1) their chemical composition using ion mobility mass spectrometry (IMMS), and (2) their bioactivity in a suite of in vitro models. For chemical read-across, we analysed petroleum substances from distinct product groups by IMMS to determine substance-specific quantitative parameters including m/z distribution, drift time, carbon numbers, and double bond equivalents. For biological read-across, we exposed various human-induced pluripotent stem cell-derived organotypic models to DMSO-soluble extracts of petroleum substances comprising several product groups. We show how dose-response profiles for cell physiological, cytotoxicity, and targeted transcriptomics (Temp0-seq)-enabled product group-specific grouping. Data integration in ToxPi software and subsequent correlation analysis revealed group-specific clustering and a high degree of correlation between biological and chemical datasets. Altogether, we demonstrate how novel analytical chemistry and in vitro screening approaches can be effectively utilized to categorize UVCBs, thereby indicating their potential applicability in regulatory submissions.

2634 Current and Future Opportunities for US Regulatory Application of Read-Across

N. Kleinstreuer, NIEHS, Durham, NC.

Toxicology in the 21st century has ushered in a scientific revolution focusing on new approach methodologies to understanding chemical hazard and safety and performing human health risk assessment. A key tool in this evolving paradigm is the chemical read-across, by which similarity to chemicals with known toxic effects is used to inform decisions on chemicals with unknown effects. Evolving work on characterizing chemical similarity moves beyond exclusively structure-based methods to hybrid approaches incorporating physico-chemical properties and in vitro bioactivity profiles providing valuable mechanistic insight. Read-across, based on both structural and biological similarity, is currently a useful strategy to increase understanding of chemical hazard without de novo testing. However, expertise, application, and acceptance of the results of a particular read-across vary within and among organizations and regions. The NTP Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM) works with sixteen US federal agencies with an interest in non-animal testing, via the Interagency Coordinating Committee on Validation of Alternative Methods (ICCVAM), and focuses on efforts driven by agency priorities both regulatory and scientific in nature, including read-across applications. The risk assessment division of the US EPA Office of Pollution Prevention and Toxics routinely uses read-across in their existing pipeline, and other offices and regulatory agencies are investigating its utility as the supporting evidence grows. ICCVAM has established a cross-federal read-across working group focused on (1) identifying and evaluating the available approaches, (2) developing guidance and best practices, and (3) addressing both scientific and non-scientific issues, including regulatory challenges. This talk will cover existing regulatory use of read-across by US federal agencies as well as opportunities for data generation and future application.

2635 Conventional Fibrin Clot Formation Is Not Required for Fibrinogen-Directed Repair of the Acetaminophen-Injured Liver

A. K. Kopce1, H. Cline-Fedewa2, M. J. Flick2, and J. P. Luyendy1.1Michigan State University, East Lansing, MI; and 2Cincinnati Children’s Hospital, Cincinnati, OH.

Activation of the blood coagulation cascade and deposition of fibrinogen in the liver are hallmark features of acetaminophen (APAP) overdose. We recently demonstrated that fibrinogen deposits in the APAP-injured liver are critical stimuli of leukocyte-directed liver repair. The canonical blood coagulation cascade is defined by thrombin-catalyzed conversion of soluble fibrinogen monomers to insoluble stabilized fibrin polymers at sites of injury. However, a lack of tools capable of distinguishing the in vivo functions of fibrinogen monomer and fibrin polymer has left the exact nature of the fibrinogen deposits in the APAP-injured liver unknown. Here, we used novel mice (termed FibΔEK mice) expressing soluble fibrinogen completely insensitive to thrombin-mediated polymer formation (i.e., locked in the monomeric form). To induce liver injury, FibΔEK mice and wild-type (WT) mice were given a single hepatotoxic dose of APAP (300 mg/kg, i.p.) or vehicle (saline) followed by analysis after 24 hours. Unexpectedly, the levels of hepatic fibrinogen deposits were remarkably similar in APAP-challenged FibΔEK mice relative to WT mice, as indicated by immunohistochemistry and capillary-based western blotting. APAP-induced liver injury, as indicated by elevated serum alanine aminotransferase activity and centrilobular necrosis, was also similar in FibΔEK mice and WT mice. Whereas complete fibrinogen deficiency dramatically reduced hepatocyte proliferation, indicative of failed liver repair, the number of proliferating hepatocytes in APAP-challenged FibΔEK mice was identical to that of WT mice. Collectively, we demonstrate for the first time that fibrinogen accumulation in the injured liver is independent of thrombin-mediated fibrin polymer formation. Moreover, the results suggest that a novel coagulation-independent form of fibrinogen deposit drives repair of the injured liver.

2636 Chronic Trichloroethylene and Arsenic-Exposed MDR-Null Mice Develop Renal Damage but No Tumors

A. L. Perry, and D. W. Threadgill, Texas A&M University, College Station, TX.

Trichloroethylene (TCE) and inorganic arsenic (iAs) are environmental contaminants and carcinogens that target the kidney. Chronic exposure to TCE is associated with increased incidence of renal cell carcinoma. While co-exposure to TCE and iAs is likely in certain populations, such as those near Superfund sites, a review of the literature did not reveal any studies on co-exposure or co-carcinogenesis of these toxicants. Our objective was to determine whether multidrug resistance gene-null mice chronically exposed to TCE and iAs could be used to model the development of renal cell carcinomas in similarly exposed human populations. An F3 mouse population derived from the FVB/N-Apc11Em1blo, Abcb11Em1blo and CAST/EU strains was exposed to trichloroethylene and arsenic for one year and kidneys from these mice were processed for H&E staining before being analyzed for neoplastic and pre-neoplastic changes. Despite use of TCE and iAs in combination and at environmentally relevant concentrations, primary renal cell tumors failed to develop. A significant increase in histologic evidence of renal disease was observed overall with any level of iAs exposure, but not with TCE exposure. We expected that inclusion of multiple toxicants in environmentally relevant concentrations, primary renal cell tumors failed to develop. A significant increase in histologic evidence of renal disease was observed overall with any level of iAs exposure, but not with TCE exposure. We expected that inclusion of multiple toxicants in environmentally relevant concentrations, primary renal cell tumors failed to develop. A significant increase in histologic evidence of renal disease was observed overall with any level of iAs exposure, but not with TCE exposure. Frontloading Nonclinical Kidney Safety Evaluation in Staphylococcus aureus Minipig Surgical Infection Model Using Novel Biomarkers

Poorly translatable pharmacology models tend to lack significant failure of Staphylococcus aureus vaccines in clinical trials. To increase the success rate of candidate vaccines, we developed a minipig surgical wound infection model which has an immune system that is similar to humans. Several studies have described surgical infection models in rodents that were characterized by infection-induced glomerulo- and tubulo-interstitial nephritis. We developed a minipig model of surgical wound infection that is anticipated to closely resemble human disease. Various plasma, serum, and urine-based biomarkers of infection, inflammation, and nephrotoxicity were assessed. Infection in the deep thigh muscles of minipigs correlated with increased signal intensities detected using PET imaging. Elevations in circulating fibrinogen and haptoglobin were detected as biomarkers of systemic inflammation. Elevations in urinary neutrophil gelatinase associated lipocalin (NGAL) was detected as a biomarker of kidney tubular injury in the absence of changes in serum/plasma NGAL, sCr or BUN. This new, more relevant animal model will enable frontloading kidney safety evaluation in preclinical studies.

Use of Human/Mouse Alanine Aminotransferase (ALT) ELISA to Evaluate Hepatotoxicity in the Humanized-Liver Mouse Model

Predicting adverse effects in humans based on experimental animal model findings can be difficult because of interspecies differences in drug metabolism and disposition. We have developed experimental animal models that have reconstituted livers with human hepatocytes (Hu-liver) to overcome these interspecies issues. Hu-liver mice are a valuable in vivo model for predicting hepatotoxicity in humans. However, the enzymatic activity of alanine aminotransferase (ALT), a conventional liver toxicity marker, cannot be used to evaluate human-specific hepatotoxicity in Hu-liver mice because of the lack of species-specific enzymatic activity. Therefore, we aimed to establish a hepatotoxicity detection method applicable in Hu-liver mice to replace ALT activity. In this study, we used human and mouse ALT ELISA kits (Elabscience Biotechnology Inc.) to evaluate D-galactosamine-induced hepatotoxicity in Hu-liver mice. We administered a single intraperitoneal dose of D-galactosamine (1,000 mg/kg) to Hu-liver and control TK-NOG mice and analyzed routine parameters (ALT activity) and ALT protein level in mice plasma. In all cases, ALT activities were higher in the Hu-liver mouse groups than in the control TK-NOG mouse groups. ALT activity was significantly higher in both Hu-liver (4.0-fold) and TK-NOG (4.8-fold) mouse groups than in the vehicle control groups at 1 d after D-galactosamine treatment. We had confirmed the species specificity of each ELISA kit in advance by conducting cross-validation studies. Human ALT protein plasma level was significantly higher (1.8-fold) in only the Hu-liver mouse group with D-galactosamine treatment. Conversely, mouse ALT protein plasma level was significantly higher in both Hu-liver (3.3-fold) and control TK-NOG (1.7-fold) mouse groups than in the vehicle control groups. These results suggest that D-galactosamine is more toxic to mouse hepatocytes than to human hepatocytes in Hu-liver mice. Thus, a combination of human and mouse ALT ELISA can be used to quantitatively evaluate human liver-specific toxicities in Hu-liver mice model.

The Effect of Antibiotics on Gut Microbiome: A Metagenomics Analysis of Microbial Shift and Antibiotic Resistance in Antibiotic-Treated Mice

L. Xu, A. Chockalingam, S. Stewart, Z. Li, and R. Rouse. US FDA, Silver Spring, MD.

There are long standing concerns about the use of oral antibiotics and their impact on the normal gut microbiota/microbiome and the emergence of antibiotic resistance. More recently, drug-microbiota/microbiome interactions have been identified that have impacted drug efficacy and/or safety through altered drug metabolism. This project characterizes the effect of different antibiotic treatment on the composition of the gut microbiota/microbiome and the prevalence of antibacterial resistance in the gut in the context of UTI treatment. This knowledge provides a foundation for stratifying the risk potential of different antibiotics and antibiotic combination therapies to negatively impact health through a microbiota/microbiome. Standard NGS procedures were used with bio-informatics to conduct metagenome analysis on fecal samples from mice experimentally infected by inoculation of E.coli into the urinary bladder. Three antibiotics (ampicillin, ciprofloxacin, fosfomycin) commonly used for UTI were administered and fecal samples collected to compare and contrast treatment influence on the gut microbiota and microbiome composition.

99 autoimmune-related genes by more than 1.5-fold (p>0.05) in the 1, 5, 9, and 13 wk cohorts, respectively. Categories of upregulated genes included interferon-driven proteins, chemokines, cytokines, complement, and macrophage/lymphocyte activation markers. Diets containing low and high DHA concentrations blocked expression of 80-90 % and 100 %, respectively, of the autoimmune genes triggered by cSiO2. These results suggest that DHA supplementation at physiologically relevant doses might be useful in preventing cSiO2 triggering of lupus and other human AD. Supported by NIH grant ES027353, Lupus Foundation grant 362470, and the Dr. Robert and Carol Diebel Family Endowment.

**2647** Dysregulated WNT Signaling in PTSD Patients Correlates with Altered Epigenetic Marks and Elevated Inflammation

M. Bam, X. Yang, P. S. Nagarkatti, and M. Nagarkatti. University of South Carolina School of Medicine, Columbia, SC.

It is now known that PTSD patients exhibit chronic systemic inflammation characterized by upregulated expression of pro-inflammatory cytokines such as IFNγ and IL-12. However, the mechanism of regulation of these genes and the cells producing these cytokines is inadequately understood. In this context, WNT/β-catenin signaling pathway is critical for the proliferation, differentiation, polarization, and survival of mature T cells. We have reported that T cells (Th1 and Th17) are increased in number in the PBMCs of PTSD patients which also correlated with the increased expression of IFNγ. However, it is not yet reported which regulatory molecules trigger a pro-inflammatory cytokine response in monocytes associated with ROS production, providing insights into potential systemic and pulmonary toxicity, and tissue damage in e-cigarette users. Supported by the 1R01HL135613, 1R01HL085613 and 1R01HL085613-S1, FDA-CTP 1R01DA042470, and T32 Toxicology training grant #T32ES007026.

**2646** Immuno-Toxicalogical Response in Monocytes to E-Cigarette Flavor Chemicals and E-Liquids

E-cigarettes are used as an alternative to smoking conventional cigarettes. These are available in over 7,000 unique flavors. Flavorings used in e-cigarettes are often generally recognized as safe (GRAS) for ingestion. However, the inhalation exposure to e-cigarette containing flavoring chemicals are not known. **Rationale:** We focused our study on the immuno-toxicalogical effects by these flavoring chemicals and flavored e-liquids on monocytes. We hypothesized that the flavoring agents and the flavored e-liquids induce reactive oxygen species (ROS) production associated with a systemic pro-inflammatory response. Monocytic cells (Mono-mac6 and U937) were exposed to flavoring chemicals, diacetyl, cinnamaldehyde, 2, 3-pentanedione, o-vanillin, maltol, coumarin, and aceton at different doses of microM ranges (10 µM to 1000 µM). Cell viability and the concentrations of the secreted inflammatory chemokine IL-8 were measured in conditioned media after treatment with selected e-cigarette flavors (café latte, melon mania, and cinnamon roll) at various concentrations. Cell-free ROS levels produced by commonly used flavoring chemicals and selected flavors of e-liquids were measured using 2′, 7′-dichlorodihydrofluorescein diacetate as a probe, and the results were expressed as hydrogen peroxide equivalents. Treatment of the cells with flavor chemicals and e-liquids caused varying degrees of cellular toxicity. Cinnamaldehyde, o-vanillin, diacetyl, café latte and melon mania produced significantly increased levels of IL-8 in a dose-dependent manner compared to their unexposed counterparts. Similarly, e-liquids and the flavoring chemicals produced significantly increased ROS concentrations in a dose-dependent manner compared to controls. Pentanedione, o-vanillin and café latte produced the highest hydrogen peroxide equivalents. Our data suggest that the e-flavor liquid constituents trigger a pro-inflammatory cytokine response in monocytes associated with ROS production, providing insights into potential systemic and pulmonary toxicity, and tissue damage in e-cigarette users. Supported by the 1R01HL135613, 1R01HL085613 and 1R01HL085613-S1, FDA-CTP 1R01DA042470, and T32 Toxicology training grant #T32ES007026.

**2648** Voltage-Gated Potassium Channel Kv1.3 Contributes to Sustained Microglial Activation and Neuroinflammation in Neurotoxicity Models of Parkinson’s Disease

S. Sarkar1, H. Nguyen1, H. Wulff2, E. Malovic1, M. Lanegley1, J. Luo1, M. Jin1, V. Anantharam1, A. Kanthasamy1, and A. G. Kanthasamy1.

1 Iowa State University, Ames, IA; and 2 University of California Davis, Davis, CA.

Protein aggregation is one of the major pathological hallmarks of Parkinson’s disease (PD). Recently, our lab demonstrated that metal toxicity leads to enhanced protein aggregation. The aggregation of misfolded α-Synuclein has been shown to activate microglia, thereby initiating chronic neuroinflammation in PD models, but the molecular targets that drive sustained inflammation is equivocal. Identifying the cellular targets contributing to microglial activation could provide potential therapeutic targets to slow down chronic neurodegeneration. In this study, we observed a significant upregulation of Kv1.3 voltage-gated potassium channel, is specifically upregulated in aggregated αSyn fibril (aSynfib)-stimulated primary microglia. Patch-clamp electrophysiological studies confirmed that the observed Kv1.3 upregulation translates to increased Kv1.3 channel activity. Additionally, we found Kv1.3 channel expression to be in three different mouse models of PD, including MPTP, AAV αSyn and MitoPark transgenic mice. Importantly, Kv1.3 channel was also upregulated in human PD postmortem samples. Furthermore, Kv1.3 knockout microglia treated with aSynfib had lower production of pro-inflammatory cytokines, demonstrating the proinflammatory functional relevance of this channel. Moreover, the Kv1.3 G protein-coupled receptor (NOD) ligands. The SMI microtissues are cultured using human monocytic cells producing these cytokines is inadequately understood. In this context, WNT/β-catenin signaling pathway is critical for the proliferation, differentiation, polarization, and survival of mature T cells. We have reported that T cells (Th1 and Th17) are increased in number in the PBMCs of PTSD patients which also correlates with the increased expression of IFNγ. However, it is not yet reported which regulatory molecules trigger a pro-inflammatory cytokine response in monocytes associated with ROS production, providing insights into potential systemic and pulmonary toxicity, and tissue damage in e-cigarette users. **2649** In Vitro 3D-Human Small Intestinal Tissue to Study Ligand-Induced Acute and Chronic Inflammation in the Gastrointestinal Tract

M. Klausner1, T. Landry1, Z. Stevens1, J. Markus2, P. Hayden1, and S. Ayehunie1. 1 MatTek Corporation, Ashland, MA; and 2 MatTek In Vitro Life Science Laboratory, Bratislava, Slovakia.

The intestinal epithelium is known to be involved in innate immune responses by recognizing pathogenic entities such as pathogen-associated molecular patterns (PAMPs) that drive innate immune receptors (PRRs). Abnormal innate immune responses have been implicated in the pathogenesis of inflammatory bowel diseases (IBD). To investigate PRR responses on the intestinal mucosa, we exposed an in vitro 3D human small intestinal (SMI) microtissue (EpiStem, MatTek) model to various TLR ligands (TLRs) and a broad-spectrum receptor (NOD) ligands. The SMI microtissues are cultured using human intestinal fibroblasts and enterocytes and their 3-dimensional polarity and morphology mimics that of native in vivo tissues. Characterization of the microtissues included evaluation of structural features, barrier properties, and expression of drug transporters and drug metabolizing enzymes. Ligands to TLR4 (LPS) and NOD2 (Muramyl dipeptide: MDP) induced gene expression of proinflammatory cytokines such as IL-1β, IL-6, and RANTES in a synergistic manner. Prolonged exposure of intestinal microtissue to IL-1β resulted in reduced tissue membrane integrity, which may be a precursor for IBD-like disease, and led to further induction of pro-inflammatory cytokines and chemokine gene expression (IL-6 and CCL20), which are known to stimulate acquired immune cell responses including release of TNF-α and IFN-γ. To simulate the effect of dysregulation of the WNT/β-catenin signaling pathway in PTSD which might be the reason for the elevated inflammation. The study provides further evidence that inflammation in PTSD is epigenetically regulated and this pathway could be useful for PTSD diagnosis and combating the inflammation. This work was supported in part by National Institutes of Health grants R01AT003961, R01AT006888, R01AI123947, R01AI129788, R01MH004375, and P20GM103641.
of immune cell responses on the intestinal epithelium, we exposed the intestinal microtissue to TNFα and IFNγ, which resulted in the reduction of membrane integrity and the release of proinflammatory cytokines. The effect of TNFα and IFNγ on the intestinal epithelium was further exacerbated if antigen-presenting cells such as dendritic cells were incorporated into the 3D intestinal tissue model. In summary, the results suggest that the intestinal microtissues in ZIKV infected brains are capable of producing various innate immune responses and that it will likely prove to be a useful tool to study the complex interactions of human intestinal epithelium with microbiome in the induction of IBD-like disease.

Zika virus (ZIKV) is an emerging virus from the family Flaviviridae. ZIKV is transmitted to humans primarily by mosquito vectors and has been responsible for epidemics throughout tropical and subtropical areas. ZIKV infection has spread rapidly in the tropical Americas since its identification in Brazil in 2014 and infections have been associated with microcephaly in newborns. However, the molecular mechanisms underlying ZIKV pathogenicity and tissue tropism are still unclear. The viral Envelope (E) protein is critical for viral attachment and entry to the host cells by binding to cellular receptors and by intra-endosomal acid catalyzed fusion. By using Mass spectrometry analysis and communoprecipitation assays, we show that the ZIKV-E protein is ubiquitinated by TRIM7, a member of the E3-ubiquitin ligase Tripartite Motif (TRIM) family of proteins. Using recombinant infectious ZIKV bearing Lysine to Arginine mutations that lack ubiquitination on E, we show that ubiquitiniation of sE is important for virus replication in specific cell types in tissue culture and for pathogenicity in vivo. Our data suggest that ZIKV hijacks the host ubiquitin system to enhance its own replication, and identifies a new host factor that could represent a potential target for development of antiviral drugs against ZIKV infections.
Flavivirus infections are a cause of great concern throughout the world due to recurrent epidemics and high mortality rates, being a public health problem. The relevance of the Zika virus (ZIKV) infection study was highlighted by the large number of infants born with microcephaly, especially in the Brazilian Northeast, in addition, some adults exhibited cases of Guillain-Barré syndrome (GBS) cause by ZIKV. In May 2016, the relationship between ZIKV infection during pregnancy and microcephaly cases was proved by our group. It is known that ZIKV, like other flaviviruses, has the ability to modulate innate and adaptive immune response of the host. Thus, in this work we aim to evaluate the role of CD8+ T cells in controlling viral replication and disease progression in murine infection by ZIKV. ZIKV Brazilian strain was used to infect C57BL/6 and CD8 deficient mice, all analysis were performed at 1, 3, 5 and 7 days post infection by flow cytometry or PCR. Wild-typeC57BL/6 animals controlled infection, unlike animals deficient in CD8 T cells, in which on the seventh day after infection it is still possible to detect viral particles in the spleen. In fact, ZIKV infection induces an increase in the frequency of CD4+ and CD8+, accompanied by CD8+ Foxp3+ and CD4+ Foxp3+ cells. The absence of viral load in spleen of control mice may be due to increase of Ifn-β expression different on the spleen of CD8 T cells deficient animals. CD8 T cells could regulate Ifn-β expression which is one of the most important cytokines in controlling viral replication and T suppressors cells could be evolved in suppressing immune response against zika virus infection.

### 2654 The Role of CD8 Cells in Experimental Zika Virus Infection

N. Ghabdan Zanluqui, C. Manganeli Polonio, L. Gomes de Oliveira, C. Rossato, C. Longo de Freitas, and J. S. Schatzmann Peron. São Paulo University, São Paulo, Brazil.

Viral infections always have been serious illnesses causes that have repercussions on morbidity and mortality increasing rates worldwide. Recently, a flavivirus transmitted by the vector Aedes aegypti, called Zika virus (ZIKV) was introduced in South America, causing a major public health problem. On February 1, 2016, the World Health Organization (WHO) declared a state of global concern after the alarming increase in the number of babies born with microcephaly and adults with Guillain-Barre syndrome in our country, both related to the infection. Genetic differences, mainly related to Interferons (IFN), may greatly influence the susceptibility to infection. The IFN are classified in general in two types: Type I IFN is a major cytokine involved in antiviral response and includes IFN-α and IFN-β, which can be secreted by all the nucleated cells during virus-triggered response, participating in apoptosis cell death induction of infected cells. On the other hand, Type II IFN (also known as IFN-y) is produced only by T cells and NK cells. It's known that during DENV infection, another flavivirus, IFN-γ-dependent mechanisms were associated with DENV resistance. Thus, in this project, we evaluated the role of IFN-y in experimental ZIKV infection. We infected the C57BL/6 WT and IFN-γ-/- mice with 1x10^5 PFU intravenously and the analysis was done 1 and 3 days post infection on spleen. Our results demonstrated an important role for IFN-γ in combating ZIKV infection, since IFN-γ-/- mice showed highest number of viral copies at spleen 1 and 3 days post infection compared to WT mice. In addition, we observed an increase in type I IFN cytokines production on the first day of infection in the WT mice, followed by a decrease, unlike the deficient animals, which production peaked on the third day. Consequently, the decrease was observed in the IRF7 and IRF9 transcription factors induction and in the interferon-induced antiviral genes (ISGs) expression, such MX1, ISG15 and IFITM3. Taken together, these data demonstrate the importance of the IFN-γ cytokine in the assembly of the antiviral response against ZIKV, once the expression of factors responsible for this response are produced later.

### 2655 Evaluation of the Role of Interferon-y in Zika Virus Infection

C. M. Polonio, N. G. Zanluqui, L. G. Oliveira, C. L. Freitas, and J. S. Peron. University of São Paulo, São Paulo, Brazil.

Zika virus (ZIKV) emerged as a global health problem and demands efforts of the scientific community to understand the underlying mechanisms involved in the host cell infection. ZIKV is part of the flavivirus genus, such as dengue virus, whose cellular invasion mechanism has been elucidated in the literature. It is clear the involvement of Axl receptor Tyro3 and Mer (TAM Family) during infection of dengue virus, a phosphatidylserine-dependent endocytosis mechanism. Studies conducted by our group showed a possible link between increased expression of TAM receptors and the infection of ZIKV, as well as the susceptibility of SJL mouse strain to ZIKV infection. This study aims to evaluate the role of TAM receptors in the Zika virus infection in SJL and C57BL/6 mice lineages. Mice were infected with 10^3 pfu of ZIKV intravenously and the organs were collected after 1 and 3 dpi. SJL strain expressed high amounts of Zikv virus RNA in the spleen compared to C57BL/6 mice. The presence of Zika virus infected Axl expression in SJL mouse at day 1, and when BGB324 (Axl blocker) was used the viral load decreased. From these data we can conclude that the treatment with Axl blocker decreases the viral load showing that Axl is one of the possible receptors that allows ZIKV infection. Furthermore, there was a difference between spleen viral load of SJL and C57BL/6 mice and also the expression of Axl receptor.

### 2656 The Role of Axl During Infection by Zika Virus in SJL and C57BL/6 Mice

L. G. Oliveira, N. G. Zanluqui, C. M. Polonio, C. L. Freitas, and J. S. Peron. University of São Paulo, São Paulo, Brazil.

Zika virus (ZIKV) is a flavivirus that causes a global health problem. The virus is transmitted by the mosquito Aedes aegypti and can cause severe diseases such as dengue fever, Zika fever, and microcephaly. Axl is a receptor that has been shown to play a role in the infection of dengue virus, which is part of the flavivirus genus. A recent study investigated the role of Axl during Zika virus infection in SJL and C57BL/6 mice. Mice were infected with Zika virus intravenously and the organs were collected after 1 and 3 days post-infection. SJL mice expressed high amounts of Zika virus RNA in the spleen compared to C57BL/6 mice. The presence of Zika virus infected Axl expression in SJL mice at day 1, and when BGB324 (Axl blocker) was used the viral load decreased. From these data we can conclude that the treatment with Axl blocker decreases the viral load showing that Axl is one of the possible receptors that allows ZIKV infection. Furthermore, there was a difference between spleen viral load of SJL and C57BL/6 mice and also the expression of Axl receptor.

### 2657 Regulatory Aspects of the Nonclinical Safety Evaluation of Zika Vaccines

C. Wrzesinski, and M. Green. US FDA, Silver Spring, MD.

FDA’s primary object in reviewing First in Human studies is to assure the safety of enrolled patients or healthy volunteers and stringent non-clinical evaluation of a new vaccine before testing in humans is a critical factor in the evaluation of safety. However, in the case of a potential pandemic outbreak a fast and efficient approach is needed to expedite the development of a safe and effective vaccine, particularly in areas of medical need without countermeasures. In the case of developing a vaccine for the Zika virus, a flexible approach was adopted that focused on assessing relevant new and available toxicologic information. Several approaches were adopted and included new toxicology studies, consideration of prior non-clinical and clinical experience with highly similar products, as well as focused toxicology studies. Additionally, toxicology studies including those evaluating potential reproductive developmental toxicities of the vaccine were considered as part of the future product development. For such vaccines developed for maternal immunization, reproductive toxicology studies need to be performed prior to starting clinical trials in pregnant women.

### 2658 Oral Exposure to 2-[1-Methyl-2-(4-phenoxyphenoxy)ethoxy]pyridine (MPEP) for 28 Days Alters Antibody Responses in Harlan Sprague-Dawley Rats

S. C. Burleson1, V. J. Johnson1, F. G. Burleson1, G. R. Burleson1, B. McIntyre2, V. G. Robinson2, S. Masten2, and D. R. Germolec2.

1Burleson Research Technologies, Morrisville, NC; and 2NIEHS, Research Triangle Park, NC.

2-[1-Methyl-2-(4-phenoxyphenoxy)ethoxy]pyridine (pyriproxyfen; MPEP) is a registered insecticide that exerts effects as a juvenile hormone analog and inhibits larval growth and development thereby preventing emergence of adult insects. MPEP is marketed for control of mosquito populations that are major vectors of infectious diseases including Zika virus. Due to the limited data available, this study was performed to determine the impact of MPEP exposure on the immune response in adult Harlan Sprague-Dawley (HSD) rats. Innate, humoral, and cell-mediated immune responses were assessed following 28 days of oral MPEP exposure at doses of 0, 62.5, 125, 250, and 500 mg/kg. Parameters evaluated included measurement of antibody production and cell-mediated immune responses. Antibody responses were measured in rats treated with ≥ 250 mg/kg MPEP, and a significant decrease in the anti-KLH IgM response was observed within the same rats following MPEP exposure. Minimal changes were observed in other immune endpoints. Neutralizing antibody responses influence the susceptibility of MPEP-exposed HSD rats to influenza virus infection and viral clearance. This work was supported by NIH contract HHSN272201400017C.
Synergistic Role of Nanoceria on the Ability of Tobacco Smoke to Induce Carcinogenic Hallmarks in Lung Epithelial Cells

L. Rubio¹, J. Bach¹, R. Marcos¹,², and A. Hernández¹,². ¹Universitat Autònoma de Barcelona, Bellaterra, Spain; and ²CIBER Epidemiología y Salud Pública, ISCIII, Madrid, Spain. Sponsor: A. Sampayo-Reyes

Ceferium oxide nanoparticles (nanoceria) have been proposed as a new promising agent in the treatment of oxidant diseases, including cancer, due to its known antioxidant properties. However, several biosafety concerns need to be solved before this nanomaterial can be applied in biomedical applications with security, as, i.e., there are no available data on the associated toxicological effects under realistic long-term exposure and co-exposure scenarios. This work aim to evaluate the transforming effects of long-term exposure to nanoceria in lung epithelial BEAS-2B cells, along with the effects associated to a common plausible tobacco co-exposure. Thus, BEAS-2B cells continuously exposed to 2.5 µg/mL of nanoceria alone or in combination with 1 and 5 µg/mL of tobacco smoke condensate (CSC) for up to 6 weeks were monitored for intrinsic and extrinsic changes associated with the acquisition of an oncogenic phenotype. Alterations in cellular morphology, growth and differentiation status were measured through the exposure, matrix metalloproteinase (MMP) activities were measured by zymography, colony formation and promotion were measured by soft agar assay, and cellular migration capacity was evaluated by wound healing assay. Results evidence no transforming ability of nanoceria in exposed BEAS-2B cells. However, results support a synergistic role of nanoceria on CSC transforming ability, as cells co-exposed to nanoceria plus CSC, when compared to cells exposed to CSC alone, showed a more noticeable spindle-like phenotype, an increased proliferation rate, higher degree of differentiation status dysregulation, higher migration capacity, increased anchorage-independent cell growth and a secretome with higher levels of MMP 9 and cell growth promoting capability. When mRNA expression of FRA-1 was evaluated as a mechanism of tobacco-induced transformation, nanoceria co-exposure was again found to exacerbate the observed expression changes. Our results point out the need for studying nanomaterials mixed exposure scenarios likely to be found in the environment and/or at working place.

Prothrombotic Risk of Silver Nanoparticles Mediated by Procoagulant Activation of Red Blood Cells

Y. Bian, K. Kim, and J. Chung. Seoul National University, Seoul, Korea, Republic of.

Silver nanoparticles (AgNPs) have been estimated to present possible toxicity during transport, uptake and degradation as drug carriers in drug delivery system and cancer therapy. High concentration of AgNPs are exposed to circulating blood cells if taken intravenously. As the most abundant blood cells in human body, the potential risk of AgNPs on red blood cells (RBCs) could not be ignored. As well as platelet, RBCs are also included in the process of procoagulant activity and thrombosis. Here, we examined AgNPs (50-100 µg/mL) significantly exaggerated procoagulant activity via phosphatidylserine (PS) exposure, which is externalized from inner to outer membrane by key enzymes regulating membrane phospholipid asymmetry. Increase of intracellular calcium and generation of reactive oxygen species (ROS) due to AgNPs-induced oxidative stress were detected and further confirmed by chelation of calcium and application of antioxidants, respectively. Additionally, intravenous injection of AgNPs (10-50 mg/kg) significantly increased thrombosis via PS-exposing RBCs. As AgNPs are applied for cancer therapy, we evaluated the risk of thrombotic events through freshly RBCs isolated from cancer patients and found the prothrombotic effects induced by AgNPs were increased. Therefore, the intravenous AgNPs cancer therapy requires to be carefully concerned.

Functionnalization of Multiwalled Carbon Nanotubes Alters the Pro-inflammatory and Fibrogenic Response in Human Pulmonary Cells In Vitro and in Mice following Pulmonary Exposure

Multiwalled carbon nanotube (MWCNT) inhalation exposure is a potential risk to human health due to their escalating production and use in consumer products. In order to guarantee their safety, the toxicity properties and mechanisms of MWCNTs must be identified. Functionalization of MWCNTs has been shown to either decrease or increase pulmonary injury depending on the type of functionalization. The International Collaboration on Nanotube Safety (ICONS) is a USA/Europe research program funded to study the potential risks of a panel of functionalized nanotubes manufactured by the company Nanocyl. The panel of MWCNTs included the original manufactured MWCNTs as well as a grinded version and ones that have been chemically or thermally purified. The purified MWCNTs were then functionalized with carboxyl or amine groups. In order to test their inflammatory and fibrogenic potential in vitro, we measured mRNA expression in a panel of pro-inflammatory and fibrogenic mediators in human macrophages (THP-1), bronchial epithelial cells (BEAS-2B) and fibroblasts (MRC-5) 24h after exposure to 8 varieties of Nanocyl MWCNTs. To test this in vivo, male C57BL6 mice were dosed via oropharyngeal aspiration with either 1.6 or 4 mg/kg of 4 varieties of Nanocyl MWCNTs with Mitsui-7 MWCNTs used as a positive control. Necropsy was performed 3 days post-exposure and bronchoalveolar lavage fluid (BALF) and lungs were collected for analysis of inflammation and fibrosis. After MWCNT exposure to all cell types, the two carboxylated MWCNTs were determined to be the most fibrogenic. The greatest inflammatory were the ground up MWCNTs and the chemically purified, aminated MWCNTs. Exposure to mice resulted in increased numbers of neutrophils and eosinophils in the BALF. We found the aminated MWCNTs having the strongest effect. The aminated MWCNTs also resulted in increased levels of pro-fibrogenic mediators in the BALF. Based on our findings, the MWCNTs with the least fibrogenic potential are the unaltered MWCNTs and the purified MWCNTs with no functionalization. The least inflammatory MWCNT is the chemically purified MWCNTs with no functionalization. Based on the results in mice, the chemically purified/aminated MWCNTs are the most inflammatory and have the highest fibrogenic potential. Funded by: NSF 15-022.

Functionalization of Multiwalled Carbon Nanotubes Alters the Pro-inflammatory and Fibrogenic Response in Human Pulmonary Cells In Vitro and in Mice following Pulmonary Exposure

Because of the increased use of engineered nano-materials (ENM), it is important to develop a better understanding of ENM bioactivity and their potential for causing inflammation and disease. Some ENM have been reported to be bioactive and to trigger a pro-inflammatory response when inhaled. Alveolar macrophages have been demonstrated to be responsible for this inflammatory response due to their release of the cytokine, IL-1β. A key step preceding and linked to IL-1β release is phagolysosomal protein permeability (LMP). Some ENM have been implicated in inducing LMP in alveolar macrophages, which in turn results in release of cathepsin B from the phagolysosome. While, LMP has been implicated in this inflammatory pathway, the mechanisms of ENM-induced LMP remain unclear. It has been reported that ENM can have interactions with lipid membranes, therefore it is hypothesized that LMP is generated by a disruption of lipid packing in the membrane, caused by the ENM interacting with membrane lipids. The cell models used in this work were bone marrow derived macrophages (BMDM) and human red blood cells (RBC). BMDM from C57BL/6 mice were selected as a model for seamed macrophages. These cells were treated with 25-50µg/mL of crystalline silica (SiO2), a material reported to cause inflammation, or titanium dioxide (TiO2) for 16 hours and cytokines were measured, as a measure of LMP. Both SiO2 and TiO2 produced significantly increased cathepsin activity with SiO2 greater than TiO2. RBC were used as a simplified surrogate for internal cellular membranes, such as the phagolysosome. RBCs were exposed to SiO2 or TiO2 ENM for four hours at doses ranging from 25-200µg/mL. Subsequently, the RBC membranes were assayed for permeability and changes to lipid packing by a hemolysis assay and fluorescence lifetime imaging microscopy (FLIM), respectively. A significant increase
in hemolysis in response to SiO2 and TiO2. FLM results indicated increases in lipid packing around the fluorescence probe Di-4ANNEDPHQ, as a result of SiO2 and TiO2 exposure. These results suggest SiO2 and TiO2 generate LMP by inhibiting natural lipid mobility that can potentially induce membrane permeability.

**2663 Cell Cycle Alterations after In Vitro Exposure to Pegylated Gold Particles in Cancerous vs. Non-Cancerous Lung Cells**

H. Lujan1, M. Criscitiello2, and C. M. Sayes1. 1Baylor University, Waco, TX; and 2Texas A&M University, College Station, TX.

In the past few years engineered metal and polymer based nanoparticles have seen an increase in use in the pharmaceutical industry as drug delivery carriers (DDC) used for cancer therapy. The increased vasculature, altered morphology, and metabolism of cancer cells allow nanoparticles to be specifically engineered to preferentially penetrate these tissues over non-cancerous cells. PEGylated gold nanoparticles are highly utilized as an excitant (i.e. DDC, the non-active ingredient) due to their increased stability over polymer based DDCs while remaining bio-inert (i.e. does not react within the body). However, as the rate of administration of therapeutics containing gold nanoparticles increases, there is a need to characterize the interactions of the excitant with different biological test systems. To identify how the gold nanoparticles interact within the lungs, a pair of cancerous and non-cancerous cell lines from the bronchus (AS49 & BEAS-2B) and pleural space (Calu-3 & Met-5A) were examined for uptake of 20nm PEGylated gold nanoparticles and nanoparticle-induced cell cycle changes. Baseline gene and protein expression of Cyclin dependent kinases (CDKs) and CDK inhibitor p21, along with normal cell morphology were examined prior to exposure. Dose-responsive changes to the cell cycle were shown regarding changes in cell viability, proliferation, morphology, DNA integrity, and perturbed expression of CDKs and CDK inhibitors. While all cell lines exhibited changes in gene/protein expression, the two cancerous cell lines and pleural space cells were more susceptible to alterations in their normal cell cycle.

**2664 Screening In Vitro Toxicity Endpoints of Carbon Nanotubes and Nanofibers from United States Facilities**

nanotubes and nanofibers (CNT/F) to advance material science applications. Unfortunately, those same characteristics that provide significant potential for application may also confer adverse health effects. CNT/F represent a broad class of materials and we hypothesized that not all CNT/F produced or utilized in US facilities confer similar toxicities. Extensive characterization was done for seven different multiwalled CNT and two CNF that were selected based on primary particle diameter ranging from 10 to 150 nm. The specific surface areas ranged from 18 to 238 m2/g and decreased with increasing primary particle diameter. Key molecular-initiating events (MIE) and functional responses were screened over a wide dose range (0.03-60 µg/mL) in a human monocytic cell line (THP-1), both wild-type and NLRP3 inflammasome deficient cells, and in primary human lung fibroblast cells (PHF). Membrane damage and cell proliferation in THP-1 challenged with CNT/F for 24 h segregated by diameter with materials greater than or equal to 50 nm in diameter inducing greater toxicity. There was ~150 fold change in IL-1β secreted in THP-1 WT vs NLRP3 deficient cells and for all the CNT/F tested, apart from having a dose-dependent increase, the level of secretions was enhanced with increasing primary particle diameter. Similarly, CNT/F exposure (0.3 µg/cm2) to PHFs elicited increased cell proliferation and collagen I production that was greater with increased primary particle diameter. Structure activity correlations to date indicate that CNT/F could be broadly classified into two groups, materials below 50 nm in primary particle diameter were less bioactive/toxic than tubules greater than 50 nm. Ongoing research and modeling will further elucidate relationships between physicochemical characteristics and toxicity profile of various CNT/F.

**2665 Cytotoxicity of Applied Nanoclusters for Cellular Imaging**

R. Aagoo1, C. Dymond1, N. Baxter2, R. Jimenez2, N. Bunce1, S. karna1, and S. Hussain1. 1Airman Systems Directorate, Dayton, OH; 2Reppinger Summer Internship Program, Dayton, OH; 3US Army Research Laboratory, Aberdeen Proving Ground, MD; and 4Air Force Research Laboratory, Wright-Patterson AFB, OH.

Nanoclusters (NCs) are recognized for their unique optical and biodispersion properties. NCs possess possible applications in tissue imaging and treatment strategies. However, the toxicity and optical properties of these compounds have yet to be evaluated in human cells. Recently a human microglial cell line was employed to investigate if noncancerous human neuronal cells can synthesize NCs and if pre-synthesized gold (Au) and iron (Fe) NCs result in cell stress and death. Cells were either treated with chloroauric acid (HAuCl4) or Au and Fe NCs for up to 72 hrs. Exposure to HAUCL4 or Fe NCs resulted in a dose-dependent loss of cell viability within the first 8hrs of exposure, with a continuing loss through 72 hrs. High HAUCL4 exposure lead to significant increased reactive oxygen species (ROS) within 24 hrs following exposure, which continued through the exposure study. Similarly, Fe NCs resulted in ROS within two hours after exposure, signal was found to rise through the exposure time. Interestingly, Au NCs did not produce a notable increase in ROS during the first 5 hours, however; once induced, ROS signal plateaued after another 24hrs. Fluorescent imaging revealed increased cell fluorescence following exposure to all compounds, with fluorescence seen in the cytoplasm during HAUCL4 and Au NC exposures; and dispersed throughout the cell during Fe NC exposure. Transmission electron microscopy confirmed microsome uptake of all compounds, and suggest localization within cellular vesicles. Inductively coupled plasma-mass spectrometry also indicated increased uptake of materials in a temporal and concentration-dependent manner. Taken together these results highlight i) the capacity for human neuronal cells to self-synthesize NCs following HAUCL4 treatment, ii) the bioavailability and cytotoxicity of pre-synthesized nanocluster, iii) the ability for human cells to uptake pre-synthesized NCs, and iv) the resulting increased intracellular fluorescence from all these material treatments.

**2666 Differentiation State of Airway Epithelial Organotypic Culture Models Is a Potential Mediator of Silver Nanoparticle-Induced Toxicity**

Engineered nanomaterials, including silver nanoparticles (AgNP), are one of the largest groups of emerging toxicants. They are used in hundreds of consumer products due to their antimicrobial properties, and have a potential to aerosolize through the manufacturing and usage of these products. AgNP are respiratory toxicants with potential to cause allergic airway inflammation; however, the genetic, environmental, and temporal factors that may mediate their toxicity have yet to be fully elucidated. This study has developed airway epithelium organotypic culture models (AE-OCM) as a platform to identify these potential mediators and use them to inform Adverse Outcome Pathways (AOP) for allergic airway diseases, such as asthma. We are quantifying gene × environment × time interactions (G×E×T) using AE-OCM derived from two inbred founder strains of Collaborative Cross mice (AJ and C57BL/6J), differentiated under two conditions (~ IL-13 and ~ IL-13; 25 ng/mL), and treated with AgNP (12.5, 25, and 50 µg/mL) at two time points—a four-hour repeated exposure over five days (5×4 hours), and 24 hours. Endpoints of interest include: changes in epithelial barrier function, cytotoxicity, and enrichment of gene ontologies for pathways associated with allergic airway inflammation. In AE-OCM + IL-13, we found significant reductions in epithelial barrier function, as measured by transepithelial electrical resistance (TEER; ohm×cm2), after AgNP treatment (25 and 50 µg/mL) at 5×4 and 24 hours compared to untreated control at day in vitro 24. We also found significant increases in cytotoxicity, as measured by LDH Release (%), after AgNP treatment (12.5, 25, and 50 µg/mL) at 5×4 and 24 hours compared to untreated control. We found few significant differences in cytotoxicity across strains, with A/J showing increased susceptibility compared to C57BL/6J. Compared to preliminary data for AE-OCM, AE-OCM + IL-13 shows reduced epithelial barrier function at baseline, and increased cytotoxicity after AgNP treatment, suggesting that differentiation state may mediate AgNP-induced toxicity.
Iron oxide nanoparticles (IONPs) are emerging as unique components of drug delivery systems, imaging techniques, environmental catalysts, components of thermoplastics, and more. Workers in IONP manufacturing facilities are known to be exposed to low doses of these particles over long periods of time. However, few studies have assessed potential adverse outcomes following this type of occupationally relevant exposure. Our previous research suggests that IONPs may induce a neoplastic-like cellular transformation, likely due to particle dissolution, release of free iron ions, and disruption of iron homeostasis. Other studies suggest that an amorphous silica coating may reduce particle dissolution, thereby reducing subsequent adverse outcomes.

We hypothesized that an amorphous silica coating (SiO2-nFe2O3) would prevent subsequent neoplastic-like cellular transformation and oxidative stress. To test this hypothesis, we used an occupationally relevant low dose of 0.02 mg/mL, while the LDH assay showed that significant cell death did not occur until the fifth day of exposure. The MTT assay indicated an IC50 of 0.02 mg/mL, while the LDH assay showed a significant (p<0.0001) reduction of cells in cultures treated with 400 μg/ml Er2O3 NPs when compared to controls. Caspase 3 and 8 levels were increased significantly (p<0.005) in cell cultures treated with 400 μg/ml Er2O3 NPs when compared to controls. Caspase 8 and 9 levels were determined to indicate a possible pathway for initiation of apoptosis. In the present study the toxicity of Er2O3 NPs was assessed under conditions.

The increased number of applications of engineered nanomaterials (ENMs) greatly increases the potential of direct human exposure to ENMs. However, the number of new ENMs presents a challenge in risk assessment. Grouping and ranking according to their potential hazard seems a promising approach. Here we tested a panel of nineteen ENMs procured from the Joint Research Centre (JRC) and commercial sources focusing on cytotoxicity and cytokine responses in the human macrophage-differentiated cell line THP-1. Macrophages are key players of the innate immune system. Physicochemical characterization of ENMs was performed using dynamic light scattering; moreover, all ENMs samples were shown to be endotoxin-free prior to testing. Following cytotoxicity screening in THP-1 cells using the Alamar Blue cell viability assay and ranking on the basis of IC50 values, the multi-walled carbon nanotubes (MWNTs), ZnO, Ag, and SiO2 NMs were found to be the most cytotoxic single-walled carbon nanotubes (SWCNTs), TiO2, BaSO4, and CeO2 NMs, as well as the nanocellulose materials, were non-cytotoxic (at doses up to 100 μg/mL). Profiling of cytokine and chemokine secretion using a multi-plex assay indicated that the TiO2, SiO2, BaSO4, CeO2, and nanocellulose materials induced potent inflammatory responses in THP-1 cells. Hierarchical clustering of cytokine responses coupled with gene expression analysis demonstrated that the panel of ENMs could be segregated into two distinct groups characterized by activation and deactivation, respectively, of PPAR (peroxisome proliferator-activated receptor) and LXR (liver X receptor/retinoid X receptor) nuclear receptor pathways. Both nuclear receptors are well-known for modulating inflammatory responses. Furthermore, using a PPAR-γ antagonist, we could show that PPAR-γ played an important role in the activation of inflammatory responses in THP-1 cells exposed to TiO2 and SiO2 NMs. These studies have shown that ENMs of different chemical composition can be grouped according to their inflammatory potential when tested under in vitro conditions.
Molybdenum trioxide nanoparticles (MoO₃ NPs) are used as: an additive in paint, an ingredient in glass and ceramics, a coating in nanowires and plastics, and in the production of metal alloys. Nanoparticles may be produced as a bi-product of copper and tungsten mining and also as a consequence of industrial applications. MoO₃ NPs use in industrial settings raises the concern for possible adverse health effects as a result of occupational exposure. The purpose of this study was to investigate the toxicity of MoO₃ NPs in rat pleural mesothelial cells (RPMCs; CCL-16; ATCC). RPMCs were cultured in Ham’s F-12 Medium supplemented with 10% fetal bovine serum, L-glutamine, and penicillin-streptomycin and grown in 5% carbon dioxide at 37°C. Cultures were divided into two groups: a control group, exposed to vehicle alone, and an experimental group that was exposed to 400 µg/mL MoO₃ NPs for 24 hours. TUNEL positive cells were evaluated at X400 and Giemsa staining. Toxicity was assessed by the MTT assay, TUNEL assay, and ROS fluorescence. Caspase 3 and 9 levels showed an increasing trend in control and treated cultures. Cultures treated with increasing concentrations of MoO₃ NPs had a decrease in cell numbers from 13% to 100 µg/mL exposures to 73% for cultures exposed to 800 µg/mL as compared to controls. A concentration of 400 µg/mL was selected for further testing as this concentration gave approximately 66% survival rate. Treated cells exhibited surface membrane blebbing with MoO₃ NPs apparent on the cell membrane surface. TUNEL positive cells were analyzed at X400 and positive apoptotic cells were counted in 20 random fields. Micrographs from cultures of RPMC’s treated with 400 µg/mL MoO₃ NPs for 24hrs. had a significant (p < 0.05) increase, 48%, in TUNEL-positive cells as compared to the control. An increase in ROS fluorescence was seen in micrographs in RPMCs treated with MoO₃ NPs when compared to the control. Caspase 3 and 9 levels showed an increasing trend in cultures treated with 400 µg/mL MoO₃ NPs. Results from this study indicate that exposure of RPMCs to 400 µg/mL MoO₃ NPs cause cytotoxicity as indicated by decreased cell viability. Increases in TUNEL positive cells and production of ROS with increasing levels of caspases suggest that MoO₃ NPs induced toxicity may be mediated through an apoptotic pathway.

2671 Toxicity of Molybdenum (VI) Oxide Nanoparticles in Rat Pleural Mesothelial Cells-CCL 216

E. A. Huber, and J. M. Cerreta. St. John’s University, Queens, NY.

Molybdenum trioxide nanoparticles (MoO₃ NPs) are used as: an additive in paint, an ingredient in glass and ceramics, a coating in nanowires and plastics, and in the production of metal alloys. Nanoparticles may be produced as a bi-product of copper and tungsten mining and also as a consequence of industrial applications. MoO₃ NPs use in industrial settings raises the concern for possible adverse health effects as a result of occupational exposure. The purpose of this study was to investigate the toxicity of MoO₃ NPs in rat pleural mesothelial cells (RPMCs; CCL-16; ATCC). RPMCs were cultured in Ham’s F-12 Medium supplemented with 10% fetal bovine serum, L-glutamine, and penicillin-streptomycin and grown in 5% carbon dioxide at 37°C. Cultures were divided into two groups: a control group, exposed to vehicle alone, and an experimental group that was exposed to 400 µg/mL MoO₃ NPs for 24 hours. TUNEL positive cells were evaluated at X400 and Giemsa staining. Toxicity was assessed by the MTT assay, TUNEL assay, and ROS fluorescence. Caspase 3 and 9 levels showed an increasing trend in control and treated cultures. Cultures treated with increasing concentrations of MoO₃ NPs had a decrease in cell numbers from 13% to 100 µg/mL exposures to 73% for cultures exposed to 800 µg/mL as compared to controls. A concentration of 400 µg/mL was selected for further testing as this concentration gave approximately 66% survival rate. Treated cells exhibited surface membrane blebbing with MoO₃ NPs apparent on the cell membrane surface. TUNEL positive cells were counted in 20 random fields. Micrographs from cultures of RPMC’s treated with 400 µg/mL MoO₃ NPs for 24hrs. had a significant (p < 0.05) increase, 48%, in TUNEL-positive cells as compared to the control. An increase in ROS fluorescence was seen in micrographs in RPMCs treated with MoO₃ NPs when compared to the control. Caspase 3 and 9 levels showed an increasing trend in cultures treated with 400 µg/mL MoO₃ NPs. Results from this study indicate that exposure of RPMCs to 400 µg/mL MoO₃ NPs cause cytotoxicity as indicated by decreased cell viability. Increases in TUNEL positive cells and production of ROS with increasing levels of caspases suggest that MoO₃ NPs induced toxicity may be mediated through an apoptotic pathway.

2672 Nanotoxicity Evaluation of Doped Silicon Nanocrystals

S. Merlus1, B. Zhi2, S. Mishra3, C. L. Haynes2, and U. Kortshagen2. 1Tuskegee University, Tuskegee, AL; and 2University of Minnesota, Minneapolis, MN.

Recent discoveries of high yield synthesis by Kortshagen et al. producing doped silicon nanocrystals (DSNCs) via nonthermal plasma reactor have sparked great research interest. DSNCs are semiconducting materials that enable various applications from biosensing, bioimaging, optoelectronic, nanoelectronics, spectroscopic and chemical sensing to subwavelength microchips. This versatile semiconductor material has yet to interact with the environment where living organisms are found, so the environmental implications remain unknown. Hence, the proposed research entails the exploration of evaluating the nanotoxicity of DSNCs in model organisms, Shewanella oneidensis MR-1 (S.oneidensis). The drop plate assay was the method used to assess the toxicity of DSNCs. TEM, XPS, and hyperspectral imaging were used to characterize DSNCs. After experimentation, results regarding the potential toxicity of DSNC were inconclusive.

2673 Topography-Driven Toxicity in Response to Nano-Aluminum and Iron Oxide Exposures

M. T. Nelson1, S. Qureshi1, M. E. Huddleston2, and S. M. Hussain1. 1Air Force Research Laboratory, Wright-Patterson AFB, OH; and 2The Ohio State Air Force Research Laboratory, Wright-Patterson AFB, OH.

Substrate effects play a profound role in regulating biological outcomes. Topography can drive cell shape, organelle positioning, cytoskeletal structure, and function. Extracellular matrix (ECM) is secreted by the cell into a highly organized and fibrous biomaterial to maintain normal cell function and organ operations. Using photolithography, ridges of 10, 20, and 40 µm widths, and via electropinning, biomimetic random and aligned nanofiber (R-NF, A-NF) substrates, were produced to simulate physiologically relevant topography. A549 alveolar type-II ‘like’ cells were cultured, and toxicity was assessed in response to exposures of 10 nm aluminum, 30 nm iron oxide, and a 1:1 mixture of the two nanoparticle powders as compared to tissue culture polyethylene (TCPs). A multiplex flow cytometry Nexin reagent was utilized to assess viability, apoptosis, and necrosis after 8, 24, or 48 h following exposures of 0, 1, 5, 10, 20, and 100 µg/mL concentrations. Reactive oxygen species (ROS) was assessed after 48 h using a fluorescent probe, IL-8 secretion was measured by ELISA, and confocal imaging was conducted to evaluate cell shape, mitochondrial potential, and stress fiber formation. A549 cells displayed elongated extensions in multiple directions, while stress fibers were centrally localize on R-NF, 40 and 10 micron width ridges. Aligned nanofiber and 20 micron width ridges resulted in 42% more toxicity, five-fold more apoptotic cell death, and increased ROS production compared to R-NF, TCP, or the 40 or 10 micron width ridges. Confocal results indicated that cells on the 10 micron ridges were bridging multiple ridges resulting in R-NF morphologies. Ridges equal to the size of the cell diameter (14.5 microns), displayed A-NF cell morphologies indicating the cell’s ability to sense the underlying topography. In all cases, cell response deviates from TCPs, with aligned morphologies significantly altering viability and apoptosis. These results suggests future in vitro analysis should take into consideration substrate design to more accurately simulate, assess, and predict in vitro adherent cell toxicity. Distribution A. Approved for public release; distribution unlimited.

2674 Studies on Mitochondrial Dynamics under the Influence of Silver Nanoparticles Based on Surface Properties

M. E. Huddleston1,2, R. L. Salisbury1,2, and S. M. Hussain1. 1Air Force Research Laboratory, Wright-Patterson AFB, OH; and 2Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD.

Silver nanoparticles (AgNPs) are increasingly used in products due to silver’s antimicrobial properties. Consumer use of such products can cause AgNP aerosolization and inhalation, potentially causing toxic effects. Nanoparticle (NP) toxicity is dependent on size, coating, shape, and charge. AgNPs increase reactive oxygen species (ROS) within cells and can trigger changes in mitochondrial membrane potential, critical for ATP formation and normal cell function. The mechanism behind AgNPs’ effect on mitochondrial structure and function remains unclear. As an inhalation model, we treated A549, an alveolar II-like cell line, with 50 nm AgNPs coated with citrate, polyvinylpyrrolidone (PVP), or branched polyethyleneimine (BPEI). The cells were evaluated using fluorescence microscopy and flow cytometry to investigate the impact of NP exposure on mitochondrial structural dynamics. To assess structural integrity impacting mitochondrial function, alterations of mitochondrial structural dynamics were correlated with elongation of individual mitochondria, changes in the interconnectivity of the mitochondrial network, and loss in mitochondrial membrane potential. The results demonstrated that the coated AgNPs increased the amount of mitochondon elongation compared to untreated cells. BPEI-coated AgNPs caused the most significant elongation at equivalent concentrations compared to the other NPs significantly and the interconnectivity of the mitochondrial network within the cell compared to untreated cells at concentrations below 50 µg/mL. Cells treated with citrate- and PVP-coated AgNPs showed less cell death and damage to mitochondrial membrane potential compared to naive cells, though the results were not statistically significant. Citrate-coated AgNPs caused significantly more damage to cells than PVP at higher concentrations. BPEI-coated AgNPs caused a dose-dependent loss in mitochondrial membrane potential and cell death when compared to naive cells. In summary, surface properties appear to impact mitochondrial structure, suggesting a possible mechanism for AgNP toxicity that could lead to new avenues of toxicological analysis.

2675 Ammonium-Functionalized Gold Nanoparticles Elicit Mitochondrial Dysfunction and Cell Death: A Transcriptomics and Proteomics Study Coupled with Functional Validation

A. Gallud1, K. Kloditz2, V. Gogvadze1, S. Katayama1, T. Skoog1, J. Ytterberg1, J. Ruiz1, S. Mojia1, Y. Chen1, D. Xue1, R. Zubarev1, J. Kere1, A. Adalsteinsson1, and B. Fehrle1,2. 1Karolinska Institutet, Stockholm, Sweden; and 2University of Bordeaux, Talence, France; 3CICBiomaGUNE, San Sebastian, Spain; and 4University of Colorado, Boulder, CO.

Systems biology is increasingly being applied in the field of nanosafety research for observing and predicting the biological perturbations inflicted by exposure to engineered nanomaterials. Here we used a combined transcriptomics and proteomics approach to assess the effects of Au nanoparticles (Au-NPs) of two different sizes (5 or 20 nm) on human
monocyte-like THP-1 cells. The role of surface functional groups was addressed by synthesizing ammonium-, carboxyl- or poly(ethylene glycol) (PEG)-modified Au-NPs. The Au-NPs were characterized using TEM, UV-Vis spectroscopy, DLS, and zeta potential measurements. We ensured that the NPs were endotoxin-free. Then, cytotoxicity screening was performed with THP-1 cells exposed to Au-NPs at doses up to 100 μg/ml using the Alamar Blue assay. Cell death was observed only for the ammonium-modified Au-NPs. Using TEM, the ammonium-modified NPs were found to be partly located in mitochondria. Next, we performed RNA sequencing and mass spectrometry-based proteomics analyses followed by pathway enrichment analysis. The importance of the surface modification, rather than primary particle size, was clearly demonstrated. Notably, the combined omics results suggested that mitochondrial function was deregulated in THP-1 cells upon exposure to ammonium-modified Au-NPs and subsequent experiments showed a pronounced drop in mitochondrial membrane potential and mitochondrial reactive oxygen species production in response to these Au-NPs. We also found that ammonium-modified, but not carboxyl-modified Au-NPs triggered cell death in *C. elegans*. These studies have disclosed cytotoxic effects of Au-NPs as a function of surface properties, and revealed the power of omics-based analyses.

### 2676 Lamellar Bodies and Mitochondria: Targets for FeO₄ and SiO₂ Nanoparticles Toxicity in A549 Cells

A. De Vizcaya-Ruiz¹, A. Solorio¹, M. Uribe¹, V. Escamilla-Rivera², and S. González-Pozos¹. ¹CINESTAV-IPN, Distrito Federal, Mexico; and ²Instituto Politécnico Nacional, Distrito Federal, Mexico.

Metal oxide nanoparticles (MNPs) are produced at high rates and occupational scenarios promote inhalation exposure. The generation of ROS has been described as a common mechanism of toxicity, however the interaction with relevant cell structures such as lamellar bodies (LB) and mitochondria represent a key target of toxicity. The aim of this study was to evaluate whether exposure to different MNPs, FeO₄ crystalline NPs and SiO₂ NPs of ~50 nm and 10–20 nm respectively, in human alveolar A549 cells alter LB and mitochondria. NPs dispersions were characterized by electron microscopy, dynamic light scattering, and laser doppler electrophoresis. Cell viability, cellular uptake, mitochondrial membrane potential and lysosomal damage were determined by MTT, transmission electron microscopy, JC-1 and lysotracker assay. Physicochemical characterization of NP dispersions with serum albumin bovine (BSA) showed hydrodynamic diameters in culture medium of 888 and 402.3 nm, for FeO₄ and SiO₂ respectively. Zeta potential was -8 mV for FeO₄ NPs and -13 mV for SiO₂ NPs. Images of transmission electronic microscopy (TEM) showed the internalization of both NP at 12 h by endocytosis with different localization. FeO₄-NP and SiO₂-NP were observed in acid compartments, mainly in LB. Also, SiO₂-NP were localized in delimited regions in the cytoplasm with morphological mitochondria changes. After 48 hours FeO₄-NP were still internalized by endocytosis NPs were not found inside lamellae. Interestingly we observed NPs near mitochondria and lipid droplets after exposure to both nanoparticles. There was no a statistically significant decrease in cell viability from the exposure to NPs. However, mitochondrial membrane potential (MMP) decreased at 6 and 12 h of exposure at the highest cell viability from the exposure to NPs. There was no a statistically significant decrease in mitochondrial membrane potential and lysosomal damage were determined by MTT, transmission electron microscopy, JC-1 and lysotracker assay. Physicochemical characterization of NP dispersions with serum albumin bovine (BSA) showed hydrodynamic diameters in culture medium of 888 and 402.3 nm, for FeO₄ and SiO₂ respectively. Zeta potential was -8 mV for FeO₄ NPs and -13 mV for SiO₂ NPs. Images of transmission electronic microscopy (TEM) showed the internalization of both NP at 12 h by endocytosis with different localization. FeO₄-NP and SiO₂-NP were observed in acid compartments, mainly in LB. Also, SiO₂-NP were localized in delimited regions in the cytoplasm with morphological mitochondria changes. After 48 hours FeO₄-NP were still internalized by endocytosis NPs were not found inside lamellae. Interestingly we observed NPs near mitochondria and lipid droplets after exposure to both nanoparticles. There was no a statistically significant decrease in cell viability from the exposure to NPs. However, mitochondrial membrane potential (MMP) decreased at 6 and 12 h of exposure at the highest concentrations of FeO₄ and SiO₂, respectively. This mitochondrial alteration seems to be preceded by an activation of the endosome-lysosome system only in exposure to SiO₂ NP. Mitochondrial damage and its accumulation in LB are potential targets of NPs toxicity, and could interfere with their metabolism and secretory functions leading to impairment of pneumocytes and thus respiratory disorders.

### 2677 Biodistribution of Inhaled Multiwalled Carbon Nanotubes in a Murine Mouse Model

M. Justus. Clemson University, Clemson, SC. Sponsor: A. Hollan

Synthetic Mimic of antimicrobial peptides (SMAMPs) are novel poly oxy-norbornene (PONs) based nanoparticle coatings that impart a positive charge on the nanomaterials. They are designed to imitate natural defense-host peptides that regulate the ability to act as an organism’s first line of defense within its immune system and simultaneously act as antimicrobial agents. In the absence of countercharged materials, positively-charged nanomaterials can cause a toxic response in a variety of aquatic species. PONs can be synthesized with a variety of different charge densities and therefore, in this study, our goal is to utilize gold nanoparticles (AuNPs) coated with SMAMPs in order to understand how differences in the charge of the coating will impact the model vertebrate organism, *D. rerio*. In order to alter the charge of the ligands, the SMAMPs were synthesized with different ratios of amine to propyl, either 50% amine or 75% amine. We then exposed *D. rerio* embryos for up to 5 days to various concentrations of either the ligands coated onto AuNPs or to the ligands alone. At lower concentrations, we saw catalytic metals that are often present during preparation. MWCNT 1020 was aerosolized using a linear feed dust-metering device to a particle attrition chamber and a single jet disperser. The aerosol was diluted to expose concentrations of 0.06, 0.2, or 0.6 mg/m³ with humidified air. Male B6C3F1/N mice were exposed for a total of 22 days over a period of one month. One week after exposure various organs were harvested, processed, embedded in paraffin, sectioned, and stained with Hematoxylin and Eosin. Examination of the lungs suggested minimal inflammation in the lungs at even the highest exposure level. The samples were analyzed by hyperspectral dark field microscopy using Cytovia to determine what tissues contained MWCNT and the relative amounts in those tissues. No particle was detected in the liver or kidneys. However, it was present in the lungs, brachial lymph nodes, mediastinal lymph nodes, and spleen. These results suggested that inhaled MWCNT spread primarily through the lymphatic system from the lungs. Funded by R2S ES022866 and R01 ES023209.
that the viability of the embryos was similar to the control despite the charge; however, there were drastic differences with the higher concentrations of ligands. For the ligand-coated NP solutions, the 75% amine ligands induced a lower viability; however, for the ligand-only solutions, the 50% amine ligands induced a lower viability compared to the 75% amine ligands. In addition, we also observed that some of the embryos exposed to either the ligand-coated NPs or the ligands-only hatched earlier than the controls. Gene expression indicated that exposure to the 50% amine at the lower and higher concentrations, as well as the 75% amine at the lower concentration instigated apoptosis, oxidative stress, or chorion degradation.

**2680 High-Throughput Hazard Assessment of a Diverse Suite of Precision-Engineered Nanomaterials Using Zebrafish**

J. Larson, S. Edwards, L. Truong, and R. Tanguay, Oregon State University, Corvallis, OR.

The biocompatibility of engineered nanomaterials (ENMs) is influenced by intrinsic physicochemical characteristics (e.g., surface chemistry). The systematic investigation of nano-bio interactions in vivo offers a powerful way to elucidate the relationships between ENM characteristics and biological outcomes. The objective of the current study was to evaluate the biocompatibility of well-characterized precision-engineered metal oxide, silica oxide, and silver silica nanomaterials using early-life-stage zebrafish (Danio rerio). All ENMs were synthesized and characterized by the HSPH-NIEHS Nanosafety Center at Harvard University, a member of the NIEHS Nanomaterials Health Implications Research consortium. ENMs were stably dispersed in ultra-pure water using a rigorous and standardized sonication protocol, which included monitoring hydrodynamic diameter and zeta potential over time. Zebrafish were dechorionated and statically exposed to each ENM (0, 2.32, 5, 10.7, 23.2, or 50 µg/ml; n=32/conc) from 6 to 120 hours post-fertilization (hpf). Two behavioral assays (at 24 and 120 hpf) and 22 developmental morphological endpoints were evaluated. Results showed that silver silica nanocomposites (4% or 16% [w/w]) yielded significant mortality at 24 and 120 hpf compared to controls. Moreover, exposure to aluminum oxide, cerium oxide, silica oxide, and iron oxide nanomaterials produced statistically significant abnormal behavior (e.g., hyper- or hypoactivity) at 24 and/or 120 hpf compared to control (p<0.05). Collectively, these results enhance our understanding of complex structure-activity relationships at the nanoscale and could contribute toward the rational design of safer nanomaterials. Future studies will investigate the role of oxidative stress and cell death in the acute toxicity of the silver silica nanocomposites and investigate the behavior of adult zebrafish that were only exposed to ENMs during early-life stages. These studies were supported by U01 ES027294.

**2681 Silica Nanoparticles Trigger the Blood Hypercoagulability and Thrombotic Effects Via JAK1/TF/PAR1 Pathway in Zebrafish**

J. Duan†, Y. Li†, S. Peng*, and Z. Sun, Capital Medical University, Beijing, China; and Academy of Military Medical Sciences, Beijing, China.

Silica nanoparticles (SiNPs) are widely applied in food sciences, industry and biomedicine, increasing the human exposure and potential health risk. However, the effect of SiNPs on circulatory system, especially on thrombus formation is largely unknown. This study explored the biological action of intravenous injection of SiNPs on thrombus effects in zebrafish (Danio rerio) and elucidated the underlying mechanisms. Using transgenic zebrafish, Tg(mpo:GFP) and Tg(fli-1:EGFP), the SiNPs-induced activation of neutrophil-mediated inflammation and impairment of vascular endothelium were assessed in the caudal vein. SiNPs significantly decreased blood flow and velocity measured by ZebraBlood analysis. In vivo particle dissolution is another important factor. Poorly soluble particles have longer retention half times in the body as compared to biosoluble particles. Here, we compare the biodistribution and retention of inhaled manganese oxide (MnOx) NPs with varying rates of dissolution in vivo. Male C57 mice (n=3-4, 14-19 g), were exposed to filtered air (FA), non-calcined MnOx NPs, or calcined MnOx NPs via whole body inhalation (WBI) for 5 hrs per day for 1 or 5 days. Organs were collected 24 hrs post-exposure and Mn content was analyzed using atomic absorption spectrometry (AAS). By day 5, retained lung Mn was higher in non-calcined MnOx (53 ± 135 ng/g) than calcined MnOx NPs (848 ± 76 ng/g), which was unexpected considering acellular dissolution measurements showed that the calcined MnOx NPs had a lower dissolution rate than non-calcined ones. The olfactory bulb (OB) had elevated Mn for both particle types. Elevated Mn was found in the hippocampus, striatum, and frontal cortex for calcined MnOx by day 5. To determine the role of solubility in the retention of NPs, C57 mice were exposed via WBI to FA, calcined MnOx NPs, or nebulized MnCl2 for 5 hrs. Organs were collected immediately, 6 hrs, 24 hrs, and 48 hrs post-exposure for measurements of Mn content. We hypothesized that upon deposition in the lungs, the MnOx particles were quickly cleared to other secondary target organs, such as the kidney (1681 ± 126 ng/g at 6 hrs vs FA, p=0.00245). The T1/2 in the lung of calcined MnOx was ~12 hrs, while that for MnCl2 was ~18 hrs. Elevations in OB tissue Mn occurred only in the MnOx-exposed mice starting 6 hrs post-exposure (1026 ± 64 ng/g). In contrast, there was no increase of measured Mn in the brains of MnCl2-exposed mice. This study demonstrates differences in biodistribution and retention of NPs of varying dissolution rates, which is a factor to consider when determining the potential toxicity of inhaled NPs. While the acellular studies did not predict well the lung retention for calcined MnOx NPs, this could potentially be explained by the binding of ionic Mn to constituents in lung tissue. Funded by NIH Grants R01ES020332, T32ES007026, and P30ES01247.

**2682 Biodistribution and Retention of Inhaled Manganese Oxide Nanoparticles in Mice: Role of Particle Solubility**

C. Wong, B. Gelein, M. Palmer, A. Kennell, G. Oberdorster, and A. Elder, University of Rochester, Rochester, NY.

Many factors can alter the translocation, biodistribution, and retention of inhaled nanomaterials (NPs): including size, shape, and surface properties. In vivo particle dissolution is another important factor. Poorly soluble particles have longer retention half times in the body as compared to biosoluble particles. Here, we compare the biodistribution and retention of inhaled manganese oxide (MnOx) NPs with varying rates of dissolution in vivo. Male C57 mice (n=3-4, 14-19 g), were exposed to filtered air (FA), non-calcined MnOx NPs, or calcined MnOx NPs via whole body inhalation (WBI) for 5 hrs per day for 1 or 5 days. Organs were collected 24 hrs post-exposure and Mn content was analyzed using atomic absorption spectrometry (AAS). By day 5, retained lung Mn was higher in non-calcined MnOx (53 ± 135 ng/g) than calcined MnOx NPs (848 ± 76 ng/g), which was unexpected considering acellular dissolution measurements showed that the calcined MnOx NPs had a lower dissolution rate than non-calcined ones. The olfactory bulb (OB) had elevated Mn for both particle types. Elevated Mn was found in the hippocampus, striatum, and frontal cortex for calcined MnOx by day 5. To determine the role of solubility in the retention of NPs, C57 mice were exposed via WBI to FA, calcined MnOx NPs, or nebulized MnCl2 for 5 hrs. Organs were collected immediately, 6 hrs, 24 hrs, and 48 hrs post-exposure for measurements of Mn content. We hypothesized that upon deposition in the lungs, the MnOx particles were quickly cleared to other secondary target organs, such as the kidney (1681 ± 126 ng/g at 6 hrs vs FA, p=0.00245). The T1/2 in the lung of calcined MnOx was ~12 hrs, while that for MnCl2 was ~18 hrs. Elevations in OB tissue Mn occurred only in the MnOx-exposed mice starting 6 hrs post-exposure (1026 ± 64 ng/g). In contrast, there was no increase of measured Mn in the brains of MnCl2-exposed mice. This study demonstrates differences in biodistribution and retention of NPs of varying dissolution rates, which is a factor to consider when determining the potential toxicity of inhaled NPs. While the acellular studies did not predict well the lung retention for calcined MnOx NPs, this could potentially be explained by the binding of ionic Mn to constituents in lung tissue. Funded by NIH Grants R01ES020332, T32ES007026, and P30ES01247.

**2683 Multiple Dose Metrics Reveal Shape and Charge-Dependent Toxicity of Au NPs**

Customizable Au nanoparticle (NP) platforms are driving innovations in drug discovery with massive therapeutic potential due to their biocompatibility, stability, and imaging capabilities; yet their development is outpacing our understanding of how their inherent properties impact their behavior and applicability. Systematic investigations of NPs whose differences are discrete must be used to identify the key parameters responsible for driving observed biological responses. Understanding biological responses is further complicated by lack of understanding with respect to the appropriate dose-metrics such as mass, surface area and particle count. Here, we investigated a suite of Au NPs comprised of two different shapes and two different surface functional groups to determine the relative contribution of shape and charge to toxicity. We compared spherical and star shaped Au NPs with either a positively charged surface functional group (branched polyethyleneamine, bPEI) or a negatively charged ionic stabilizer (citrate) and evaluated their uptake and toxicity in embryonic zebrafish using a variety of characterization methods and found that the most commonly used techniques of TEM and hydrodynamic diameter are not appropriate for irregularly shaped nanomaterials due to their assumption of spherical shape. Instead, we used measured 2D surface area and 2D perimeter from multiple TEM images to better estimate particle counts and surface area. We validated this method by comparing dose metrics calculated for spherical particles and found it to be in agreement with calculations from TEM diameter and hydrodynamic diameter. After comparing the dose metrics of mass, surface area, and particle count, citrate-stabilized AuNPs stars elicited the highest toxicity (LOAEL = 5 mg/L) followed by the anionic Au-Cit stars (LOAEL = 25 mg/L). Neither of the spherical particles elicited a response even at 50 mg/L. Our findings indicate the importance of considering both shape and charge in nanomaterial design. In addition, we show that commonly used nanomaterial characterization techniques can be modified to calculate important estimates of irregularly shaped nanomaterial dose metrics and demonstrate that an assumption of spherical shape for irregularly shaped particles is inappropriate.
Pulmonary exposure to carbon nanotubes or nanofibers (CNT/F), known to induce inflammation, toxicity, or tumorigenesis, is a concern due to increased production and dry powder handling. CNT/F represent a large class of materials if it is unclear if another similar toxicity. Our aim was to simultaneously test the pulmonary effects induced by CNT/F with variable physicochemical properties obtained from U.S. facilities. Characterization was done for seven different multiwalled CNT and two CNF selected based on nominal diameter ranging from 10-150 nm. Cytotoxicity, inflammation, and histopathology was assessed in mice 1, 7, 28, and 84 d following oral exposure to 4 or 40 nm CNT and CNF. Utilized doses and material preparation for in vivo dosing were representative to ongoing occupational exposures. Lactate dehydrogenase (LDH) activity, a marker of cytotoxicity, was dose-dependently increased in bronchoalveolar lavage fluid (BALF) resolving toward baseline by 84 d in all groups. In materials with a diameter greater than or equal to 50 nm, LDH was persistently increased. Polymeroma pericellular cell infiltration (%PMN), a marker of inflammation, was increased in all materials at 1 d post-exposure to 40 µg (50 nm: 31.1%, ≥50 nm: 37.1%). With exposure to materials less than 50 nm, PMN influx mostly resolved by 7 d while materials greater than or equal to 50 nm indicated persistent inflammation (7 d: <50 nm: 10.5%, ≥50 nm: 48.9%). For complement, inflammatory gene expression in lung tissue (e.g., Il1b, Il6, Ccl22, Cxcl12) and protein levels in BALF (e.g., Il1b, Il6, I5, Ccl22, Cxcl11), were elevated to a greater extent in materials with a nominal tube diameter greater than or equal to 50 nm. In contrast, microscopic evaluation of lung sections at 84 d post-exposure indicated that histopathology does not appear distinguishable between CNT/F using diameter. In conclusion, general cytotoxicity and inflammation exhibited a relationship with nominal diameter, with a threshold of sustained effects at approximately 50 nm and greater, which was dissimilar to histopathology. Ongoing research and modeling techniques will elucidate relationships between physicochemical characteristics and toxicities of various CNT/F.
Mitsui-7 MWCNTs (MWCNTs) are strong lung tumor promoters in B6C3F1 mice. B6C3F1 mouse lung tumors have many molecular and morphological similarities to human pulmonary tumors. In previous work, we demonstrated that exposure to inhaled MWCNTs following exposure to a DNA damaging agent caused potent promotion of lung tumors. To investigate a possible threshold for MWCNT-induced carcinogenesis, we exposed B6C3F1 mice to a single dose of either methylicholanthrene (MC, 10 µg/g BW, i.p.) or vehicle (corn oil). One week after i.p. injections, mice were exposed by inhalation to MWCNTs (5 mg/m³, 5 hours/day, 5 days/week) or filtered air (controls) for a total of 2, 5 or 10 days. At 17 months post-exposure, mice were euthanized and examined for lung tumor formation. Thirty percent of the filtered air controls, 33% of the MWCNT-exposed, and 47% of the MC-exposed, had a mean of 0.33, 0.33 and 0.4 tumors per mouse, respectively. By contrast, 94% of mice receiving MC followed by 10 days MWCNT had an average of 2.9 tumors per mouse while 81% of mice exposed to MWCNTs for 5 days had an average of 1.9 tumors per mouse, and 73% of mice exposed to MCNTs for 2 days had an average of 1.2 tumors per mouse. Additionally, mice exposed to MWCNTs or MC followed by MWCNTs had larger tumor volumes than their corresponding control groups. Preliminary data indicate a dose response in the percent of animals with tumors as well as the number of tumors per animal following exposure to MC and MWCNTs. In this study, mouse MWCNT lung burden approximates feasible human occupational exposures. Therefore, the results of this ongoing study indicate that caution should be used to limit human exposures to MWCNTs.

Inhalation of ambient ultrafine particles and engineered nanomaterials are associated with adverse airway responses, including allergic asthma. Generation of reactive oxygen species by inhaled nanoparticles (NPs) may activate immunological adjuvant pathways and enhance local sensitization to environmental and occupational allergens. To test the hypothesis that NP redox status is associated with adjuvant activity, we modified the redox activity of cerium dioxide (CeO2) NPs by incorporating increasing quantities of zirconium (Zr) into the crystalline structure of the CeO2 NPs. Female BALB/c mice were intranasally sensitized with ovalbumin (OVA) or OVA + 200 µg CeO2 (doped with 0%, 27% or 78% Zr) on days 1, 3, 6, and 8, and then challenged with OVA alone on days 22 and 23. Twenty-four hours later serum was collected to assess OVA-specific IgE and IgG1, bronchoalveolar lavage fluid (BALF) collected for quantitation of inflammatory cells, and lungs processed for detection and morphometric evaluation of eosinophils and intraepithelial mucous substanes (IM). OVA-sensitized and -challenged mice had minimal increases in serum IgE or IgG1 compared to non-sensitized mice (PBS control). However, marked increases in IgE and IgG1 were observed after co-sensitization with CeO2 (doped with 0%, 27% and 78% Zr) compared to OVA alone. OVA-sensitized and -challenged mice had increased BALF macrophages and eosinophils compared to controls. Sensitization with OVA + CeO2 (0% Zr) enhanced BALF total cells (2.3-fold increase), macrophages (2.8-fold), eosinophils (15-fold), and lymphocytes (3.8-fold) compared to OVA alone. Doping of CeO2 with 78%, but not 27% Zr further enhanced BALF total cells, macrophages, and eosinophils by 50-100% compared to OVA without Zr doping. Allergic inflammatory, epithelial, and mucous cell responses were minimal in lung tissues of OVA-sensitized and challenged mice, but marked eosinophilic alveolitis and bronchiolitis, and a modest increase in IM were induced by co-sensitization with OVA and all zirconium-doped CeO2 NPs. Mice sensitized with CeO2 (78%Zr) had more parenchymal eosinophils than CeO2 (0%Zr), but mucous and inflammatory cell responses were similar for all CeO2 NPs. Our results suggest that CeO2 can act as potent airway adjuvant for allergic sensitization, and that the redox activity of engineered NPs can affect the character and severity of allergic airway responses.
**2692** The Synthesis of Gum Arabic-Modified CdTe Quantum Dots with Low-Cytotoxicity for In Vivo Applications

E. O. Uzunuigbe1, A. Kiplagat2, N. R. Sibuyi2, M. Meyer2, A. P. Kappo1, and M. O. Onanì1.1 University of Zululand, KwaDlangezwa, South Africa; and 2University of the Western Cape, Cape Town, South Africa.

Gum Arabic (GA) is a natural glycoprotein polymer with low cytotoxicity and is often used in the food and pharmaceutical industries. Polymers are often used as capping agents in nanoparticles synthesis to prevent nanoparticle agglomeration and to reduce nanoparticle toxicity. CdTe quantum dots (QDs) have potential applications as probes for in vivo diagnostics. However, these nanoparticles have significant cytotoxicity. In this study we aimed to synthesise CdTe QDs with high luminescent properties for applications in in vivo bio-imaging. Two different synthesis methods were used. We capped the QDs with GA to reduce the cytotoxicity and improve the solubility of the nanoparticles. These QD-GA nanoparticles were characterized using Ultraviolet-visible (UV–vis) spectroscopy, Photoluminescence (PL) spectroscopy, High-Resolution Transmission Electron Microscopy (HRTEM) and Fourier Transform InfraRed spectroscopy (FTIR). Also, the hydrodynamic particle size, polydispersity index (PDI) and Zeta potential of GA capped QDs were also evaluated to ascertain their colloidal stability. The cytotoxicity of the QDs were evaluated on two human cancer cell lines, namely HeLa and PC-3 using the WST-1 assay. The PL intensity of the QDs synthesised using the two methods were 678nm and 675nm, respectively. HRTEM analysis showed that the average particle size were 3.45nm and 3.9nm, respectively. The average PDI and Zeta potential were 0.27 ± 0.02 and 0.35 ± 0.02. The cytotoxicity assays showed that GA capping reduced the cytotoxicity and improved the stability of the QDs. These nanoparticles can potentially be used for in vivo applications.

**2693** Involvement of ROS Generation in Copper Oxide Nanoparticles-Induced AP-1 Activation

M. Ding1, B. Tabatha1, J. Aldinger1, and J. Zhao1.1 NIOSH, Morgantown, WV; and 2School of Medicine, Ningbo University, Ningbo, China. Sponsor: Y. Yuan

Occupational exposures to copper dusts or fumes have been reported to be harmful to human health, with possible risk of cancer among copper smelter workers. Copper (II) oxide (CuO) nanoparticles have not, to our knowledge, been extensively examined for potential carcinogenic or genotoxic effects. To investigate the mechanisms of CuO-induced pathogenesis, the effect of CuO on AP-1-MAPKs and ROS generation were investigated. The results indicated CuO caused a 2-fold increase in AP-1 activity in JB6 cells. The induction of AP-1 activity in cultured cell lines was time and dose-dependent. The signal transduction pathways for AP-1 activation were also investigated. Western Blot analysis demonstrated that CuO stimulates phosphorylation of p38 MAPK and ERKs. CuO also generated ROS when incubated with the cells as measured by electron spin resonance (ESR). Nano-sized CuO generated more ROS than the fine sized particles when incubated with the cells. Finally, co-incubation with a CD36 competitive ligand sulfo-N-succinimidyl oleate (SSO) or a CD36-specific antibody, uptake of GNPs was reduced. GNP exposure also induced mitochondrial membrane potential while pre-treatment with the CD36 antibody attenuated these changes. In addition, macrophages exposed to non-functionalized GNPs at concentrations of 0.5, 10, or 100 μg/ml for 1 or 3 h were harvested for metabolomic profiling and both metabolite and lipid fractions were examined. Principal component analysis showed all groups to be different from the control and one another. The number of compounds changed following exposure appeared to be both concentration- and time-dependent. Specifically, a total of 481 compounds < 0.01% altered following the exposure to 100 μg/ml of GNPs, whereas 291 compounds were altered following exposure to 50 μg/ml (Fold Change > 2; p<0.01). Compounds were associated with pathways such as spingolipid and cholesterol metabolism, glutathione synthesis, energy metabolism, inflammatory signaling and others. Lastly, a number of metabolic differences were found in common between cells exposed to the CD36 receptor ligand and GNPs suggesting CD36-dependent and independent responses. Together our data demonstrates the influence of functionalization on GNP-macrophage interactions, the role of CD36 in the cellular response, and metabolic pathways disrupted due to exposure.

**2694** Bismuth Sulfide Nanoparticle-Induced Nephrotoxicity and Autophagy-Associated Mechanisms

L. Zhang, Soochow University, Suzhou, China.

Bismuth compounds have been widely used in electronics industry, alloy manufacture, cosmetics and medicine. Recently bismuth nanoparticles (BiNP) were synthesized for imaging and diagnostic purpose, while safety concern of bismuth cannot be ignored. Here, we prepared ultrasmall BiNP and showed an enhanced tumor CT imaging, but BiNP revealed a moderate nephrotoxicity in mice, including the elevated amounts of creatinine and blood urea nitrogen (BUN) in blood and urine. Pathologically, we found the increased amount of apoptosis in proximal tubule cells, indicating the injury of BiNP. In the meanwhile, the autophagy marker LC3II significantly increased in the kidney of the BiNP treated mice. The autophagy inducer rhamnycin can alleviate the kidney injury by BiNP, while chloroquine deteriorated the BiNP induced nephrotoxicity, as indicated by the creatinine, BUN, the kidney injury marker KIM-1, and pathological observations for the number of apoptotic cells. In vitro studies showed the cytotoxicity of BiNP on human embryonic kidney 293 cells (HEK293) compared to other cell types. The occurrence of monodansylcadaverine fluorescence staining and the amount of LC3II that can be inhibited by 3-MA indicated autophagy induced by BiNP. BiNP were capable of entering cells and localized in the cytoplasm observed by transmission electron microscopy with bismuth element confirmed by energy dispersive X-ray analysis. Mechanistically, we found that BiNP induced autophagy was through AMPK pathway but not P38 and MAPK pathway, followed by the inhibition of mTOR activity, with further increase of downstream protein expressions such as Beclin1, Atg12, and p62. With our novel finding of bismuth induced autophagy, potential approaches may be applied to reduce the nephrotoxicity by bismuth.

**2695** Alterations in Metabolite Profiles of Macrophages Exposed to Graphene Nanoplatelets

S. Adamson, and J. Shannahan. Purdue University, West Lafayette, IN.

Graphene nanoplatelets (GNPs) are novel 2D nanoparticles consisting of planar stacks of graphene with thickness of only 2-12 nm but width and length dimensions up to microns. GNPs are widely applicable due to their conductivity of electricity and heat, and their abundant surface area for drug delivery systems. Although human exposures are increasing, our knowledge regarding immune-specific responses to GNPs and mechanisms of interactions is lacking. Our current study utilized a metabonomic profiling approach to evaluate macrophage responses to GNPs. Further we assessed the potential role of the scavenger receptor CD36 in mediating these GNPs-induced responses. RAW264.7 macrophages were exposed to GNPs without functionalization or functionalized with cysteamine or amineylation at concentrations of 0, 25, 50, or 100 μg/ml for 1, 3, and 24h. Following exposure, no cytotoxicity was observed. Concentration-dependent changes in internalization were determined by alterations in side-scatter using flow cytometry. Non-functionalized GNPs internalized more than functionalized GNPs. Following incubation with a CD36 competitive ligand sulfo-N-succinimidyl oleate (SSO) or a CD36-specific antibody, uptake of GNPs was reduced. GNP exposure also induced mitochondrial membrane potential while pre-treatment with the CD36 antibody attenuated these changes. In addition, macrophages exposed to non-functionalized GNPs at concentrations of 0, 50, or 100 μg/ml for 1 or 3 h, or SSO for 1 h were harvested for metabolomic profiling and both metabolite and lipid fractions were examined. Principal component analysis showed all groups to be different from the control and one another. The number of compounds changed following exposure appeared to be both concentration- and time-dependent. Specifically, a total of 481 compounds < 0.01% altered following the exposure to 100 μg/ml of GNPs, whereas 291 compounds were altered following exposure to 50 μg/ml (Fold Change > 2; p<0.01). Compounds were associated with pathways such as spingolipid and cholesterol metabolism, glutathione synthesis, energy metabolism, inflammatory signaling and others. Lastly, a number of metabolic differences were found in common between cells exposed to the CD36 receptor ligand and GNPs suggesting CD36-dependent and independent responses. Together our data demonstrates the influence of functionalization on GNP-macrophage interactions, the role of CD36 in the cellular response, and metabolic pathways disrupted due to exposure.

**2696** Cytotoxicity of Copper (II) Oxide Nanoparticles in Rat Intestinal Cells: Effect of Simulated Gastrointestinal Fluids and Generation of Oxidative Stress

Metallic oxide nanoparticles (NPs) have applications in industry, medicine and commercial products. Exposure to NPs can occur by inhalation, dermal contact and oral ingestion. We have previously reported on the dose- and time-dependent cytotoxicity of CuO NPs (size < 50 nm) in rat intestinal cells (IEC-6) from the aspect of oral ingestion. This study assessed the effect of pretreating CuO NPs (1 mg/ml) with simulated gastrointestinal (GI) fluids (pepsin at pH 2 to 6, pancreatin at pH 7, bile salts at pH 7; incubated sequentially) on cytotoxicity in IEC-6 cells. The treated NPs were isolated by ultracentrifugation, suspended in media and probe sonicated before dosing the cells. Cells were exposed for 24 hr with the treated NPs (0.1 - 100 μg/ml) and cytotoxicity was assessed using a colorimetric method that measures mitochondrial activity. The zeta potential (ZP) and hydrodynamic diameter (HD) of similarly treated CuO NPs were measured after each incubation step. The ability of non-functionalized GNPs at concentrations of 0, 50, or 100 μg/ml for 1 or 3 h, or SSO for 1 h were harvested for metabolomic profiling and both metabolite and lipid fractions were examined. Principal component analysis showed all groups to be different from the control and one another. The number of compounds changed following exposure appeared to be both concentration- and time-dependent. Specifically, a total of 481 compounds < 0.01% altered following the exposure to 100 μg/ml of GNPs, whereas 291 compounds were altered following exposure to 50 μg/ml (Fold Change > 2; p<0.01). Compounds were associated with pathways such as spingolipid and cholesterol metabolism, glutathione synthesis, energy metabolism, inflammatory signaling and others. Lastly, a number of metabolic differences were found in common between cells exposed to the CD36 receptor ligand and GNPs suggesting CD36-dependent and independent responses. Together our data demonstrates the influence of functionalization on GNP-macrophage interactions, the role of CD36 in the cellular response, and metabolic pathways disrupted due to exposure.
minescent assay. Pretreatment of CuO NPs with GI fluids increased the cytotoxicity by 30% at 5 μg/ml relative to non-treated NPs. No differences were observed at the other concentrations. The lowest ZP (−3.4 mV) and highest HD (5104 nm) of the NPs was observed after incubation with pepsin at pH 2. Raising the pH stepwise one pH unit to pH 6 and incubating with pepsin increased ZP and decreased HD. Consistent changes in ZP and HD of CuO NPs were not observed at the other two steps of pretreatment. The 24-hr exposure of IEC-6 cells with pristine CuO NPs showed a dose-dependent increase in cellular H2O2 and a concomitant decrease in GSH. In summary, treating CuO NPs with simulated gastrointestinal fluids can alter their ZP and HD, but the modifications result in minimal alteration in cytotoxic effects of the particles. Pristine CuO NPs can generate oxidative stress within the cells, which is a potential mechanism of action for these particles. Consideration of the exposure scenario and mechanism of action of NPs are important aspects for the risk assessment of this emerging material. This abstract does not represent US EPA policy.

**2699** Assessment of Inflammatory and Oxidative Stress Response in Human Primary Bronchial Epithelial Cells Cultured in Air-Liquid Interface following Aerosolized Carbon Nanoparticle Exposure

S. Upadhyay1, J. Ji1, X. Mihai1, S. Jitong1, M. Malmlof2, K. Ganguly3, L. Gerde1,2, and L. Palmberg1, K. Karolinska Institute, Stockholm, Sweden; 3Inhalation Sciences Sweden AB, Stockholm, Sweden.

Carbon nanoparticles (CNPs) generated by incomplete combustion of diesel exhausts constitute an important component of the fine particulate matter (PM) related air pollution. CNPs are also used for the manufacturing of black ink, paint, plastic, and reinforcing agent in rubber goods. The widespread use of CNPs designated it as an evolving source of human exposure by inhalation exposure. Therefore, in this study we investigated the inflammatory and oxidative stress responses of NPs to assess their pulmonary toxicity by using a physiologically relevant in vitro human airway model combined with a newly developed exposure system. Human primary bronchial epithelial cells (PBECs) were cultured in an air-liquid interface. PBECs were exposed to 5, 17, and 25 μg/well aerosolized CNPs (Printem®) using the XposeALI® exposure system. After 24-hr exposure, cells were allowed to clean as control incubated in 5% CO2 at 37°C for 24h. Transcript expression of inflammation (IL6, CXCCL8, TNFα, NFKB), oxidative stress (HMOX1, SOD3, Gpx, GSTA1), and tissue injury (MMP9, TIMP1) markers were assessed using qRT-PCR. Protein levels of CCL8 and MMP-9 were measured using ELISA. P<0.05 was considered significantly different. An increased expression of tissue injury markers MMP9 and TIMP1 (p<0.05) were observed after exposure to the lowest CNP dose. An increased expression of tissue injury markers MMP9 and TIMP1 (p<0.05) were observed after exposure to 5 and 17 μg CNP / well. However, no significant changes of CCL8 and MMP-9 secretion were observed following exposure to CNP. Our data demonstrate induction of markers for inflammation and oxidative stress in association with alteration of tissue injury markers, which may be responsible for CNP-mediated pulmonary toxicity. Additionally these physiologically relevant in vitro models combined with XposeALI® exposure system is an optimal in vitro approach to assess air pollutant-induced human health hazards.
Engineered nanomaterials (ENM) are particles that are less than 100 nm in at least one dimension, fabricated for their unique properties applicable to medicine, cosmetics, chemistry, and other fields. One type of ENM, nickel oxide nanoparticles (NiO-nps) are particularly valuable in electronics, optics and batteries. Unfortunately, ENM demonstrate varying levels of bioactivity. Some ENM have been found to cause phagolysosome membrane permeability (LMP) in macrophages. This results in the release of lysosomal enzymes, such as cathepsins, into the cell's cytosol, resulting in inflammatory cytokine release and possible cell death.

To study the bioactivity of NiO-nps effect on cell membranes, we exposed two membrane models to NiO-nps, compared to well-studied titanium dioxide nanoparticles (TIO-nps). We hypothesized that NiO-nps would have similar bioactivity as TIO-nps. An LMP assay was performed by incubating bone marrow derived macrophages from Balb/c mice for 16 hrs. with both ENM at doses ranging from 12.5 to 50 µg/ml and measured levels of cytosolic cathepsin activity. Hemolysis assays and fluorescence lifetime imaging microscopy (FLIM) were performed on human red blood cells (RBC) as a surrogate for phagolysosome membranes. RBC were exposed to ENM at doses from 25 to 200 µg/ml for 4 hrs. FLIM was performed by using the fluorescence probe Di-4-ANEPPDHQ to determine ENM-induced changes in lipid membrane structure. Intensity weighted average lifetimes were determined using a PicoQuant MT200 time-resolved confocal microscope. Hemolysis assays results showed that TIO- induced hemolysis was significantly increased from the control at 50 and 100 µg/ml, while NiO induced hemolysis was significantly greater at 200 µg/ml. LMP data indicated that TIO- generated increased cathepsin release at 25 to 50 µg/ml compared to control. However, NiO resulted in no increase in cytosolic cathepsin activity. FLIM measurements of TIO- exposed RBC showed a significant increase in fluorescence lifetime at 50 and 100 µg/ml, while NiO did not affect the lifetime. We conclude that nickel oxide is not as bioactive in lipid membranes as titanium dioxide.

Nanoclay-enabled composite technology continues to expand based on incorporation of organomodified nanoclay (ONC), montmorillonite coated with different quaternary ammonium compounds, within polycarbonate, before the forecasts in the confluence of action. This study hypothesized that pre- and post-incinerated ONC exposed elicited differential modes of action on pulmonary cells compared to uncoated nanoclay, and that relevant human in vitro models correlate with in vivo effects. To assess ONC life cycle pulmonary toxicity, differentiated human monocytes (THP-1), fetal airways were dispersed into a miRQant MT200 (T. G. Kornberg1, 3. K. Fujita1, 2. S. Take2, R. Tani2, S. Endoh1, 2. J. Maru1, 2. S. Obara1, 2. and K. Honda1, 2). 1National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; and 2Technology Research Association for Single Wall Carbon Nanotubes (TASC), Tsukuba, Japan.

Graphene and related materials (GRM) have novel optical and thermal characteristics and are expected to be adopted for industrial applications; however, there are concerns with respect to the safety of carbon nanomaterials. In addition to direct interaction with the cell membrane, the proposed mechanisms of toxicity development include ROS generation and direct action on the DNA, but these remain to be clarified. In this study, (grant numbers ED481B 2016/190-0 and ED481B 2016/190-0) and the project NanoToxClass (ERA-SIINN/001/2013), N. Fernández-Bertolé was supported by an INDITEX-UDC fellowship, and F. Brandão by the grant SRFH/BD/101606/2014, funded by FCT (subsidized by national fund of MCTES).

Iron oxide nanoparticles (ION) have unique physicochemical properties, including superparamagnetism, which make them very promising for biomedical applications such as in magnetic resonance imaging, in hyperthermia-based cancer therapy, and in targeted drug/gene delivery. For all these uses, ION must be introduced in the organism, and previous studies showed that they can cross the intact blood-brain barrier. Besides, ION surface may be coated with different materials in order to increase their stability, prevent agglomeration and offer a platform for functionalization. Thus, although ION show in general a good biocompatibility, it is of paramount importance to deeply know how potential risks for the nervous system associated to ION exposure.

Hence, the main aim of this work was to assess genotoxic effects of silica-coated ION on glial cells (A172 astrocytes). Comet, 4’H2AX and micronucleus assays were performed, and experimental conditions involved 3 and 24 h incubations, 5-100 µg/ml dose range, and presence/absence of serum in the cell culture media. Results obtained showed slight induction of genotoxicity by ION, limited to long exposure times and highest concentrations, and independent on presence of serum in the cell culture medium. DNA double strand break production was only detected at the highest concentrations and longest time tested in comparison to untreated samples, probably related to the ION concentration at those conditions. No aneugenic effects were observed. This study contributes to increase the knowledge on the effects of ION on nervous system cells, and helps to provide a basis to define conditions to use ION in biomedical applications with minimal risk for patients' health. This study was supported by the New Energy and Industrial Technology Development Organization (NEDO), Japan.
**2705 Toxicity Responses of Various Fibrillar and Crystalline Nanocellulose Materials: Differences and Similarities**

E. R. Kisin¹, N. Yanamala¹, A. L. Menas¹, S. Friend¹, G. V. Shurin², U. B. Vogel¹, D. Beezhold¹, and A. A. Shvedova¹,².¹ NIOSH, Morgantown, WV;²University of Pittsburgh, Pittsburgh, PA;¹National Research Centre for the Working Environment, Copenhagen, Denmark; and West Virginia University, Morgantown, WV.

Extensive research of new nanostructured cellulose materials has resulted in advances in material properties and unique product applications. New technologies facilitated the creation of bacterial, nanocrystalline and micro/nano-fibrillar cellulose derived from natural sources that are easily integrated into bio-based and recyclable products. The aim of the current study was to compare five different nanocellulose (NC) particles using in vitro approaches to determine if several physico-chemical characteristics (i.e. size, shape, origin) yield specific cytotoxicity effects. Human lung epithelial cells (A549) were exposed to NC for 24 and 72 h to determine how variations in the properties contribute to cellular outcomes, such as cytotoxicity, oxidative stress, and cytokine secretion. Our results showed that nanofibrillated cellulose (NCF) induced stronger cytotoxicity and oxidative stress responses compared to cellulose nanocrystals (CNC). CNC, on the other hand, caused a significantly stronger inflammatory response compared to NCF. Additionally, immunostaining indicated that only CNC particles were taken up by the cells. Clustering analysis of the inflammatory cytokines/chemokines revealed a similarity of NCF to the carbon nanofibers response, while CNC was akin to that of chitin, a known immune modulator and activator of innate cells. Taken together, these results indicate that size and shape of NC particles are critical to determining their toxicity: CNC and NCF induce distinctly different patterns of toxic and inflammatory response in lung cells.

**2706 The Intracellular Fate of Multiwalled Carbon Nanotubes in Macrophages Using Laser Scanning Confocal Raman Microscopy**

M. Huynh, C. Mikoryak, B. Wang, P. Pantano, and R. Draper. University of Texas at Dallas, Richardson, TX.

Both the production and use of multiwalled carbon nanotubes (MWN)s are rapidly increasing worldwide despite the possible adverse effects they may have on human health. The Biosciences Group at UT Dallas is interested in understanding the interactions of polymer- and protein-coated MWNTs with macrophages that are the first responders to invaders in the body. This information is relevant for improving the biomedical efficacy of MWNT therapeutics, for understanding mechanisms of MWNT biocompatibility, and for designing methods to ameliorate MWNT toxicity. To better understand potential mechanisms of MWNT toxicity, it is important to know whether MWNTs physically enter cells and where they locate in cells. We have developed three methods to measure the subcellular location of MWNs and reconstruct 3D images of cell-associated MWNs using confocal Raman microscopy. 3D images of cells are reconstructed with stacks of optical sections from confocal planes to place the subcellular MWN locations in the context of the intact cell. The results at 37 °C show that polymer- and protein-coated carboxylated-MWNs (C-MWNs) are within punctate vesicles, most likely in the endosomal/lysosome system. Conversely, at 4 °C, C-MWN signals are only found at the periphery of the cells around the membrane, suggesting that the uptake of C-MWNs is through an energy-dependent receptor-mediated endocytosis pathway. Future work will involve cluster analyses and live-cell imaging to access whether MWNs that induce cytokine release can be correlated with damage to the lysosomal membrane and redistribution of MWNs to the cytoplasm. If successful, this will result in a relatively rapid technique that can be used to determine whether lysosomal damage has occurred because of MWN exposure, and could also be applied to many other types of Raman-active nanoparticles that may induce pro-inflammatory responses.

**2707 Differences in Multi- and Single-Walled Carbon Nanotube-Induced DNA Methylation: Alterations in Association with Nuclear Deposition**

D. Oner¹, M. Ghosh¹, M. Ameloot², H. Bove², K. Van Landuyt¹, L. Godderis¹, and P. Hoet¹.¹KU Leuven, Leuven, Belgium; and ²VUHasselt, Hasselt, Belgium.

Subtle DNA methylation alterations mediated by carbon nanotubes (CNTs) exposure might contribute to pathogenesis and disease susceptibility. In order to understand the epigenetic toxicity, in particular DNA methylation alterations, of single-walled (SW)CNTs and short multiwalled (MW)CNTs, we performed genome/gene-wide, gene-specific DNA methylation and RNA-expression analyses after multiwalled bronchial epithelial cells (16HBE14- cell line). In addition, the presence of CNTs on/in the cell nucleus was evaluated in a label-free way using femtosecond pulsed laser microscopy. Generally, a higher number of SWCNTs, compared to MWCNTs, was deposited at the cellular and nuclear level after exposure. Nonetheless, both CNT types were in physical contact with the nuclei. No global (S-mC) DNA methylation alteration was observed for both CNTs. After exposure to MWCNTs, 2398 genes were hypomethylated (at gene promoters), and after exposure to SWCNTs, 589 Cpg sites (located on 501 genes) were either hypo- (-493 Cpg sites) or hypermethylated (96 Cpg sites). Cells exposed to MWCNTs exhibited a better correlation between gene promoter methylation and gene expression alterations. Differentially methylated and expressed genes induced changes (MWNTs > SWCNTs) at different cellular pathways, such as p53 signalling, DNA damage repair and cell death. On the other hand, SWCNT exposure showed hypermethylation on functionally important genes, such as SKI proto-oncogene (SKI), glutathione S-transferase pi 1 (GSTP1) and shroom family member 2 (SHROOM2) and neurofibrillarosis type 1 (NFI), which the latter is both hypermethylated and downregulated. After exposure to both types of CNTs, epigenetic alterations may contribute to toxic or repair responses. Moreover, our results suggest that the observed differences in the epigenetic response depend on particle type and differential CNT-nucleus interactions.

**2708 Cytokine Production by Rat Mesothelial Cells Exposed to Carbon Nanotubes as a Means of Assessing Long-Term Risks for Mesothelioma**

S. Sridharan¹, A. J. Taylor-Just², and J. C. Bonner³. North Carolina State University, Raleigh, NC.

Multiwalled carbon nanotubes (MWNTs) are a type of highly durable engineered nanomaterial with many industrial applications but are structurally similar to asbestos fibers. It has been shown previously that MWNTs cause fibrosis and inflammation in the lungs of mice. Prolonged exposure to MWNTs could potentially cause neoplastic transformation of mesothelial cells in the pleural lining of the lungs leading to mesothelioma. However, it is not known whether MWNTs cause mesothelioma in humans. A biomarker of human mesothelioma is osteopontin (OPN), a cytokine that produced by mesothelial cells that mediates cell migration. We hypothesize that long-term exposure to MWNTs would cause transformation of normal rat mesothelial cells to mesothelioma cells in vitro that can be predicted by an increase in OPN. Normal rat mesothelial cells (NRMs-2) were grown in six-well cell culture plates and exposed to t(6)- or r(5)-MWNTs for 45 weeks. With each new cell passage, MWNTs were reintroduced to the cell medium for a final concentration of 0.1 μg/ml. Expression of the mRNA encoding OPN was measured using real-time qPCR, the concentration of OPN secreted protein in vitro was measured using an ELISA, and cell invasion assays were used to analyze the ability of cells to exhibit neoplastic characteristics. Rat pleural mesothelioma cells (ME1) were used as a comparison to NRM2 cells. Mesothelioma (ME1) cells spontaneously produced high levels of OPN whereas untreated control NRM-2 cells did not. There was a significant increase in OPN mRNA expression in NRM-2 cells after chronic exposure to r-MWNTs but not t-MWNTs. In the invasion assay, ME1 cells spontaneously showed increased invasion compared to untreated NRM2. Surprisingly, chronic exposure to t-MWNTs but not r-MWNTs caused increased invasion of NRM2 cells. Induction of OPN mRNA does not correlate with increased invasion of MWNT-treated mesothelial cells. Further study is needed to assess reliable biomarkers of mesothelial cell transformation to predict the carcinogenicity of MWNTs. Funding: Supported by NIEHS grant RO1-E502089 and NIEHS P30-E5025128.
Neutrophils are a circulating leukocyte found in the blood that migrates into tissues during inflammation. They are highly phagocytic, and due to the presence of cytotoxic granules, they are known to be very important microbialicidal cells. Since it has been demonstrated that tissue-resident macrophages secrete pro-inflammatory cytokines following exposure to silver nanoparticles (Ag-NP), which activate the inflammatory response, we wanted to determine how the neutrophils would respond to the presence of Ag-NPs since they will likely migrate into exposed tissues. 10 nm PVP-coated Ag-NPs were incubated with primary neutrophils isolated from human blood, and it was noted using microscopy that at doses greater than 10 micrograms per milliliter (μg/mL), the neutrophils were completely destroyed within an hour. Even a 1 hour incubation with 10 μg/mL resulted in a 20% reduction in neutrophil cell viability. Neutrophil activity was assessed at sub-toxic doses to determine the full extent at which these cells are being affected by Ag-NPs. At 1 and 10 μg/mL doses with 1 hour of exposure, a significant decrease in myeloperoxidase activity was observed, which suggests a defect in bactericidal activity of these cells. Although we do not observe any detectable Ag-NPs in our TEM images, we hypothesize that they were taken up by these active phagocytes, and dissociated quickly into silver ions that impacted neutrophil cellular viability and function. Since neutrophils are an essential cell in the clearance of microbial pathogens, it is important to assess whether the use of Ag-NPs as antimicrobial agents will impact the removal of infectious agents.

NiO and NiOH Nanoparticles Induce Oxidative Stress-Mediated Cellular Signaling Deregulation

M. H. Cambre¹, B. Wang¹, F. Hou², H. Lee¹, L. Harper¹, and Y. Huang¹. ¹Missouri University of Science and Technology, Rolla, MO; ²University of Wisconsin-Milwaukee, Milwaukee, WI; and ³National Dong Hwa University, Hualien, Taiwan.

Nanomaterials have become increasingly popular in the production of a wide range of products including cosmetics, pharmaceuticals, cancer research, printer toners, food, electronic manufacturing, and many other products. In this study, we examined toxicity of Ni in two different forms, NiO and NiOH. Crystalline structure analyses revealed that NiO has a cubic shape and NiOH is hexagonal. Measurement from the Brunauer–Emmett–Teller method indicated that the specific surface areas of NiO and NiOH are 73.45 m²/g and 103.17 m²/g, respectively. The point-of-zero charge analyses showed that surface charge of NiO is neutral in cell media while NiO is slightly negatively charged. Surface charge of nanoparticles may influence bioavailability. Exposure to NiO and NiOH induced oxidative stress in A549 cells, which produced consequential alterations in cell functions. Caspase 3 activity was increased upon exposure to NiO or NiOH (N=3, Ps < 0.05). Semi-qualitative staining demonstrated a dose-dependent loss of mitochondrial membrane potential by NiO or NiOH. Exposure to NiOH caused a higher degree of apoptosis in A549 cells than exposure to NiO. Suppression of cell proliferation in A549 cells occurred upon exposure to NiO at concentrations above 25 μg/mL, and all tested concentrations of NiOH (N=3, Ps < 0.05). NiO caused an increase of cells in the S and G2 phases while NiO resulted in an increase of cells in the S phase. The collective outcome was reflected in differential cell viability. NiO produced a statistically significant (N=3, Ps < 0.05) higher reduction in cell viability than NiO in concentrations of 50 μg/mL. NiO dissolution from NiO and NiO and particle morphology may play crucial roles in toxicological outcome.

Fibroblast to Myofibroblast Differentiation in Response to the Mechanical Properties of Engineered Nanomaterials (ENMs) and Asbestos

A. E. Simmons, I. Wong, and A. Kane. Brown University, Providence, RI.

The mechanisms responsible for initiating fibroblast differentiation and impacting wound healing efficacy following exposure to ENMs and asbestos are currently underevaluated. To broaden our understanding of the fibroblast-driven wound healing response, I aim to evaluate a model of fibroblast to myofibroblast differentiation following exposure to ENMs and asbestos fibers. I hypothesize that exposure to high aspect ratio, stiff ENMs drives fibroblast to myofibroblast differentiation, and that mechanical and paracrine signaling is responsible for cytoskeletal organization and increased extracellular matrix (ECM) expression. I utilize IMR90 cells (human normal, lung, embryonic fibroblasts) exposed to particles/fibers with a variety of physical properties and geometries, including carbon black spherical particles (M120), crocidolite asbestos fibers, Mitsui multi-wall carbon nanotubes (MWCNT-7), and flexible MWCNTs (flex-2), to evaluate material properties that drive fibroblast to myofibroblast differentiation. Using α-smooth muscle actin (α-SMA) as a myofibroblast marker, the data supports that MWCNT-7 and asbestos induce significant a-SMA expression after 72 hours. The increase in a-SMA corresponds to significant upregulated protein expression involved in calcium signaling, cytoskeletal organization, and ECM production. In addition, ENMs and asbestos elicit significant upregulation of epidermal growth factor receptor, a response previously reported following asbestos exposure. In the future, we hope to further clarify mechanisms that drive myofibroblast function and modify the model to include relevant substrate stiffness to healthy and fibrotic lung microenvironments. This research is supported by the NIEHS Grant T32 ES057272 and the NIEHS Superfund Research Program P42 ES05660. Proteomics data were collected with the help of Drs. Ahsan and Solomon through the COBRE CCRD Proteomics Core - SP30GM110759.

E. Åkerlund1, F. Cappellini1, S. Di Bucciancio1, M. Islam1, S. Skoglund1, R. Derr1, I. Odnevall Wallinder2, G. Hendriks2, and H. L. Karlsson1, 1Karolinska Institutet, Stockholm, Sweden; 2KTH Royal Institute of Technology, Stockholm, Sweden; and 3Toxys, Leiden, Netherlands.

Nickel (Ni) compounds are classified as carcinogenic to humans but the underlying mechanisms are still poorly understood. Furthermore, effects related to nanoparticles (NPs) of Ni have not been fully elucidated. The aim of this study was to investigate genotoxicity and mutagenicity of Ni and NiO NPs and compare the effect to soluble Ni from NiCl₂. We employed different models; i.e. exposure of 1) human bronchial epithelial cells (HBEc) by DNA strand break analysis (comet assay and γ-H2AX staining); 2) six different mouse embryonic stem (mES) reporter cell lines (ToxTracker) that are constructed to exhibit fluorescence upon the induction of various pathways of relevance for (geno)toxicity and cancer; and 3) mES cells followed by mutagenicity testing (Hprt assay). The results showed increased DNA strand breaks (comet assay) for the NiO NPs and at higher concentrations also for the Ni NPs whereas no effects were observed for Ni ions/complexes from NiCl₂. By employing the reporter cell lines oxidative stress was observed as the main toxic mechanism and protein unfolding occurred at higher doses for all three Ni-containing materials. Oxidative stress was also detected in the HBEc cells following NP-exposure. None of these materials induced the reporter related to DNA damage and stalled replication forks. A weak, mainly not statistically significant increase in mutations was observed for all Ni-containing materials. We conclude that the NPs show more pronounced genotoxic effects compared to Ni ions/complexes, indicating more serious health concerns. The mechanism appears to be oxidative stress-driven rather than direct DNA binding.

Cytotoxic Effect of Mycosynthesized Silver Nanoparticles: A Mechanistic Perspective Study

I. R. Gupta1, and M. Rai2. 1Institute of Science, Aurangabad, India; and 2Sant Gadge Baba Amravati University, Amravati, India. Sponsor: U. Apte

Silver nanoparticles (AgNPs) have emerged as most widely used nanomaterial especially in healthcare and medicine. Physically and chemically synthesized AgNPs are already being preferred for such applications, while fungal mediated synthesis of AgNPs, termed as mycosynthesised AgNPs are gaining attention in the recent era. With the rise in applications, the reports of their toxic effect on cells of human origin are also increasing. Hence, there is a pressing need to study their nanotoxicological aspect. Past studies mainly focused toxicity of AgNPs prepared by chemical and physical methods. On the contrary, the toxicity of mycosynthesised AgNPs remained a neglected issue. As far as human exposure is concerned, these nanoparticles can enter the human body through oral, dermal and nasal exposure. Hence present study utilized the representative cell lines of these routes viz. IEC6, HaCat and A549 respectively representing intestine, skin and lung. The exposure study utilized AgNPs synthesized by Fusarium oxysporum. The rationale behind using this fungus is that many studies reported it to synthesize AgNPs rapidly and at low cost. After synthesis, they were characterized by various methods. The visual observation of change in color from colorless to brown gave the primary confirmation of synthesis. Further characterization by UV-Vis Spectrophotometry shown the characteristic peak around 420 nm, FTIR analysis confirmed the capping of nanoparticles by fungal proteins, X-ray diffraction study confirmed the presence of elemental composition to be silver, Nanosight LM20, and Zeta potential analysis showed the presence of polydisperse and stable nanoparticle respectively. Transmission Electron Microscopy showed the nanoparticle size ranging from 5-25 nm. During in vitro toxicity assessment studies, MTT assay revealed their IC50 value to be 8 µg/mL. Lactate dehydrogenase leakage assay concluded that they cause damage to the cell membrane, leading to leakage of cellular content. Through Reactive Oxygen Species assay, it was found to induce accumulation of reactive radicals, damaging cellular materials including the DNA which was confirmed by DNA fragmentation assay. In summary, the mycosynthesized AgNPs shown the mechanistically similar mode of action to damage all the three cell lines, showing the similar damage to cell irrespective of the organ of origin.

Nanoceria Dissolved in Acidic Environment Is Stabilized by Some Carboxylic Acids

Nanoceria is an abrasive used to prepare integrated circuits by chemical mechanical planarization and is also a diesel fuel additive, among other applications. It has therapeutic potential for multiple conditions with an oxidative stress/inflammation component including cancer, radiation damage, bacterial infection, sepsis, wounds, stroke-induced ischemia, and retinal degeneration. The objective was to determine conditions that contribute to its dissolution and to identify carboxylic acids that stabilize it under aqueous conditions. Citric acid is a stabilizing agent for hydrothermal nanoceria syntheses and for nanoceria dispersions. Citrate-coated nanoceria (primary particle size ~4 nm, hydrodynamic diameter of agglomerates ~14 nm) was introduced into 2 kD MWCO Slide-A-Lyzer™ dialysis cassettes immersed in iso-osmotic media. Samples were repeatedly withdrawn over 28 weeks from within the cassette and media surrounding the cassette for cerium quantitation by ICP-MS and high resolution electron microscopy. Dissolution-induced nanoceria transformation occurred at pH 4.5, increasing cerium in media surrounding the cassette and decreasing primary particle size. Citric, malic, and lactic acids and ammonium maintained the ~14 nm agglomerates, which grew to ~1 micron in media containing 7 other carboxylic acids. Nanoceria transformation occurred over 3 phases. 1) Formation of superstructures and initiation of pH-dependent nanoceria dissolution. 2) Oxidative nanoceria dissolution and reduction of primary particle (but not secondary structure) size. 3) Appearance of porous structured agglomerates, assuming a skeletal appearance. In contrast, nanoceria was stable for months in iso-osmotic citrate at pH 7.2, water, and in the presence of horseradish peroxidase and hydrogen peroxide at pH 6.1 (a condition that degrades carbon nanotubes). By extension of these observations, acidic environments, as found in phagolysosomes, may degrade nanoceria by dissolution. Carboxylic acids form coordination complexes with metal ions. Formation of cerium-chelate complexes after nanoceria dissolution may enable cerium redistribution within and across the cell, and uptake into plant roots. Ligands that enable nanoceria dissolution in acidic environments may greatly affect nanoceria’s fate (dissolution rate and size). Supported by 1R01GM109195.

Influence of Titanium-di-Oxide Nanomaterial Agglomeration on Toxicity and Biological Responses In Vitro

S. Murugadoss1, S. Van Den Brule2, N. Sebaihi3, F. Brassinne4, J. Mast4, L. Godderis5, D. Lison5, and P. Hoet6. 1Katholieke Universiteit Leuven, Leuven, Belgium; 2Université Catholique de Louvain, Brussels, Belgium; 3FPS Economy, Brussels, Belgium; and 4Center for Veterinary Agrochemical Studies and Research, Brussels, Belgium.

Nanoparticles (NPs) of size 1-100 nm can be potentially toxic due to their very high surface area compared to their bulk counterparts. Agglomeration and Aggregation (AA) of NPs reduces their toxicological impact, but their toxicological relevance is not fully elucidated. The rise in applications, while fungal mediated synthesis of AgNPs, termed as mycosynthesised AgNPs are gaining attention in the recent era. With the rise in applications, the reports of their toxic effect on cells of human origin are also increasing. Hence, there is a pressing need to study their nanotoxicological aspect. Past studies mainly focused toxicity of AgNPs prepared by chemical and physical methods. On the contrary, the toxicity of mycosynthesised AgNPs remained a neglected issue. As far as human exposure is concerned, these nanoparticles can enter the human body through oral, dermal and nasal exposure. Hence present study utilized the representative cell lines of these routes viz. IEC6, HaCat and A549 respectively representing intestine, skin and lung. The exposure study utilized AgNPs synthesized by Fusarium oxysporum. The rationale behind using this fungus is that many studies reported it to synthesize AgNPs rapidly and at low cost. After synthesis, they were characterized by various methods. The visual observation of change in color from colorless to brown gave the primary confirmation of synthesis. Further characterization by UV-Vis Spectrophotometry shown the characteristic peak around 420 nm, FTIR analysis confirmed the capping of nanoparticles by fungal proteins, X-ray diffraction study confirmed the presence of elemental composition to be silver, Nanosight LM20, and Zeta potential analysis showed the presence of polydisperse and stable nanoparticle respectively. Transmission Electron Microscopy showed the nanoparticle size ranging from 5-25 nm. During in vitro toxicity assessment studies, MTT assay revealed their IC50 value to be 8 µg/mL. Lactate dehydrogenase leakage assay concluded that they cause damage to the cell membrane, leading to leakage of cellular content. Through Reactive Oxygen Species assay, it was found to induce accumulation of reactive radicals, damaging cellular materials including the DNA which was confirmed by DNA fragmentation assay. In summary, the mycosynthesised AgNPs shown the mechanistically similar mode of action to damage all the three cell lines, showing the similar damage to cell irrespective of the organ of origin.
USPION exhibit physicochemical properties that are advantageous for theranostic biomedical products, such as intravenously administered medical imaging contrast agents; however, the toxicity mechanisms are not completely elucidated. Therefore, the goal of this study was to evaluate cellular interactions of USPION (PVP-coated) on human coronary artery endothelial cells (HCAECs) as a vascular cell model. USPION had an average size of ~20 nm, were negatively charged, and of spherical shape as assessed by transmission electron microscopy (TEM), dynamic light scattering, and zeta potential analyses, respectively. Using the alamar blue (AB) assay, cells treated with 25 or 200 µg/mL exhibited decreased cell viability to ~80% and 50% of controls, respectively, after 6 h of USPION exposure. Cellular uptake was evaluated by TEM after 3 h exposure of HCAEC to 25 µg/mL USPION. To evaluate the role of reactive oxygen species (ROS) production on cytotoxicity, cells were incubated with DCFDA dye, exposed to 25, 50, 100 or 200 µg/mL of USPION for 6 and 16 h, and fluorescence emission was evaluated by fluorescence spectrophotometry and microscopy. To further determine the role of ROS, HCAEC were pretreated with the antioxidant N-acetyl-cysteine (NAC) for 1 h prior to USPION (100 µg/mL) treatment, and cell viability was assessed by AB. Internalization of USPION in secondary lysosomes and perinuclear localization was observed as early as 3 h of exposure. No ROS production was apparent when using spectrophotometric DCFDA assay and fluorescence was detected in only a few cells exposed to 200 µg/mL USPION, with signal interference caused by particle overload in the cytoplasm. Our results indicate that there is no evidence of increased ROS production after USPION exposure nor increased cell viability by pretreating HCAEC with NAC prior to USPION exposure; thus, the toxicity mechanism appears unrelated to ROS production under the experimental conditions used.

**2720 DHA-Supplemented Diet Reduces Nanoparticles-Induced Lung Inflammation with Methylation Changes**

N. N. Alvarez1, E. Cole2, P. Fletcher2, P. Shaw2, A. Hollian2, and Y. Cho1.1Clemson University, Clemson, SC; and 2University of Montana, Missoula, MT.

Nanoparticles such as multi-walled carbon nanotubes (MWCNT) have many benefits and are used for many different purposes, such as medical and personal products. Exposure to MWCNT has been found to cause inflammation and lung disease, but the mechanism is still uncertain. It is becoming increasingly evident that dietary and environmental influences can result in physiological changes through epigenetics. Epigenetic alterations are known to hold substantial potential as biomarkers for environmental exposures; this, in turn, may provide insight into mechanisms of environmentally related diseases and allow for a better understanding of disease etiology. Therefore, we utilized a murine model to determine the effect of dietary docosahexaenoic acid-supplemented diet (DHA-SD) on MWCNT-induced inflammation, lung disease, and epigenetic changes. Balb/c mice were fed with normal diet or 50µM DHA-SD for 4 weeks, then both normal and DHA diet-mice were exposed to either dispersion media, 50 µg FA-21 (high Ni-MWCNT), or silica (SiO2) as a positive control via oropharyngeal instillation. One week post-exposure to particles, lung and blood were harvested for analyses and DM controls. No significant BBB changes were observed using SCIP assay on mouse brain endothelial cells (MBEC) and 2) myography using naiv thoracic aorta from male C57BL6 mice incubated with 1% serum from exposed mice to evaluate vasodilatory changes. Analyses of BALF inflammatory cytokine levels revealed dose-dependent increases in IL-1β, IL-4, IL-5, TNF-α and KC/GRO. Maximal neutrophil influx was observed 1d following the 3 µg dose, but at 3d following the 10 µg dose. A significant increase in TNF-α gene expression was observed with serum containing the exosomal fraction when compared with exosome depleted fractions and protein controls. No significant changes were observed using sodium fluorescein cerebral uptake assay. Further evaluations of BBB integrity will be done via immunohistochemistry. Evaluation of other systemic parameters are ongoing. These preliminary findings suggest that MWCNT pulmonary exposure induces inflammatory activation in the lungs of C57BL6 mice in a dose- and time-dependent manner and may produce serum bioactivity via exosomal delivery.
Engineered nanoparticles are used throughout industry and consumer products; however, we are just now beginning to mechanistically understand how inhalation exposure to nanoparticles may impact human health. Most research efforts have focused on pulmonary disease endpoints such as fibrosis, allergic-type reactions, and cancer, while the area of viral pathogen susceptibility remains less well explored. Previous work in our group has determined that respiratory epithelial cell (SAECs) to single-walled carbon nanotubes (SWCNTs) increases host susceptibility to Influenza A virus (IAV) infection. To better understand the molecular mechanisms that contribute to these observations, we investigated how SWCNTs modulate the host innate immune response, with a focus on lipid metabolism enzymes such as sphingosine-1 phosphate lyase (SPL) and sphingosine kinase 1 (SK1), and expression of interferon-stimulated genes (ISGs), specifically interferon-induced proteins with tetratrico peptide repeat (IFITMs) and interferon-induced transmembrane proteins (IFITMs). We hypothesized that SWCNTs are inhibiting expression of the lipid metabolism enzyme, SPL, resulting in decreased expression of ISGs, and thus increased viral titers. For our approach, we exposed SAECs to 20 μg/ml pristine SWCNTs for 24 hours, followed by exposure to IAV for 24 hours. We quantified viral infection with viral titers and the mRNA expression of SPL, SK1, IFITM genes via quantitative real-time polymerase chain reaction (qRT-PCR). Gene expression analysis showed that SWCNTs did not alter the expression of ISGs alone, but did significantly repress IAV-induced expression of several specific ISGs. Lipidomic analysis via LC/MS-MS demonstrated significant changes in sphingolipid and ceramide species. The importance of the balance between lipid metabolism enzymes, rather than their individual levels was also demonstrated. Future work will focus on the impacts of inhibition or over-expression of SPL and SK1 on the interaction between SWCNTs and IAV in SAECs. These studies highlight the important role that lipids play in the immune response, as well as the importance of assessing pathogen susceptibility when determining the environmental health and safety of nanomaterials.

Carbon Nanodots (CNDs) are a new class of carbon nanomaterials at the forefront of research for inherent therapeutic and biological applications. Their fluorescence and stability permit biological labeling, bio-imaging, and drug delivery. In this study, we studied the effects of CNDs on human NADPH oxidase-1 (NOX1), glutathione S-Transferase (GST) and glutathione reductase (GR) on human EA.hy926 endothelial cells. Our results indicated that CNDs at various concentrations showed no adverse effects on EA.hy926 cells. Further, there was a significant increase in the levels of NAD(P)H: quinone oxidoreductase-1 (NOX1), a vital cellular defense against oxidative stress and overproduction of reactive oxygen species (ROS). We also significantly reduced TNF-α-induced expressions of IL-8, monocyte chemotactic protein 1 (MCP1) and Interleukin Molecule 1 (ICAM-1), three important markers of vascular inflammation. Overall, these results suggest that CNDs could serve as a viable option for the treatment of inflammatory diseases such as atherosclerosis.
ACD response. Interestingly, we have identified that 20 nm silica NPs, a common NP in consumer goods, suppress the late phase inflammation and edema in a mouse model of ACD. Upon examination of the skin tissue, it appears as though 20 nm silica NPs reduce inflammatory cytokines (IL-6, IL-1β, and KC) and mast cell degranulation 24 hours after NP and DNPβ application. The suppressive effects of silica NPs also appear to be both size- and charge-dependent. Furthermore, NPs and aminated NPs fail to suppress the ACD response. Preliminary evidence suggests a direct effect of the NPs on skin, rather than a change in the bioavailability of DNPβ due to NP binding. When applying both 20 nm and 400 nm at a constant surface area, only the 20 nm silica NPs suppress the ACD response. Future studies will include looking at activation signals for the TLR4 downstream pathway including MyD88, TAK-1, IKK complex, and NF-κB in BEAS-2B cells stimulated with NiNP and LPS. This response was specific to NiNP as no other MNPs were able to increase IL-6 and IL-8 expression. Also, the synergistic effect of NiNP on LPS-induced cytokine production was only observed in human bronchial epithelial cells (BEAS-2B). NiNPs selectively increase LPS cytokine expression in human BEAS-2B cells to enhance IL-6 and IL-8 production at both mRNA and protein levels suggesting that they are able to promote further inflammation in the lung. Further study will help to elucidate the mechanism of adjuvant effect of NiNPs on LPS-induced lung inflammation and will include looking at activation signal for the TLR4 downstream pathway including MyD88, TAK-1, IKK complex, and NF-κB in BEAS-2B cells stimulated with NiNP and LPS. Supported by NIH Grant R01-ES020897, NIEHS Training Grant T32ES007046, and NSF Grant 15-022.

**2726 Requirement of STAT6 in Exacerbation of Allergic Lung Inflammation in Mice by Multi-Walled Carbon Nanotubes**

Multi-walled carbon nanotubes (MWCNTs) have numerous applications in electronics, engineering and medicine. There is increasing evidence that MWCNTs can have harmful effects upon inhalation. Of particular susceptibility are individuals with asthma, an allergic lung disease characterized by elevated levels of IgE, immune response, airway hyper-sensitivity, mucus cell metaplasia and airway remodeling. Signal transducer and activator of transcription 6 (STAT6) is a transcription factor with roles in TH2 type inflammation. With this study we sought to examine the role of STAT6 in MWCNT-induced asthma exacerbation. Furthermore, we hypothesized that STAT6 is required for exacerbation of allergen-induced lung inflammation by MWCNTs. Male C57BL6 and STAT6-/- mice were dosed via intranasal aspiration on days 0, 2, 4, 14, 16 and 18 with either vehicle, HDM, or a combination of HDM and tMWCNT; n=41. Necropsy was performed by NIEHS Grant R01ES020897 (JCB), NIEHS Training Grant T32ES007046, and NSF Grant 15-022 (JCB).

**2727 Selectively of Nickel Nanoparticles in Enhancement of LPS-Induced Pro-Inflammatory Cytokine Production in Human Bronchial Epithelial Cells In Vitro**

Nickel nanoparticles (NINPs) are commonly used as a catalyst for the production of multiwalled carbon nanotubes (MWCNTs). Nickel serves as an allergen that can directly activate the Toll-Like Receptor 4 (TLR4). TLR4 is also activated by Lipopolysaccharides (LPS), a ubiquitous component derived from gram-negative bacteria that is known to induce lung inflammation by causing secretion of pro-inflammatory cytokines (e.g., IL-6, IL-8). Recently, it was found that metal nanoparticles (MNPs) enhanced allergy in the presence of LPS in mice. Since major route of exposure for NiNPs is through inhalation, we hypothesized that NINPs would exacerbate LPS induced lung inflammation through amplification of downstream signaling intermediates (e.g., NF-κB, MyD88) to enhance IL-6 and IL-8 production. Human bronchial epithelial cells (BEAS-2B) were stimulated with NINPs (4 ug/cm²), LPS (50 ng/ml), or both. Cell supernatants and mRNAs were collected after 6, 24, and 48hr after the exposure to measure IL-6 and IL-8 protein secretion and mRNA expression levels, respectively. Different cell lines including human monocytic cells (THP-1) and mouse bronchial epithelial cells (E10), and different MNPs (cobalt, silver, and gold) were used to determine the species specificity and selectivity of nanoparticles on enhancement of LPS-induced cytokine production. NINPs synergistically increased LPS production of IL-6 and IL-8 both at mRNA and protein level in BEAS-2B cells. This response was specific to NiNP as no other MNPs were able to increase IL-6 and IL-8 expression. Also, the synergistic effect of NiNP on LPS-induced cytokine production was only observed in human bronchial epithelial cells (BEAS-2B). NiNPs selectively increase LPS cytokine expression in human BEAS-2B cells to enhance IL-6 and IL-8 production at both mRNA and protein levels suggesting that they are able to promote further inflammation in the lung. Future research will continue to identify the mechanism of action of these small negatively charged silica NPs.

**2728 Pulmonary Engineered Nanomaterial Exposure during Late Gestation Attenuates Plasma Estrogen**

Maternal exposure to engineered nanomaterials (ENMs) during gestation is associated with uterine vascular impairments as well as endothelial disruptions that may lead to altered gestational outcomes. We have previously shown that nano-titanium dioxide (nano-TiO2) inhalation impairs endothelium-dependent arterial dilation in uterine arterioles of pregnant rats. However, the mechanism underlying this dysfunction has not been fully determined. One possibility is alterations in the steroid hormone estrogen (E2), which is elevated during pregnancy. Furthermore, E2 is critical for synthesis of the hormone kisspeptin (Kiss), which is a potent vasconstrictor. Therefore, we examined how circulating E2 and Kiss are involved in nano-TiO2-induced vascular dysfunction. Pregnant (gestation day (GD) 10) Sprague-Dawley (SD) rats were exposed to nano-TiO2 aerosols (11.3 ± 0.1 mg/m3/hr, 5 hr/d, 8.2 ± 1 day; n = 6) or sham exposed (n = 6) to evaluate endocrine consequences of maternal exposure. Plasma was collected on GD 20 to evaluate circulating levels of E2, progesterone (Pg), luteinizing hormone (LH), follicle stimulating hormones (FSH), prolactin (PRL) and corticosterone (CORT). In a separate set of experiments, virgin or pregnant rats were exposed via intra-tracheal instillation to nano-TiO2 (100 µg) suspended in 200 µL of vehicle (normosol and 5% fetal bovine serum, n = 7) or sham controls (n = 5). 24 hours later thoracic aorta was dissected and multiple 2-3 mm segments were cut and mounted in each wire myograph chamber (DMT 620M) containing physiological salt solution (PSS) at 37°C. After 60 min of equilibration, the maximum contractile response was determined using high-potassium PSS (KPSS). Vessels were then washed with PSS and allowed to relax until initial tension returned. Contractile responses were determined via addition of a single dose of 50 µL phenylephrine (1 x 10−6), norepinephrine (50 µL of 0.1 x 10−4 to 1 x 10−1 M), and plasma E2, which was added to the PSS. Plasma E2 was significantly decreased at GD 20 in exposed (11.08 ± 2.5 %) vs. sham controls (94.7 ± 10.53%). These studies represent the first evidence pulmonary ENM exposure perturbs the normal gestational endocrine vascular axis via a Kiss dependent mechanism of dysfunction. Supported by NIH ES015022.

**2729 Nanoparticles Exposure and Health Effect Markers in Frozen Exhaled Breath Condensate**

S. Liu1, C. Wang2, W. Wu1, W. Hou3, and H. Lee4. 1National Health Research Institutes, Miooli County, Taiwan; 2Trilogy General Hospital, Taipei, Taiwan; 3National Cheng Kung University, Tainan, Taiwan; and 4Fu Jen Catholic University, New Taipei, Taiwan.

Exhaled breath condensate (EBC) could be an ideal biological matrix, as it could provide information about the subsequent biological effects of an inhalation exposure and as a biomarker of lung disease. The purpose of this study is to examine whether biomarkers in EBC could be correlated with nanoparticle concentration in EBC. 18 indium tin oxide (ITO)-exposed nanomaterial workers and 23 non-exposed controls were recruited from nanotechnology factories. A questionnaire was used to collect detailed information about life style, personal habits, disease history and occupational history. EBC was collected by an ECoScreen turbo (Viasys GmbH, West Germany).
Höchberg, Germany). The particle size-number distribution of ultrafine particles (PM0.1) were assessed NanoSight LM10 HS system (Nanosight Ltd., Salisbury, UK) using the Nanoparticle Tracking Analysis (NTA). The biomarkers measured for each aspect of toxic endpoints included: 1. Inflammation and oxidative damage markers, such as Clara cell protein (CC16), nitric oxide (FeNO), and 8-hydroxydeoxyguanosine (8-OHdG). 2. Cardiovascular biomarkers, such as fibrinogen, vascular cell adhesion molecule (VCAM), intercellular adhesion molecule-1 (ICAM-1), high-sensitivity C-reactive protein (hsCRP), and heart rate variability (HRV). 3. Lung function test. We found plasma Gpx (glutathione peroxidase) level was significantly higher in high particles concentration workers (log concentration≧8.1) than low particles concentration workers (log concentration<8.1). 8-isoPGF2alpha in EBC was not correlated with concentration (x10^8 #particles/mL), % of UFP and particles number of UFP. Particles concentration (x10^8 #particles/mL) was also not associated with 8-OHdG in urine, plasma and WBC as well as SOD in plasma. The possible reasons for the correlation between particles concentration and elevated levels of both Th1 and Th2 cytokines over control are increased levels of CXCL1/KC, LDH and protein in the BALF. The lung inflammation induced by Nano-Ni was confirmed by histological examination, which showed inflation of a large amount of polymorphonuclear (PMN) cells and macrophages in the alveolar space, alveolar septa, peribronchial and peribronchiolar areas. Nano-Ni also caused increased MMP-2/9 protein levels and activity in the BALF. By six weeks after exposure, Nano-Ni-exposed mice developed chronic lung inflammation as evidenced by infiltration of neutrophils and enlarged foamy macrophages and extensive pulmonary fibrosis. Nano-Ni-exposure caused acute biomarkers and chronic inflammation in BALB/c mice, but at a much lesser degree. Nano-Ni-P caused a moderate acute neutrophilic inflammation, but mostly resolved by six weeks. Nano-Ni-C only caused mild acute and chronic inflammation. Our results suggest that Nano-Ni exposure can cause severe acute and chronic lung inflammation and injury while surface modification such as carbon coating can alleviate Nano-Ni-induced lung injury.

2730 Surface Area- and Mass-Based Comparison of Lung Toxicity and Allergic Exacerbation in an Ovalbumin Asthma Model following Pulmonary Exposure to Fine and Ultrafine Nickel Oxide

K. A. Roach, S. E. Anderson, A. B. Stefaniak, H. L. Shane, D. Schwegler-Berry, and J. R. Roberts. NIOSH, Morgantown, WV.

The correlation of specific nanomaterials' physico-chemical properties with toxicological responses is an area of growing interest with implications for the selection of appropriate dose metrics in nanotoxicity studies. In this study, the role of nickel oxide mass and surface area in the induction of pulmonary inflammation and exacerbation of respiratory allergy was explored. To address this concept, 181 nm fine (NiO) and 90 nm ultrafine (NiONP) particles were characterized and incorporated into an in vivo time course study and ovalbumin (OVA) asthma model. Particle toxicity was compared at equal masses of 40 micrograms and at equal surface areas of 1.92 mm^2. For the time course study, female BALB/c mice were exposed once to particles or vehicle control by oropharyngeal aspiration and euthanized 1, 10, 19, or 29 d post-exposure, which represent critical time points in the OVA model. For the OVA model, mice were exposed with particles on d 0, sensitized to OVA via IP injection on d 1 and 10, challenged with OVA by aspiration on d 19 and 28, and euthanized on d 29. In the time course study, exposure to mass-normalized doses of particles resulted in significantly elevated lactate dehydrogenase levels, lung neutrophil number, and mediastinal lymph node size in mice exposed to NiONP, which persisted to 29 d post-exposure. However, normalization of doses for surface area mitigated all differences between particles, suggesting that NiO surface area drives pulmonary inflammation. In the OVA model, exposure to equal masses of NiO and NiONP induced differential mechanisms of immune cell infiltration. Exposure to NiO caused increased pH over allergy controls and higher levels of Th2 cytokines in the lavage fluid. Exposure to NiONP resulted in significantly increased lymph node size over all other groups and elevated levels of both Th1 and Th2 cytokines over control animals, but reduced serum OVA IgE levels. Interestingly, normalization of doses for surface area in the OVA model mitigated differences in serum IgE and Th2 cytokine levels, but not eosinophil influx to the lung and Th1 cytokines. Overall, findings suggest that although surface area of NiO dictates pulmonary injury and inflammation, it may not be the only physico-chemical property responsible for modulation of immune responses in the lung.

2731 Comparative Mouse Pulmonary Toxicity of Nickel Nanoparticles with Different Surface Modification

Y. Mo and Q. Zhang. University of Louisville, Louisville, KY.

With the development of nanotechnology, a large amount of nanoparticulates are being produced or will be produced. Due to their specific physical and chemical properties, nanoparticulates have been increasingly used in the fields of engineering, information technology and biomedicine. Nickel nanoparticles, because of their low melting point, high magnetism, high surface area, and high reactivity, have found applications in various areas including industry, environment, and biomedicine. Thus occupational and non-occupational exposure to nickel nanoparticles are increasing. It is necessary and urgent to study the adverse effects of nickel nanoparticles on individuals as well as to find ways to alleviate their toxicity. In this study, we examined and compared the short-term and long-term effects of three kinds of nickel nanoparticles with different surface modification on mouse lungs. Mice were intratracheally instilled with nickel nanoparticles without surface modification (Nano-Ni), nickel nanoparticles partially passivated with oxygen (Nano-Ni-P), or nickel nanoparticles coated with a thin layer of carbon (Nano-Ni-C). Control mice were instilled with normal saline. Our results showed that Nano-Ni exposure caused severe acute lung inflammation at day 3 after exposure, which was reflected by increased number of neutrophils and increased levels of CXCL1/KC, LDH and protein in the BALF. The lung inflammation induced by Nano-Ni was confirmed by histological examination, which showed infiltration of a large amount of polymorphonuclear (PMN) cells and macrophages in the alveolar space, alveolar septa, peribronchial and peribronchiolar areas. Nano-Ni also caused increased MMP-2/9 protein levels and activity in the BALF. By six weeks after exposure, Nano-Ni-exposed mice developed chronic lung inflammation as evidenced by infiltration of neutrophils and enlarged foamy macrophages and extensive pulmonary fibrosis. Nano-Ni-exposure caused acute biomarkers and chronic inflammation in BALB/c mice, but at a much lesser degree. Nano-Ni-P caused a moderate acute neutrophilic inflammation, but mostly resolved by six weeks. Nano-Ni-C only caused mild acute and chronic inflammation. Our results suggest that Nano-Ni exposure can cause severe acute and chronic lung inflammation and injury while surface modification such as carbon coating can alleviate Nano-Ni-induced lung injury.

2732 Lung Deposition and Retention of Multi-Walled Carbon Nanotubes after 28-Day Inhalation and 28-Day Post Exposure in SD Rats

E. M. Faustman, University of Washington, Seattle, WA.

The newly revised OECD inhalation toxicity testing guidelines 412 and 413 require measurement of lung deposition and retention of poorly soluble nanomaterials in order to evaluate their clearance and biopersistence. With this aim, male SD rats were exposed to MWCNT at 0, 0.257, 1.439 and 4.255 mg/m^3 for 28 days (6h/day, 5day/week, 4week). After 28 days of exposure, the rats were sacrificed at post-1, 7, and 28 days and bronchoalveolar lavage (BAL) fluids were obtained to evaluate changes in inflammatory cells and markers. Blood biochemistry, hematology and histopathology examinations of the lungs were also conducted. The lung deposition and retention of MWCNT were evaluated by elemental carbon (EC) content in the lungs after digestion of lung cells (PMN) and LDH in the BAL fluids increased in a significant concentration-dependent manner after 28 days of MWCNT exposure and at 7 and 28 days post exposure compared with the controls. Lung deposition and retention of MWCNT in the lungs showed concentration and time dependency after 28 days of MWCNT exposure and post-exposure 7 and 28 days. Based on these endpoints examined a NOAEL was identified at 0.257 mg/m^3 for 28 day subacute inhalation of MWCNT. (1159).

2733 Role of Toll-Like Receptor 5 in Multi-Walled Carbon Nanotube-Induced Lung Injury

S. Hussain1, A. Taylor2, L. Degraff2, M. George1, A. Rice1, J. C. Bonner3, and S. Garlantziotis1. 1. NIEHS, Research Triangle Park, NC; and 2. North Carolina State University, Raleigh, NC.

Innate immune responses play a significant role in mediating environmental lung injury. Toll-like receptors (TLRs) recognize exogenous (pathogen-associated) or endogenous (danger-associated) molecular patterns and shape innate immune responses. Bacterial Flagellin is the only known ligand for TLR5. However, we have recently demonstrated a significant contribution of TLR5 in sterile lung injury induced by either ozone or short fragment hyaluronan, suggesting that TLR5 may be involved in lung injury responses. The contribution of TLR5 in nanomaterial-induced lung injury is completely unknown. We aimed at investigating the role of TLR5 in multi-walled carbon nanotube (MWCNTs)-induced lung injury. We exposed wild type and TLR5 KO mice to well characterized tangled or rod-like MWCNTs (single oropharyngeal aspiration of 2 mg/kg) and studied lung injury at days 1 and day 21 post exposure. Lung lavage analyses and histology were employed to assessed lung injury and inflammation. Measurement of total lung collagen and morphometry was used to evaluate pulmonary fibrosis. Both forms of MWCNT induced significant lactate dehydrogenase and cytokine release in bronchoalveolar lavage fluid at day 1 and day 21. Lavage fluid from TLR5 KO mice had higher amounts of total proteins and LDH at day 21 post exposure. Inflammatory and fibrotic mediators such as (osteopontin, platelet derived growth factor-aa and transforming growth factor-beta) were elevated at days 1 and 21 after both forms of nanotube
exposure. However, the magnitude of inflammatory response was significantly higher in rigid rod-like MWCNT exposed TLRS KO mice. In conclusion, these results demonstrate a potential role of TLRS in mediating MWCNT induced lung injury. Further studies are underway to explore the mechanistic basis of observed responses.

2734 Mouse Pulmonary Dose- and Time Course-Responses Induced by Exposure to Nitrogen-Doped Multi-Walled Carbon Nanotubes

D. W. Porter1, N. Wu2, M. Orandle1, B. T. Chen1, M. G. Wolfarth1, L. Battelli1, M. Andrew1, S. Tsu,ruoka1, M. Endo1, R. Cruz-Silva3, M. Terrones3, and V. Castranova2. 1 Virginia University, Morgantown, WV; 2 Penn State University, University Park, PA.

Multi-walled carbon nanotubes (MWCNT) can be modified by doping them with other elements. These modifications change the intrinsic properties of MWCNT and may also alter their bioactivity. In this study, we compared the in vivo bioactivity of nitrogen doped multi-walled carbon nanotubes (NDMWCNT) to pristine MWCNT to test the hypothesis that nitrogen doping would alter their bioactivity. First, characterization of the MWCNT and NDMWCNT was conducted. High resolution TEM confirmed the multilayer structure of MWCNT with an average layer distance of 0.36 nm, which was not altered by nitrogen doping. TEM analyses indicated the nanomaterials had similar widths (NDMWCNT=53 nm, MWCNT=49 nm) and lengths (NDMWCNT=4.73 µm, MWCNT=3.86 µm). Comparison of MWCNT and NDMWCNT XPS spectra demonstrated presence of a N1s peak, while FTIR spectra indicated the presence of N-H bonding only in the NDMWCNT sample. For in vivo studies, male C57BL/6J mice received a single dose of either dispersion medium (DM; vehicle control), 2.5, 10, or 40 µg/mouse of MWCNT, or 40 µg/mouse of NDMWCNT. Animals were euthanized at 1 and 7 days post-exposure for whole lung lavage (WLL) studies. NDMWCNT caused time- and dose-dependent pulmonary inflammation. However, on an equivalent mass basis, it is less than that caused by MWCNT. Activation of the NLRP3 inflammasome was assessed by qPCR in lung mRNA. A significant increase in NLRP3 transcripts was observed in NDMWCNT-exposed mice relative to MWCNT-exposed mice. At 56 days post-exposure, histopathological analyses determined lung fibrosis in MWCNT-exposed mice was greater than that determined for NDMWCNT-exposed mice. These data indicate that nitrogen doping of MWCNT decreases their bioactivity, and that lower activation of the NLRP3 inflammasome by NDMWCNT relative to MWCNT may be responsible.

2735 Multi-Walled Carbon Nanotube Inhalation Alters Expression of SP-D and Inflammation in the Rat Lung

When aerosolized, multi-walled carbon nanotubes (MWCNT) pose an inhalational hazard. Previous studies have shown that rats exhibit a dose dependent acute inflammatory response without altering mucous disbursement and that MWCNT are not retained in the lungs for up to 30 days. Surfactant protein-D (SP-D) is an airway epithelial cell-derived lung collectin, an important modulator of the innate and adaptive immune response, and a regulator of apoptotic cell clearance in the lung. The objective of this study was to examine the effects of long term MWCNT exposure via inhalation, on levels of SP-D expression. Male Sprague Dawley rats were exposed to aerosolized MWCNT at 0.06, 0.2, and 0.6 mg/m3 for a total of 22 days over the course of one month. Bronchoalveolar lavage (BAL) fluids were taken 5 days post-exposure to obtain BAL differential cell counts and total protein concentration. Adherent lung samples were analyzed for SP-D gene expression and accumulation of neutrophils and macrophages. Native gel electrophoresis and Western blot analysis for SP-D levels in cell-free BAL fluid were performed and BAL cell counts and SP-D levels were correlated by regression analysis. Exposure to MWCNT’s induced a significant change in BAL neutrophil counts and SP-D protein expression. Rats exposed to 0.2 mg/m3 of aerosolized MWCNTs had significantly lower levels of SP-D than control rats exposed to ambient air. However, rats exposed to a concentration of 0.6mg/m3 MWCNTs expressed significantly more SP-D when compared to the control group. The increase in SP-D level in this group coincided with a significant increase in numbers of neutrophils found in BAL cell differentials. Additionally, there was a negative correlation between numbers of macrophages in the BAL of this high concentration exposure group and the levels of SP-D in BAL supernatant. This data suggests that chronic exposure to MWCNT contributes to increased expression of SP-D which may alter macrophage uptake of MWCNT and attenuation of inflammatory cell accumulation in BAL. 2736 Kinetic Time Courses of Inhaled Silver Nanoparticles in Rats

S. Andriamasinoro1, D. Dieme1, C. Desvergne2, S. Alessandra-Maria3, M. Debia1, S. Haddad1, and M. Bouchard1. 1 University of Montreal, Montreal, QC, Canada; 2CEA Grenoble, Grenoble, France; and 3Institute of Research of Hydro-Quebec, Montreal, QC, Canada.

Silver (Ag) NPs are emerging priority substances closely monitored by main health and safety agencies. Despite their extensive use, there is a lack of data on their in vivo behavior in the body, in particular following inhalation, the predominant route of exposure in the workplace. We thus evaluated the toxicokinetics of Ag NPs after inhalation in rats exposed nose-only to 20 nm Ag NPs during 6 h at a concentration of 15 mg/m3 (21834 ± 85512 particles/cm3). The generated aerosol showed a uniform size distribution of Ag agglomerates with a geometric mean (± SD) of 791 ± 1.888 µm. The time courses of Ag concentration in lungs, blood, tissues and excreta were established over 14 days following the onset of inhalation. All samples were analyzed using inductively-coupled plasma mass spectrometry (ICP-MS). Elimination profiles revealed that feces was the dominant excretion route and represented on average (± SD) 5.1 ± 3.4 % of the inhaled exposure dose compared with urinary excretion, which amounted to 0.01 ± 0.006 %. In the lungs, highest percentage of inhaled dose was observed at the end of the 6-h inhalation and reached 1.9 ± 1.2 %. Blood concentrations increased progressively post-inhalation, reached a maximum at 168 h and decreased thereafter, but values remained 80 times lower than lung levels. In extrapulmonary organs, such as liver, spleen, and kidney, concentrations were also much lower than lung concentrations, representing less than 0.2 % of dose at all times and peak levels were reached at t = 72 h followed by a progressive decrease over the 14-day sampling. Results show that only a small percentage of inhaled dose reached the lungs - the majority of dose most plausibly remained in the upper respiratory tract - and that Ag NPs also poorly translocated to the systemic circulation.

2737 Short-Term Inhalation Study of Graphene Oxide Nanoplates

E. M. Faustman, University of Washington, Seattle, WA.

Graphene oxides possessing unique physicochemical properties are expected to be applied within industrial science for electronics, pharmaceuticals and medicine. However, the toxicity of graphene oxide exposure has not been clarified. Therefore, a short-term inhalation toxicity study of graphene oxide was conduct by using a nose-only inhalation exposure system for male Sprague-Dawley rats. A total of four groups (15 rats per group) were exposed: (1) control (fresh air) (2) low concentration (0.76 ± 0.16 mg/m3) (3) moderate concentration (2.60 ± 0.19 mg/m3) (4) high concentration (9.78 ± 0.29 mg/m3). The rats were exposed to graphene oxide for 6 h/day for 5 days followed by recovery 1, 3, and 21 days. The concentration of graphene oxide did not change body weight, and organ weight of the rats after the short-term exposure during the recovery period. Minimal differences were observed in the level of lactate dehydrogenase, alkaline phosphatase, total protein, and albumin between the exposed and control groups suggesting minimal liver and kidney damage. In addition, no significant difference was observed in the bronchoalveolar lavage cell differential such as lymphocytes, macrophages, and PMN. Graphene oxide ingested alveolar macrophages were observed in the lungs of all concentration groups from post 1 day to post 21 days. Thus, these short-term inhalation studies provide important initial information about toxicities between graphene and graphene oxide following nose-only exposures in lung and lack of toxicity in other organs.
Comparison of the Toxicological Effects of Multi-Walled Carbon Nanotubes and Nitrogen-Doped Multi-Walled Carbon Nanotubes on Rat Lung Function

K. A. Russ, J. Thompson, and J. S. Fedan. NIOSH, Morgantown, WV.

The toxicological effects of multi-walled carbon nanotubes (MWCNT) have been widely investigated. Outcomes can range from initiating pulmonary inflammation and fibrosis to cardiovascular and central nervous system effects in animal models. Previous studies in our laboratory have shown that inhalation of MWCNT (Mitsui-7) results in airway hyperactivity to methacholine (MCh) in rats. Nitrogen-doped multi-walled carbon nanotubes (N<sub>2</sub>-MWCNT) are MWCNT that have been functionalized to incorporate nitrogen. They are utilized in applications such as lithium batteries and as matrix fillers in composite materials. N<sub>2</sub>-MWCNT are shorter and more brittle than their MWCNT counterparts, which may reduce toxicity. The purpose of this study was to determine if exposure to N<sub>2</sub>-MWCNT results in alterations in lung function that are comparable to those observed after MWCNT exposure. Sprague-Dawley rats were administered MWCNT or N<sub>2</sub>-MWCNT (25, 50, or 250 µg) in dispersion medium by intratracheal instillation. Lung resistance (R<sub>L</sub>), dynamic compliance (C<sub>dyn</sub>), and reactivity to MCh aerosol were examined at 1 and 7 days after treatment with 25, 50, and 250 µg MWCNT. Additionally, baseline R<sub>L</sub> was decreased at 7 days after treatment with 50 µg MWCNT without a corresponding change in reactivity to MCh. The only alteration observed in N<sub>2</sub>-MWCNT exposed animals was a decrease in baseline R<sub>L</sub> at 7 days after 250 µg N<sub>2</sub>-MWCNT exposure, with no corresponding change in reactivity to MCh. These results suggest that N<sub>2</sub>-MWCNT are less toxic than MWCNT with respect to lung function.

Pulmonary Toxicity and Gene Expression Changes in Response to Multi-Walled Carbon Nanotube Exposure in Rats

Carbon-based nanomaterials have significant commercial and industrial applications and, therefore, human exposure to them potentially resulting in adverse health effects should be anticipated. Understanding the molecular mechanisms underlying the toxicity induced by carbon nanotubes has merit in the prevention of the adverse health effects potentially resulting from their exposures. Currently, a rat toxicity model was employed to investigate the molecular mechanisms underlying the pulmonary toxicity induced by exposure to multi-walled carbon nanotubes (MWCNT). Rats were exposed, by whole-body inhalation exposure, to air or an aerosol containing MWCNT particles (5 mg/m<sup>3</sup>, 6 hours/day, 3 days). Toxicity and global gene expression profiles were determined in the lungs of the rats, 16-hours following the last exposure. MWCNT particles, often associated with alveolar macrophages (AMs), were detected in the lungs of the exposed rats. Lung histological changes resulting from MWCNT exposure were mild and consisted mainly of interstitial accumulation of macrophages. Bronchoalveolar lavage (BAL) toxicity parameters such as lactate dehydrogenase activity, number of AMs and PMNs, oxidant production by phagocytes, and levels of multiple cytokines (IL-1β, IL-10, MCP-1, MIP-2, and TNF-α) were significantly altered in response to inhalation exposure to MWCNT in the rats. Global gene expression profiling by next generation sequencing identified a large number of significantly differentially expressed genes (fold change >1.5 and FDR p value <0.05) in the lungs of the MWCNT exposed rats, compared with the controls. Bioinformatics analysis of the gene expression data identified significant enrichment of several disease/biological functions (for example, cancer, organismal injury and abnormalities, cell cycle, respiratory disease, cellular movement, and inflammatory response) and canonical pathways (for example, LXR/RXR activation, granulocyte and agranulocyte adhesion and diapedesis, complement system, acute phase response, and atherosclerosis signaling). Taken together, the data provided insights into the molecular mechanisms underlying the pulmonary toxicity induced by inhalation exposure of rats to MWCNT.

Characterization of Pulmonary Toxicity following Graphene Inhalation

J. R. Roberts<sup>1,2</sup>, M. Barger<sup>2</sup>, K. A. Roach<sup>2</sup>, W. McKinney<sup>1</sup>, T. B. Chen<sup>1</sup>, D. Schwegler-Berry<sup>1</sup>, A. Stefanik<sup>1</sup>, I. S. Chaudhuri<sup>1</sup>, A. Kyrlidis<sup>1</sup>, M. S. Orandle<sup>1</sup>, V. K. Kodali<sup>1</sup>, N. V. Yamamula<sup>1</sup>, and A. Erdely<sup>1,2</sup>.<sup>1</sup>NIOSH, Morgantown, WV;<sup>2</sup>West Virginia University, Morgantown, WV; and<sup>1</sup>Cabot Corporation, Billerica, MA.

Graphene is a 2D nanomaterial with unique physicochemical properties making it highly marketable for applications in numerous industries. Our previous studies have shown that toxicity varies depending on size and oxidative form of graphene following a single bolus-dose aspiration in mice, with exposure to reduced graphene oxide (rGO) resulting in the greatest degree of lung injury and inflammation. The goal of this study was to characterize pulmonary toxicity following subacute inhalation of rGO. C57BL/6J mice were exposed to rGO (2.41 µm MMAD, 2.69 GSD) by whole body inhalation at 5.0 mg/m<sup>3</sup> for 5 h/d for 19 d, 0.5 mg/m<sup>3</sup> for 5 h/d for 19 d, or 0.5 mg/m<sup>3</sup> for 0.5 h/d for 19 d to achieve depositions with a two order of magnitude range. Controls were exposed to filtered air. Lung burden of rGO, parameters of lung toxicity and inflammation, and histopathology were analyzed 0, 3, 7, and 14 days post-exposure. Lung burden at 0 d was 0.78, 6.47, and 34.4 µg per lung for the low, middle, and high dose. Following high dose exposure, lactate dehydrogenase (LDH) in lung lavage fluid (LLF, lung injury) and total lavage cells (inflammation) were increased up to 1 m compared to control. The cellular increase was due primarily to macrophage influx. Neutrophils were also significantly increased; however, this cell population accounted for less than 1% of the total cells. Inflammation and injury resolved by 3 m. Inflammatory and tissue remodeling proteins in LLF followed a similar pattern. Pathologic analysis indicated increased macrophages in the lungs at 0 and 3 d as minimal, resolving over time. Particle burden in macrophages was also observed to decrease over time. Following middle dose exposure, total lavage cells increased at 3 d, due primarily to macrophage influx, and resolved by 1 m. Significantly fewer inflammatory proteins were elevated in LLF following exposure to the middle dose compared to the high dose, with resolution by 1 m. There was no difference in lung cellularity following low dose exposure. No lung pathology or increased LDH in LLF were observed following middle or low dose exposures. Exposure to rGO led to an acute dose-dependent increase in lung injury and inflammation, which resolved over time, with 0.5 mg/m<sup>3</sup> causing a minimal degree of inflammation representing the low observable effect level.

Developmental Toxicity Assessment of Four Different Preparations of Multi-Wall Carbon Nanotubes in Mice after Repeated Intratracheal Instillation

N. Kobayashi<sup>1</sup>, R. Tanaka<sup>1</sup>, Y. Ikashiri<sup>1</sup>, and A. Hirose<sup>1</sup>.<sup>1</sup>National Institute of Health Sciences, Kanagawa, Japan; and<sup>1</sup>Biosafety Research Center, Shizuoka, Japan.

Some studies have reported that maternal exposure to manufactured nanomaterials, including carbon nanotubes, may induce reproductive and developmental toxicity, such as teratogenicity. In order to initiate grouping and read across for filling data gaps in the developmental toxicity of carbon nanotubes via airway exposure, we conducted repeated intratracheal instillation studies of various preparations of multi-walled carbon nanotubes (MWCNTs) in pregnant mice. Four types of MWCNT dispersions (bulk, heat-treatment, single dispersion by Taquann method, and heat-treatment after single dispersion) were repeatedly administered to pregnant Crlj:CD1(ICR) mice on gestational days 6, 9, 12, and 15 at dosages of 4.0 mg/kg/day. Ten pregnant mice per group were dissected on gestational day 17, and then developmental toxicity was evaluated. The body weights of the heat-treatment MWCNTs exposed mice significantly decreased. In the other 3 groups, the body weights of MWCNTs exposed mice also decreased, although the changes were not statistically significant. Body weight of fetuses was significantly decreased in the bulk, the heat-treatment, and the heat-treatment after single dispersion MWCNTs exposed group. External malformations of fetuses were observed in the bulk and the heat-treatment MWCNT exposed groups. No statistically significant difference was observed between the control group and all MWCNT exposed groups in the numbers of corpora lutea, number of implantations, and placental weights. These results suggested the teratogenic effects caused by the intratracheal exposure of MWCNTs are dependent on their dispersion methods. Further examinations are needed to clarify the mechanism of the developmental toxicity by MWCNTs.

The inhalatory route is considered their main form of entry of nanoparticles (NPs) and the lung is a vulnerable target organ given its direct interaction with the environment, being the alveolar region more susceptible. Exposure to metallic NPs, titanium dioxide (TiO2) and zinc oxide (ZnO), widely used in the manufacturing of diverse products (textiles, food products, electronics, etc.), leads to reactive oxygen species (ROS) generation and cytotoxicity. Alveolar cells produce pulmonary surfactant, constituted by lipids and surfactant proteins (A, B, C and D), which main functions are to maintain pulmonary homeostasis and the immune response; and have been reported to be affected by exposure to cigarette smoke and particulate matter. Our work aims to evaluate the relationship between the exposure to TiO2 and ZnO NPs and the expression of surfactant proteins in A549 human lung epithelial cells. Propidium iodide and MTS assays showed that the exposure after 12, 24 and 48 h to TiO2 and ZnO NPs in different concentrations (2.5, 5.0, 10, 15 and 20 µg/mL of ZnO; 25, 50, 100, 150 and 200 µg/mL of TiO2) do not affect cell viability. The production of ROS determined at 3, 12 and 24 h; showed an increase in the generation of superoxide anion (O2·−) after 12 and 24 h and hydrogen peroxide (H2O2) after 24 h of exposure to TiO2; in the treatment with ZnO an increase in O2·− was observed after 24 h, in a concentration dependent manner, respectively. In regard to the surfactant proteins, after 12 h of treatment with TiO2 (25, 50 and 100 µg/mL) a slight decrease of SP-A and SP-D was observed, while the exposure to ZnO (5.0, 10 and 15 µg/mL) induced an increase; for SP-B, in both NPs treatments an increase of surfactant proteins was observed. We conclude that the exposure to non-cytotoxic concentrations of TiO2 and ZnO NPs induced ROS and reduced of SP-A and SP-D, possibly from the increase in pro-inflammatory cytokines, deriving in tissue damage and a possible alveolar collapse.

An increasing number of engineered nanomaterials (ENMs) has been used in many industrial sectors or consumer products, thus an inhalation exposure to these materials may occur either in occupational environments during their production or consumer use. Citrate capped gold nanoparticles (Au NPs) in suspension (50 µg/mL) and silver (~7 nm) supported on silica (~10 nm) nanospheres (15%Ag@SiO2) were provided by the ENM Resource and Coordination Core (ERCC) with full physicochemical and morphological characterization. The nanomaterials were used as supplied without further modification. Toxicity assessment was performed using an in vitro air-liquid interface method exposure to these materials at 15%Ag@SiO2. Exposure to Au NPs did not affect cell viability. The production of ROS determined at 3, 12 and 24 h, in a concentration dependent manner, respectively. In regard to the surfactant proteins, after 12 h of treatment the expression of surfactant proteins, after 12 h of treatment with TiO2 (25, 50 and 100 µg/mL) a slight decrease of SP-A and SP-D was observed, while the exposure to ZnO (5.0, 10 and 15 µg/mL) induced an increase; for SP-B, in both NPs treatments an increase of surfactant proteins was observed. We conclude that the exposure to non-cytotoxic concentrations of TiO2 and ZnO NPs induced ROS and reduced of SP-A and SP-D, possibly from the increase in pro-inflammatory cytokines, deriving in tissue damage and a possible alveolar collapse.
2745 Toxicity Assessment of Aerosolized Engineered Nanoparticles following In Vivo Respiratory Exposure

B. R. Steines1, A. A. Adamcakova-Dodd1, Y. Wang2, B. E. Givens2, S. Areecheewakul1, R. Altmaier1, P. T. O’Shaughnessy1, A. K. Salem1, and P. S. Thorne1.

University of Iowa, Iowa City, IA.

With the ever increasing use of engineered nanomaterials (ENMs) in modern technology, there is a corresponding increase in risk of exposure (both occupational and consumer) and a need to evaluate the health effects these materials may have on the body. Here, gold nanoparticles (Au NPs; 18.4 nm diameter) in suspension (50 µg/mL) and silver supported on silica nanoparticles (15%Ag@SiO2; 17.2 nm diameter) were evaluated. Toxicokinetic assessment was performed in vivo on mice in a nose-only inhalation system (inExposure, Scireq, Emka Tech.). Generated Au NP aerosol concentrations were 764 µg/m³. Particle size distribution yielded a geometric mean diameter of 42 nm with a geometric standard deviation of 1.75. Controls were exposed to the Au NP suspension fluid where the particles were removed by multiple high-speed centrifugations. Aerosol concentration for 15%Ag@SiO2 exposure was 3.5 ± 1.1 mg/m³. Particle size distribution yielded a geometric mean mobility diameter of 91 nm. Shams were exposed to HEPA filtered laboratory air. For both materials, mice were necropsied immediately (0 wk) or 3 weeks (3 wk) after the last exposure. In Au NP exposed mice, bronchoalveolar lavage (BAL) analyses of total and differential cell counts, cytokines, total protein, and lactate dehydrogenase (LDH) did not show significant differences compared to sham-exposed mice. Additionally, pulmonary mechanics measurements and histopathology evaluations showed no significant differences. Whereas sub-acute exposure to 15%Ag@SiO2 caused a significant increase of total cell recruitment into the lungs (measured in BAL fluid) at 0 wk post exposure (1,760 ± 10³ cells/mouse) compared to shams (47 ± 10³ cells/mouse). At 3 wk post exposure, cell numbers returned to normal (40 ± 10³ cells/mouse). The percentage of neutrophils in BAL fluid was 51% at 0 wk and 7% at 3 wk post exposure compared to 1.6% in shams. Additionally, there was a significant difference in cytotoxicity between sham and 15%Ag@SiO2-exposed males. Histopathological analysis of lung tissues showed marked increases in lymphocyte and neutrophil presence in several exposed samples.

2746 Safety of Novel Antimicrobials Based on Silver Nanoparticles Assessed by Methods In Vivo

H. Bendova1, J. Sosnovcova1, K. Kjejlova1, J. Chrzl1, M. Dvorakova1, D. Krsek1, H. Kolarova1, D. Ocadlikova1, S. Janousek1, and D. Jirova1.

Due to antimicrobial properties, nano silver has been traditionally used in a variety of applications such as cosmetics (toothpaste), health care (treatment of burns, chronic wounds), textile coatings, and food packaging. Increased dermal application of silver nanoparticles is connected with another concern, namely potential adverse health effects. The high toxicity of single layer graphene and multi-layer graphene is usually attributed to its high surface to volume ratio providing more efficient contact of nanoparticles with microorganisms. The aim of the currently performed project research ALTERBIO is to identify and select innovative antimicrobial agents, based on silver nanoparticles (AgNPs) able of covalent bond within a polymeric system and without undesirable effects on human health and the environment. Within the project, promising agents with proved efficient and stable antimicrobial effects were subjected to a battery of toxicological tests to avoid local and systemic toxicity hazard. In compliance with the current European legislation restricting the use of experimental animals, the toxicological methods employed comprise exclusively in vitro procedures based on cellular and tissue models either of human origin or mimicking human tissues such as 3D models EpiDermTM (OECD TG 439), EpiOcularTM (OECD TG 492) and organotypic HET-CAM. The tests performed so far showed that AgNPs bound to montmorillonite are not irritant to skin or eye including mucosa. None of the tested samples showed endocanal disruption potential in the XenoScreen YES/YAS Assay (based on transfected Saccharomyces cerevisiae strains) and in the estrogen receptor transactivation assay (OECD TG 455). Although the results of chromosomal aberration test (OECD TG 471) showed a distinct degree of mutagenicity, the skin penetration/absorption test (OECD TG 428) did not prove permeation of silver nanoparticles through the skin barrier. Newly developed antimicrobial silver-based nanomaterials were proved as safe for dermal applications. The study was supported by TE02000006 Centre for alternative environment friendly high effective polymer antimicrobial agents for industrial applications (ALTERBIO).

2747 Platox In Vitro and In Vivo Investigations (28-Day Inhalation) to Generate Valid Toxicity Data for Risk Assessment of Carbon-Based Nanoplatelets

O. H. Creutzenberg1, C. Ziemann1, H. Oliveira2, L. Farca2, and S. Burla3.1Fraunhofer ITEM, Hannover, Germany; 2Cesam & Ciceco, Aveiro, Portugal; and 3Biotox Srl, Cluj-Napoca, Romania. Sponsor: G. Dassenbrock.

Carbon-based nanoplatelets (CNP) represent a new class of 2-D nanostructures in multiple variants and with interesting functional properties (e.g. material enforcement and electrical conductivity). A very high toxicity among members of the carbon family is not expected for CNP platelets, however, for other CNP architectures. Commercial CNP candidates (ACS Material, USA) were selected, covering single layer or multi layer graphene, carbonyl graphene, single layer graphene oxide, and graphite oxide. Technical soot (Printex 90) served as particulate, non-platelet reference. The CNP were analyzed on sterility and endotoxin content; morphology (SEM pictures) and the specific surface area (BET method) were evaluated. As in vitro screening models both, primary rat alveolar macrophages (AM) and MRC-5 human lung fibroblast cells were analyzed on membrane damage (LDH release) and metabolic activity (AlamarBlue test). Interestingly, the two single layer graphene samples induced marked concentration-dependent membrane damage in AM after 24 h of incubation, with a BMD30 of 3.2 and 2.5 µg/cm², whereas no such effect was observed for MRC-5 cells. Some LDH release was also observed for single layer graphite oxide (BMD30: 39.3 μg/cm²). The other materials were nearly inactive. Significant effects on metabolic activity were not observed. In AM, single layer graphene CNP additionally induced direct DNA damage and release of PGE2. In conclusion, single layer graphene showed a geno toxic potential in vitro in AM, but not in lung fibroblasts. Based on the in vitro screening data and for validation, a single layer (highest) and a multilayer (lowest toxic potential) were selected for in vivo investigations. The dose range finding (DRF) test, with oral gavage instillation (0.02 and 0.2 mg/rat, each) single layer graphene was confirmed as the most inflammogenic sample in bronchoalveolar lavage fluid (BALF) inducing the recruitment of neutrophils and eosinophils. In the subsequent 4-week nose-only inhalation study with the same total dose (predicted by MPPD model) the inflammatory response of single layer graphene was weaker and no eosinophils were detected in BALF. Histopathological examination is underway. PLATOX funding: FP7- ERA-NET SIINN.

2748 Naknowbase: A Nanomaterials Relational Database Populated with Extant Data from the US EPA Office of Research and Development (ORD)

1Oak Ridge Associated Universities, Research Triangle Park, NC; 2US EPA, Research Triangle Park, NC; and 3Duke University, Durham, NC.

The continued emergence and growth of nanotechnology, including nanomaterials (ENM) in industry and commerce, raises the possibility of environmental releases of ENM, and the need to predict potential environmental consequences. A substantial amount of research has been published on this topic, but the information is difficult to assimilate and synthesize for broader scientific inquiry. In 2016, a relational data base (“Naknowbase”) was developed featuring parameters relevant to the physical and chemical features of ENM and their potential actions in environmental and biological systems. This year, the database was populated with relevant data from peer-reviewed articles published by ORD authors. To do so, an initial search of internal EPA publication records yielded approximately 400 articles responsive to terms such as “nanoparticles”, “nanomaterials” and major ENM constituents (Ag, TiO2 etc). From those articles, literature reviews, articles concerning nanomaterial synthesis or green chemistry, and articles unrelated to nanomaterials and their environmental effects, were excluded. 68 manuscripts dealing with the release of nanomaterials into the environment, environmental fate transport or transformation, exposure or effects on ecological or biological systems were identified as high priority. Authors of the articles who were current EPA employees were contacted and requested to provide the original data in a formatted data entry template. Where data from original authors was unavailable, data were extracted from electronic versions of the papers by trained curators. To date, data have been collected from about 50 of the 68 high priority manuscripts. The database is currently available within the Agency as a downloadable SQL file with corresponding schema. Future efforts, as priorities allow, will include continued data curation, high priority manuscripts. The database is currently available within the Agency as a downloadable SQL file with corresponding schema. This abstract does not reflect US EPA Policy.
In this study, the in vitro dermal penetration method in OECD428 Skin Absorption: In Vitro Method using Franz (diffusion) cells was used to determine percutaneous absorption levels and distribution of zinc oxide in human skin from a formulated cosmetic product (sunscreen) containing nanoparticles of ZnO (14% in weight). The diffusion cell contained a donor compartment and a jacketed receptor compartment maintained at 37°C by a thermostatic jacket, separated by a membrane (human skin) that was in contact with the receptor fluid. Test item was spread on the skin membrane (exchange surface: 0.64cm²) and the skin disks were exposed to the test item for 24h. Receptor fluid samples were collected at 0 and 24h post application and then any remaining test item was collected. Two samples of stratum corneum (collected by tape stripping) were used to evaluate distribution between the upper and the lower stratum corneum layers. The stratum corneum, epidermis and dermis were analyzed by ICP-MS for quantification of total zinc. Absorption is considered to be the relative percentage of the dose recovered in the skin layers and receptor fluid after 24h skin contact versus the total amount applied on the skin surface (as recommended by OECD428). The average mass balance was 114±12% (EMA guideline acceptance criteria: ±15% for precision and accuracy). The concentration of zinc oxide in receptor fluid was lower than the limit of quantification (1.00 µg/mL; i.e. <0.5% of the applied dose). The absorbable amount in skin (following washing) was 1.1% for the last pool. This indicates that the compound reaches the inner level stratum corneum that is in contact with the epidermis. Zinc was also found in the exposed skin (epidermis and dermis) at 1.4% of the dose applied. The absorbable amount in skin (following washing) was 9.7% of the applied dose. Dermal absorption is primarily a diffusion-driven process, therefore test substance in the lower layers of the stratum corneum should be assumed to form a reservoir that may contribute to AD pathogenesis.

Alzheimer’s disease (AD) is a debilitating progressive neurodegenerative disease that usually starts slowly and worsens over time. Though AD etiology is believed to be multifactorial, there is considerable evidence showing the role of copper exposure in beta-amyloid (βA) aggregation and AD pathogenesis. Owing to the fact that βA aggregation takes place in the synaptic cleft where copper is found in high concentrations, copper exposure especially in the form of nano particles can be more detrimental. Though copper-induced oligomeric forms of βA accumulate and significantly damage the brain cells, inducing cognitive dysfunctions, the mechanism that initiates and promotes βA oligomerization remains unknown. We hypothesized protein radical formation as an initiating mechanism for βA oligomerization. Therefore, we used the highly sensitive immuno-spin trapping technique to investigate protein radical formation as a possible mechanism of βA oligomerization. Here, we have investigated copper ions and nano particles induced βA radical formation. The results clearly showed that both variants of copper nano particles (25 nm and 70 nm sizes) significantly produced βA radical in presence of hydrogen peroxide. To further validate copper nano particle-induced protein radical formation in biological context, we exposed IMR-32 hippocampal neuroblastoma cells expressing βA to both variants of copper nano particles and analyzed protein radical formation using confocal microscopy. Confocal microscopy results showed protein radical formation in IMR-32 cells exposed to either variant of copper nano-particles in presence of hydrogen peroxide. Taken together, these results suggest that both variants of copper nano particles induce βA radical formation which can lead to βA oligomerization, and therefore contributes to AD pathogenesis.
Nanoparticles (NPs) upon entry into a physiological environment, accumulate a coating of biomolecules or biocorona (BC) altering NP properties and cellular interactions. Association of the BC is governed by NP properties, time, and the physiological environment. Variability in the formation of the NP-BC between individuals and the effect of lifestyle changes remains unknown. We hypothesized that incubation of NPs in plasma from different human subjects would form distinct BCs that exercise would result in alterations in the NP-BC. Blood samples were collected from non-exercising individuals prior to and following a 7-day exercise routine. Fe3O4 NPs (20 nm and PVP coated) were incubated in plasma for 8 h and a proteomics approach was utilized to evaluate NP-BCs. Fe3O4 NPs were evaluated due to their use in biomedical applications. The analysis of all pre-exercise NP-BCs revealed the association of distinct proteins. The NP-BCs that formed from the 10 pre-exercise samples had 99 proteins in common. Quantitative analysis demonstrated that these 99 proteins absorbed on the NP in differing amounts. Association of apolipoprotein-C1, complement C4B, and transthyretin with NPs trended with cholesterol levels. No unique proteins were found to associate with NPs based on sex. Comparisons of the NP-BC that formed prior to and following the exercise regiment demonstrated alterations. In general, the BC formed following exercise was more complex or unique as determined by increased numbers of distinct proteins that bound. Although many proteins were shared between these samples, differences in abundance were found. Specifically, NP association with apolipoproteins, complement proteins, coagulation factors, and others were reduced, whereas association of immunoglobulins, fibrinogen, insulin growth factor-2 and others were increased following exercise. To determine the biological impact of these BCs, human macrophages were exposed to Fe3O4 NPs with BCs at 25 µg/ml for 24 h and variations in cytotoxicity, internalization, and inflammatory response (gene expression of TNF-α, IL-6, and IL-8) were examined. BCs that bound to inflammatory cells influenced and modulated the inflammatory response by cells. These findings demonstrate that humans will likely form unique BCs on NPs and that lifestyle changes such as exercise can influence NP-biomolecule interactions. NIEHS ES024392.
of erenumab to birth mothers during gestation. Postnatal evaluation included: external, visceral and skeletal evaluations and behavioral assessments. Pregnant monkeys were assigned to receive vehicle (n=20) or erenumab (n=30) at 50 mg/kg. Subcutaneous administration of erenumab to pregnant cynomolgus monkeys at 50 mg/kg Q2W was well tolerated. The mean maternal/infant serum erenumab concentrations on postpartum days (PPD) or birth days (BD) 14, 28, and 91 were 66/117 µg/mL, 23/46 µg/mL, and 0.009/0.188 µg/mL, respectively. Erenumab concentrations were generally below the LLOQ after PPD91 in adult females and after BD91 in all of the infants. There were no erenumab-related changes in clinical signs, food consumption, body weights, gestation length, or pregnancy/postpartum outcomes (i.e., fetal or infant losses). Overall fetal loss was 3 of 20 (15.0%) in the control group and 4 of 23 (17.4%) in the erenumab group. Fetal losses in the erenumab group (both total and per trimester) were comparable to the control group and less than historical control values at the Testing Facility (average fetal loss of 22.5% and range of 38.9%). There were no erenumab-related effects on gestation length or on infant sex ratio. The overall incidence of infant loss (2 of 17 or 11.8% for controls, 3 of 19 or 15.8% for erenumab) was comparable between the 2 groups and within the historical control range of the Testing Facility for 18 previous ePPND studies (range of 0% to 20% infant loss; average of 10.1%). There was no difference, subcutaneous administration of erenumab to pregnant cynomolgus monkeys at 50 mg/kg Q2W from GD20-22 until parturition was well tolerated. No maternal toxicity was observed, and there were no effects on fetal/infant losses or growth and development through 6 months postpartum. This study supports the safe use of erenumab in women of child-bearing potential who experience migraines.

2758 Perinatal Prozac Exposure and Tryptophan Manipulation Reduces Pup Survival and Sex-Dependently Increases Autism Related Behaviors in Mice

V. R. Garbarino, T. Santos, M. A. Javors, L. C. Daws, and G. G. Gould, University of Texas Health Science Center at San Antonio, San Antonio, TX.

Autism is a developmental disorder with increasing incidence that now affects 1 in 68 US children, primarily males. Genetic and environmental studies show that positive or negative aberrations in serotonergic signaling during development can contribute to autism etiology. Controversial literature also suggests maternal use of selective serotonergic signaling during development can contribute to autism etiology. The vertebrate zebrafish (Danio rerio) embryo is an emerging model for screening teratogenic compounds. We aim to understand the developmental toxicity effects of environmental pollutants by using zebrafish embryos to identify compounds that negatively affect neumast of the lateral line, a system of tactile sense organs in fishes. The zebrafish neuromasts are mechanoreceptors that respond to the flows of water, and are structurally and functionally similar to human inner ear hair cells. Neuromasts are positioned along the zebrafish body through migration of the neuromast primordium formed near the otic vesicle. Transgenic zebrafish (TgTg expressing fluorescence in neuromasts) were used in a primary high throughput screen (HTS) of 294 compounds from EPA’s ToxCast phase I chemical inventory, primarily consisting of pesticides and antimicrobials. This generated a list of 48 potential hits that altered neuromast development and/or migration. These hits were re-screened with a higher number of replicates to confirm and characterize effects, and to determine the lowest effect levels (LELs). This resulted in 22 confirmed neuromast disruptors. A univariate analysis was performed on the confirmed hits to identify ToxCast in vitro assays that significantly correlated with the identified in vivo neuromast disruptors. Several assays for serotonin signaling were retained. In conclusion, our results identified several environmental pollutants with neuromast disrupting capacity. This suggests that the developing zebrafish embryo is an efficient in vivo model that can be used for rapid identification of compounds interfering with neuromast development and has the potential to be developed into a predictive toxicity model. This abstract does not necessarily reflect US EPA policy.

2759 Embryonic-Only Arsenic Exposure Alters Skeletal Muscle Satellite Cell Function in Killifish (Fundulus heteroclitus)

D. B. Szymkowicz, K. L. Schwindinger, and L. L. Bain, Clemson University, Clemson, SC.

Arsenic is a contaminant found worldwide in drinking water and crops. Epidemiological studies have correlated arsenic exposure with reduced weight gain and improper muscular and neuronal development. In vitro studies have also shown that arsenic impacts myogenic and neurogenic differentiation. The purpose of this study was to determine if embryonic-only arsenic exposure permanently reduces the population or function of muscle satellite cells, using killifish as our model organism. Killifish embryos were exposed to 0, 50, 200, or 800ppb AsIII until hatching, and fish were raised in clean water for 28, 40, or 52 weeks. To assess baseline cell populations, trunk skeletal muscle sections were collected at each time point. To assess cellular function, skeletal muscle injuries were induced at each time point by injection of cardiotoxin into the trunk of the fish. Muscle sections were collected at 3, 7, and 10 days post-injury. Collagen expression was examined to assess the level of fibrosis. PCNA and myogenin expression were quantified to compare proliferating cells and newly formed myoblasts. At 28 weeks, baseline collagen levels were 2.0- to 2.2-fold greater in the fish embryonically exposed to 200 or 800ppb arsenic. Although no significant differences were seen at 40 weeks, fish were increased by 2.1- to 2.2-fold at 52 weeks. After cardiotoxin injury, collagen levels remained higher in 28 week old arsenic exposed fish even after 10 days of recovery. At 40 and 52 weeks, there were still slight increases in collagen levels during the recovery period, but this was not significant. Baseline PCNA levels were higher in exposed fish at 40 and 52 weeks following cardiotoxin injury, PCNA is statistically reduced in exposed groups at day 3 of the recovery period. By day 10, a slight reduction in PCNA expression remains, but this is not significant. Based on these results, arsenic exposure during early life stages may be impairing muscle satellite cells, leading to reduced skeletal muscle regeneration after tissue injury.

2760 Developing the Zebrafish Neuroumat as a Predictive Toxicity Model

R. Sachanandani1, S. Thrikawala1, C. Stephani2, N. Nguyen3, M. Sobieski2, R. S. Judson4, D. Chilukuri1, J. Gustafsson3, and M. Bondesson4, 1University of Houston, Houston, TX; 2Institute of Biosciences and Technology, Houston, TX; 3US EPA, Research Triangle Park, NC; and 4Indiana University, Bloomington, IN.

Pyriproxyfen is a pyridine based larvicide categorized as a juvenile hormone analog and is widely used to control agricultural, veterinary and human health pests. It is also used in drinking water sources for mosquito control in Brazil, which lead to the debate that exposure to pyriproxyfen may cause microcephaly. We used the vertebrate zebrafish model to evaluate the effects of pyriproxyfen on the neuronal development. Zebrafish embryos were treated with increasing concentrations of pyriproxyfen and were imaged and assessed for morphological malformations. We identified three different malformations in the head region: narrow head, short head and small eyes. Quantification of the effects showed that both the length and width of the head were significantly shorter in pyriproxyfen treated embryos at 10 µM and higher concentrations. Next, we used the transgenic zebrafish line Ngn1:GFP to visualize the neuronal system. Two malformations were observed in the brain region after pyriproxyfen exposure: a small midbrain and a neural tube closure defect in the hindbrain region. Pyriproxyfen altered the expression of the neuronal marker syn2a and glial cell markers gfab and mbp, as determined by qPCR. However, the expression of the neuronal marker genes ngn1 and elavl3 was not changed. Furthermore, transcrip-
tomic analysis was performed to identify the molecular mechanisms altered by pyriproxyfen exposure, which potentially could lead to the observed phenotype. In conclusion, our results show that pyriproxyfen exposure affects the morphology of the brain and alters the expression of glia-specific genes during early embryonic development in zebrafish.

**2762 Developmental Regulation of Nuclear Factor Erthroid-2 Related Factors (nrf/s) by AHR1b**

A. Ulinn1, J. Henderson1, M. Pham1, J. Meyo1, Y. Chen1, S. J. Karchner1, J. V. Goldstone2, M. E. Hahn2, and L. M. Williams1. 1Bates College, Lewiston, ME; and 2Woods Hole Oceanographic Institution, Woods Hole, MA.

Interactions between regulatory pathways provide additional mechanisms for organisms to both adapt to their environment and respond to endogenous stress. One interaction recently identified in adult mammals, cell cultures, and fish embryos occurs between the aryl hydrocarbon receptor (AHR) and members of the nuclear factor erthroid-2 related factor (nrf) family. Each transcription factor regulates numerous downstream genes involved in the cellular response to toxicants and oxidative stress; they each also play a role in normal development. The zebrafish model was chosen to explore the role of AHR regulation of nrf genes during development and in response to toxicant exposure, as there are three ahr and six nrf genes in the zebrafish genome. We have previously shown that each nrf gene in zebrafish has several anabolic response elements (XRE): cis-promoter elements that are theoretically AHR binding sites. To determine whether an AHR protein, AHR1b, is responsible for transcriptional regulation of nrf genes during development, a loss-of-function assay using a morpholino knockdown approach was conducted followed by a Choromatin Immunoprecipitation (ChIP) direct binding study. The expression of nrf1a was dependent on AHR1b and its expression was directly regulated through site-specific XREs in its cis-promoter at 24 hours post fertilization. However, nrf1a expression was not altered by exposure to TCDD (2,3,7,8-tetrachlorodibenzo-p-dioxin), a toxic ARH receptor agonist. The expression of nrf2a and nfe2 were induced by TCDD, and AHR1b directly regulated their expression by binding to specific cis-XRE promoter elements. Lastly, nrf2b and nrf3 were neither induced by TCDD nor regulated by AHR1b. Taken together, these results show that AHR1b transcriptionally regulates nrf genes in a site-specific manner via binding to cis-promoter XREs during development. These data provide a clearer picture of the importance of this interaction during the sensitive embryo life stage, and provide a better understanding of how combinatorial molecular signaling protects embryos from potentially embryotoxic events following toxicant exposure. **2763 Developmental and Reproductive Toxicity Studies in Sprague Dawley Rats and New Zealand White Rabbits with Palbociclib**

N. Catlin1, C. J. Bowman1, S. M. Engel1, A. Sacaan1, E. M. Lewis2, and G. D. Cappon. 1Pfizer Inc., Groton, CT; and 2Charles River Laboratories, Horsham, PA.

Palbociclib (IBRANCE®) is a selective inhibitor of the cyclin-dependent kinase (CDK) 4 and 6, approved for the treatment of breast cancer. Fertility and early embryonic development toxicity studies were conducted in male and female rats via oral gavage at doses up to 100 and 300 mg/kg/day, respectively. Males were dosed for 4 cycles (each cycle comprises 3 weeks consecutive daily dosing followed by a 1 week non-dosing period), and paired with untreated females during the last two weeks of the 15 week dosing period. Females in a separate study were dosed once daily beginning 15 days before cohabitation, during cohabitation and continuing until gestation day (GD) 7. In the males, there were no effects on functional fertility at any dose, but there were microscopic changes in the testes with secondary findings in the epididymides at ≥30 mg/kg; 100 mg/kg also resulted in lower epididymal and testicular weights, sperm density, and sperm motility. There were no effects in females following doses up to 300 mg/kg. Developmental toxicity studies were conducted in rats and rabbits with daily doses up to 300 and 20 mg/kg, administered from GD6-17 and GD7-19, respectively. In the presence of maternal toxicity (lower body weight gain and food consumption compared with control), low fetal body weights and relative organ weights were observed at 100 mg/kg in rats and small forepaw phalanges were noted in a few fetuses at 20 mg/kg in rabbits. Palbociclib was not teratogenic in rats or rabbits. Fetal skeletal variations in rats (increased incidence of cervical ribs at ≥100 mg/kg) and rabbits (increased incidences of 13 ribs at ≥10 mg/kg) were considered palbociclib-related but non-adverse since both are considered.

**2764 Endodermal Ossification in Developing Long Bones of F1 Offspring following Administration of Andecaliximab to F0 Dams during Gestation and Lactation**

A. Tomkinson1, S. Moore2, M. Adamo2, M. Guillot2, J. Bienvenue2, K. Robinson2, and L. Burns-Naas1. 1Gilead Sciences, Inc., Foster City, CA; and 2Charles River Laboratories Montreal ULC, Senneville, QC, Canada.

Matrix metalloproteinase 9 (MMP9) has been shown to be related to trabecular bone architecture. In a pre/postnatal development study, F0 dams were administered an anti-MMP9 antibody andecaliximab (andeca) every 3 days IV at 10, 30 or 100 mg/kg/dose or vehicle GD 6 through LD 21. Skeletal bone radiographs, bone length, bone densitometry (pQCT), and histopathology of selected bones were assessed in F1 offspring on Days 21, 49, and 105 pp. Andeca was associated with increased with increasing dose (milk 10-20% of serum conc.). F1 serum exposure increased with dose, and F1: F0 serum ratios ranged from 2% at 10 mg/kg/dose to 60% at 100 mg/kg/dose on LD 11, and were < 1% by LD 21. F1 survival, clinical condition, body weight and behavioral and reproductive function were unaffected. At 100 mg/kg/dose, animals presented persistent slight (< 9%) decreases in femur length. At Day 21 pp, these findings were associated with widespread changes in long bone physis, including increased thickness, metaphysis enlargement and/or increased radiographic bone correlating microscopically with physeal hypertrophy and increased trabecular metaphyseal bone, which were consistent with mild increases in metaphysis bone mineral content and density. Radiographic and microscopic changes observed at Day 21 pp in long bone epiphysis and metaphysis were fully resolved by Day 49 pp. Bone densitometry changes at Day 49 pp consisted of increased total area at the femur distal metaphysis, associated with increased bone mass persisting to Day 105 pp and radiographic enlargement of the femur distal metaphysis. Additional findings at Day 105 pp included a few bent radii (varus), and radiographic bone loss in the proximal humerus occasionally associated with a luxation and/or osteophytes and/or enlargement of the proximal epiphysis. These results indicate that andeca exposure when administered to F0 dams during gestation and lactation, and support the pharmacologic role of MMP9 in endochondral ossification of developing long bones. Additional studies may be required for further validation.

**2765 Sensitivity to Monoamine Uptake Inhibitors is Modified by Methylmercury and d-Amphetamine Exposure in Adolescence**

S. B. Simpson, S. R. Boomhower, K. R. Johnson, and M. C. Newland. Auburn University, Auburn, AL.

During adolescence, monoamine neurotransmission is continuously developing and may be more vulnerable to early exposure to the environmental neurotoxicant, methylmercury (MeHg). To test this hypothesis, we examined sensitivity to the dopamine, norepinephrine, and serotonin reuptake inhibitors d-amphetamine (d-AMP), desipramine, and clomipramine (respectively) following exposure to MeHg during adolescence. Water containing 0 ppm and 3 ppm MeHg was given to two groups of twenty-four male C57BL/6 mice during adolescence (postnatal days 21-60). Within each group, mice were also given i.p. injections of saline or d-AMP (1 mg/kg/day) from postnatal days 28 to 42. This produced four treatment groups (n = 10-12/group): Control, d-AMP, MeHg, and d-AMP + MeHg. As adolescent mice lever pressed under fixed-ratio schedules of reinforcement (FR 1, 15, 30, 60, and 120). Following baseline, acute intraperitoneal injections of d-AMP (0.3 - 1.7 mg/kg) desipramine (5.6 - 30 mg/kg), and clomipramine (5.6 - 30 mg/kg) were administered, with each dose-response determination separated by a week. Rates of lever pressing were analyzed using Mathematical Principles of Reinforcement, a model that describes operant (voluntary) behavior in terms of motivational, motoric, and memorial factors. Adolescent d-AMP and d-AMP + MeHg exposure enhanced sensitivity to acute d-AMP and desipramine. Adolescent d-AMP and MeHg exposure also enhanced...
sensitivity to acute clomipramine; though, this enhanced sensitivity was blocked by combined exposure to d-AMP + MeHg in adolescence. These data demonstrate that there are long-term alterations in monoamine sensitivity following adolescent exposure to methylmercury and d-amphetamine.

Using novel in situ placental perfusion methodology we were able to conclusively identify and quantify ENM translocation from the maternal to fetal compartment. Collectively, our results reported using this model may allow for its future use in ENM screening prior to therapeutic application during pregnancy.

Obesity rates have increased significantly over the past 150 years. Mounting evidence suggests that exposure to certain environmental chemicals may alter lipid metabolism, accumulation and promotion of adipogenesis leading to weight gain. Tetrabromobisphenol A is a brominated flame retardant commonly used throughout the world. TBBPA has been shown to promoting lipid accumulation and weight gain, in zebrafish, following exposure (10 mM-1 μM) during several stages of development and to induce lipid accumulation in murine 3T3-L1 cells through activation of PPARy. This study was conducted to determine the effects of early life exposure to TBBPA on metabolic endpoints. Wistar rats (n=15 litters per dose) were exposed by oral gavage to 0, 0.1, 0.25, 250 mg TBBPA/kg BW from gestation day 6 to postnatal day 90. Daily body weights, monthly body mass composition, and glucose, insulin, leptin, and adiponectin serum levels data (weaning, peripubertal, postpubertal and 1 year timepoints) were determined in male and female pups. A subset of animals was aged out to 1 year to investigate any persisting effects due to developmental exposure. Glucose tolerance challenge and an insulin sensitivity test were performed on male and female pups at 9 months and 1 yr of age (5-6 per dose). Multivariate analysis of variance (MANOVA) analysis showed that females in the high dose group were leaner later in life compared with controls (68.45±1.30 % lean, 62.41±2.26 % lean, respectively) at beginning at PND 242. There were not any significant body weight differences, but fat mass gain of treated females plateaued whereas control females continued to gain fat throughout life. These effects were absent in males. Microarray analysis of 1 yr old female livers showed gene expression changes in the high dose group related to adipogenesis pathway and metabolic disease. Further investigation is being conducted but some genes of interest are FABP7, CSRP2, and HSPP1. Overall, findings from this study shows that TBBPA has persistent effects on numerous metabolic endpoints.
consumption values compared to non-dosed rabbits. Mean total body weight gains of animals administered CO or DI were 20 and 11% lower, respectively, than rabbits that were not gavaged. These results clearly demonstrate that feed fiber content and vehicle selection can affect maternal health parameters typically used in identifying a MTD.

2770 Harm-Reduction Tobacco Inhibits Osteogenesis Via Misregulation of Survival Signaling Networks

While conventional smoking habits are on the decline in the United States, other forms of tobacco usage have risen to the forefront of public health concern. Of particular interest is the trend of pregnant women turning to purported harm-reduction tobacco products (HRTPs). Women who struggle with nicotine addiction may turn to these products as they are advertised to pose less harm to users than conventional cigarette smoking. However, initial studies suggest that use of HRTPs during pregnancy does not reduce adverse pregnancy outcomes and may have adverse effects on the fetal skeleton. Though reproductive and developmental toxicity has been well established for conventional tobacco use during pregnancy, the biological processes responsible for how HRTPs impact early bone development remains unclear. Here we provide evidence that HRTPs, snus, smokeless tobaccos, and reduced tar/nicotine cigarettes are teratogenic to the developing skeleton using embryonic stem cell (ESC) and mouse models. To assess in vitro embryotoxicity, ESCs were differentiated into osteoblasts during concurrent exposure to snus or reduced tar/nicotine cigarettes. HRTP exposure was found to have a teratogenic effect that decreased osteoblast differentiation at subtoxic levels in vitro. Mouse embryos exposed in utero to HRTPs demonstrated abnormal craniofacial and long bone development. Teratogenic doses were also found in vitro to possess increased cellular reactive oxygen species levels and reduced nuclear FOXO1 and FOXO3, two transcription factors that drive free radical scavenging enzymes response. Investigation of upstream signaling kinases identified elevated AKT activation following HRTP exposure while co-administration of AKT inhibitor was found to rescue osteogenesis. Overall, our results suggest that HRTP exposure during development misregulates survival kinase signaling and creates a state of oxidative stress. Together, these events may drive the ultimate disruption of normal skeletal development.

2771 Evaluation of DART Data Pertaining to Reclassification of Chloroform as a Proposition 65 Reproductive Toxicant

California’s Office of Environmental Health Hazard Assessment (OEHHHA) recently reconsidered chloroform for listing as a reproductive toxicant under Proposition 65. This analysis evaluated the animal developmental and reproductive toxicity (DART) data for chloroform to determine if the weight of evidence supported its continued classification as a reproductive toxicant. A total of 14 animal studies that addressed developmental endpoints were considered in the evaluation. Data were tabulated and no observed adverse effect levels (NOAELs) identified. NOAELs tended to be substantially higher in the gavage oral dosing studies compared to the inhalation studies. Among the 8 in utero developmental toxicity studies, consistent findings of maternal toxicity (including statistically significant decreased maternal body weight gains and/or body weight gains and decreased food consumption) were associated with both gavage oral and inhalation exposures. High dose exposures (≥200 mg/kg/day) were also associated with very early (peri-implantation) losses. Based on the body weight data, the NOAEL for maternal toxicity was established in inhalation studies at 3 ppm (4 mg/kg/day). Statistically reduced fetal weights as well as alterations/delays in ossification were also consistently observed in the in utero developmental toxicity studies and occurred at doses equal to or above those at which maternal toxicity was seen. Examination of these data indicated that the offspring effects of chloroform were likely secondary to maternal toxicity and not a direct effect of exposure. The NOAEL for offspring effects was established in inhalation studies as 10 ppm (12 mg/kg/day). Findings among the 4 reproductive studies were consistent with those from the in utero developmental toxicity studies, and NOAELs from these studies (which did not involve inhalation exposure) were generally higher than those from the in utero developmental toxicity studies. Findings from 2 in vitro developmental toxicity assays provided limited useful information in the overall evaluation. For the purposes of human health risk assessment, we conclude that chloroform is not a direct developmental toxicant and that doses that are protective of the maternal animal should also be protective of developing offspring. Given this information, chloroform does not warrant listing as a reproductive toxicant under Proposition 65.

2772 Transcriptomic Analysis of Vascular Disruptor Effects in Embryonic Zebrafish

B. Bhattacharya1, S. Thirikawala2, P. Sachanandani3, F. Mesmar4, C. Williams5, and M. Bondesson Bolin4. 1Indiana University Bloomington, Bloomington, IN; 2University of Houston, Houston, TX; and 3Royal Institute of Technology, Stockholm, Sweden.

Zebrafish is an effective model for studying vascular perturbation during embryonic development because of its small size and rapid vascular development, which can be followed using transgenic fish expressing GFP in vascular endothelial cells. Using this model, we previously identified 22 new vascular disruptors. Here, we present a transcriptomic analysis of gene expression changes after exposure to four of the zebrafish vascular disruptors: trifluorotributin, rotenone, pyrroclastin, and pyridaben. At two days post exposure, RNA sequencing of the whole transcriptome was performed, following pathway analysis using Ingenuity Pathway Analysis (IPA). We specifically focused on expression changes that were common between the four vascular disruptors. All vascular disruptors altered expression of genes involved in the canonical pathways relating to vascular development, like vasculogenesis, angiogenesis, endothelial cell development, cardiovascular development and other related functions. We found that expression of HIF1AN, EGR1, CTGF, CYR61, TCAP were downregulated by exposure to vascular disruptors, indicating that angiogenesis, vasculogenesis, and endothelial cell development were affected. The results also showed that apoptosis was downregulated by exposure to these four compounds, while genes involved in proliferation had an increased expression. We also looked into factors that affect mitochondrial pathways and found that the expression of several genes in the cytochrome C oxidase pathway were altered by vascular disruptor exposures. Expression of ATPF1 and HSPD1, known to be involved in mitochondrial membrane potential and mitochondrial protein functions, were induced by all exposures. We are now performing experiments to further investigate the findings from the IPA analysis.

2773 Potentiation of Dioxin-Induced Edema by Oxidative Stress in Developing Zebrafish

Previously, we reported the involvement of cyclooxygenase type 2b - thromboxane pathway and oxidative stress in causing edema response by 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) in early larval zebrafish. We recognized that edema by lower concentration of TCDD was abolished by either thromboxane receptor (TP) antagonist or antioxidants. In the present study, we studied the possible interaction of aryl hydrocarbon receptor (AhR) pathway and oxidative stress. Paraoxon, an oxidative stress inducer itself did not affect edema formation, but it augmented edema by lower concentration of TCDD at 55 hpf (pre-cardiac edema). TCDD-induced edema was abolished by antioxidants in the presence or absence of paraoxon. Paraoxon also potentiated edema caused by U46619, a TP agonist. Different to TCDD, antioxidants only inhibited the potentiation effect of paraoxon. TCDD-induced edema and potentiation of paraoxon to U46619 or TCDD were augmented in Nr2a2a morphants. Sulforaphane, an activator of Nr2f, suppressed TCDD-evoked edema regardless of the presence of paraoxon in both 55 and 72 hpf larvae. Sulforaphane also abolished potentiation effect of paraoxon to U46619 without affecting U46619-evoked edema. Taken together, these results suggest the enhancing role of oxidative stress in edema by TCDD and TP activation in developing zebrafish. 1) Teraoka et al., 2014. Aquatic Toxicol.
Influence of Pregnancy and Fasting on Metabolome Plasma Analysis in a Rat Prenatal Toxicity Control Study

J. Keller¹, W. Mellert¹, S. Sperber¹, X. Jiang¹, V. Strauss¹, H. G. Kamp¹, E. Fabian¹, T. Walk⁷, M. Herold², and B. van Ravenzaay¹. ¹ BASF SE, Ludwigshafen am Rhein, Germany; and ² Metanomics GmbH, Berlin, Germany.

BASF and metabolomics established a database (MetaMapTox) for the detection of toxicological modes of action (MOA) based on metabolic profiles in rat plasma of > 750 compounds. Approximately 250 different endogenous metabolites are measured and more than 100 toxicological MOAs can be differentiated. The database was built with plasma from non-pregnant, fasted rats and lacks information on the metabolite profile of non-fasted, pregnant rats. In the present prenatal toxicity control study (OECD 414), Wistar rats received no more than drinking water by gavage, non-pregnant rats were treated equally. Plasma metabolic profiles of pregnant and non-pregnant Wistar rats under fasting and non-fasting conditions were compared. The influence of fasting conditions on the embryonic and fetal development was examined. Fasting resulted in a moderate body weight reduction compared to controls (90% in pregnant, 94% in non-pregnant rats). All reproductive and embryo-fetal parameters were not altered. A principal component (PC) analysis was applied to a separate if FLX affects groups. The first principal component (PC1, largest possible variance) was pregnancy, the second largest possible variance (PC2) was fasting. We noted an interaction component between fasting and pregnancy which was not observed in fasted, non-pregnant rats. Metabolites typically altered in Progesterone, 17α-Estradiol and Androstenedione in pregnant rats and Hydroxybutyrate and Adrenaline in fasted rats. The gained knowledge will improve characterization of maternal toxicity by metabolomics.

Fluoxetine Affects the Differentiation of Dopaminergic Neurons In Vitro

D. Lupu¹, M. Varshney², I. Navalte², I. Inzunza², J. Lipinski¹, and B. van Ravenzaay¹. ¹ Budafok University of Health Sciences, Budapest, Hungary; ² University of Washington, Seattle, WA; and ³ Swedish Toxicology Sciences Research Center, Södertälje, Sweden. Sponsor: M. Öberg.

Three recent meta-analyses suggest an association between prenatal exposure to the antidepressant drug fluoxetine (FLX) and an increased risk of autism in children. This study aimed to investigate if FLX affects processes involved in dopaminergic neuronal differentiation as a possible mechanism underlying this link, possibly via interference with the estrogen system. Mouse neuronal precursors (wild-type (WT) and estrogen receptor β knock-out (ERβKO)) were differentiated to midbrain dopaminergic progenitor cells (mDPCs) and concomitantly exposed to therapeutically relevant FLX concentrations. Dopaminergic progenitors were then evaluated for expression of differentiation and stemness markers, as well as of nuclear estrogen receptors (ERs), using qPCR. In WT cells, FLX treatment led to a significant increase in early regional specification markers Orthodenticle homeobox 2 (Otx2) and Homeobox engrailed-1 and 2 (En1 and En2). On the other hand, two transcription factors essential for mDA neurogenesis, LIM Homebox transcription factor 1 alpha (Lmx1a) and Paired-like homeodomain transcription factor 3 (Ptx3) were significantly down-regulated by FLX treatment. Finally, the stemness marker Nestin (Nes) was significantly increased and the neuronal differentiation marker β3-tubulin (Tubb3) significantly decreased in WT mDPCs. Additionally, the expression of both ERα and ERβ was significantly down-regulated in WT cells after FLX treatment, suggesting an involvement of these receptors in the observed effects. Indeed, in ERβKO cells, FLX had no or even opposite effects on the genes involved in mDPCs specification, on Nes and on Tubb3. These findings suggest that FLX increases induction of dopaminergic precursors at the expense of differentiation to serotonergic neurons, yet decreases the maturation of dopaminergic neurons. These effects seem to be partly ER-dependent as no or even opposite effects were observed in ERβ-deficient cells. Further studies are needed to link these molecular events to development of the dopaminergic system and address if these findings could partly underlie the association between prenatal FLX exposure and increased autism risk in children.

Embryonic Exposures to Perfluorobutanesulfonic Acid (PFBS) Impair Growth and Pancreatic Organogenesis in the Zebrafish, Danio rerio

K. E. Sant, O. L. Venezia, P. P. Sinno, and A. R. Timme-Laragy. University of Massachusetts, Amherst, MA.

Since phase-out of more persistent perfluorosulfonates from American non-stick and stain-resistant products in the early 2000s, perfluorobutanesulfonic acid (PFBS) has replaced these compounds as a primary surfactant. Compared to other longer chain perfluorosulfonates which have human half-lives of 5-10 years, PFBS has a half-life in the human body of just over 1 month. Environmental, ecological, and human concentrations of PFBS have been steadily rising in recent years, raising concerns about potential negative health effects. We have previously found that embryonic exposures to a related and more persistent compound, perfluorooctanesulfonic acid (PFOS), decreased pancreas length and insulin-producing islet area in zebrafish embryos (Danio rerio). The objective of this study was to identify the extent to which embryonic PFBS exposures disrupt pancreatic organogenesis and to compare these findings with historical PFOS toxicity data. Zebrafish embryos were exposed to 0 (0.01% DMSO), 16, or 32 µM PFBS daily beginning at 1 day post fertilization (dpf) until microscopic examination at 4 and 7 dpf. Embryos from two different transgenic fish lines (Tg(lnsulin:GFP) and Tg(ptf1a:GFP)) were examined using fluorescent microscopy for islet area and total exocrine pancreas length, respectively. Embryos exposed to PFBS had increased incidence of tail and spinal deformities, delayed inflation of the swim bladder. PFBS embryos were shorter than control embryos, and had 5-13% shorter pancreata. Islet area decreased by 12-13% due to PFBS treatment, but to a lesser degree than historical PFOS data. Overall, this work suggests that developmental exposures to PFBS can perturb embryonic development and pancreatic organogenesis, and that further risk assessment is warranted. Funding for this work was provided by the National Institutes of Health R01ES025748 and R01ES0282801 to AT-L, and F32ES028085 to KES.

A 3D Microphysiological Model of Sonic Hedgehog Signaling for Toxicity Testing

B. P. Johnson, D. Beebe, and R. Lipinski. University of Wisconsin - Madison, Madison, WI.

Human development is orchestrated via secretion and sensing of small molecules through the tissue microenvironment. Sonic Hedgehog (SHH) signaling in the developing facial processes are a prototypic example, whereby SHH ligand is produced, processed, and secreted from the ectoderm. In turn, the ligand is shuttled through the extracellular matrix where it binds mesenchymal receptors, initiating a gradient of transcriptional response with high proximal to low distal activity. Genetic or chemical disruption in any part of the pathway can lead to orofacial clefting (cleft lip, cleft palate), serious birth defects. Modeling this complex cellular interplay in vitro has many applications for toxicity testing and beyond. Using the adverse outcome pathway framework as a guide, we constructed a 3D microphysiological model of epithelial-mesenchymal SHH signaling. Using microscale physical phenomenon, we created and epithelial monolayer which covers a 3D extracellular matrix where it binds mesenchymal receptors, initiating a gradient of transcriptional response with high proximal to low distal activity. Recapitulating a hallmark pathway response, a live cell dual luciferase reporter assay shows SHH ligand produced from the epithelium generates a reproducible gradient of pathway activity in the adjacent mesenchyme, with high proximal activity decreasing to no activity 500 microns into the gel. Endogenous SHH pathway activation was efficiently inhibited in dose-response by small molecule inhibitors of epithelial secretory (SHH production/cholesterol modification/palmitoylation), ECM transport (SHH ligand) and mesenchymal sensing targets (Smoothened, Gli1) at IC50s comparable to in vivo. Supporting the utility of this approach for high-content chemical screening, microscale devices are molded into commercial microtiter plates (40 devices/plate), are viable for at least 30 days, recover after wash-out and can be re-dosed, and are well suited for luminescent, fluorescent and high-content imaging readouts. Together, these findings demonstrate a novel and practical microphysiological model with broad utility for investigating epithelial mesenchymal interactions and disruptions in development.
Human obesity is a complex metabolic disorder disproportionately affecting people of lower socioeconomic strata, and ethnic minorities, especially African Americans and Hispanics. Although genetic predisposition and a positive energy balance are implicated in obesity, these factors alone do not account for the excess prevalence of obesity in lower socioeconomic populations. Therefore, environmental factors, including exposure to pesticides, heavy metals, and other contaminants, are agents widely suspected to have obesogenic activity, and they are also spatially correlated with lower socioeconomic status. To investigate whether a causal relationship between exposure to the heavy metal, cadmium (Cd), and obesity in a cohort of children exists, we analyzed an extensive collection of first trimester maternal blood samples obtained as part of the Newborn Epigenetics Study (NEST) for the presence of Cd, and these results were cross analyzed with the weight-gain trajectory of the children through five years of age. Next, the role of Cd as a potential obesogen was analyzed in an in vivo zebrafish model. Our results indicate that the presence of Cd in maternal blood during pregnancy is associated with increased risk of juvenile obesity in the offspring, independent of other variables, including lead (Pb) and smoking status. This effect was recapitulated in a zebrafish model, in which exposure to Cd at a level approximating those observed in the NEST study was associated with increased juvenile abdominal adiposity. In conclusion, our findings identify Cd as a potential human obesogen. Moreover, these observations are recapitulated in a zebrafish model, suggesting that the underlying mechanisms may be evolutionarily conserved, and that zebrafish may be a valuable model for uncovering pathways leading to Cd-mediated obesity in human populations.

The development of new pharmaceuticals benefits from continuous advances in biomedical research for both adults and children. Safety evaluation of new pediatric medicines is performed by the conduct of toxicology studies using juvenile animals. The minipig is now considered as a useful alternative non-rodent species for safety testing of pharmaceuticals. Human parallels in many features of its anatomy, physiology and biochemistry make the minipig a good model for man. For use in juvenile toxicology studies, the development of main organs or systems (including immune system) of the minipig still requires further characterization. In addition, the immune system could evolve towards gene expression and biological pathways in the zebrafish vertebrate model system depending on carbon chain length. The zebrafish model is ideal for developmental and molecular toxicity studies. Zebrafish were exposed to control or 4, 40 or 400 ppb of the PFCAs throughout embryonic development. Global gene expression profiles for each PFCa were then determined. Categories of gene function and diseases were identified for altered genes using Ingenuity Pathway Analysis. Cancer was the top disease identified among all the PFOA treatments unlike PFHxS and PFBA. However, most of the PFHxS and PFBA treatments did identify gastrointestinal diseases as one of the top diseases similar to PFOA. One of the top pathways identified among all PFBA treatments was FXR/RXR activation, which plays a role in numerous metabolic pathways. These findings further the comparison between the PFCAs and provide guidance on additional molecular and disease pathways to target for a more thorough understanding of the potential adverse health outcomes of an embryonic exposure to PFOA, PFHxS, or PFBA.

Confined parking garages with insufficient ventilation can create hazardous environments for people breathing the air. Some possible health effects from inhalation of gasoline-related compounds (for example, BTEX, benzene, toluene, ethylbenzene, and xylenes) include eye, nose and throat irritation, headaches, loss of coordination, nausea, damage to liver, kidney and central nervous system. This study provides a preliminary assessment of the air quality of an underground parking garage in downtown Washington, DC. It focuses on VOCs (volatile organic compounds) in the air that can impact public health. In June 2017, samples were collected and exposed in 15-minute intervals once a week during lunch hours ranging from 11 am to 1 pm. For each sampling interval, three solid-phase microextraction (SPME) fiber coatings were exposed in the parking garage, and analytes with a high affinity for the sorbent were selectively adsorbed. Humidity and temperature were noted since they are known to influence VOC volatility and absorbance onto the SPME fiber. The analytes were thermally desorbed from the fiber into a gas chromatograph – mass spectrometer (GC-MS) to identify volatile organic components. During the same sampling interval, a photoionization detector (PID) was used in assessing total VOCs in the garage. Total VOC concentrations ranged from 100 to 600 ppb, measured in isobutylene equivalents. The chemical composition captured by the SPME/GCMS consisted of BTEX and other aromatic/organic compounds. Some compounds were acetone, propylbenzene, ethanediol, and alkane. Known sources for these compounds include gas emissions, automobile exhaust, cleaning products and tobacco smoke. This study indicated that locations such as underground parking garages associated with these sources can have a complex mixture of volatile organic compounds at levels as high as a few hundred ppb.
Commuting by car exposes drivers and passengers to pollutants such as VOCs (volatile organic compounds) that can affect one’s health. The VOCs benzene, toluene, ethylbenzene, and xylene (BTEX), are particularly harmful for those who suffer from respiratory and cardiovascular diseases. This study was done to examine the identity and levels of VOCs inside the cabin of a vehicle, during a normal commute through the city of Washington D.C. (from Arlington, VA to North East, D.C.). Ten tests were run over a five-week period. A MiniRAE3000 monitored total VOC concentrations, and SPME (solid-phase micro extraction) field samplers collected samples from air. These SPME samples were later analyzed for chemical composition by GC/MS (gas chromatography mass spectrometry). In general, total VOC levels were higher in downtown DC and decreased in suburban areas of Arlington. Chemical compositions of the VOCs collected by SPME in downtown DC were similar for all ten tests. The most prominent VOCs included BTEX. High exposure to these toxins can cause damage to the overall health of the driver and passengers. The National Institute of Occupational Safety and Health short-term exposure limit is 1.0 ppm (3.2 mg/m³) for benzene and 151 ppm (560 mg/m³) for toluene. The time-weighted average recommended exposure limits for 10-hour workdays during a 40-hour workweek are ~0.3 ppm in isobutylene equivalents; given published correction factors, 0.1 ppm benzene is equivalent to 0.2 ppm in isobutylene equivalents. While further calibration is necessary to determine precise benzene concentrations, BTEX levels during the commute were well below short-term exposure limits but could approach exposure limits for those spending 10-hour workdays in traffic areas with consistently high levels of BTEX.
Polycyclic aromatic hydrocarbons (PAHs) play a central role in the carcinogenic effects of combustion-derived pollution, but have also been linked to CVD. Pyrene is among the most abundant PAHs on CPMs, but has received little toxicological attention due to its low carcinogenicity. However, our recent results suggested that pyrene triggered calcium influx ([Ca2+]i) in human endothelial cells (HMEC-1), and potentiated proinflammatory responses in bronchial epithelial cells induced by other agents. Here we explored the mechanisms of pyrene-induced ([Ca2+]i) in HMEC-1. Pyrene induced a prolonged ([Ca2+]i) that seemed to be initiated by Ca2+-release from intracellular stores and followed by a later phase of extracellular Ca2+-influx. Use of pharmacological inhibitors indicated that the initial phase was linked to store operated calcium channels (SOCE)/endoplasmic reticulum (ER), possibly involving inositol 1,4,5-trisphosphate receptor (IP3R). However, a role of transient receptor potential channels (TRPC) could not be excluded. The late phase seemed more linked to plasma membrane and calcium release-activated channels (CRAC). Pyrene also changed the membrane microstructure, rendering the membrane more fluid. Both the pyrene-induced ([Ca2+]i) and membrane alterations appeared to depend on activation of aryl hydrocarbon receptor (AhR)-signalling. Furthermore, addition of cholesterol inhibited the increase of membrane fluidity and ([Ca2+]i) triggered by pyrene, indicating that membrane alterations at least partly preceded the Ca2+-entry. By contrast, pyrene did not induce genomic alterations by pyrene, indicating that membrane alterations at least partly depended on activation of AhR-signalling as indicated by lack of CYP1A1/-1B1 gene expression. Instead, pyrene suppressed CYP1-expression by the prototypical carboxylic acid receptor (CAR)-signalling. Pyrene also induced membrane wrinkle formation of extracellular Ca2+. These responses seem to be initiated by Ca2+-release from extracellular stores and followed by a later phase of extracellular Ca2+-influx. Use of pharmacological inhibitors indicated that the initial phase was linked to store operated calcium channels (SOCE)/endoplasmic reticulum (ER), possibly involving inositol 1,4,5-trisphosphate receptor (IP3R). However, a role of transient receptor potential channels (TRPC) could not be excluded. The late phase seemed more linked to plasma membrane and calcium release-activated channels (CRAC). Pyrene also changed the membrane microstructure, rendering the membrane more fluid. Both the pyrene-induced ([Ca2+]i) and membrane alterations appeared to depend on activation of aryl hydrocarbon receptor (AhR)-signalling. Furthermore, addition of cholesterol inhibited the increase of membrane fluidity and ([Ca2+]i) triggered by pyrene, indicating that membrane alterations at least partly preceded the Ca2+-entry. By contrast, pyrene did not induce genomic AhR-signalling as indicated by lack of CYP1A1/-1B1 gene expression. Instead, pyrene suppressed CYP1-expression by the prototypical carcinogenic PAH, benzo[a]pyrene. We propose that pyrene is an AhR-ligand that specifically triggers non-genomic signalling, involving IP3R/SOCE-mediated Ca2+-release from ER, followed by CRAC- and possibly also TRPC-mediated entry of extracellular Ca2+. These responses seem to be initiated by AhR-mediated membrane remodeling. Thus, pyrene and other PAHs could possibly affect vascular tone and contribute to development of CVs by distorting endothelial ([Ca2+]i).-
expressions of cleaved-caspase 3 and cleaved-caspase 9 at 4 hr were the highest ones. In conclusion, the autophagy was firstly induced, then the apoptosis was mediated via the intrinsic apoptotic pathway, and finally the necrosis was caused in BEAS-2B cells exposed to low concentrations of crotonaldehyde.

### 2790 Crude Oil Vapor Effects upon Airway Epithelial Ion Transport and Lung Function in the Rat
J. A. Thompson, NIOSH, Morgantown, WV.

Crude oil vapor (COV) is a mixture of hydrocarbon vapors and volatile organic compounds (VOCs). Workers in the oil and gas industry are potentially exposed to COV while conducting routine tasks such as manual sampling, gauging and filling crude oil storage tanks from oil tanker trucks. The effects of COV inhalation exposure on the pulmonary system are unknown. Previously, we found there were no significant changes in pulmonary function or airway epithelial ion transport after acute inhalation exposure to COV (300 ppm total VOCs, 6 h/d, 1 d). In the current study, the effects of a sub-chronic inhalation exposure of COV on lung function and epithelial ion transport were investigated. Rats in whole body chambers were exposed to 300 ppm total VOCs for 28 d. Experimental endpoints were measured at 18 h, 28 h and 90 d post-exposure. Total VOCs, benzene, toluene, ethylbenzene, and xylene concentrations were monitored and regulated during exposures to maintain concentration constancy. Transepithelial potential difference (Vt), transepithelial resistance (Rt), and short-circuit current (isc) were measured in tracheae mounted in Ussing chambers and treated with the ion transport inhibitors amiloride (Na+ channel blocker; apical), 5-nitro-2-(3-phenylpropylaminol)benzoic acid (NPPB; Cl− channel blocker; apical), and ouabain (Na+K+ pump blocker; basolateral). Compared to air-breathing controls, the isc response to NPPB was increased significantly at 28 d post-exposure, indicating an increase in CI transport in the airway epithelium. There were no changes in Vt or Rt at 18 h or 28 d post-exposure, although the dynamic conductance (Gdyn) and resistance to inhaled methacholine (MC1) were measured in anesthetized rats. COV significantly increased basal Rt compared to air-breathing controls at 90 d post-exposure. There was no effect of COV on basal Cdyn or reactivity to inhaled MC1 at any time point. Our results indicate that sub-chronic exposure to COV changes airway ion transport and pulmonary function.

### 2791 Three Dimensional (3-D) Printer Emission-Induced Cell Toxicity
Y. Qian, M. Farcas, A. Stefaniak, C. Qi, D. Hammond, A. Knepp, and L. Bowers. NIOSH, Morgantown, WV; and NIOSH, Cincinnati, OH. Sponsor: V. Castranova

Three dimensional (3-D) printing with polymer thermoplastics is known to emit millions to billions of ultrafine particles (diameter <100 nm) and volatile organic compounds that are formed by thermal decomposition and/or vaporization and condensation of the filament. There is a paucity of data on potential toxicity of these emissions. As such, we generated emissions from a commercially available 3-D printer while operating with acrylonitrile butadiene styrene (ABS) or polycarbonate (PC) filaments in a 0.5 m³ environmental chamber. Particles were collected into serum free cell culture media using a liquid impinger sampler and the size and number concentration determined using nanoparticle tracking analysis. The mean sizes of PC and ABS-emitted particles in cell culture media were 160 ± 57 nm and 181 ± 21 nm, respectively. To determine the cytotoxicity of 3-D printer emissions, human small airway epithelial cells (SAEC) were seeded in a 96-well plate at a density of 1.5 × 10⁴ cells per well and treated for 24 h with 1 × 10⁴ particles/ml from PC and ABS emissions, followed by the cellular viability assays. The results showed that the exposures of PC and ABS emissions to SAEC significantly decreased the cell viability by 67% and 31%, respectively. Furthermore, it was found that the exposure of the PC emission significantly induced more toxicity than that of the ABS emission. Our preliminary data indicate that the emissions generated by 3-D PC and ABS filaments induce a toxic response in SAEC, and the emission of the PC filaments is significantly more toxic than that of the ABS filaments. Further studies are in progress to evaluate the mechanisms of 3-D printer emission-induced cellular toxicity.
bacterial clearance, and diminished Th2 responses. Cessation of SHS exposure for 21 d restored previously suppressed responses, including phagocyte recruitment, IgA secretion, and mucous cell metaplasia. However, in contrast with FA-Tg + mice, the SHS-Tg + mice had pronounced epithelial necrosis, alveolar space consolidation, and lymphoid hyperplasia; indicating lagged unfavorable effects of early postnatal SHS exposure in life. Taken together, these data suggest that early exposure to SHS may predispose muco-obstructive disease patients to exacerbated bacterial infections.

2795 Electronic Cigarette Chemicals Transfer from a Vape Shop to a Nearby Business in a Multi-User Building

C. Khachatourian1, P. Jacob2, N. Benowitz2, and P. Talbott1.
1University of California Riverside, Riverside, CA; and 2University of California San Francisco, San Francisco, CA.

Electronic cigarettes (EC) are nicotine delivery devices that produce aerosol without combustion of tobacco and therefore they do not produce sidestream smoke. Nevertheless, users exhale large clouds of aerosol that can result in passive exposure of non-users. The exhaled aerosol settles on indoor surfaces where it can produce a residue analogous to thirdhand smoke from conventional cigarettes. We refer to this residue as EC exhaled aerosol residue (ECEAR). The objective of this study was to determine if exhaled EC aerosol transferred from a vape shop to a mini-mall, where it was produced, to a nearby business (field site) where it could deposit as ECEAR. The buildup of ECEAR was evaluated in commonly used fabrics (cotton and paper towels) placed inside the field site across from the vape shop. Fabrics were subjected to short (days) and long-term (months) exposures. Flavor chemicals, nicotine, nicotine alkaloids, and tobacco-specific nitrosamines (TSNAs) were identified and quantified in unexposed controls and field site samples using analytical chemical techniques. Several flavor chemicals present in EC refill fluids and aerosols were detected in ECEAR samples from the field site. Nicotine, nicotine alkaloids, and TSNAs were detected in extracts of paper and cotton towel fabric from the field site. The most abundant marker of EC aerosol contamination (highest concentration found = 23,260 ng/g of fabric). Nicotine and nicotine alkaloids were detected after 1 day of exposure in the field site (154 ng/g of nicotine/g of paper), and these chemicals generally increased as exposure times increased. TSNAs, which have been linked to carcinogenesis, were also detected in short- and long-term-exposed samples from the field site. In a multiuser mini-mall, chemicals in EC aerosol traveled from a vape shop into an adjacent business where they deposited forming ECEAR. Tenants occupying multi-user buildings and regulatory agencies should be aware of this potential environmental hazard.

2796 Subacute Acrolein Exposure-Induced Inflammation in the Larynx

Purdue University, West Lafayette, IN.

Acrolein exists abundantly in cigarettes and contributes to the most non-cancer toxicity in the respiratory system among components of cigarette smoke. Symptoms commonly complained by smokers pertain to hoarseness and lowered fundamental frequency of voice. However, the mechanism of the voice impairment induced by smoking remains elusive. This study was designed to investigate if subacute inhalation exposure to acrolein in rats caused an inflammatory reaction in larynxes. Sprague Dawley rats (male, 4-month old) were exposed to either 3-ppm acrolein (treatment) or filtered air (control) in a whole-body exposure chamber for 5 hr/day, 5 days/week, for 4 weeks. Laryngeal tissues were dissected at 4 hr after the last exposure. Pathological changes of inflammatory cells and tissue damage were evaluated in the true vocal folds. The qPCR analysis showed that the expressions of cytokines and chemokines were increased in acrolein-exposed tissues compared to control tissues. Furthermore, the expression of metalloproteinases was upregulated in acrolein-exposed tissues. These findings suggest that exposure to acrolein induces inflammation in larynx, which involves NF-κB regulation and alteration of gene expressions of proinflammatory cytokines. Our data builds the groundwork for further mechanistic investigation of inflammation induced by acrolein in larynx structure and its role in the dysfunction of vocal folds during cigarette smoke. Supported by NIH/NIDCD R01DC011759.

2797 Nicotine Characterization of an In Vitro Inhalation Exposure System Using Conventional and Next-Generation Tobacco Products: A US/UK Inter-Laboratory Comparison

D. Sheehan1, M. Aragon1, J. Adamson2, M. Gaca2, H. Raabe1, and H. Behrsing1.
1Institute for In Vitro Sciences, Inc., Gaithersburg, MD; and 2British American Tobacco, Southampton, United Kingdom.

Comparative analysis of data from interlaboratory studies utilizing different exposure systems is an important step in standardizing in vitro testing of next generation tobacco and nicotine products (NGPs). Dosimetric characterization can align different systems and add confidence to the biological data obtained following exposure, allowing for a better dose-response assessment. Three in vitro aerosol exposure systems (Borgwaldt RM205, Virocell VC10 and VC1) were compared in two laboratories - US and UK - with three different types of nicotine delivery products - 3R4F reference cigarette (at ISO and HCl regimes), an e-cigarette (Vype ePen) (at CRM81 regime) and a tobacco heating product (glo) (at modified HCl regime). Cambridge filter pad (CFP) air was used to generate aerosol allowed 24h perfusion of cells, exposure products, exposure systems and laboratories. CFP aerosol was extracted with solvent, spiked with an internal nicotine standard and quantified by UPLC/MS MS. The cigarette at ISO was 0.080 mg/puff in both labs, and at HCl was 0.193 mg/puff in the UK and US respectively. The e-cigarette was 0.069 mg/puff in both labs and the glo was 0.048 and 0.050 mg/puff in the UK and US respectively. A General Linear Model ANOVA demonstrated that nicotine profiles were characteristically different between products and puffing regimes (p=0.000, where <0.05 was considered statistically different) but were the same within product category across different laboratories, exposure systems and puffing regimes. Such information is especially important when establishing new inhalation exposure facilities and characterizing exposure systems to demonstrate consistency with established inhalation exposure results. Interlaboratory studies help to demonstrate transferability and reliability when aligning different in vitro methods, laboratories and products. Furthermore, thorough dosimetric characterization provides confidence in the in vitro response to NGPs compared to traditional combustible cigarettes. The interlaboratory data further suggest that the nicotine quantification method employed is an appropriate approach to compare different exposure systems in different locations.

2798 Reversibility of In Vitro Biological Effects in Cigarette Smoke-Exposed 3D Lung Tissue Models Following Switching to a Tobacco-Heating Product

British American Tobacco, Southampton, United Kingdom.

Tobacco heated products (THPs) potentially offer a safer alternative to combustible cigarettes. Recent in vitro studies have shown reduced biological effects of THPs compared to 3R4F reference cigarette smoke. Existing in vitro data, however, has been generated performing acute, single exposures not reflective of consumer use. Furthermore, the reversibility of the biological effect of cigarette nicotine quantity switching to THPs has not been extensively studied in vitro. A feasibility study was conducted to assess the potential of using MucilAir™ tissues in a 4 week repeated exposure study. Tissues were exposed to 3R4F smoke (15 mins x3 times a week) for 2 weeks after which the cohort were split into three conditions - further 2 week repeated exposure and switching to THP or a switch to air. The Borgwaldt RM205 generated whole aerosols at the Health Canada Intense smoking regime. Endpoints assessed included cytotoxicity, tight-junction integrity and cytokine expression (panel of 33 cytokines). The results were compared to a continuous air exposure control at week 4. During the 4 week repeated exposure the case remained below 10% for all tested conditions and TEER above 500 Ω/insert, indicative of tissue integrity. After two weeks 3R4F repeated exposure, an increase in cytokine expression was observed (14 FC>1.5, p<0.05), however following 4 week 3R4F repeated exposure, a strong differential cytokine expression was demonstrated, with 14 responsive cytokines in the culture media including MMP-9, IL-6, IL-4, IL-1α, VEGF at p<0.05, FC>1.5. However, tissues that were switched to THP aerosols for 2 weeks following 3R4F repeated exposure, demonstrated lower cytokine expression with only eotaxin-3 and MMP-9 remaining.
2799 An Approach to Testing Undiluted E-Cigarette Aerosol In Vitro Using 3D Human Airway Epithelium

With the increasing emergence and subsequent popularisation of electronic nicotine delivery systems (ENDS), suitable and fit-for-purpose in vitro test methods are required to enable relevant pre-clinical ENDS assessment. Current in vitro exposure systems have complex aerosol generation and dilution principals that may not be practicable when assessing less toxic aerosols, such as those from e-cigarettes. In this study, 3D human airway tissues (MucAir™), were exposed to cigarette or e-cigarette aerosols at the air-liquid interface (ALI) using a modified Vitrocell VC10 to deliver undiluted aerosols, thereby fixing the dose and varying the exposure duration (mins). Following exposure, nicotine in the cell-culture media and cellular functional endpoints, including TEER, cilia beat frequency and cytotoxicity, were assessed. Using 3ARF scientific reference cigarettes two smoking regimes, ISO and HCl, were initially tested and resulted in IC50s of 5.2 and 2.1 mins respectively with equivalent cell media nicotine concentrations of 1458 ng/mL and 1640 ng/mL. Using a high aerosol delivery, open tank e-cigarette device (Vype eBox), and blended tobacco (18mg/mL nicotine) liquid in this modified VC10 system (CRM 81 regime), a cytotoxicity dose-response curve was obtained having an IC50 30 mins with corresponding nicotine 10957 ng/mL. Functional endpoints tested following e-cigarette exposures indicated a loss in mucociliary clearance and cell tissue integrity observed at exposure durations >20 mins. To further test the aerosol generation of the modified exposure system, a positive control aerosol was tested in parallel. Addition of 0.025% cinnamaldehyde to the e-liquid formulation increased cytotoxicity of the delivered undiluted aerosol, inducing 80% cytotoxicity after 20 mins of exposure, compared to 0% cytotoxicity with regular e-liquid at the same exposure duration, further substantiating the aerosol delivery technique. Nicotine dosimetry assessments further demonstrated that adaptations made to the VC 10 did not adversely affect performance, enabling the generation of consistent and significantly higher delivery of e-cigarette aerosols. This study has enabled the delivery of undiluted cigarette and e-cigarette aerosols to in vitro 3D human reconstituted lung epithelia at the air-liquid interface, which in turn has reduced exposure times from hours to minutes.

2800 Comparison of In Vitro Cytotoxicity and Genotoxicity of Condensates Derived from E-Vapor Products and Combustible Cigarettes

U. Doshi1, S. Hurtardo2, W. Gardner1, R. Wolz2, W. J. McKinney1, and K. M. Lee1. 1Altria Client Services, Richmond, VA; 2Charles River Laboratories, Skokie, IL; and 3Entholpy Analytical, Richmond, VA.

The FDA draft guidance (2016) on premarket tobacco application for e-vapor products recommends full toxicity assessment including in vitro genotoxicity and cytotoxicity. Herein, we collected the condensates from e-vapor products (MarkTen™ with menthol and non-menthol flavors) and reference (3RF) cigarettes, on a Cambridge filter followed by an impinger filled with ethanol at 0°C. The condensates were then tested using standard in vitro assays: Neutral red uptake (NRU) for cytotoxicity, Salmonella mutagenicity (Ames), and micronuclei (MN) for genotoxicity. E-liquids used for e-vapor products contained aerosol formers (propylene glycol [PG] and glycerol), water, nicotine (up to 2.5%) and flavor mixtures. The condensates (up to 47 mg total particulate matter (TPM)/mL) were analyzed for key formulation components and carbonyls, stored frozen at -70° C, tested in vitro with 48h of collection, and assessed for stability up to 8 weeks in storage. The 3RF condensate tested positive in the NRU assay (IC50 of 0.048±0.004 mg/mL TPM), whereas the e-vapor condensates showed viability >80% (IC50 could not be estimated). The 3RF condensate tested positive in the Ames assay in strains TA1537 and TA98, whereas the e-vapor condensates did not in any of the five strains tested. The 3RF condensate also tested positive in the MN assay but no significant effect was observed with the e-vapor condensates. Key formulation components as well as carbonyls were detected in e-liquid condensates and were stable for up to 8 weeks at -70° C. In summary results from this study are consistent with the literature findings that e-vapor product aerosols have substantially lower biological activity than combustible cigarettes.

2801 An Impact of Exposure to Aerosols from Nebulized E-Liquids on Human Organotypic Airway Cultures

E-cigarettes (e-cig) comprise a variety of electronic devices used to heat an e-liquid. The e-liquids are typically composed of nicotine and varying flavors in propylene glycol and glycerol-based solutions. More than 7000 e-liquids can be found on the market. Some flavors have been categorized as Generally Recognized as Safe (GRAS), by the US FDA when used as food ingredients but their potential toxicity when inhaled is largely unknown. With the increasing use of e-cigs and variety of e-liquids, robust toxicity evaluations are needed. This study showed that nebulizing e-liquids to generate aerosols is a promising testing approach to assess their potential toxicities. Organotypic airway cultures were exposed to nebulized aerosols of two different e-liquids: 1) a propylene glycol and glycerol solution containing nicotine without flavors (PG/G/NIC), and 2) a propylene glycol and glycerol solution containing nicotine without flavors (PG/G/NIC/Flavors). The flavor mixture contains a selection of 28 flavors representing their respective FDA when used as food ingredients but their potential toxicity when inhaled is largely unknown. With the increasing use of e-cigs and variety of e-liquids, robust toxicity evaluations are needed. This study showed that nebulizing e-liquids to generate aerosols is a promising testing approach to assess their potential toxicities. Organotypic airway cultures were exposed to nebulized aerosols of two different e-liquids: 1) a propylene glycol and glycerol solution containing nicotine without flavors (PG/G/NIC), and 2) a propylene glycol and glycerol solution containing nicotine without flavors (PG/G/NIC/Flavors). The flavor mixture contains a selection of 28 flavors representing their respective chemical groups according to relevant toxicological data; their concentration was derived from the maximum use levels. Tissues exposed to air or nebulized cigarette smoke (CS)-bubbled phosphate-buffered saline (PBS) were used as benchmark comparisons. Culture morphology, secreted proinflammatory mediator profile, and Affymetrix array-based whole transcriptome were analyzed after exposure. Exposure characterization included measurements of the deposited PG, G, and NIC concentrations in exposure chambers. Culture morphology was not different across the groups. Concentrations of secreted proinflammatory mediators following exposure to PG/G/NIC aerosol were not different from the air-exposed controls. However, concentrations of interleukin (IL6 and IL8 higher in samples exposed to PG/G/NIC/Flavors aerosol compared with those in the air-exposed samples. Changes in the gene expression profiles were detected; the number of the altered genes after exposure to PG/G/NIC or PG/G/NIC/Flavors aerosols were substantially lower than those exposed to aerosolized CS-bubbled PBS.

2803 The Use of Human 3D Reconstructed Bronchial Tissue to Study the Effects of Cigarette Smoke and E-Cigarette Aerosol on a Wide Range of Cellular Endpoints

L. Czekala1, M. Stevenson1, L. Simms1, N. Tschierske1, A. Miano2, and T. Walele1. 1Imperial Tobacco Ltd, Bristol, United Kingdom; and 2MatTek Corp., Ashland, MA. Sponsor: F. Ayala-Fierro.

In 2015, Public Health England concluded e-cigarettes are around 95% less harmful than smoking tobacco cigarettes and in 2016 the Royal College of Physicians stated e-cigarettes should be promoted widely as a substitute for smoking. However, some recent data has indicated that e-cigarette aerosol can potentially produce reactive oxygen species which may give rise to inflammation, DNA damage and reduced cell viability. In this study, biological endpoints were investigated in the EpiAirway™ 3D in vitro model (MatTek Corp), a highly differentiated human airway culture derived from primary tracheal/bronchial epithelial cells. EpiAirway™ tissue was exposed at the air-liquid interface to whole smoke from a conventional tobacco cigarette and aerosol generated from an e-cigarette device using two different e-liquids (commercial and experimental e-liquid both with 2.4% nicotine). Smoke or aerosol was generated using a VITROCELL™ VC 1 smoking machine following Health Canada Intense and CRM81 regime, respectively. The integrity of the epithelial barrier of tissues, was measured before and 24 hours after exposure using trans-epithelial electrical resistance. Tissue viability was assessed using the MTT assay. Conditioned media were collected 24 hours after the exposure, to determine tissue secretion of the pro-inflammatory cytokines IL-6 and IL-8. The 8-Isoprostane assay evaluated oxidative stress response. Tissue morphology was assessed by H&E staining. The TUNEL assay was used to detect apoptotic cells;
2804 Toxological Assessment of Aerosol from Flavored E-Liquids in Sprague Dawley Rats: A 90-Day Sub-Chronic Inhalation Study

J. Ho1, W. Xia1, D. Sciscio2, E. Veljkovic2, B. W. Phillips1, S. Lebrun2, G. Vuillaume2, P. Leroy2, J. Hoening2, M. C. Peitsch2, and P. Vanscheeuwijk1. 1Philip Morris International Research Laboratories Pte. Ltd., Singapore, Singapore; and 2Philip Morris Products S.A., Neuchatel, Switzerland.

Relatively few in vivo inhalation studies were performed to evaluate the toxicity of flavor compounds commonly added to e-liquids. The toxicity of chemical groups of flavor substances was characterized in a 90-day sub-chronic inhalation study according to the OECD 413 testing guidelines using a selection of 28 flavors, which represented their respective chemical groups according to the relevant toxicological data. Sprague-Dawley rats were exposed for 6 h/day, 5 d/week for 13 weeks to aerosols of e-liquid (propylene glycol (PG), vegetable glycerin (VG) and nicotine), with three concentrations of flavor compound mixture, or VG with medium concentration of flavor compound mixture. The target test atmosphere concentrations of nicotine, PG and VG were 23 µg/L, 1520 µg/L and 1890 µg/L, respectively. The lowest concentrations of the 28 flavors tested in this study corresponds to the current maximum use levels in tobacco products. Rats exposed to the nicotine-containing aerosols had gender-specific changes to body weight—lower in males, higher in females. Subtle changes of the respiratory physiology parameters indicated a mild irritancy of the flavor mixture in both sexes, while the presence of nicotine countered this effect. Low level of inflammatory cells in the bronchoalveolar lavage fluid of animals in all groups, indicating minimal inflammatory inflammation. Slightly higher activity of alkaline phosphatase, and lower concentrations of metabolic markers were noticed mainly in serum from nicotine-exposed groups. Organ weight changes including higher liver and adrenal weights, and lower thymus weights were observed following nicotine exposure. There were few histopathological findings among which minimal laryngeal squamous metaplasia due to PG/VG exposure, with partial reversibility following a 42-day recovery period. Microscopic findings in adrenal glands and thymus were considered secondary due to stress. In summary, nicotine and PG/VG exposure-related findings were seen without synergistic effects caused by the flavors.

2806 Characterization of E-Cigarette Aerosols in Two Different Exposure Regimens for a Nose-Only Rodent Inhalation System

E. Benson1, and K. M. Lee2. 1Battelle, West Jefferson, OH; and 2Altria Client Services LLC, Richmond, VA.

Inhalation studies require reliable exposure generation and characterization regardless of the type of product being tested. In this study, an established rodent nose-only inhalation exposure setup was adapted to generate aerosols from a cig-like e-vapor product and conventional (3RF) cigarettes using a rotary cigarette smoking machine (CSM). For the e-vapor product, aerosols were generated in two ways. The first was using the CORESTA CR81 puffing regime (30-sec puff interval, 3-sec puff duration, and a puff volume of 55 mL) for 180 puffs/cartridge. The second was using a modified regime with a longer puff duration (CRM81, except for 5-sec puff duration) and a puff count of 120 to 130 puff/cartridge. The 3RF-cigarette smoke aerosols were generated using smoking regimens 30-sec puff duration and 1500 µg/L nicotine, and the e-vapor TPM concentration met the target concentration within 6% for each exposure cohort with or without active feedback control. The MMAD was initially slightly higher for the modified regime compared to the CRM81 regime, however following modifications to the exposure generation system the particle size was comparable (~1.1 um) for both e-vapor exposure regimes. Ratios of e-vapor aerosol constituents (nicotine, PG, and glycerol) were similar and did not change from the CSM to nose ports. For the 3RF CSM connected to two exposure carousels, TPM was within 1% of target (550 µg/L), the MMAD was at ~0.7 µm and the CO/TPM ratio was ~1.2. This work provides the basis to establish repeated rodent nose-only inhalation exposure regimes.
ogy for the assessment of whole aerosols. Cigarette smoke from TPM test matrices was deemed positive under almost all test conditions in all assays. For NRU, Ames, MLA, Bhas 42 and IVMN assays, responses were observed at 60µg/mL, 240µg/plate, 60µg/mL, 50µg/mL and 30µg/mL, respectively. In contrast, THP TPM failed to elicit a response in each of the assays up to 240µg/mL. Cigarette smoke was also deemed positive in the Ames assay at doses up to 50µg/cm³. THP aerosols were negative at doses exceeded 25µg/cm³. Given a weight of evidence approach, these data demonstrate that THP test matrices are negative at doses equivalent and exceeding those of cigarette smoke where positive responses are observed, suggesting THPs may offer significant reduced risk potential compared to cigarette smoking.

2808 Chronic Toxicity and Carcinogenicity of 2,3-Butanedione (Diacetyl) Vapors in Rodents

D. L. Morgan¹, G. P. Flake¹, M. D. Stout¹, C. L. Johnson², and L. H. Kooistra². ¹NIAMS, Research Triangle Park, NC, and ²Charles River Laboratories, Durham, NC.

2,3-Butanedione (BD, diacetyl) is a common ingredient in artificial butter flavor formulations used in many food and beverage products. While consumption of the amounts of BD present in food is generally considered to be safe, occupational exposure to BD vapors has been associated with obstructive bronchiolitis (OB), an irreversible fibroproliferative disorder of the small airways. Acute and repeated short-term exposure to BD has been shown to cause significant respiratory tract toxicity and OB in rodents; however, the effects of chronic BD inhalation are unknown and were investigated in this study. Wistar Han rats and B6CF1/N mice (50/sex/species/concentration) were exposed to 0, 12.5, 25, 50, and 100 ppm BD 6 h/day, 5/d/wk for 105 wk. Survival and body weights of male and female rats and mice exposed to 50 ppm were significantly less than controls. BD exposure caused a spectrum of nonneoplastic lesions of the nose, larynx, trachea, lung, and eye in male and female rats and mice, primarily in the 25 and 50 ppm groups. The most severe lesions were observed in the nasal cavity and included respiratory epithelial hyperplasia, squamous metaplasia, and necrosis; olfactory epithelial atrophy, respiratory metaplasia, and necrosis. Although OB was not observed, significant fibrosis was present in the nose of rats and mice exposed to 25 and 50 ppm BD, and in the trachea of both rats and mice and in the lung of rats exposed to 50 ppm BD. Rare squamous cell carcinomas of the nasal mucosa occurred in 3 male and 3 female rats exposed to 50 ppm. A squamous cell papilloma was also present in the nasal cavity of 1 male rat exposed to 50 ppm. No squamous cell carcinomas or papillomas of the nose occurred in control rats. In mice, rare adenocarcinomas of the nasal cavity occurred in 25 ppm females. No nasal neoplasms were observed in exposed male mice or control mice. BD is mutagenic and can form adducts with 2-deoxyguanosine. The sustained cytotoxicity and cell proliferation in the nasal cavity caused by chronic BD exposure may have predisposed animals to nasal carcinogenesis.

2809 Comparison of E-Vapor Carrier Mixtures to Air Control and Cigarette Exposure Using 90-Day Inhalation Studies in Rats

C. R. Cogqins¹, T. B. Langston², K. M. Lee³, M. J. Oldham², and W. J. McKinney². ¹Carson Watts Consulting, King, NC, and ²Altria Client Services, Richmond, VA.

Propylene glycol (PG), glycerin and water are used as the carrier in e-vapor product formulations. OECD 413 compliant (BALF analysis) 90-day nose-only inhalation studies were performed where Sprague Dawley rats were exposed (160 min/day, 7 days/wk) to aerosols generated from three different carrier mixtures of PG, glycerin and water. Biological responses were compared to the current filtered air (Control). In addition, histopathological findings in respiratory tract were also compared to literature values from Sprague Dawley rats exposed to mainstream (2RF4) cigarette smoke. To acknowledge procedural differences in histopathology evaluations among studies, for each change noted, a “histopathology response” was determined by multiplying the severity of each change by its incidence. The most severe histopathology response from each change, from either sex, was added together to obtain an overall histopathology response for all changes noted in the nose, larynx and lung. The e-vapor and 2RF4 groups were then compared at “daily presented dose (DPD)” (exposure time multiplied by concentration (mg/L)). Compared to the control groups, the e-vapor carrier groups showed no differences in body mass, clinical chemistry, hematology, organ weights or urinalysis, and histopathological findings (incidence and severity). In the bronchoalveolar lavage (BAL) parameters measured after 13 weeks of exposure, e-vapor groups showed a slight but non-statistically significant increase in LDIH in males but not females. In histopathology response, the e-vapor carrier groups displayed a flat dose-response in the nasal and laryngeal findings similar to the air control. At comparable DPD, the average nasal and laryngeal response to cigarette smoke was 3 and 13 times greater, respectively, than the average response from the e-vapor group. The lung histopathology response for the e-vapor carrier group showed increasing scores with increasing DPD; however, it required over 3 times higher DPD to obtain the same response as cigarette smoke. In conclusion, there were no significant differences in biological endpoints between e-vapor carrier and filtered air control groups. In contrast, e-vapor carrier exposures showed substantially reduced histopathological responses in all regions of the respiratory tract compared to mainstream cigarette smoke exposure.

2810 Lung Inflammation and Emphysema in A/J Mice in Response to Chronic Exposure to Aerosol from a Candidate-Modified Risk Tobacco Product and Mainstream Cigarette Smoke

E. Wong¹, K. Luetitch², K. Trivedi³, E. Guedj², C. Nury², T. Schneider², Y. Xiang², A. Elamin⁴, B. Titz⁵, P. Leroy⁶, G. Vuillaume⁶, E. Veljkovic⁶, N. Ivanov⁶, P. Vanscheeuwijk⁶, M. Peitsch⁶, and J. Hoeng². ¹Philip Morris International Research Laboratories Pre Ltd, Singapore, Singapore; ²Philip Morris Products S.A., Neuchatel, Switzerland.

Chronic exposure to cigarette smoke is the leading cause of chronic obstructive pulmonary disease and lung cancer. The A/J mouse model was used to evaluate lung inflammation, emphysema and the underlying molecular changes upon life-time exposure to cigarette smoke (CS) from the 3RF4 reference cigarette or to aerosol from the Tobacco Heating System (THS) 2.2, a candidate modified risk tobacco product (MRTP) at three concentrations. A/J mice were exposed for 6 hours per day for 5 days per week for up to 18 months. Quantification of pulmonary inflammation, assessment of matrix metalloproteinase (MMP) activity in bronchoalveolar lavage fluid (BALF), lung function tests, lung morphometric assessments by stereological approach, histopathological evaluation, targeted proteomic analysis of BALF, as well as transcriptome and proteome analysis of the lungs were performed at selected interim and terminal dissections. Exposure to CS resulted in pulmonary inflammation, increased MMP activity, altered lung function, enlargement of distal airspaces in the lungs and molecular changes, all indicative of emphysema. Only minimal effects on the lungs were observed following THS2.2 aerosol exposure that were independent of THS2.2 aerosol concentration and duration. Biological analysis identified perturbed molecular processes that are consistent with CS exposure of the lungs, but only minor perturbations of cell stress responses were noted following THS2.2 aerosol exposure. Biological network analysis identified perturbed molecular processes that are consistent with CS exposure, but only minor perturbations of cell stress responses were noted following THS2.2 aerosol exposure. In summary, lung inflammation, emphysematous changes and molecular perturbations were significantly lower in mice exposed to aerosol from THS2.2 as compared to CS exposure.

2811 A Six Month Systems Toxicology Inhalation/Cessation Study in ApoE−/− Mice to Investigate Cardiovascular and Respiratory Exposure Effects of Two Candidate Modified Risk Tobacco Products Compared with Conventional Cigarettes

B. Phillips¹, J. Szostak¹, E. Guedj¹, E. Wong¹, M. Talikka¹, S. Lebrun¹, B. Titz², F. Martin², G. Vuillaume³, P. Leroy³, A. Buettner³, N. V. Ivanov³, P. Vanscheeuwijk³, M. C. Peitsch³, and J. Hoeng². ¹Philip Morris International, Singapore, Singapore; ²Philip Morris Products S.A., Neuchatel, Switzerland; and ³Histovia, GmbH., Overath, Germany.

Cigarette smoking causes adverse health effects that may occur shortly after smoking initiation and lead to the development of cardiovascular disease (CVD) and chronic obstructive pulmonary disease (COPD) as well as cancers. To reduce the risk for smokers to develop smoking-related diseases, modified risk tobacco products (MRTPs) are being developed. Engaging a systems toxicology approach, combining physiological, histological and omics endpoints, the effects of a 6-month exposure to cigarette smoke (CS) or to aerosols from two candidate MRTPs termed CHTP1.2 and THS2.2, were investigated in ApoE−/− mice. In addition, the impact of cessation or switching to CHTP 1.2 aerosol exposure after 3 months of CS exposure was evaluated. Our results demonstrated that exposure to CS at a concentration of 28.0 µg nicotine/L cause adverse effects on the lungs including increased
lungs, lung inflammation, aortic plaque formation and a dysregulation of the heart transcriptome. In contrast, exposure to either THS2.2 or CHTP1.2 aerosol at matched nicotine concentrations did not induce lung inflammation or enhance plaque development. Cessation or switching to CHTP1.2 aerosol exposure reversed lung inflammatory responses and halted progression of aortic plaques. Biological pathways, including “Drug metabolism-cytochrome P450”, “Focal Adhesion”, “ECM-receptor interactions” and “Tryptophan metabolism” were significantly impacted by CS exposure in heart tissue, but not by exposure to CHTP 1.2 or THS2.2 aerosols. Both, cessation and switching to CHTP1.2 aerosol reduced these perturbations to levels similar to those in sham animals. In conclusion, in this ApoE-/− mouse study, exposure to THS2.2 and CHTP1.2 aerosol had minimal adverse respiratory and cardiovascular effects. In addition, cessation or switching to CHTP1.2 aerosol exposure delayed the progression of CS-induced atherosclerotic and lung emphysematous changes.

2812 Investigating the Effects of Nicotine Using a Human Multi-Organ-Chip Approach

Currently, analyzing the effects of substances and the interaction of a lung and liver co-culture in vitro is unfeasible. However, TissUse’s Multi-Organ-Chip (MOC) platform provides preclinical insight on a systemic level using human tissue. It enables the direct prediction of effects of chemicals and their metabolism on real-life models. In order to be able to elucidate the toxicity of inhaled compounds, we adjusted the MOC design for the optimal co-cultivation of a human liver equivalent and the MucoAir™ lung model. Tissue integrity and function were evaluated using metabolic analysis, measurement of trans-epithelial electrical resistance and cilia beat frequency, immunohistochemistry, gene expression analysis and albumin secretion. Viability and homeostasis could be demonstrated for 14-day lung/liver co-cultures. Initial tests with nicotine, applied either apically to the lung model or systemically, indicated active compound metabolism and the utility of the current MOC set-up for future research into the biological effects of inhaled compounds on the homeostatic co-culture.

2813 Pathway Analyses of Global Metabolomic Profiles Identify Enrichment of Caffeine, Energy, and Arginine Metabolism in Smokers, But Not Moist Snuff Consumers
G. Liiu, D. P. Lee2, E. Schmidt1, A. Kennedy1, Q. T. Tran1, and G. L. Prasad1. 1RAIS, Winston Salem, NC; 2OmicsInsight, Durham, NC; and 3Metabolon, Durham, NC.

Existing US epidemiological data demonstrate that consumption of smokeless tobacco, particularly moist snuff, is less harmful than cigarette smoking. However, the molecular and biochemical changes due to moist snuff consumption relative to smoking remain incompletely understood. Based on metabolomic profiling data of saliva, plasma and urine from moist snuff consumers (MSC), cigarette smokers (SMK), and non-tobacco consumers (NTC), we reported that smokers exhibit elevated oxidative stress and inflammation relative to MSC and NTC. In this study, we investigated the effects of tobacco consumption on additional metabolic pathways using pathway-based analysis tools. To this end, metabolic pathway enrichment analysis, and topology analysis were performed through pair-wise comparison of global metabolomic profiles of SMK, MSC and NTC. The analyses identified >8 significantly perturbed metabolic pathways in SMK compared to NTC and MSC in all three matrices. Among these differentially enriched pathways, caffeine metabolism, energy metabolism, and arginine metabolism were mostly observed. In comparison, much fewer enriched metabolic pathways were identified in MSC compared to NTC (5 in plasma, none in urine and saliva). This is consistent with our transcriptomics profiling results that show no significant differences in peripheral blood mononuclear cell gene expression between MSC and NTC. These findings, taken together with our previous biochemical, metabolomic and transcriptomic analysis results, provide a better understanding of the relative changes in healthy tobacco consumers, and demonstrate that chronic cigarette smoking, relative to the use of smokeless tobacco, results in more pronounced biological changes, which could culminate in smoking-related diseases.

2814 Distinct Gene Expression Changes in Peripheral Blood Mononuclear Cells Exposed to Combustible Versus Non-Combustible Tobacco Product Preparations
Q. T. Tran1, S. Arimilli2, B. Madahian3, R. Homayouni2, and G. Prasad1. 1RAIS, Winston Salem, NC; 2Wake Forest University, Winston Salem, NC; and 3Quire Inc., Memphis, TN.

Cigarette smoking exerts diverse physiological effects including immune suppression. Existing US epidemiological data show that consumption of smokeless tobacco products, such as moist snuff, is less harmful relative to cigarette smoking. In efforts to understand the molecular changes due to consumption of different tobacco product classes, we have shown recently that smokers exhibit distinct peripheral blood mononuclear cells (PBMCs) gene expression patterns relative to moist snuff users and non-tobacco consumers (NTCs). To better characterize the biological effects exerted from the use of different tobacco products, a genome-wide gene expression study, using a PBMC in vitro model, was performed. We investigated global gene expression changes in PBMCs exposed to aqueous extracts of cigarette smoke (whole smoke conditioned media [WSCM]) and moist snuff extract (moist smoke tobacco extract [STE]) prepared from reference tobacco products (3R4F and 2S3, respectively). PBMCs were isolated from whole blood of four healthy NTC donors and exposed under different doses of WSCM or one dose of STE. Global gene expression profiling was performed using Affymetrix HTA 2.0 arrays. Our results showed that 5,421 genes (2,809 upregulated and 2,612 downregulated) were dose-dependently changed by WSCM (pFDR < 0.001). Some gene expression changes detected in the in vitro system were also observed in clinical studies. For example, PER2 and SLAMF7 were suppressed by WSCM while CCR2 and HHEX genes were upregulated by WSCM commonly in both in vitro and clinical studies. WSCM exposures, but not STE, uniquely affected genes involved in immune cell development and inflammatory response. Ingenuity Pathway Analysis identified upstream regulators, such as TNF, IL18, and NFκB to be likely responsible for the observed gene expression changes and that these cascading signals were generally suppressed by WSCM, but not STE. Collectively, these findings suggested that combustible and non-combustible tobacco products produce distinct biological effects which could explain the observed chronic immune suppression in smokers.

2815 Heat Shock Proteins Are Key Regulators of Cigarette Smoke-Induced Cardiac Hypertrophy
G. Ichihara1, S. Ichihara2, Y. Kitamura3, Y. Suzuki3, T. Ohhashi3, and S. Okawa3. 1Tokyo University of Science, Noda, Japan; 2Jichi Medical University, Shimotsuke, Japan; and 3Mie University, Tsu, Japan.

Smoking is related to the risk of cardiovascular events. The present study was designed to identify proteins in the left ventricular tissues with altered expression in spontaneously hypertensive rats (SHR) after exposure to cigarette smoke and to find possible molecular targets associated with the pathogenesis or progression of cigarette smoke-induced cardiac hypertrophy. SHR and control, Wistar Kyoto rats (WKY) were exposed to cigarette smoke at low (2 puffs/min for 30 min) or high dose (2 puffs/min for 120 min). Using the two-dimensional fluorescence difference gel electrophoresis (2D-DIGE) combined with MALDI-TOF/TOF tandem mass spectrometry, we compared differences in the expression of proteins in the whole left ventricles after exposure to cigarette smoke for 8 weeks. The left ventricular/body weights were significantly increased by cigarette smoking at high dose in both SHR (3.37 × 10⁻³ vs 3.98 × 10⁻³) and WKY (2.21 × 10⁻³ vs 2.51 × 10⁻³) (p-values < 0.01). Cigarette smoke developed prominently concentric hypertrophy and fibrosis of the heart. Proteomic analysis identified 32 protein spots with significant alterations, including 16 up-regulated and 16 down-regulated proteins in the left ventricles of SHR exposed to cigarette smoke compared with non-exposed SHR. Of the total alterations, heart shock protein 70 kDa and heat shock protein beta-6 showed significant up-regulation in the left ventricles of SHR exposed to cigarette smoke. The study also confirmed that cigarette smoke induced the cardiac hypertrophy. The results suggest that heart shock proteins are key regulators of the cigarette smoke-induced cardiac hypertrophy.
Research has shown that the electronic nicotine delivery system (E-cigarette/vape; ENDS) contains banned toxic chemicals that cause cytotoxicity, oxidative stress, and inflammatory response and induce gene expression signatures similar to tobacco smoke (TS). Our aims were to investigate whether or not ENDS can cause vascular endothelial dysfunction (VED) similar to that induced by traditional cigarettes and to characterize the cellular and molecular mechanisms of such effects. Male C57/BL6 mice were exposed for 32 weeks to vaporized nicotine (VN), TS (4 hrs/day, 5 days/week), or for 6 weeks of infused nicotine (1.5 mg/kg). A smoke/vape generating system (Cairo University Laboratory Inc., Cairo, Egypt) was used to generate TS and VN. The system was designed, tested, and certified by a licensed engineer to deliver TS (35-ml puff of 2-seconds duration once every 30 seconds) and VN (55-ml puff of 4-seconds duration once every minute). 3R4F reference research cigarettes and locally available e-liquid containing 2.4% nicotine were used to generate TS and VN, respectively. VED was evident by observing impairment of acetylcholine (Ach)-induced endothelium-dependent relaxation, with a shift to the right and downward in the Ach-concentration response curve in thoracic aortic segments of test groups. Aorta of test groups, compared to controls, showed increased reactive oxygen species (ROS) generation, increase oxidative damage and elevation of protein carbonylation. Tetrahydrobiopterin (BH4) level and endothelial nitric oxide synthase (eNOS) expression and phosphorylation were decreased in the aorta homogenate of test animals, compared to controls. Furthermore, all groups of exposed animals showed variations in blood pressure and blood pressure compared to controls. Thus, ENDS, and infused nicotine induced VED and hypertension, with TS showing the highest effects, through the generation of ROS that depleted BH4 and impaired eNOS activation. Overall, our study shows that ENDS causes vascular endothelial function similar to that induced by TS, and may trigger vascular disease through similar mechanisms.
Toluene diisocyanate (TDI) is a highly reactive compound used in the production of polyurethane foams and other industrial products. Human exposure to TDI occurs mainly through inhalation of vapors in occupational settings where TDI is produced or used, but dermal exposure to TDI is also possible during some production or use operations.

In a recently published epidemiological study, Pinkerton et al. (2016) reported increased lung cancer risk in workers with potential dermal exposure to TDI. To evaluate the hypothesis that dermal, but not inhalation, exposure to TDI may be associated with an increased risk of respiratory cancers in humans, we critically reviewed and integrated the evidence from relevant epidemiological, toxicological, and toxicokinetic studies of TDI. We evaluated the quality of the studies we identified, then determined how these studies’ strengths and limitations could impact the interpretation of their results. We then applied the Bradford Hill considerations for causal inference to integrate the evidence from these studies to address whether TDI is likely to be carcinogenic via the dermal exposure route. In addition, we considered the potential for confounding and bias in epidemiological studies, as this potential can affect the ability to make causal inferences based on these studies’ results.

In our analysis, we found that the reported associations between TDI exposure and respiratory cancers in epidemiological studies of polyurethane foam workers do not support TDI being a causal factor for those cancers, because there are other explanations that are more likely than causation, such as confounding by smoking and low socioeconomic status. Experimental animal and genotoxicity studies indicate that the carcinogenic potential of TDI depends on its conversion to toluene diisocyanate (TDI). TDI is not known to induce tumors in rodents. TDI has no evidence of TDA being systemically available after dermal exposure to TDI. Also, systemic uptake of TDI is very low after dermal exposure, and any absorbed TDI is more likely to react with biomolecules on or below the skin surface than to form TDA. Even if some TDA formation occurs after dermal exposure to TDI, TDA does not induce respiratory tumors in experimental animals after either dermal or oral exposure. Based on our analysis, we conclude that the available evidence indicates that dermal TDI exposure does not cause respiratory cancers in humans.

**2823 Derivation of a Parenteral PDE Value for Zirconium Pursuant to the ICH Q3D Elemental Impurities Guideline**

Elemental impurities may arise from various sources and their levels in drug products must be controlled within acceptable limits. The International Conference on Harmonisation (ICH) has derived permitted daily exposure (PDE) values for some elemental impurities, but not for zirconium (Zr). The current work was performed to derive a PDE value for Zr pursuant to the methodology outlined in the ICH Q3D elemental impurities guideline. This involved identifying the most suitable point of departure and applying modifying factors to account for species extrapolation (F1), individual variability (F2), study duration (F3), severity of toxicity (F4), and effect level (F5). Following identification and review of publicly available nonclinical information for various Zr salts, the PDE value for Zr was based on the results of a combined repeat-dose oral toxicity/reproductive and development toxicity screening study in Sprague-Dawley rats that was GLP-compliant and conducted per OECD guidelines. In this study, no toxicologically relevant systemic or reproductive/developmental effects were observed in parenteral animals or offspring at Zr acetate dose levels that provided Zr up to 530 mg/kg/day; thus, this was considered to be the NOAEL. Applying a cumulative modifying factor of 500 (F1 = 5, F2 = 10, F3 = 10, F4 = 5, F5 = 1) to the NOAEL resulted in an oral PDE value of 1.06 mg/kg/day. Given the reported low oral bioavailability of zirconium compounds (<1%), a modifying factor of 100 to extrapolate from oral to parenteral exposure was applied (per ICH Q3D). A final 10-fold factor was applied to reduce potential systemic Zr exposure to a level within reported background circulating levels in humans, resulting in a parenteral PDE value of 0.0606 mg/kg/day (equivalent to 0.053 mg/day, or 53 µg/day, based on a 50 kg body weight). With regard to local effects, the results of various studies indicate that Zr compounds are neither skin irritants nor sensitizers. The major outcome of this work is the establishment of a parenteral PDE value of 53 µg/day for Zr. This PDE value can be used to assess risks associated with exposure to Zr as an impurity in parenteral drug products.
the revised standard, and 2) to quantify dermal loading and hand-to-mouth transfer efficiency of selected FRs from these products. Five manufacturers of baby products containing PUF, one bath product, three changing pads, and one sleep positioner, were purchased in 2015 in both California and Colorado (n=10) and analyzed for the presence of FRs. Tris (1-chloro-2-propyl) phosphate (TCP) was found in all ten products tested (203 to 43,000 μg/g). Tris (2-chloro-1,3-diphenyl) phosphate (TDCPP) was found in only a single product (63 μg/g). Two products that contained the highest levels of TCPP, the bath product and one of the changing pads, were each handled by three participants for 15 s, and a wipe sample of one hand was collected to determine dermal transfer. After accounting for the average of TCPP found in the lab blank and other lab materials (range <0.010 μg/L – 0.237 μg/L), the amount of TCPP loaded onto the hands of the participants was below detection.

Additionally, we evaluated hand-to-mouth transfer from the three participants handling the bath product; after handling, the participants presented three fingers from their second hand into saliva. We concluded that the transfer of TCPP from hands to saliva was below detectable levels. It is hypothesized that the covering foam components reduced transfer to hands. These data show that FRs continue to be added to baby products; however, the transfer of FRs onto hands and exposures as a result of hand-to-mouth transfer from these products is expected to be negligible for TCPP. Further research is needed to estimate the role of other routes of exposure, such as inhalation and dermal absorption.

**2827 Evaluation of Interspecies Differences in Susceptibility to Thyroid Perturbation**

S. Pacheco Shubin, and T. A. Lewandowski, Gradient, Seattle, WA.

The potential effect of goitrogenic chemicals on thyroid homeostasis has become a significant concern in the field of regulatory risk assessment. In particular, the developing brain can be affected by changes in maternal thyroid hormones during pregnancy. Much of the experimental work evaluating the thyroid effects of goitrogenic chemicals has been conducted in rats, both as a matter of convention and to allow comparison to the existing scientific literature. Yet rats (or rodents more broadly) are stated to be particularly sensitive to disruption of thyroid homeostasis due to a number of physiological factors these animals do not share with humans (e.g., shorter thyroid hormone half-life, lower colloid stores). While the basic elements of thyroid homeostasis are conserved across species, there appear to be important species differences in sensitivity, which can in turn impact the use of data obtained in rats to derive human safe levels of exposure. We investigated published studies of eight different thyroid active compounds (methyl iodide, ethylene thiocyanate, perchlorate, nitrate, resorcinol, propyl uracil, and sulfamethazine), which produce their adverse effects by interfering with different aspects of thyroid homeostasis. The thyroid disrupting effect of each of these chemicals has been studied in rats as well as at least one other species (e.g., mice, rabbits, dogs, and/or monkeys) which allows for comparison of cross-species sensitivity. Among the studies we reviewed, the same doses that produced effects in the rat often either produced no effects at all or effects of much lower severity. For example, five-week exposures to propyl uracil (a thyroid perturbing inhibitor) at 30 mg/kg produced classic goitrogenic effects (decreased triiodothyronine [T3] and thyroxine [T4], increased thyroid stimulating hormone [TSH]) in rats but no effects in mice at the same dose and similar time frame. The exceptional sensitivity of the rat thyroid to perturbation by exogenous chemicals suggests that caution is warranted in the use of such data for quantitative risk assessment. We also proposed that future studies of potential thyroid hormone effects consider use of alternative animal models in addition to, or in lieu of, rats.
ture database was searched through November 2016. To be included, a study had to assess exposure to environmental chemicals prior to two months of age or 14 days in humans or rodents, respectively. The search returned 18,218 studies that were screened for relevance. Forty human studies, 50 animal studies and 41 reviews were identified as relevant. Human study designs included case-control (n=30), cohort (n=9) and ecological (n=1). The most frequently reported outcomes were: mercury (n=13), air pollution (n=12) and particulate matter (n=11). Rodent studies were considered relevant if they included at least one measurement of deficits in reciprocal social communication and social interaction or repetitive stereotyped behaviors. Twenty five environmental chemical exposures were investigated in developing rodent data. Of these, chlorpyrifos (n=9), mercury (n=5) and lead (n=3) were the most frequently reported. Seven reviews (17%) were systematic-reviews or meta-analyses, but only five assessed the quality (risks of bias) of the primary studies and all were limited to human studies. Pesticides, mercury and air pollution were the most reviewed environmental expo-
sures. This scoping review characterizes and summarizes the primary research and reviews that have been conducted on early life exposure to environmental chemicals and autism. Whereas most research effort to-date has been dedicated to assessing mercury and components of air pollution, other environmental chemicals have not been adequately studied. Validated animal models could improve the efficiency by which environmental chemicals are investigated and provide a way to prioritize chemicals for evaluation in humans.

2829 The Risk Assessment on Human Health Based on Environmental Concentration of Medicinal Chemicals for Human Use in Urban Rivers in Japan

1Teikyo Heisei University, Tokyo, Japan; 2Tokyo Metropolitan Institute of Public Health, Tokyo, Japan; and 3National Institute of Health Sciences, Tokyo, Japan.

Chemicals used as the active ingredients in medicines are discharged into the aquatic environment. Although the amount of each chemical might be small present, it has been feared affect derived by the chemical and physiological properties to the organism. However, we still know little about what kind of impact on wildlife in the environment and on human health. In view of the background, we have measured the actual environmental concentrations of 31 kinds of active ingredients in urban rivers in Japan, once per season in 2015-2016. The active ingredients exceeded 100ng/L at maximum detected concentrations were sulpiride, crotamiton, acetoaminofen, clarylcyromycin, olmesartan, lorzepam, valsartan, DEP, bezafibrate, epinastine, irbesartan, ketoprofen, losartan and candesartan. Among target ingredients, the detection concentration of active ingredient in medicines for the lifestyle-related diseases tended to be higher. There was a tendency higher concentrations were detected in winter during four seasons while the flow rate of the river decreased. It must be con-
sidered that five kinds of active ingredients used for antihypertensive agents were detected in high concentrations exceed 100ng/L. These ingredients might be discharged in the same amount every day for long term and are thought to effect on wildlife in the environment and on human health. The similar mechanism due to their similar structure. Evaluating on human health effect, if these five ingredients coexist, the total value of the ratio of the maximum detected concentration to the minimum daily dose became 0.0038, which makes it difficult to keep a three-digit margin. Regarding the case of lorzepam, its value was 0.004 with only one ingredient. It is necessary to grasp the daily actual concentration, and it may be necessary to consider the correspondence. In the future, it would need to be evaluated in consideration the combined action of multiple active ingredients based on the mechanism of action. This research is supported by the Research on Regulatory Science of Pharmaceuticals and Medical Devices from Japan Agency for Medical Research and development,AMED.

2831 Derivation of an Oral Reference Dose for Trimethyl Silanol

R. Galante1, K. Licko2, and M. H. Whitaker3. 1ToxServices LLC, Ann Arbor, Mi; 2Water Quality Association, Lisle, Il; and 3ToxServices LLC, Washington, DC.

Trimethyl silanol is an organosilicon compound used as the precursor to a variety of silicone materials, including polymeric/oligomeric fluids, elastomers and resins. Trimethyl silanol is identified as a volatile extractible from drinking water using US EPA Method 524.2. This poster describes an oral reference dose (RfD) for trimethyl silanol to assess health risks following oral exposure. Trimethyl silanol is predicted to partition into the lipid bilayer of membranes and cross into the blood brain barrier to cause toxicity. In vivo genotoxicity studies, there is no evidence of mutagenicity, but there is mixed evidence of clastogenicity. In vivo chromosomal aberration assays in rats are negative for clastogenicity. Transient narcotic effects are reported in repeated dose experiments in rodents at oral doses as low as 150 mg/kg/day, and inhalation concentra-
tions of 2.2 mg/L/6hr in an OECD Guideline 412 study. At higher oral doses in rat studies, adverse effects include growth retardation (≥350 mg/kg/day) and hepatotoxicity (750 mg/kg/day), including increased liver weight and proliferation of the bile ducts are reported. A prenatal developmental toxicity study in rats reported reduction in fetal weight, delayed ossification and increased incidence of cartilaginous variations at a maternal oral dose of 450 mg/kg/day, in the presence of maternal toxicity. A NOAEL of 50 mg/kg/day is assigned for this study, based clinical signs of toxicity among dams, including uncoordinated movement and decreased activity, and decreased body weight gain among dams at trimethyl silanol doses at and above 150 mg/kg/day. A NOAEL of 50 mg/kg/day was selected as the point of departure for derivation of trimethyl silanol’s RfD. Using the BMDL scaling approach, a human equivalent dose (NOAELHED) of 13 mg/kg/day was derived from the 50 mg/kg/day NOAEL. Using total uncertainty factors (UF) of 1,000 (3x and 10x for inter- and intra-species extrapolation, respectively, 3x for subchronic to chronic extrapolation, and 10x for database deficiency, as no chronic toxicity, carcinogenicity, or two-generation reproductive toxicity studies are available), a 0.013 mg/kg/day oral RfD was calculated as the quotient of the NOAELHED and combined UF. This oral RfD can be used to derive a chronic drinking water action level for trimethyl silanol.

2830 Oral Risk Assessment and Acceptable Drinking Water Levels for the Organophosphate Flame Retardant Tris (1-Chloro-2-Propyl) Phosphate (TCP) (TCP)

K. D. Cox, and V. Bhat, NSF International, Ann Arbor, Mi.

General population exposure to tris (1-chloro-2-propyl) phosphate (TCP) may occur from the widespread use of this flame retardant in rigid and flexible polyurethane materials, some of which have drinking water contact applications. The purpose of the present assessment was to incorporate toxicity data from both published and unpublished studies in addition to recent NTP data in order to derive an oral RfD from which to establish drinking water criteria. Absent any human health effect data, hazard identification relied on laboratory animal data. Identified treatment-related effects following subchronic oral exposure to TCP in rats and mice included weight loss, lymphocyte depletion as well as hepatic, renal and thyroid effects. In an OECD guideline-compliant two-generation reproduction study in Wistar rats, a significant decrease in uterine weight was reported in all treated groups of F1 female rats and high-dose F1 females as well as increased incidences of runts in all treatment groups. Two developmental studies in rats reported minimal treatment-related adverse effects. The weight of evidence indicates the potential for mutagenic activity in vitro. No in vivo mutagenicity data were identified while in vivo assessments of clastogenicity were either negative or reported effects at high-doses likely exceeding the MTD. Epidemiological or chronic animal data are not available since results from recently conducted NTP bioassays have not yet been released and as such, there is Inadequate Information to Assess Carcinogenic Potential of TCP. Recognizing that a read-across of carcinogenicity based on structurally similar compounds is confounded by differences in metabolism, target organs, severity of effects and potency. The lowest benchmark dose (BMDL010) of 16 mg/kg-day was selected as a weight-of-evidence point-of-departure for the oral RfD, based on the human equivalent BMDL010 of 16 mg/kg/day for the increment in mean relative uterine weight and human equivalent BMDL010 of 16 mg/kg/day for the litter-based incidence of runts at PND 21. Using a total uncertainty factor of 300x (3x interspecies, 10x intraspecies, 3x subchronic, 3x database), an oral RfD of 0.05 mg/kg/day was determined for TCP. When considering RfD or MRL values established for other organophosphate flame retardants, the present RfD value is comparable. The resulting Total Allowable Concentration in drinking water was 0.4 mg/L.
K. Towle1, D. Drechsler2, F. Fung3, R. Novick4, D. Paustenbach4, and A. Monnot1, 1Cardno ChemRisk, San Francisco, CA; 2Cardno ChemRisk, Boulder, CO; 3Cardno ChemRisk, Aliso Viejo, CA; and 4Cardno ChemRisk, Jackson Hole, WY.

Kathon CG is a commonly used cosmetic grade preservative that contains active ingredients methylchloroisothiazolione (MCI) and methylisothiazolione (MI), which have been identified to have a high allergen potential. The objective of this study was to perform an evaluation of daily exposure to Kathon CG via application of various personal care products. We estimated the dermal exposure to MCI and MI following daily application of rinse-off (body wash and shampoo) and leave-on (body lotion and face cream) personal care products. We calculated an estimated daily dermal exposure using the amount of product applied, a retention factor, the MI/MCI concentration in the product, and the surface area of the body where the product was applied. We assumed that the products contained the maximum recommended concentration of Kathon CG: 0.1% by weight in rinse-off products and 0.05% by weight in leave-on products. The active ingredients MCI and MI compose 1.15% and 0.35% of Kathon CG, respectively. We used the 50th and 95th percentile amount of product applied per day among adult women from consumer use practice data, and based on dermal modeling data, we conservatively assumed a maximum skin adherence of 10 mg/cm². Additionally, per consumer data, we assumed one application of shampoo, body wash, and body lotion per day, and two applications of face cream. We applied a retention factor of 0.01 in rinse-off products and 1.0 in leave-in products. We compared estimated daily dermal exposures (µg/cm²) to reported MCI and MI no expected sensitization induction levels (NELSILs) of 0.83 µg/cm² and 15 µg/cm², respectively. The estimated product-specific daily dermal exposures did not exceed the NELSILs in either the 50th or 95th percentile exposure scenarios. Under the 95th percentile exposure scenario, the highest daily dermal exposure was from face cream (6.7x10⁻² µg/cm² [MCI] and 2.1x10⁻² µg/cm² [MI]), while the lowest daily dermal exposure was from body wash (1.9x10⁻³ µg/cm² [MCI] and 5.9x10⁻³ µg/cm² [MI]). This evaluation provides evidence that use of the products under the examined exposure scenarios does not result in an exposure above the MI and MCI NELSILs, and that use of different products may drive an individual's exposure to MI and MCI.

2833 Assessment of Risks to Home Health Care Workers from Exposure to Nebulizer-Administered Pharmaceuticals during Patient Care
E. Frank1, S. Ishau1, S. Reutman1, J. Reichard1, and A. Maier1, University of Cincinnati, Cincinnati, OH.

Home health care workers (HHCWs) are one of the fastest-growing workforces in the US public sector. The home healthcare workplace presents numerous challenges for occupational risk assessment because the agents are highly variable environments and engineering controls for environmental risks, such as ventilation, are often absent. The use of inhaled medications administered via nebulizer is very common in home healthcare. Nebulizers used in healthcare are not self-contained, and medications administered via nebulizer are used in a use simulation. The objective of this work is to assess risks of HHCW exposure to common nebulizer-administered drugs when they administer care in the home. Based on consultation with subject matter experts in home healthcare, we assessed the exposure and health risks of three medications commonly encountered in home healthcare for assessment. These were albuterol, budenoside, and ipratropium. Acceptable daily exposure (ADE) limit values were derived for the inhalation route based on clinical safety/efficacy and non-human toxicity data for each drug with consideration of short-term vs chronic dose-response and local vs systemic effects. Occupational exposure scenarios were determined based on expert consultation and inhalation dosimetry relevant to these was modeled using the Multiple Path Particle Dosimetry model and data characterizing nebulizer aerosols from the HHCW use simulation. Deposition of nebulizer aerosols was increased at tidal volumes and breathing rates representing moderately heavy work as compared to resting levels. This increased deposition in the head region, however, deposition to the tracheobronchial and pulmonary regions was slightly reduced in the heavy work scenario. Mass deposition rate increased sharply as a function of airborne concentration as the distance from the nebulizer output closed to 6’. Variation of body posture did not significantly impact the deposited dose of nebulized medication. Together, these data provide industrial hygienists with risk information applicable to the most common use scenarios of nebulized medicine in the home healthcare workplace.

2834 Investigation of Multiple Modes-Of-Action of Octylphenol and Nonylphenol and Their Relevance to Human Health Risk Assessment
J. Klapacz1, K. Coady1, W. Drogue2, T. Osimitz2, and B. Loeys3, 1The Dow Chemical Co, Midland, MI; 2Science Strategies LLC, Charlottesville, VA; and 3RegNet Environmental Services, Washington, DC.

Nonylphenol (NP) and 4-tert-octylphenol (OP) are data-rich compounds that have a range of adverse effects, some linked to estrogenicity, but all having demonstrable thresholds. Based on the effects seen in rat multigenerational in vivo guideline tests, the weak estrogenic activity of NP and OP does not predict the entire suite of observed adverse effects in biological systems. In the case of OP, the Points of Departure effect (decreased body weight and body weight gain) at the Lowest Observed Adverse Effect Level (LOAEL) is not due to an estrogenic MOA. For NP, estrogenic activity (accelerated vaginal opening in offspring) as well as non-reproductive systemic toxicity (kidney effects and decreased sperm motility) are found at the same concentration. The LOAELs for each of these effects were below combustible cigarette yields. These findings indicate that NP and OP have multiple modes of action (MOAs) that influence the toxic responses in biological systems. In a battery of high throughput in vitro assays, (i.e., ToxCast®), NP and OP both interacted with multiple biological pathway targets below their lower cytotoxicity limits, including estrogen receptor, pregnane-X receptor/xenobiotic metabolism, vitamin D receptor, mitochondrial toxicity, cell cycle targets, and cytokines. Moreover, in vitro and in vivo mechanistic studies also demonstrate presence of multiple MOAs such as endocrine activity, oxidative stress, calcium signaling perturbations, cellular toxicity and inflammation/immune responses that can contribute to observed atypical effects. Overall, the evidence demonstrates that multiple biological pathways are perturbed by NP and OP within the same concentration range as estrogenic effects. Thus, multiple MOAs need to be considered when defining the Points of Departure for these compounds, and their weak estrogenic activity may not be the most sensitive effect for use in hazard and risk assessments. Concentrations of NP and OP detected in human biomonitoring studies are orders of magnitude below Points of Departure for human health. The NP and OP case studies illustrate the need to incorporate the concept of potential MOAs and their potential to contribute to observed effects, in the context of expected human exposure in characterizing potential risk to humans. Sponsored by ALKYLPHENOLS & ETHOXYLATED RESEARCH COUNCIL.

2835 Electronic Nicotine Delivery Systems (ENDS) Open Devices and Market Fruit Liquid Chemical Risk Assessment
D. T. Szabo1, A. Hudson2, A. Amantana1, and C. Culbert1, 1RAI Services Company, Winston-Salem, NC; and 2R.J. Reynolds Tobacco Company, Winston-Salem, NC.

Open electronic nicotine delivery systems (ENDS) are refillable devices and have grown in popularity within recent years. 2017 Market analysis indicates fruit flavors are part of a top selling category of liquid formulations. Identification of interactions between liquid formulations and orally-inhaled devices may mitigate potential unexpected consumer exposures. In this study, nineteen popular fruit flavored e-liquid mixtures and their open ENDS generated aerosols were screened for thirty compounds. Aerosolization used a machine puffing regime of 55 mL puff volume, 30 second interpuff and 3.3 second puff duration (0.3 seconds for push button actuation). Liquid and aerosol measurements include propylene glycol, glycerol, flavor ingredients, carbonyls, and metals. Flavor ingredients detected with higher frequency included diacetyl, acetoic acid, acetic acid, acetyl propionyl, benzoaldehyde, butyric acid, and propionic acid. Although considered generally recognized as safe (GRAS) by recognized bodies for oral consumption, these ingredients have been identified as possible inhalation hazards. ENDS aerosol levels of these flavor ingredients underwent a risk assessment with results indicating lower levels than the lowest observed adverse effect, and lower than estimated non-cancer hazards from relevant regulatory-derived thresholds. Lead, chromium, and nickel were not present in liquids but detected in aerosols suspecting the device as the source of leachates. The majority of formaldehyde yields generated from ENDS were below combustible cigarette yields. These findings indicate that the presence of carbonyls and metals were dependent on liquid formulation interaction with the device. Generally, the lower yields of select analytes from ENDS, compared with combustible cigarettes, supports migration of current adult smokers to ENDS would be a benefit to public health.
### 2836 An Inhalation Risk Assessment of Indium and Indium Compounds for Derivation of an Occupational Exposure Limit

K. Unie1, A. Burdick2, B. Brooks2, A. Madl3, J. Dimitri4, W. Davis2, J. Mason6, R. Sinor2, D. Huet5, M. Zarick2, and B. Vtvermoes3. 1Cardno ChemRisk, Pittsburgh, PA; 2AIBM, Boulder, CO; 3Cardno ChemRisk, Orange County, CA; 4AIBM, San Jose, CA; 5AIBM, Essex Junction, VT; 6AIBM, Broom, QC, Canada; and 7AIBM, Yorktown Heights, NY.

Indium is an important metal used in many modern-day technologies such as flat panel displays, solar panels, and other microelectronic devices. Over the last decade, the industrial use of indium has grown appreciably due to increased demands for consumer and commercial electronics. The increased industrial use of indium has also lead to a greater number of potential occupational exposures to indium. Case reports have emerged describing a progressive and often irreversible lung disease in a small number of workers primarily employed in indium production and reclamation facilities. OSHA has not yet established an occupational exposure limit (OEL) for indium. Both NIOSH and ACGIH have evaluated OELs for Indium compounds, but these recommendations were made more than 20 years ago. The purpose of this evaluation was to comprehensively review the current toxicological information pertaining to indium to derive an updated OEL for indium and indium compounds. Based on the current data, three critical health endpoints were identified: alveolar proteinosis (animal and human), bronchiolo-alveolar hyperplasia (animal), and lung tumors (animal). The available data suggest that cellular infiltration such as accumulation of alveolar macrophages, chronic inflammation, and remodeling (e.g., proteinosis, fibrosis, hyperplasia) are precursor events to neoplasia. For this analysis, two different approaches were used to derive an OEL. Depending on the dose-response curve for each end-point, a LOAEL approach (alveolar proteinosis) or bench mark dose approach (hyperplasia, lung tumors) was used to derive a point-of-departure (POD) from chronic inhalation studies conducted in rats exposed to indium oxide. Each POD was evaluated based on a weight-of-evidence consideration of toxicokinetics, toxicodynamics, and other uncertainties. Overall our analysis supports the use of animal data for the derivation of an OEL for respirable indium of 0.03 µg/m³.

### 2837 Dose-Response Effects of Dietary Methionine Intake on Radiation-Induced Toxicity: An Experimental and Computational Study

L. E. Ewing1, A. Lumen2, I. R. Miousse1, R. Pathak1, S. Garg1, C. Skinner1, S. Melnyck1, H. Hendrickson1, R. Landes1, A. Tackett1, M. Hauer-Jensen1, and I. Koturbash1. 1University of Arkansas for Medical Sciences, Little Rock, AR; and 2US FDA/NCTR, Jefferson, AR.

Methionine (Met) is an essential amino acid needed for a variety of processes in living organisms. Ionizing radiation (IR) depletes tissue Met concentrations and leads to reduced DNA methylation and glutathione synthesis. Hence, Met supplemented diet (MSD) was proposed to improve the response to total body irradiation (TBI). To test this hypothesis, we exposed mice to 3 or 8.5 Gy of TBI while feeding either Met adequate diet (MAD) or MSD for 3.5 or 6 days (tissue harvest) or up to 30 days (survival). Strikingly, our studies indicated that MSD, compared to MAD, potentiated acute IR toxicity, resulting in earlier lethality at sub-lethal dose of 8.5 Gy. Early lethality post TBI was also observed after exposure to 3 Gy, a dose generally not associated with mortality. Hind-limb protection during exposure to 8.5 Gy of TBI resulted in 50% mortality by day 9 post-IR in mice on MSD, while 90% of mice fed MAD survived 30 days. These findings suggest the prevalence of gastrointestinal syndrome in MSD-induced acute radiation toxicity. MSD also led to substantial alterations in one-carbon metabolism in proximal jejunum and disbalance between the jejunal and plasma Met concentrations. Thus, we sought to quantify the Met whole-body kinetics and the combinatorial dose-response relationship using computational analysis. A PBPK model is currently being developed to describe systemic and tissue distribution of Met across various doses. Metabolism, the primary clearance pathway for Met, was included in the model in liver, kidney, and small intestine compartments using saturable enzyme kinetics. Oral doses of Met for MAD (650 mg/kg) were simulated and compared with experimental data for model calibration and verification purposes. The first-generation PBPK model predicted the measured systemic exposure of Met and the tissue-specific distribution at MAD. We are currently developing the dose-response model taking into account the PK alterations due to MSD. The findings of the PBPK model calibrated in vivo in mice will be extrapolated to humans with the ultimate goal of assessing the risk of co-exposure to Met and IR and developing appropriate clinical mitigation strategies for adverse effects in cancer patients.

### 2838 A Critical Analysis of the Toxicological Mode-of-Action of Automotive Brake Dust

T. J. Cook1, M. K. Peterson2, and B. D. Beck1. 1Gradient, Seattle, WA; 2Gradient, Leavenworth, WA; and 3Gradient, Cambridge, MA.

The role of inhaled chrysotile-containing brake dust as a causative agent in the development of mesothelioma has been a source of debate with some epidemiological studies reporting a significant association, while others report no association. To address the plausibility of an association between brake dust containing chrysotile and mesothelioma, a critical analysis of the available in vitro and in vivo evidence was conducted to identify plausible mechanisms of action (MOA) and their implication for causality and understanding of dose-response. Using literature from multiple sources, including the National Library of Medicine’s PubMed database, the Scopus literature search engine and TOXNET, and MOA frameworks developed by different organizations such as the International Programme on Chemical Safety (IPCS), we identified two possible MOAs for further consideration: 1) frustrated phagocytosis resulting in an inflammatory response; and 2) direct physical interaction with chromosomes. It was found that the literature better supported frustrated phagocytosis leading to an inflammatory response and that this MOA involves the following sequence of events: 1) deposition of fibers deep into the lung; 2) production of reactive oxygen species (ROS) by macrophages unable to engulf the fibers; 3) inflammatory response and exacerbated ROS production, possibly potentiated by fiber-associated iron; 4) DNA damage subsequent to persistent ROS generation; and 5) dysregulation of cell proliferation, including cells that contain damaged DNA, by growth factors related to the inflammatory response. Fiber type, length, and biopersistence substantially influence this MOA, with studies showing longer and more durable fibers to be more likely to trigger an adverse physiological response. We considered this MOA in the context of the short fiber length, limited biopersistence in animal studies, and limited biological reactivity of chrysotile-containing brake dust, as well as the inconsistent human epidemiological evidence. It was concluded that the evidence supports a threshold dose-response relationship and that there are exposure concentrations of chrysotile-containing brake dust below which no adverse health effects would be expected to occur in humans.

### 2839 Safety in Mice of a Nanovaccine against Nicotine Addiction

M. Ehrlich1, B. S. Jortner2, I. Hinckley3, S. Werre2, K. Boes1, Z. Zhao2, Y. Hu2, and C. Zhang2. 1Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA; and 2Virginia Tech, Blacksburg, VA.

The Zhang laboratory has developed a series of biodegradable lipid-polymeric hybrid nanoparticles as potential vaccines against nicotine addiction. Safety of one vaccine was examined in groups of male, CD-1 mice given a one-time, subcutaneous dose that included 0.356 mg/mL of carrier protein (keyhole limpet hemocyanin (KLH)) in PBS. Doses were administered to provide 0 (vehicle control, Group 1), 25 (low dose, Group 2) or 125 µg (high dose, Group 3) of the KLH carrier protein. A baseline neurobehavioral assessment was performed 3 days prior to dosing, and then again at 1, 2, 4, 7, 14, 28 and 56 days post-dosing (n=10/dose group). Each assessment consisted of clinical observations scored as either normal/abnormal or yes/no (observational category is present/absent) along with a recording of body weight. Evaluation of behavioral endpoints indicated that the groups did not differ for any of the categorical endpoints, which included home cage, open field and reflex assessments. Also, after adjusting for baseline weight, the groups did not differ for all follow-up time points. Cohorts of animals (n=3/dose group/time-point) were sacrificed on post-dose days 1 and 7 to collect tissues for clinical pathology and histopathology. Review of clinical pathological findings did not reveal obvious abnormalities. Histopathological analysis of multiple mouse organs only revealed minimal to moderate focal acute inflammation of the deep dermis and adjacent subcutis of the nanovaccine injection site in 3/3 mice on post-exposure day 1. At day 7 a more chronic appearance of the injection site inflammation was noted, with lymphocytes and macrophages seen in the deep dermis, panniculus muscle and adjacent subcutis. With no detectable lesions outside of the site of injection after nanovaccine administration, results do not tentatively support its safety. Funded by U01DA036850 to C. Zhang.
Alzheimer’s Disease (AD) is a neurodegenerative disease with the majority of occurrences being sporadic in nature. In this sporadic form, environmental factors such as air pollution are believed to contribute to the pathological development of the disease. Of particular concern is exposure to the ultrafine (UFP, <0.1 μm in aerodynamic diameter) fraction of particulate matter air pollution. UFPs can deposit in all regions of the respiratory tract, evade macrophage mediated clearance, undergo secondary translocation, and induce inflammation. We hypothesize that exposure of a triple transgenic AD mouse model (3xTgAD) to concentrated UFPs can accelerate AD progression and affect performance in tests of cognitive function as compared to filtered air (FA) exposed mice. UFPs from ambient air were concentrated using the Harvard Ultrafine Concentrated Ambient Particle System (HUCAPS). Cohorts of male mice were exposed at 2.5-3 months of age for 2 weeks (4 hours/day, 4 days/week) to FA or HUCAPS. Starting one-month following exposure, a battery of behavioral tests was performed to assess spatial learning and memory, recognition memory, and locomotor function. We previously showed that the overall rate of spatial learning was diminished in the radial arm maze test following HUCAPS exposure, independent of genotype. Further analysis using linear mixed modeling shows that these deficits resulted from decreased recognition memory in all regions due to HUCAPS exposure while working memory remained unaffected. No effects were found on long-term recognition memory (novel object recognition test), but the initial session showed lower exploratory activity in non-transgenic (NTg) mice and HUCAPS exposure diminished exploratory activity in both NTg and 3xTgAD mice. Locomotor testing showed that basal locomotor activity for NTg mice was lower than in the 3xTgAD mice and HUCAPS exposure diminished exploratory activity specifically for 3xTgAD mice. Overall these results suggest that HUCAPS exposure prior to onset of AD pathology can diminish the rate of learning by inhibiting reference memory while having no effect on working or long-term recognition memory and that this effect is not dependent on genotypic background. Funding Sources: NIH R01ES020332, T32ES007026, P30ES001247.

Traffic-Generated Air Pollution-Exposure Mediated Expression of Factors Associated with Onset and/or Progression of Multiple Sclerosis in a Female Mouse Model

Z. Ghanbari Adivi1, J. Lucero1, N. Simpson1, J. D. McDonald2, and A. K. Lund1. 1University of North Texas, Denton, TX; and 2Lovelace Biomedical Research Institute, Albuquerque, NM.

Multiple Sclerosis (M.S.) is disorder of the central nervous system (CNS) associated with inflammation, aberrant immune signaling, and demyelination, which has a higher prevalence in females. Over the past several years, epidemiological studies have reported strong associations between air pollution exposure and occurrence of M.S.; however, the mechanisms involved have not yet been fully elucidated. Thus, we examined the sequence of events leading to a mixture of pulmonary and engine emissions (MVE) on the brains of female Apolipoprotein (Apo) E-/- mice, both ovary-intact (OV+) and ovariectomized (OV-). Mice were exposed to either filtered air (FA, controls) or mixed gasoline and diesel vehicle emissions (MVE: 200 PM, μg/m³) for 6hr/d, 7 d/wk, for 30d. We then analyzed MVE-exposed mediated alterations in myelination, CD4+ and CD8+ T cells, and expression of reactive oxygen species (ROS) via immunohistochemistry and DHE staining, respectively. Alterations in interleukin (IL)-1β, tumor necrosis factor (TNF)-α, estrogen receptor (ER) α, estrogen receptor (ER) β, and progestrone receptors A/B (PRo A/B) transcript were analyzed via real-time RT-qPCR. MVE-exposure mediated significant alterations in myelination across multiple regions in the cerebrum (decreased by as much as 50%), which was associated with a 4-fold increase in CD4+ and 5-fold increase in CD8+ positive staining. We also observed a 2-fold increase of ROS in the CNS, as determined by DHE, which appeared to be related to MVE-exposure vs. ovary status. MVE-exposure induced expression of PRoA/B (18-1, 5-fold) and TNF-β (1, 2-fold) mRNA in the cerebrum that was strongly associated with ERα expression, which was interestingly observed to be reduced in expression with MVE-exposure. Modification of PRoA/B expression in the CNS was not significant. In conclusion, these findings suggest that exposure to inhaled MVE may mediate changes in ER expression, associated with increased CD4+/CD8+ infiltration into the CNS, regional demyelination, and induction of inflammatory mediators IL-1β, TNF-α, and ROS in female mice +/- ovaries. Research funded by NIEHS R00 ES0126586 and UNT RIG Grant GA9306 to A.K.L.

Assessment of Study Quality (Risk of Bias) in Understanding the Relationship between Congenital Heart Defects (CHDs) and Exposures to Trichloroethylene (TCE)

J. D. Urban1, S. Harvey1, L. C. Haws1, and D. Wilkoff2. 1ToxStrategies, Inc., Austin, TX; 2ToxStrategies, Inc., Katy, TX; and 2ToxStrategies, Inc., Asheville, NC.

In the US EPA IRIS assessment of TCE, the Agency selected CHDs obtained in a rat drinking water study as a sensitive endpoint for development of both the RFD and RIF. This decision has been controversial due to notable study limitations and the inconsistency of the findings relative to the rest of the TCE literature. Due to “concerns raised about study quality,” the TCE-CHD literature was recently re-evaluated in what was termed a “systematic evaluation” (Makris et al., 2016). While this re-evaluation has the appearance of a “systematic review” (SR), it lacks several critical elements of an SR, most notably an assessment of risk of bias (RoB) - a measure of confidence in whether the design and conduct of a study compromised the credibility of the link between exposure and outcome. Herein, we evaluated RoB for the TCE-CHD human and animal literature and integrated such using the NTP OHAT approach. To account for critical study design features of animal studies, some of the relevant RoB domains in the NTP OHAT RoB tool were refined and expanded. The single animal study reporting TCE-CHD effects was found to have high RoB for multiple domains, including selection bias and performance bias. Most of the remaining animal studies in the evidence base demonstrated low RoB for these and other domains. RoB was present for all studies for study group concealment and blinding as these elements were generally not reported by study authors. The human studies tended towards high RoB in the domains of detection bias (e.g., deficiencies in exposure characterization) and confounding bias; one human study was insufficient for RoB analysis (ecological study). Integration of RoB results with other factors (e.g., inconsistency, lack of dose-response, low magnitude) supports a moderate to high level of confidence that TCE is not associated with CHDs. Results of this evidence-based approach suggest that the single CHD-positive study is unreliable for use in developing toxicity factors based on: high RoB, inconsistency with animal studies of lower RoB, and a limited human dataset that does not demonstrate causality. These results demonstrate the importance of assessing study quality (recommended by NAS and a required component of TSCA assessments) and highlight the need to re-evaluate the current toxicity values for TCE using an evidence-based approach that integrates data quality.
Ten Factors for Considering the Mode-of-Action of Cr(VI)-Induced Intestinal Tumors in Rodents

C. M. Thompson1, M. Suh2, D. M. Proctor3, L. C. Hawks4, and M. A. Harris1. 1ToxStrategies, Katy, TX; 2ToxStrategies, Mission Viejo, CA; and 3ToxStrategies, Austin, TX.

The determination of whether a chemical induces a specific cancer through a mutagenic or non-mutagenic mode of action (MOA) plays an important role in whether linear or nonlinear low-dose extrapolation is used to derive safety criteria. Currently, no formal framework exists for determining whether environmental chemicals act through a mutagenic or non-mutagenic MOA. As a result, most MOA determinations are made on an ad hoc basis. Eastmond (Mutat Res 751 (2012)) recently conducted a systematic investigation of MOA determinations by U.S. and international regulatory agencies and organizations, and identified 10 key factors that influence MOA determinations. These factors include: i) nature of tumors, ii) mutations in tumors, iii) chemical properties, iv) toxicokinetics, v) structural similarity to other carcinogens, vi) understanding relevant genotoxicity assays, vii) in vivo genotoxicity, viii) origins of observed genotoxicity, ix) data quality and reproducibility, and x) evidence for alternative MOAs. These 10 factors were used to assess the likelihood of a mutagenic or non-mutagenic MOA for gastrointestinal tumors induced by oral exposure to hexavalent chromium (Cr(VI)) in drinking water. Comprehensive assessments were conducted on in vivo genotoxicity, toxicokinetics, and MOA. To our knowledge, this is the first demonstration of using the 10 factors identified by Eastmond for making MOA determinations. Based on these analyses, we conclude that the MOA for Cr(VI) induced gastrointestinal tumors is non-mutagenic. Comparisons between Cr(VI) and intestinal carcinogens previously determined to have non-genotoxic MOAs revealed similar data sets, thus further supporting the MOA conclusion for Cr(VI). As such, threshold risk assessment approaches for oral Cr(VI) exposure are appropriate. The analyses also indicate that an adverse outcome pathway (AOP) for intestinal carcinogenesis mediated by chronic villus wounding and regenerative hyperplasia would benefit future risk assessment efforts of intestinal carcinogens.

Toxicity and Recovery in the Duodenum of B6C3F1 Mice following Treatment with Intestinal Carcinogens; Captan, Folpet, and Hexavalent Chromium: Evidence for an Adverse Outcome Pathway

C. M. Thompson1, J. C. Wolf2, M. Suh2, D. M. Proctor3, L. C. Hawks4, and M. A. Harris1. 1ToxStrategies, Katy, TX; 2ToxStrategies, Experimental Pathology Laboratories, Sterling, VA; 3ToxStrategies, Mission Viejo, CA; and 4ToxStrategies, Austin, TX.

High concentrations of hexavalent chromium [Cr(VI)], captan, and folpet induce duodenal tumors in mice. Many regulatory agencies have concluded that captan and folpet induce duodenal tumors by non-genotoxic threshold mechanisms, despite some evidence for genotoxicity in vitro. Recent studies on the effects of Cr(VI) in the small intestine support that the mode of action (MOA) for Cr(VI)-induced tumors involves non-genotoxic threshold mechanisms. Evidence is mounting that there may be a generic adverse outcome pathway (AOP) for intestinal tumors mediated by chronic villus wounding and regenerative crypt hyperplasia. Using standardized tissue collection procedures and diagnostic criteria, we compared the duodenal histopathology in B6C3F1 mice following exposure to captan, folpet, and Cr(VI) to determine whether they share similar histopathological characteristics. B6C3F1 mice (n=20 per group) were exposed to 180 ppm Cr(VI) in drinking water, 12000 ppm captan in feed, or 16000 ppm folpet in feed for 28 days. After 28 days of exposure, examination of H&E stained transverse sections revealed villus enterocyte hypertrophy and mild crypt epithelial hyperplasia in all exposed groups. A subset of mice allergic to recover after 38 days of duodenal samples were generally indistinguishable from those of unexposed mice. The changes in the villi and lack of observable damage to the crypt compartment suggests that toxicity was mediated in the villi, which is consistent with earlier studies on all three agents. In addition to H&E staining, immunohistochemical (IHC) staining for Ki-67, a well-known marker of cell proliferation, was similar among treated animals. These findings indicate that structurally diverse agents can induce similar (and reversible) phenotypic changes in the duodenum. These intestinal carcinogens likely converge on common pathways involving irritation and wounding of the villi leading to crypt regenerative hyperplasia that, under protracted high-dose exposure scenarios, increase the risk of spontaneous mutation and tumorigenesis. These findings set the stage for the development of an AOP for intestinal cancer.

Use of Clinical Data to Inform Risk Assessments of Food Additives: A Case Study of Sodium Benzoate

K. Zu, J. Goodman, D. M. Pizzurro, and T. A. Lewandowski. Gradient; Cambridge, MA.

Sodium benzoate and its potassium salt are common preservatives in foods and beverages and have an acceptable daily intake (ADI) of 0-5 mg/kg body weight (bw) based on a no observed adverse effect level (NOAEL) of 500 mg/kg bw/day in rodents and a total uncertainty factor (UF) of 100. We recently derived a chemical-specific adjustment factor (CSAF) of 2 for benzoic acid and its salts for the pharmacokinetic component of the interspecies UF based on pharmacokinetic data in rodents and humans, which would change the total UF to 50 and increase the ADI to 0-10 mg/kg bw. Sodium benzoate is also used clinically as a therapeutic agent to treat urea cycle disorders, but risk assessments of benzoic acid and its salts by various regulatory and scientific bodies have not considered clinical data. Here, we evaluate clinical studies of sodium benzoate to inform the basis of a risk assessment of benzoic acid and its salts. Through a thorough review of clinical studies, we identified 29 published clinical studies of sodium benzoate, including 13 case reports, 11 case series, and 5 clinical trials involving administered doses of sodium benzoate greater than the current ADI. These studies involved patients across all life stages, including infants. Doses up to 500 mg/kg bw/day (100-times the current ADI) were administered and well tolerated in patients, with no treatment-related adverse effects. Most of these clinical studies were observational in nature, however, and none were designed to systematically evaluate long-term safety of sodium benzoate. Toxicity, such as vomiting and irritation, occurred only after a single or accidental overdose at around 800 mg/kg bw-day and ceased once exposure was discontinued. The highest therapeutic dose of 500 mg/kg bw-day for sodium benzoate in humans is comparable to the NOAEL of 500 mg/kg bw-day for benzoic acid in rodents, which supports that the UF for interspecies differences in pharmacodynamics can be reduced or possibly eliminated. Also, the doses of sodium benzoate in children with urea cycle defects and in adults with impaired liver functions (250-500 mg/kg bw-day and 71-143 mg/kg bw-day, respectively) are comparable and are at least one order of magnitude higher than the current ADI, and
also suggest that the UF for human variability in pharmacodynamics may be reduced. In conclusion, though limited, the clinical evidence reduces the uncertainties in the ADI derivation and demonstrates that clinical data can inform risk assessments of food and beverage ingredients.

### 2848 A Class-Based Evaluation of 2,5-Dimethyl-2,5-Hexanediol in Drinking Water

M. Boylan, G. Kuan, and M. H. Whittaker. ToxServices LLC, Washington, DC.

2,5-Dimethyl-2,5-hexanediol is an unregulated semi-volatile chemical identified as a drinking water contaminant using US EPA Method 525.2. This poster uses a class-based risk assessment to establish a corresponding drinking water action level for 2,5-dimethyl-2,5-hexanediol according to the requirements of NSF/ANSI Standard 61: Drinking Water System Components - Health Effects. This class-based, read-across risk assessment approach operates on the hypothesis that structurally similar chemicals have similar mechanism of action. Structurally similar chemicals identified ChemIDplus included propylene glycol mono-t-butyl ether, which is part of a chemical class that is cleared to a Total Allowable Concentration (TAC) in water of 0.4 mg/L. To determine whether or not 2,5-dimethyl-2,5-hexanediol could be included as part of this class-based consistency, ToxMatch was employed to calculate a Tanimoto coefficient to assess the similarity of 2,5-dimethyl-2,5-hexanediol and propylene glycol mono-t-butyl ether. A Tanimoto coefficient of 0.6 has been suggested as a cut-off in the evaluation of structurally similar chemicals. ToxMatch predicted a Tanimoto coefficient of 0.333, indicating that 2,5-dimethyl-2,5-hexanediol is not structurally similar to propylene glycol mono-t-butyl ether. 2,2,4-Trimethyl-1,3-pentanediol, a plasticizer known as TXIB, is cleared to a TAC and SPAC of 0.4 and 0.04 mg/L along with its metabolites. The metabolism of TXIB following oral exposure produces a diol, 2,2,4-trimethyl-1,3-pentanediol (TXMP). Comparison of 2,5-dimethyl-2,5-hexanediol to TXMP yields a Tanimoto coefficient of 0.786, indicating these chemicals are structurally similar enough to justify including 2,5-dimethyl-2,5-hexanediol in TXIB's risk assessment. Inclusion of Tanimoto coefficients as part of drinking water risk assessments will help to ensure that properly structured surrogates are selected as part of this risk assessment process.

### 2849 Evaluation of Potential Health Risks Associated with the Ingestion of Asbestos

The inhalation of asbestos, depending on the fiber type and dose, is associated with the development of mesothelioma and other asbestos-related diseases. However, little is known about the risk and development of asbestos-related disease associated with the ingestion of asbestos, which can occur through multiple exposure pathways. There is evidence of release of asbestos fibers from asbestos-cement pipes used in water distribution systems that potentially contaminate drinking water. Data from animal and human studies were analyzed using a weight-of-evidence approach to make conclusions regarding the potential risk of disease associated with asbestos ingestion. Human and animal studies that evaluated exposure due to ingestion were identified by peer-reviewed literature searches. Disease endpoints of interest included all gastrointestinal-related cancers. Regarding animal studies, our analysis identified 23 studies that examined multiple organ-specific cancer pathways after ingestion of various asbestos fiber types; most studies exposed animals to asbestos-containing food. These studies employed a variety of doses in multiple animal species. Inconsistent dose-response protocols made it difficult to compare doses between studies that used different protocols (e.g. 0-360 mg/week versus a 1-10% diet). Regardless of this challenge, the studies reported that the asbestos fibers, irrespective of fiber type and dose, failed to produce any definitive gastrointestinal carcinogenic effect. Our analysis also identified 10 studies that examined the influence of ingestion of asbestos-contaminated water, for concentrations from 1 to 71,350 million fibers per liter (MFL), on the incidence of cancer in humans for different sources of asbestos and cohorts from world-wide. A majority of the epidemiology studies reported statistically significant increases in multiple organ-specific cancer endpoints for concentrations much higher than the EPA’s maximum concentration level of 7 MFL. However, these findings are inconclusive due to several critical study limitations including flawed study design, small sample size, selection bias, lack of individual exposure history, lack of adequate latency, and the inability to account for confounders including occupation history, diet, and smoking history. Based on our analysis, there is no evidence of a relationship between ingestion of asbestos and an increased incidence of gastrointestinal tract cancers.

### 2850 Use of the ATSDR Intermediate MRL for Soluble Uranium Compounds in lieu of an Outdated IRIS Reference Value (RfD) for Soluble Uranium Salts in the Regional Screening Levels (RSLs) for Chemical Contaminants at Superfund Sites

K. Salinas, and M. Stiftelman. 1SRC, Inc., N. Syracuse, NY; and 2US EPA, Seattle, WA.

Human health toxicity values in the RSLs are selected based on a recommended hierarchy of sources, namely 1) U.S. EPA’s Integrated Risk Information System (IRIS), 2) Provisional Peer-Reviewed Toxicity Values (PPRTVs), and 3) other (“Tier 3”) sources (e.g. ATSDR, CalEPA). However, the PPRTVs provide flexibility to encourage risk assessors to select toxicity values according to the “best science” available (up-to-date data that are relevant, publicly available, and peer-reviewed). The purpose of this study was to determine if the ATSDR intermediate MRL for soluble uranium compounds was more suitable for use in the RSLs than the IRIS RfD. The chronic RfD (last revised by IRIS in 1989) is 0.003 mg/kg-day based on moderate nephrotoxicity in a 30-day study in rabbits (Maynard and Hodge 1949). Several limitations to this study have been noted (including few animals per group, limited endpoints evaluated, and the absence of raw datasets); IRIS identified (in 2002) new studies which were likely to change the RfD value, but did not produce an updated assessment (Gilman et al. 1998). A subsequent analysis of the uranium dataset by the ATSDR program (in 2013) resulted in 15X lower intermediate MRL of 0.0002 mg/kg-day based on histopathological kidney effects in a contemporary 91-day study in rats (Gilman et al. 1998). Based on these data, the Superfund Technical Support Center (STSC) responded to a request from EPA Region 10 to evaluate the use of the intermediate duration MRL (rather than the chronic RfD) for the RSLs. STSC supported the use of the intermediate MRL because the new data were considered reliable, and the methods used to derive the toxicity values were similar (excepting small differences with respect to dosimetries adjustments and the adjustment of kidney endpoints). ATSDR concluded that continued exposure is not likely to induce more severe effects since the critical effect (regeneration of the tubular epithelium) occurred at low doses. Therefore, the intermediate MRL is expected to be protective for chronic exposure durations (365 days or more), OSRT suggested that regional risk assessors consider whether additional uncertainty is warranted on a case-by-case basis.

### 2851 Derivation of a Human Estimate of Toxicity for the Ultra-Potent Opioid Carfentanil: Reducing Animal Usage

M. S. Feasel, R. S. Lawrence, T. S. Moran, R. S. Kristovich, and C. S. Whalley. US Army Edgewood Chemical Biological Center, Aberdeen Proving Ground, MD.

Carfentanil is an ultra-potent opioid of public health and chemical weapons defense concern. Exposure to carfentanil has been seen in both illicit drug use and in the resolution of a hostage situation in Russia in 2002. While opioid pharmacology and toxicology are well researched topics, carfentanil remains unstudied relative to its clinically used counterparts like fentanyl. Similarly to fentanyl, carfentanil elicits toxicity from central nervous system depression, largely in regions of the brain involved in spontaneous respiratory rhythmogenesis. By depressing the respiratory centers of the brain, respiratory failure occurs, and can lead to death. Carfentanil is of concern because it is reportedly 100 times more potent than its prototype, fentanyl, in analgesic assays in rodents. Carfentanil has very little human relevant data to indicate its toxicity in man for use in public health or chemical defense risk assessments. The present study was designed to test the hypothesis that carfentanil physiologically based pharmacokinetic (PBPK) modeling could accurately reflect observed PK in vivo in a surrogate animal model, and be translated to a human equivalent predication of toxicity. Studies were carried out to assess opioid receptor subtype specificity, potency, and efficacy. Carfentanil metabolism was studied in both rabbit and human liver microsomes to assess its intrinsic clearance. A metabolite identification study was undertaken to identify metabolites that could contribute to prolonged exposure or toxicity, and to generate a library of metabolites to be used in a forensic setting to identify carfentanil as a culprit agent in overdose or mass casualty exposures. Additionally, two key physicochemical properties of carfentanil were quantified in both rabbit and human blood: plasma protein binding and red blood cell - plasma partitioning. These properties have important roles in PBPK modeling, and can be used in a forensic setting to indicate where carfentanil can be found. Finally, the rabbit in vitro derived properties were incorporated into the PBPK model to accurately model the in vivo PK seen in the very
limited rabbit exposures. This model was then translated to a human PBPK model and an equivalent toxic dose was optimized. This predicted human toxic dose (0.34 μg/kg) was calculated to be very close to a post hoc human LD50 value published in a study by researchers at the U.S. DEA (0.29 μg/kg).

2852 Acrobiphylloine: A PDE Case Study
M. Rodda, E. Gillio Tos, A. lavello, L. Brunasso Cattarelio, and A. Conto. Chemsafe SRL, Colleverto Giacosa (TO), Italy.

After the revisions of Chapters 3 and 5 of the EU GMP Guide in 2015, more attention has been given to the cross contamination topic. At the same time, a guideline of the EMA was published introducing the concept of Permitted Daily Exposure (PDE) values. The approach for setting PDE limits is the same outlined in ICH Q3c guideline on residual solvents and in ICH Q3d guideline on elemental impurities. The background for that was the request of the pharmaceutical industry to be able to decide itself on a risk-based approach whether a product can be produced in a multipurpose facility or not. Acrobiphylloine (ACE) is an interesting case because there are no pre-clinical data available on ACE in public literature. Nevertheless, ACE is obtained by targeted salification of ambroxol (AMB) and theophylline-7-acetic acid (TAA). Therefore, the PDE assessment has been performed on its two components: TAA and AMB. The Point of Departures (POD) for AMB and TAA are a 52-week study in dogs and a reproductive toxicity study in mice, respectively. Regarding selection of the AFs, interspecies and intraspecies variability, reference study duration and bioavailability adjustment have to be considered. The peculiarity of ACE case study is the possibility to readjust PDE values according to the stochiometric ratio of TAA and AMB in ACE. The resulting oral PDE for ACE is equal to 3.7 mg/day. The daily therapeutic dose is used as alternative approach to assess PDE value for ACE. Regarding selection of the AFs, interspecies variability, duration of therapy, adverse effects, therapeutic dose and bioavailability adjustment have to be considered. The results of PDE for ACE is equal to 4 mg/kg/day. The results from the two different methodologies above exposed suggests that the assessment performed on the two components of ACE should be considered in order to evaluate similar contingencies. Moreover, the approach based on the daily therapeutic dose is more expeditious than the approach based on the components of the reference API.

2853 Derivation of an Oral Reference Dose (RFD) for Di 2-Ethylhexyl Cyclohexan-1,4-Dicarboxylate (DEHC): An Alternative to Phthalate Plasticizers
B. J. Hughes, K. D. Cox, and V. S. Bhat. NSF International, Ann Arbor, MI.

Di 2-ethylhexyl cyclohexane-1,4-dicarboxylate (DEHC, CAS 84731-70-4) is an ester of polyaromatic acid assessed in a wide variety of ecotoxicological and mammalian toxicity assays as a substitute for phthalate ester-type plasticizers. Laboratory animal data indicate that DEHC has a low acute oral and dermal toxicity, is non-irritating to the skin and eyes, and is a non-sensitizer. In an OECD 422 combined repeat dose toxicity study with a reproductive/developmental toxicity screening test with Sprague-Dawley rats, minimal effects were observed on the liver, spleen, and thyroid. In a subsequent 90-day subchronic study in Sprague-Dawley rats, no toxicological effects were noted. Therefore, DEHC was neither mutagenic nor clastogenic in in vitro studies with or without metabolic activation. Results from the OECD 422 study suggest that DEHC is neither teratogenic or a reproductive toxicant. Although the dataset lacks chronic and multigenerational reproduction studies, the current evidence from screening studies indicates low potential for genetic toxicity or reproductive effects. Where data gaps exist for DEHC, a read-across approach was used to assess the toxicological endpoints of interest. Di-ethylhexyl terephthalate (DEHT, CAS 6422-86-2) and 1,2-cyclohexane dicarboxylic acid, diisomonyl ester (DINCH, CAS 4744919-59-0) have higher tiered studies to provide the data lacking for standard setting. DEHT and DINCH were chosen as the closest read-across source substances due to similar anticipated physical/chemical properties, metabolism and available safety profiles, one a terephthalate and the other an ortho-cyclohexane diacid. The current study emphasizes the challenges of evaluating the safety of novel compounds that lack certain empirical data and the proper selection of analogs for read-across. An oral reference dose (RFD) for DEHC was calculated using the human equivalent NOAEL from the OECD 422 study in Sprague-Dawley rats. A total uncertainty factor of 100 was comprised of interspecies (3x), intraspecies (3x), subchronic to chronic (1x), LOAEL to NOAEL (10x), subchronic to chronic (1x) and database uncertainty (3x) factors, resulting in an RFD of 0.3 mg/kg/day.

2854 The Evaluation of Snus Toxic Effects on Human Vascular Endothelial Cell
L. Qiao, C. Hua, Y. Kang, X. Li, P. Shang, J. Zhao, and F. Xie. Zhengzhou Tobacco Research Institute, Zhengzhou, China. Sponsor: R. Meng

Snus is popular in Europe and America. Although Snus is considered to be healthier than cigarettes, it is recently reported that Snus may have adverse effects on cardiovascular system. In this study, we evaluated the toxic effects of Snus solution on human vascular endothelial cell (HUVEC). DMSO and aqueous solutions of Snus were produced, then HUVEC was exposed to these two solutions with certain concentration gradient for 3h and 24h. Next, HUVEC cytotoxicity was examined by neutral red and LDH. The results showed mild toxic effects on the cell survival for both solutions. In addition, Snus aqueous solution could promote cell proliferation under low concentration. After that, the cell apoptosis was tested by Annexin V/FACS after 3h exposure and TUNEL assay after 24h exposure, but in either case, no effects were observed for both solutions. We then tested the mRNA expressions of four apoptosis associated genes by qPCR. The expression level changed differentially for different solutions treatment. In the case of 3h treatment, both solutions did not affect BAD, BAX and TP53 expressions, but inhibited BCL-2 expression. For 24h, Snus aqueous solution increased BAD and TP53 expressions, but reduced of BCL-2 expression, while Snus DMSO solution increased the expression of BAX, BAD, TP53. We also checked the IL-6 and IL-8 expression by ELISA to examine whether the inflammation was affected after 24h exposure. We observed that Snus aqueous solution could promote IL-8 secretion, and Snus DMSO solution only inhibited IL-6 secretion. In conclusion, Snus solutions showed slight toxicity for HUVEC based on the evaluations of survival, apoptosis and inflammation effects in vitro.

2855 Genotoxicity and Carcinogenicity Risk Assessment of Prucalopride
H. Wang, K. Lane, S. Parker, and M. Placke. Shire, Lexington, MA.

Prucalopride (PRU) is a highly selective 5-hydroxytryptamine type-4 (5-HT4) receptor agonist used to treat chronic idiopathic constipation. During development, follow-up mechanistic studies were conducted to de-risk and understand the positive Ames test (positive in the TA100 strain with absence of or reduction in revertant frequency) that was observed in the Aroclor-induced genotoxicity assay of PRU. The acute oral toxicity was examined in a 14-day gavage study in rats and mice, and the NOAEL was 3500mg/kg/day. The NOAEL for the 28-day repeated dose toxicity was 1200mg/kg/day for rats and 500mg/kg/day for mice. The NOAEL for the 2-year rodent bioassays (neoplasia of the liver in rats and tumors in mice) was 150mg/kg/day for rats and 100mg/kg/day for mice. In these studies, the absence of any genotoxicity or evidence for tumorigenicity was considered to be positive. Additional mechanistic studies in mice and rats revealed the potential for PRU to biomarker animal data, but no studies showed positive results. Following the mechanistic studies, follow-up genotoxicity studies were performed to further characterize the genotoxic hazard, including a mouse lymphoma assay, an in vitro human lymphocyte assay, a UDS assay in primary rat hepatocytes, an in vivo UDS-test, an in vivo gene mutation assay with liver tissue from a Big Blue transgenic rodent model, and a transgenic mouse model. In the transgenic mouse model, no increases in liver neoplasms were observed in mice injected with PRU. However, in the UDS-test, PRU increased the expression of BAX, BAD, TP53. We also checked the IL-6 and IL-8 expression by ELISA to examine whether the inflammation was affected after 24h exposure. We observed that Snus aqueous solution could promote IL-8 secretion, and Snus DMSO solution only inhibited IL-6 secretion. In conclusion, Snus solutions showed slight toxicity for HUVEC based on the evaluations of survival, apoptosis and inflammation effects in vitro.

2856 In Vitro Oxidative Stress Responses of Different Arsenic Species

Arsenic (As) is a known carcinogen. Previous studies have demonstrated that As would induce oxidative stress in the in vivo tests, which could be an important part to explain the mechanism on causing cancers. However, the environmental and occupational exposure levels of As will make a great difference according to the chemical species. In this study...
the cytotoxicity and oxidative stress responses of four As species, i.e. arsenite (As(III)), arsenate (As(V)), monomethylated arsenic (MMA) and Dimethyl arsenic (DMA), were tested to analyze oxidative stress caused by these chemical species. GBW standard reagents of the four arsenic species were used for the tests and were investigated for the cytotoxic response and oxidative stress response (intracellular reactive oxygen species, ROS and extracellular reactive oxygen species, SOD) on A549 cells after 4-hour exposure for ROS and SOD and 4-hour and 24-hour exposure for cytotoxicity at the same molar mass of As. Results showed that As(III) had exhibited cytotoxicity greatly (i.e. less than 70% viable cells vs. negative control) at the range from 60-100 µmol/L after the 24-hour exposure, whereas the other 3 species did not show significant cytotoxicity in both 4-hour and 24-hour exposures. Under the 4-hour exposure condition, ROS fluorescence intensity increased to 140.3% and 177.6% for As(III); 117.1% and 108.0% for MMA; 109.3% and 120.0% for DMA, respectively at the concentrations of 20 µmol/L and 100 µmol/L As, when compared with the negative control. Extracellular SOD generated under the condition of 100 µmol/L As and 4-hour exposure was 3.28-fold, 1.93-fold, 1.97-fold and 0.96-fold for As(III), As (V), MMA and DMA, respectively, of negative control. In general, all the As species have induced clear oxidative responses of A549 cells, although the cytotoxic results of As(V), MMA and DMA did not show significant differences at low doses. The study on oxidative stress caused by arsenic species might plot a clear picture to identify the different toxic characters. These results could be important to further reveal the mechanisms of As toxicity and help assess the hazards of environmental As exposure.

2857 Toxicological Challenges for Indigenous People in Colombia

In Colombia indigenous people are minority groups settled in specific areas legally constituted and protected by the constitution, granting them their territories and natural resources. However, they are experiencing different toxicological vulnerabilities due to several anthropogenic activities, mostly mining operations, with few regulatory mechanisms to guarantee their ethnic and cultural diversity. The aim of this work was to identify negative impacts of external activities on environmental degradation and the effect on human health in indigenous people of Colombia. To review the subject, text mining was carried out in several databases. The results showed that the most common activities carried out in indigenous territory are coal and gold mining; mining promotes air and water pollution, together with deforestation, loss of biodiversity and soil for cultivation and incorporation of metals to the trophic network. Exposure to toxics has been measured at the individual level, especially mercury, found at high concentrations in indigenous living in several river basins of the Colombian Amazon. In the department of Guajira, open-pit coal mining has been linked to respiratory diseases and displacement-related physiological effects. It has to be underlined, that in many native communities where mining activities are carried out, there is no public health data related to their environmental or toxicological impacts, and health information is based just on perception complaints. The lack of data and the existence of many mining exploration applications and title requests in protected areas makes it clear, that it is necessary to take urgent measures for the preservation of these indigenous territories to warrant their survival, and in the long run, our own as well. It is also important their participation in the decision-making processes regarding their territory, making use of the ethnic minority prior, free and informed consultation for any type of project in their zones, aiming to reduce mining vulnerability and intervention in their ancestral territories.

2858 Incorporating ToxCast Data into Naphthalene Human Health Risk Assessment
L. A. Bailey1, and L. Rhomberg2. 1Gradient, Middlebury, VT; and 2Gradient, Cambridge, MA.

Chronic inhalation of naphthalene vapor causes nasal olfactory epithelial tumors in rats and benign lung adenomas in mice. Assessment of the available human data does not establish an association between naphthalene and increased respiratory cancer risk. Therefore, cancer risk assessment of naphthalene in humans depends entirely on experimental evidence derived from rodents. The United States Environmental Protection Agency’s (US EPA) Toxicity Forecaster (ToxCast) Database contains 882 in vitro assays for naphthalene, with more than 750 assays conducted with human cells. All of the available naphthalene ToxCast assays were reviewed and used for the following analyses: 1) a physiologically-based pharmacokinetic (PBPK) model for naphthalene (Campbell et al. 2014), the naphthalene inhalation concentrations corresponding to relevant activity concentrations for all active naphthalene assays were determined, and compared to the naphthalene human equivalent concentration (HEC) derived in our recent naphthalene paper (Bailey et al., 2015); 2) Target endpoints for active assays in the context of proposed modes of action for naphthalene were evaluated; and 3) ToxCast assays were reviewed to determine which assays might be used for the positive based on proposed modes of action and carcinogenic endpoints identified for naphthalene. Although there are numerous and recognized limitations and uncertainties within the naphthalene ToxCast data, the results from our analyses of these data are consistent with and provide additional support for the conclusions described in our 2015 analysis of naphthalene.

2859 Prenatal Exposure to Bisphenol A and Hyperactivity in Children: A Systematic Review and Meta-Analysis
J. R. Rochester1, A. L. Bolden2, and C. F. Kwiatkowski3. 1The Endocrine Disruption Exchange, Grand Junction, CO; and 2The Endocrine Disruption Exchange, Eckert, CO.

Attention-deficit hyperactivity disorder (ADHD) has increased in prevalence in the past decade. Studies attempting to identify a specific genetic component have not been able to account for much of the heritability of ADHD, indicating there may be gene-environment interactions underlying the disorder, including exposure to environmental chemicals. Based on several studies, we chose to examine bisphenol A (BPA) as a possible contributor to ADHD in humans. BPA is a widespread environmental chemical that has been shown to disrupt neurodevelopment in rodents and humans. Using the Office of Health Assessment and Translation (OHAT) systematic review framework, we designed a protocol to determine the association between early life exposure to BPA and hyperactivity, a key diagnostic criterion of ADHD. Searches of PubMed, Web of Science, and Toxline were completed for all literature to January 1, 2017. All rodent and human studies measuring exposure to BPA and hyperactivity were included. Studies were evaluated using the OHAT risk of bias tool. A review of the literature identified 29 rodent and 3 human studies. The effects in humans were assessed qualitatively including difference between the sexes. For rodents exposed to 20 µg/kg/day BPA, we estimated the size and direction of the effect in a random effects meta-analytical model. A random effects meta-analysis showed significantly increased hyperactivity in male rodents. In humans, early BPA exposure was associated with hyperactivity in boys and girls. The systematic review, meta-analysis, and the hazard identification conclusion will be presented, as well as suggestions for future research and risk assessment. This study indicates that BPA may contribute to hyperactivity in children, and precautions should be taken to avoid exposures, especially in pregnant women.

2860 Risk Assessment of Polycyclic Aromatic Hydrocarbons in Some Herbal Remedies in Enugu, Nigeria

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental pollutants that contaminate various biological media. Some PAHs are known carcinogens with broad range of toxicity to human health. Benzo[a]pyrene (BaP), is the most toxic PAH characterized toxicologically. This study was set to determine the risks posed by PAHs in some herbal remedies in Enugu. Two hundred and thirty samples were analyzed for the presence of the United State Environmental Protection Agency (US EPA) 16 priority PAHs using gas chromatography-mass spectroscopy/flame ionization detection (GC-MS/FID) (Clarus 500 Series). Determinations of PAH concentration, total toxicity equivalency, total carcinogenicity, carcinogenic index and carcinogenic risk were assessed. Results showed that 11 out of the 16 priority PAHs by US EPA, 3 out of the 8 carcinogenic PAHs by IARC and 3 of the 4 European Union PAHs (EU-PAHs) were present in all the herbal remedies studied. Benzo(a)pyrene was not detected in any of the samples. The total PAH concentrations, total toxicity equivalency and total carcinogenicity of the herbal remedies were normalized to the cancer potency equivalent factor of BaP (BaP = 1), and were found to be higher than the WHO target limit of BaP-TEQ of 1 ng/m³. The percentage carcinogenicity of the 3 carcinogenic PAHs found in the samples ranged from 88.98% to 98.09%, indicating that the herbal remedies have the potency to induce cancer. The sources of PAH contamination as determined by the diagnostic ratios indicated pyrolytic and petrogenic sources, and amounts of contamination in the herbal remedies. The carcinogenic risk assessment showed the
The current oral MRLs for DEHP are based on reduced fertility at ≥140 mg/kg/day in intermediate-duration studies and testicular at ≥25 mg/kg/day in chronic-duration studies. Numerous studies published since the last toxicological profile update indicate that reproductive effects can occur following exposure to much lower doses. Furthermore, while reproductive effects are among the most well-studied endpoints associated with DEHP exposure in experimental animals, recent studies show that DEHP exposure may induce other effects at lower doses. Following acute oral exposure to DEHP in animals, effects observed at low doses include: 1) altered glucose homeostasis in rat offspring following maternal exposure to ≥1 mg/kg/day during gestation; 2) abnormal Leydig cell clustering in fetal rat testes following maternal exposure to ≥10 mg/kg/day during gestation; and 3) Leydig cell toxicity (proliferation, reduced testosterone production) in male rats exposed to ≥10 mg/kg/day for 11-14 days. Recent intermediate-duration studies in animals have shown the following low-dose effects: 1) enhanced immune responses in sensitized mice exposed to ≥0.03 mg/kg/day for 28-52 days; and 2) various developmental effects, including decreased offspring body weight, male and female reproductive effects, impaired renal function and altered glucose homeostasis in rodents following in utero and/or early postnatal exposure to doses as low as 0.04 mg/kg/ day. Human epidemiological studies published since the last profile update have also suggested potential associations between DEHP exposure and endocrine, immunological, reproductive, and developmental effects. Taken together, the updated information suggests that it may be appropriate to derive a new acute oral MRL and revise the existing intermediate oral MRL for DEHP. In addition, this information also suggests that derivation of a chronic oral MRL may no longer be supported, because recent acute and intermediate-duration studies identify adverse effects at doses much lower than those tested in available chronic studies.

**2862 Identifying Systematic Review Topics through Scoping Reviews of PAHs and Melamine**

C. F. Kwiatkowski1,2, K. J. Rochester1, K. Schultz1, and A. L. Bolden1.

1The Endocrine Disruption Exchange, Eckett, CO; 2North Carolina State University, Raleigh, NC; and 3University of Colorado, Boulder, CO.

Systematic reviews are increasingly being used to answer important questions in toxicology and environmental health, including for the purpose of risk assessment. Surveying the available literature through “scoping reviews” is a valuable first step in determining the feasibility and scope of subsequent systematic reviews. Scoping reviews aid in the formulation of research questions and development of protocols, including the selection of populations, exposures, comparators, and outcomes. Scoping reviews do not assess study quality or direction of effects, they are useful for identifying research gaps and recommending specific avenues for future research. We recently published two reviews that demonstrate the role of scoping. For both, the methods included a priori protocols, comprehensive literature searches, independent screening for study inclusion, and systematic categorization and summarization of relevant studies. Data extraction included the number and age of subjects, the models used, exposure routes and duration, doses administered or concentrations measured, and outcomes assessed. The review of polycyclic aromatic hydrocarbons and female reproduction identified 75 relevant studies. The top three studied chemicals were benzo[a]pyrene (42 studies), naphthalene (14), and phenanthrene (10). Two endpoints were deemed the most appropriate for systematic review: fertility (36 studies), and pregnancy/fetal viability (15 studies). These endpoints have ample research for systematic review, as well as an appropriate level of evidence. The design of the scoping reviews demonstrated the feasibility of completing systematic reviews of these endpoints.

**2863 Prostaglandin Analog: PDE Assessment and Relationship with the Therapeutic Dose**

E. Gillio Tos2, M. Rodda, A. Iavello, L. Brunasso Cattarello, and A. Conto.

1Chemsafe SRL, Colleretto Giacosa (TO), Italy.

After the revisions of Chapters 3 and 5 of the EU GMP Guide in 2015, more attention has been given to the topic cross contamination. At the same time, a guideline of the EMA was published introducing the concept of Permitted Daily Exposure (PDE) values. The approach for setting PDE limits is the same outlined in ICH Q3c consensus guideline on residual solvents and in ICH Q3D consensus guideline on elemental impurities. The background for that was the request of the pharmaceutical industry to be able to decide itself on a risk-based approach whether a product can be produced in a multipurpose facility, or not. Bimatoprost (amide prodrug of 17-phenyl-PGF2α), Tafluprost (difluoroprostaglandin derivative of PGF2α), Travoprost (isopropyl ester prodrug of PGF2α), and Unoprostone (free acid analog of PGF2α) were selected as examples for clinical use to lower patients’ intraocular pressure (IOP). Recently, PGAs were approved as a first-line treatment for glaucoma. Though PGAs are intended for ocular administration, it may occur, particularly in chemical-pharmaceutical companies, that PGAs contaminate molecules intended for other routes of administration. Our assessment focuses on the intravenous route. By definition, when a medication is administered intravenously, its bioavailability is 100%. A common approach for the selection of the Point of Departure (POD) and Adjustment Factors (AFs) can be applied to the prostaglandin analogs group. The result of the above suggests that the substance has a POD of PDE. The purpose of this review is to demonstrate a well-established safety profile at therapeutic dose and comparable preclinical data. Pre-clinical studies conducted during the organogenesis period were judged to be the most relevant POD. Regarding selection of the AFs, interspecies and intraspecies variability, NOAEL and bioavailability adjustment have to be considered. The assessment results highlight a consistent relationship between the therapeutic dose of PGAs and the PDE value irrespective of the therapeutic route of administration. Moreover, a group assessment methodology focused on APIs with the lowest therapeutic doses is considered a possible appropriate and resource efficient solution for companies, particularly those in the chemical-pharmaceutical industry, with a large portfolio of APIs.

**2864 Toxicological Evaluation of a Sulphonated Nanocellulose from Khaya senegalensis Seeds in Rats**

C. A. Otuechere1, A. Adewuyi1, O. Adebayo2, C. Anazodo1, and F. Pereira1.

1Redeemer’s University, Ede Town, Nigeria; and 2Federal University of Minas Gerais, Belo Horizonte, Brazil.

Nanocellulose is currently gaining attention due to its unique properties. This attention includes its application as building blocks for developing novel functional materials, plant drug and also in drug delivery systems. However, its safety remains largely untested or less understood. Thus, sulphonated nanocellulose (KSS) was prepared from cellulose (KSC) isolated from Khaya senegalensis seed (KS). KS, KSC and KSS were characterized using Fourier transformed infrared (FTIR), X-ray diffraction (XRD), thermogravimetric analysis (TG), particle size distribution (PSD), zeta potential and scanning electron microscopy (SEM). The impact of KSS on selected rat markers of oxidative stress, inflammation and apoptosis in Wistar rats was also investigated. Thus, male rats were randomly assigned to four groups of five animals each and were treated with KSS (0, 50, 75 and 100 mg/kg BW) respectively, for 14 days. Thereafter, bio-markers of renal oxidative damage, inflammation and immunohistochemical expressions of iNOS and COX-2 in the kidney of the rats were evaluated. The results revealed that the crystallinity of KSS was 70.40%, monomodal with a mean size of 0.0149 μm and a flaky surface with few agglomerations. KSS had no effect on markers of kidney function and oxidative damage, although there was a generalized hypotension after 14 days of exposure. Lastly, KSS enhanced the antioxidant status and immunohistochemical expressions of iNOS and COX-2 in the kidney of the rats. While the biomedical applications of KSS may appear plausible, our data suggest that it could induce renal toxicity via the combined impacts of electrolyte imbalance and inflammation.
The neonicotinoid insecticide nitenpyram has excellent efficiency against pests and low toxicity for mammals. However, increasing studies have shown that neonicotinoids have adverse effects on non-target organisms. It is not known whether nitenpyram exposure negatively affects human health. Genotoxic potential of nitenpyram on human bone marrow mesenchymal stem cells (HBMSCs) was evaluated. Cytotoxicity was analyzed using the Water-soluble formazan method (WST-8) in a 48-h assay. For following exposure studies, non-cytotoxic concentrations of nitenpyram (50-250 μg/ml) were selected. Nitenpyram (>125 μg/ml) significantly induced formation of MNs and the counts of MNs was concentration-dependent. According to the results of Annexin-FITC assay, no apoptotic bodies were observed, thus eliminating the interference of apoptotic bodies on MNs counting. Nitenpyram (>125 μg/ml) led to the formation of oxidative stress in HBMSCs, as evidenced by an increase in reactive oxygen species (ROS) content, the decrease of total antioxidant capacity (T-AOC) and changes in the activity of superoxide dismutase (SOD). Furthermore, the expression levels of key antioxidants (e.g. bromine and chlorine) were similar, with differences depending on acute dose-response data. The toxicidrome-based approach allows for applicability across a range of chemicals, as the results of a given analysis can be applied to chemicals with similar acute clinical signs and symptoms. Risk assessors and planners may use this approach to estimate the long-term health effects following acute chemical exposures using more robust data available.
Acetaminophen (APAP) is one of the most commonly used as an over-the-counter analgesic/antipyretic drug given to children around the world. It is known to cause high dose related hepatotoxicity in children and adults. APAP metabolism involves cytochrome 450 (CYP) enzymes and several Phase II conjugation reactions, including glutathione (GSH). The vulnerability to hepatotoxicity is driven by the balance between metabolic activation and detoxification and may be altered in early-life stages. This study evaluates how APAP is a primary hepatotoxic drug to N-acetyl-p-benzoquinone imine which conjugates by direct interaction with GSH and excreted in urine via glucuronide, sulfate and GSH enzymatic pathways. At high acute dose, detoxification rapidly depletes GSH allowing excess benzoquinone imine to bind critical proteins in the liver leading to hepatocyte injury. The primary objective of this study is focused on conducting a comprehensive systematic literature search of ontogeny of enzymes (CYP2E1, UGT, SULT, GST) involved in metabolism in humans and experimental animals and integration of hepatotoxicity data for early life-stages and adults. The data analysis suggests that the causes hepatotoxicity profile shifts in early-life. The human metabolic profile was obtained from the liver bank pediatric pharmacokinetic data for APAP. However, the major determinant of early-life vulnerability appears to be lower expression of CYP2E1, resulting in less oxidation of APAP to toxic metabolites in children compared to adults. There is little indication from metabolic studies that supports the contention that there is a window of vulnerability to APAP liver toxicity in early-life. It would be useful to explore these findings further in physiologically based toxicokinetic/toxicodynamic models incorporating life-stage differences in APAP metabolism enzymes including their polymorphisms and nutritional status (e.g., malnutrition) data. One might employ enzyme ontogeny database for example from the URL (https://www.dropbox.com/s/uzizi5q3jdjov0gm/Enzyme_Ontology_Master_11_14_2013_mdb?dl=0) together with the physiological parameters database (https://cpub.epa.gov/ncea/cfm/recorddisplay.cfm?deid=202847) including model development software (https://megens.useconnect.co.uk). Disclaimer: The authors declare there exist no real or perceived conflict of interest.
feine, did not induce lipid accumulation at treatment concentrations up to 100 μM. Rat and human steatosis assays were run with concentrations of AMP that encompass the rat in vivo LOEL. In preliminary data, 48 hour treatment with AMP induced modest neutral lipid accumulation at 316 μM in rat vs. 1000 μM in human MPCPs, without significant effect on viability. After 96 hours, lipid accumulation was only detected at concentrations that caused statistically significant loss of viability. We are currently refining evaluation of the time- and dose-dependence of steatotic response and will perform reverse dosimetry using the human PBPK model.

Multiple regulatory bodies (US EPA, ECHA, Health Canada) are currently tasked with prioritizing chemicals for data collection and risk assessments. These prioritization efforts are driven by the many chemicals in commerce, or in the environment for which detailed risk assessments have not been performed. Ideally, the incompletely assessed chemicals posing the highest risk would be given the highest priority to go into a time-consuming and expensive high-level risk assessment process. In order to assist these efforts, we have developed a web-based application that enables a rapid, flexible and transparent prioritization process. The tool includes multiple data streams related to human and ecological hazard, exposure, and physico-chemical properties (persistence and bioaccumulation). For human hazard, the data streams include quantitative points of departure (PODs) that are compiled from multiple sources such as EPA ToxRefDB, ECHA, COSMOS; estimated PODs from high-throughput in vitro screening assays and computational models; and qualitative measurements and predictions of specific endpoints (e.g., genotoxicity, endocrine activity). For ecological hazard, quantitative PODs are taken from the EPA EXPO databases. Exposure information includes production volume, quantitative predictions using the EPA (EPA) ExpoCast and SHEDS models, biomonitoring data, and qualitative information such as media occurrence, use profiles and likelihood of consumer and childhood exposures. The tool allows users to select a chemical list, as well as to specify input data types, weights, and overall prioritization scoring schemes. The use of the tool is illustrated by prioritizing chemicals related to TSCA and the Safer Choice Ingredient List. The TSCA list has more “High” priority chemicals than does SCIL, as expected from their use profiles. Additionally, we show that there are significant data gaps for many chemicals in both of these lists, which may need to be filled using additional experiments or computations. The underpinning data streams for this application are already available in the EPA CompTox Chemistry Dashboard and have been repurposed to deliver this application. This is in keeping with our overarching software development methodology of providing multiple “building blocks” in the form of databases, web services and visualization tools to inform web services and visualization components to deliver fit-for-purpose applications to the relevant audiences. This abstract does not necessarily represent US EPA policy.

Human health risk assessment relies on comprehensive toxicity studies, mostly in animals, for identifying potential adverse health effects and corresponding effect levels from chemical exposures. However, the majority of chemicals currently in commerce lack the data necessary for traditional hazard identification and dose-response analysis, preventing regulatory agencies from establishing chemical-specific reference values and clean-up levels at contaminated sites. Previously, we introduced a read-across framework to address data gaps for target chemicals with limited in vivo toxicity information. The methodology relied on the integration of evidence for evaluation of structural, metabolic and toxicity-like analogues in order to select the single best analogue as the basis for quantitative read-across to target chemicals. This approach has been implemented to support screening-level risk assessment of data-poor chemicals of interest to the U.S. Environmental Protection Agency (EPA) Superfund program. Case study examples are presented herein, outlining lessons learned from the practical application of techniques in chemical grouping and read-across to quantitative risk assessment. Furthermore, a revised framework is proposed, incorporating lessons learned coupled with scientific and technological advances in the field of read-across and predictive toxicology. The new framework includes important considerations for fit-for-purpose, target chemical profiling, analogue identification, and evaluation and incorporation of data derived from new approach methods. Altogether, this work emphasizes the translational nexus between computational and expert-driven risk assessment with the potential to inform a broad landscape of regulatory decision-making. The views expressed in this abstract are those of the authors and do not necessarily reflect the views and policies of the US EPA.

Systematic reviews involve the identification and synthesis of information from all available evidence related to a review question. Conducting 10-fold increases in eosinophils and neutrophils). Histopathologic evaluations, propose a framework to minimize relevant data losses and maximize efficiency.

Systematic reviews are expensive and time-consuming, especially in terms of data extraction, in which subject matter experts must review full text documents to extract specific data elements. While natural language processing-based information retrieval technologies are now widely used to increase the efficiency of the literature screening and prioritization step, the use of information extraction algorithms in the data extraction step is still nascent. In this research, we used published evidence tables from EPA’s IRIS assessments, together with the corresponding full text articles, to test the accuracy of a combination of information extraction algorithms on a number of structured data elements. Specifically, we used a combination of conditional random field algorithms, supervised machine learning based on support vector machines, Naive Bayes, and maximum entropy classifiers, and hand-crafted rules based on parsing sentences into their grammatical elements, to extract structured data elements including species, strain, route of exposure, dose regimen, and chemical. Extracted entities included sentences, in which the sentence containing the information relevant to the data element is extracted, and concepts, in which the specific concept is fully extracted. By comparing the machine extracted results to the expert extracted results in the published evidence tables for the same set of studies, we found extraction accuracy rates ranging from F1-scores of 28% to 89%. We quantitatively assess the effect of training data size and present the comparative performance of the various algorithms tested individually and in a pipeline using the F1, recall, and precision metrics. Finally, we estimate potential time savings from the use of automated data extraction algorithms and, based on our presented empirical findings, propose a framework to minimize relevant data losses and maximize efficiency.

Currently, there is no fully accepted approach to identify chemicals as respiratory sensitizers. This work was conducted in vivo approach to identify low molecular weight respiratory sensitizers and differentiate them from dermal sensitizers and irritants. BN rats were administered 2 equipotent dermal applications of a dermal (2,4-dinitrochlorobenzene; DNBC or hexyl cinnamaldehyde; HCA) or respiratory (trimellitic anhydride; TMA) sensitizer or a highly reactive aldehyde (orthophthalaldehyde; OPA) in methylenetric ketone (Mek, vehicle) to induce systemic sensitization. Two weeks later, treated and control (MEK only) rats were challenged with the same substances via inhalation of TMA induced pulmonary inflammation in sensitized rats, IgE levels increased relative to baseline in rats sensitized with TMA and control (MEK only) rats were challenged with the same substances via inhalation for 0 (air only), 15, 30 or 60 min (n=4/dose) to characterize the C x dose response. Measured endpoints included functional respiratory parameters, serum IgE, airway hyperreactivity (AHR), pulmonary inflammation, and nasal/lung histopathology. In addition, the right apical lung lobe was analyzed for targeted gene (Th1/Th2 immunological pathways, airways, inflammation) expression changes. Serum levels increased relative to baseline in rats sensitized with TMA and OPA but not DNBC or HCA. Bronchoalveolar lavage (BAL) indicated only inhalation of TMA induced pulmonary inflammation in sensitized rats, compared to controls. At peak response, exposure to TMA decreased BAL total protein (4-fold), DLH (3-fold), and total cells 5-fold (approximately) and induced significant increases in NKC. Microarray analysis revealed no changes in pulmonary inflammation in any treatment group when compared to controls. OPA-exposed rats exhibited...
dose-dependent nasal lesions indicative of exposure to a direct-acting highly reactive vapor. Functional respiratory parameters and AHR were not discerning endpoints in this short-term assay. Candidate gene biomarkers contribute to the ability to identify and distinguish potential respiratory sensitizers. This integrated in vivo approach enabled identification and differentiation of respiratory sensitizers, dermal sensitizers and irritants. The relevance in the mouse study and characterization of the immune, cellular and inflammatory responses underscore the need to examine multiple endpoints and take a WOE approach as the effects of epithelial irritation and chemical reactivity can impact regional dosimetry and interpretation of results.

**2877 Missing Toxicokinetics Data Offers Opportunities to Improve an Oral Cancer Slope Factor for Isoprene**

B. J. Lampe, and V. Bhat. NSF International, Ann Arbor, MI.

General population exposure to isoprene occurs via inhalation with background environmental exposures of 0.5 ppb. Oral exposure may occur when isoprene is used as a monomer in rubber articles intended to contact food or drinking water. The NTP considers isoprene as "reasonably anticipated to be a human carcinogen" and IARC classified isoprene as possibly carcinogenic to humans (Group 2B) based solely on inhalation exposure data given the lack of chronic oral data. Although an oral slope factor for isoprene has not been established, no oral slope factor has been proposed. In the current analysis, an oral cancer slope factor is derived based on the chronic inhalation studies in rats and mice and considers toxicokinetic and metabolic data after inhalation in rats, mice, and humans. These studies suggest interspecies differences in metabolism contribute to varying sensitivities to isoprene toxicity among humans, rats, and mice. Benchmark dose modeling of adverse effects from the chronic rodent studies identified the combined incidence of mammary gland adenomas and carcinomas in rats as the most sensitive endpoint and thus critical effect. Humans are anticipated to be less sensitive than rodents due to more closely resemble rats than mice with respect to sensitivity to isoprene exposure. However, species-specific areas under the curve (AUC) values in humans, rats or mice are not available for the toxic moiety (or the parent compound) to derive a dosimetric adjustment factor for inhalation-to-oral extrapolation. Without these data, the resulting oral cancer slope factor of 7.7 x 10^{-3} (mg/kg-day)^{-1} considers chemical- and species-specific blood:air partition coefficients, but is unable to account for metabolic rate differences that likely result in much lower AUC in humans compared to rats or mice. The missing toxicokinetics data could inform a physiologically-based pharmacokinetic model that offers opportunities to improve an oral cancer slope factor for isoprene.

**2878 Using Machine-Learning and SWIFT-Active Screener to Reduce the Expense of Evidence-Based Toxicology**

Evidence-based toxicology employs the rigorous and transparent methodologies of Systematic Review (SR) in order to synthesize and reach consensus about targeted questions related to the health effects of environmentally important chemicals. A critical and time-consuming step in this process is screening the available literature to select relevant studies for further analysis. We have recently evaluated our collaborative, web-based screening tool, SWIFT-Active Screener, in order to assess its ability to reduce the overall screening burden associated with creating and maintaining a systematic review. By employing a machine learning methodology called "Active Learning", and through a novel statistic, we have developed an automated, supervised machine-learning method that can automatically classify the relevance of studies screened. Active Screener can significantly reduce the overall screening burden compared to traditional approaches. Previously, we have demonstrated the theoretical advantage of using Active Learning to prioritize rank documents by simulating the review process using a large set of more than 100,000 titles and abstracts already screened by human screeners during 20 different systematic reviews. Compared to traditional screening, this method resulted in an average 54% reduction in screening burden, while still achieving 95% recall or higher; when tested on a subset of the 13 studies containing >1,000 articles, the reduction in screening burden improved to 71%. Here, we extend that work by evaluating the performance of our SWIFT-Active Screener application on several recent systematic reviews conducted using our software by organizations such as NIEHS, EPA, USDA, TEDX and EBT. Results from these "real world" data sets are similar to results previously observed in simulation. For example, in the largest of the projects evaluated, 20,883 references were dual-screened using Active Screener, with 99% recall achieved after screening only 42% of the total collection. Given that each abstract takes, on average, 1 minute to screen per screener, the resulting savings in effort for this review alone was approximately 400 hours. More than 4,000 systematic reviews are performed each year in the fields of environmental health and evidence-based medicine, with each review requiring, on average, between six months to one year of effort to complete; for this reason, we anticipate that machine learning screening tools such as Active Screener can help to greatly reduce the total cost of evidence-based toxicology.

**2879 Accelerating the Pace of Chemical Risk Assessment Workshop: Advancing Use of New Alternative Methods for Regulatory Support**

M. R. Gwinn1, T. Bahadori1, M. Rasenberg2, T. Sobanski2, T. Barton-Maclaren2, R. Thomas3, and R. Kavlock1. 1US EPA, Washington, DC; 2IChA, Helsinki, Finland; 3Health Canada, Ottawa, ON, Canada; and 4US EPA, Research Triangle Park, NC.

The tides of acceptance of new alternative methods (NAMs) are changing. Numerous scientific papers have been published recently that explore the boundaries of data applicability and propose approaches that combine new and conventional methods. The modernization of the Toxic Substances Control Act, the implementation of REACH, the next phase of the Canadian Chemical Management Plan, and many international chemical management policies and laws have escalated the demand for sharing of data and knowledge across the regulatory landscape. This interest and regulation is fueling the momentum to examine how NAMs might transform regulatory evaluation of chemicals and pragmatically evaluate barriers to acceptance. These barriers include potential limitations of existing technologies, differing regulatory needs for decision making, and lack of understanding in applying NAMs. In order to better understand what is needed for the acceptance of the use of NAMs for chemical risk assessment, recent workshops were convened comprising key international regulatory agencies to discuss progress in applying the new tools to prioritization, screening, and application to quantitative risk assessment (QRAs) of different levels of complexity. Most progress has been made in screening and prioritization, but ultimately to modernize quantitative risk assessment, there is a need to demonstrate how the data and tools can be incorporated into future QRAs. Scientific and regulatory needs for the quantitative application of NAMs to QRAs were identified, and example case studies were undertaken as intergovernmental collaborations to address these needs. Case study topics include use of NAMs for exposure evaluation, assessing data poor chemicals, or specific chemical classes, including per- and poly-fluorinated substances. Results of these case studies will be presented and the role of the NAM to address the chemical management or risk assessment challenge will be discussed. These efforts are an important step in increasing the confidence in use and acceptance of NAMs in regulatory chemical risk assessment. Disclaimer: The views expressed are those of the authors and do not necessarily represent the policies of the US EPA, the European Chemicals Agency, or Health Canada.
set to identify relevant studies, which saves the effort of finding seeds within the dataset to be classified. Recall in the chemical-agnostic simulations was between 83 and 100% and we eliminated the need to manually screen approximately 65-80% of studies; however, variance between actual and predicted recall was greater than the random seed method owing to the external and non-random origin of agnostic seed data. The mutual recall for agnostic simulations was significantly improved using supervised machine learning on the discards from the supervised clustering stage to reach recall of 90% while still eliminating upwards of 40% of studies from screening. These simulations demonstrate that supervised clustering is a transparent and reliable method for reducing manual screening while ensuring literature searches are comprehensive. Further, a chemical-agnostic seed set was shown to be effective in identifying relevant studies in search results with very low precision.

2881 Comparing Toxicological Tipping Points from High-Content Imaging to Rat Subchronic Hepatotoxicity Doses

A major challenge to using in vitro high-throughput screening (HTS) data in risk assessment is the identification of toxicological “tipping points” between adaptation and adversity. Toxicological tipping points represent a systems threshold, or critical point, beyond which biological pathways invoke permanent perturbations that eventually lead to adverse effects. Previously, we have proposed a formal approach to utilize time-course high-content imaging (HCI) data to identify tipping points in vitro. Here, we analyzed toxicological tipping points for chemicals in rat primary hepatocytes and used quantitative in vitro to in vivo extrapolation (QIVIVE) to compare them with rat subchronic lowest observed adverse effect levels (LOAELs). First, we selected 88 chemicals from ToxRefDB that produced subchronic effects in rats. Next, we treated rat primary hepatocytes with 10 concentrations (0.2 to 100µM) of these 88 chemicals. We used HCl to measure endoplasmic reticulum stress, mitochondrial function, lysosomal mass, steatosis, apoptosis, DNA texture, nuclear size and cell number at 6 time points (1, 3, 6, 24, 48 and 72h). After processing and normalizing the data to calculate cell-state trajectories produced by each chemical treatment, we examined the occurrence of tipping points. For chemicals that produced tipping points, critical concentrations were estimated and extrapolated to oral equivalent doses using (q)IVIVE, and were compared rat subchronic LOAELs for liver effects. Overall, we found 47/88 chemicals produced tipping points while the remaining 41/88 chemicals showed transient perturbations followed by system recovery. For 20/47 chemicals the oral equivalent doses corresponding to tipping points were 5-100 times lower than LOAELs observed in rat subchronic. Our results show the utility of in vitro tipping points as a sensitive estimate of a systems threshold between adaptation and adversity that is supported by in vivo data. Toxicological tipping points offer a novel approach for estimating their point of departure and evaluating chemical safety using HTS data. This abstract does not reflect US EPA policy.

2882 Building toward an Environmental Health Sciences Ontology

Environmental Health Science (EHS) information is increasingly complex and voluminous. Coordination in how this information is collected and shared across organizations has been an ongoing topic for government agencies, academics, and professional scientific societies. Consistent capture, transmission, and analysis of these data for comprehensive risk assessment, scientific, and regulatory applications will depend upon standardization and integration of the data across all of these organizations. Simultaneously, systematic review is increasingly used across many organizations to assist in gathering, screening, reviewing and extracting data collections for specific purposes. While data collection methods have been identified for a systematic review process are a valuable asset that is often not recognized as such. Proper organization and curation of these data collections will further increase their value not only for the initial purpose but also for future applications, yet to be defined. The proof-of-concept pilot project described in this presentation focuses on human health risk assessment to develop a data coordination blueprint that is flexible and sustainable, based in large part on the definition of needs established in a 2014 EHS Language Workshop (http://dx.doi.org/10.1289/ehp.1510438) and several prior SOT sessions. The intent of the project is to move from simple constructs (glossaries) to more harmonized, integrated and interoperable taxonomies and domain-specific ontologies. First, an inventory was developed of work already in progress across EPA (e.g., EPA’s Science Vocabulary) and other federal agencies (e.g., the Standard for Exchange of Nonclinical Data [SEND] Protocol developed by FDA). The second phase develops a strategy to leverage commonalities and bridge inconsistencies in moving toward a holistic, sustainable and consistent approach to gathering, extracting, curating, and disseminating EHS data. The initial results of this work will be presented. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA.

2883 The Many Ways for Keratinocytes to Influence Dendritic Cells and Their Response to Chemicals

J. Hennen, J. Lichter, M. T. Schellenberger, N. K. Peter, M. T. Silva e Sousa, and B. Blömke. Trier University, Trier, Germany.

Small chemicals can induce skin sensitization upon dermal exposure, which may result in tolerance or allergic sensitization. Here, activation of dendritic cells (DC) is crucial. However, keratinocytes provide additional capacities for xenobiotic metabolism and can release inflammatory mediators, modulating the DC response to chemicals. We addressed the question how keratinocytes influence DC and their response to stimuli, and studied changes at early time points in a coculture of THP-1 cells as surrogates for DC with HaCaT keratinocytes. Focussing on phase I xenobiotic metabolism revealed an increased cytochrome P450 1 (CYP1) enzyme activity in THP-1 cells at 48h for HaCaT cells at all time points that even increased at 72h. Synthetic enzyme activity at 48h. In contrast to that, but as expected, THP-1 cells were found to not contribute to CYP1-dependent metabolism. Coculturing THP-1 with HaCaT also added further glutathione and other targets for protein-reactive chemicals as well as phase II enzymes. Exposure in vitro to 10 µM 4-nitrobiphenyl diminished the rapid depletion of glutathione in THP-1 cells, underlining the enhanced capacity for conjugation of xenobiotics. Upregulation of DC activation markers such as CD86 and CD54 occurs in response to inflammatory molecules. While keratinocytes including HaCaT can release a plethora of mediators such as interleukin-1α and tumor necrosis factor (TNF)-α, THP-1 cells lack significant competence, and were reported to not upregulate CD86 in response to TNF-α. We found that in the presence of keratinocytes, exposure to cytokines such as TNF-α upregulated both CD86 and CD54 on THP-1 cells. Enhanced responsiveness was also observed after exposure to chemicals in coculture, enabling sensitive upregulation of CD54 after exposure to a set of sensitizers. In sum, keratinocytes contribute to the DC response to chemicals and can enhance their responsiveness, indicating that both cell types are needed for a balanced assessment of sensitization potential and potency of chemicals.

2884 The Correlation between Liver Tumor Incidence and Short-Term Liver Weight Change in Rodents

K. Shao, and Q. Chen. Indiana University, Bloomington, IN.

Chemically induced liver neoplasms are serious adverse effects and require expensive long-term animal carcinogenesis studies to detect. Therefore, it is invaluable to identify some early indicators of liver tumor occurrences to prioritize research effort and allocate resources. In this study, we focus on investigating the correlation between short-term liver weight change and liver neoplasm incidence using published National Toxicology Program (NTP) data. We screened all 593 published NTP technical reports (TRs) and identified compounds investigated in 174 TRs that have at least one species/sex combination with positive clear-evidence liver tumor. Then, we collected the data of absolute and/or relative liver weight at early stages reported in these TRs. If no liver weight data were reported in the same TR report, we attempted to find data from short-term toxicity studies documented in NTP’s TOX reports. Finally, we found 78 compounds with both long-term cancer data and short-term liver weight data available for data analysis. We first employed the benchmark dose (BMD) method to analyze the dichotomous (long-term) and continuous (short-term) dose-response data and to estimate a biologically meaningful BMD for each dataset. Then we calculated the correlation coefficient for those corresponding BMDs estimated from adequately fitted model to determine the correlation between these two sets of BMDs. Multiple dose-response models were applied to take model uncertainty into account. Preliminary results show that the correlation coefficients can range from -0.26 to 0.86, with a mean of 0.53. In addition, more than 43% of correlation is greater than 0.6, which indicates a fairly strong association. Generally, although considerable uncertainties still exist, there is a relatively high agreement between the BMD estimates from the liver tumor data and short-term liver weight data.
Recent determinations by regulatory agencies are focused on safe doses ((e.g., reference concentrations (RfCs) or reference doses (RfDs)) for developmental and reproductive toxicity (DART) endpoints (i.e., RfD, DT or RfC, DT). However, there seems to be an inconsistent approach being used for calculating these safe doses. We identified and examined seven specific issues based on recent regulatory activities for TCE, PFOA, PFOS, and paracetamol. Based on our review, we determined that the following are pertinent to development of a DART safe dose: (1) Use of effects from acute and short-term exposures. These effects should be used for long-term risk management decisions when they represent the chemical’s critical effect, but with some caveats. (2) Use of appropriate dose metrics. The dose metric metric, for example, accumulation of damage or tissue concentration of the chemical may be better characterized by either the area under the curve (AUC) or the peak concentration (Cmax), depending, as appropriate, on a broad view of the pharmacological and toxicological exposure of the chemical and an embryological foundation. (3) Incorporation in the risk assessment of the severity of DART endpoints in relation to the toxicity evident in other studies. DeRosa et al. (1985) ranking scheme provides a useful tool for incorporating severity of effects into the risk assessment process. (4) Consideration of maternal toxicity when deriving RfD, DT or RfC, DT. Estimation of a DART safe dose may be appropriate, if it is determined that the developmental toxicity is due to the chemical itself and not from maternal toxicity evoked by the chemical. (5) Appropriateness of adjusting exposure durations in DART studies for continuous exposure. Such duration adjustments depend on whether the observed developmental toxicity is due to Cmax or AUC. Development of a DART safe dose when the population exposed does not include pregnant women or children. While it is not necessary to develop RfD, DT or RfC, DT when the population exposed does not include pregnant women or children, exceptions were identified that call for such safe doses to be considered. (6) Incorporation of critical information into the risk DART assessment process. Such integration is appropriate, but on a case-by-case basis. Other issues relevant to DART are identified and recommendations are made to further assist in deriving appropriate DART safe doses

2886 Toxological Risk Assessment for Respiratory Medical Devices: Comparison of Methodology ISO 10993 Vs. ISO 18562

Respiratory medical devices come into contact with patients at a particularly vulnerable point and time. As a result, the exposure assessment for these devices is an important aspect of evaluating the safety of these products, and needs to be particularly concerned with potential releases of trace chemicals from the device materials, with special attention given to airborne releases of volatile organic compound (VOCs). ISO 10993 is the traditional standard for the evaluation of biocompatibility of medical devices and provides a framework for the safety evaluation. However, in addition to not sufficiently address the exposure through the airway, ISO 18562, on the other hand, focuses on of exposure via inhalation, while ISO 10993 does not sufficiently address the exposure through the air pathway. Therefore, we systematically examined acute median lethal dose (LD50), and reproductive/developmental no-observed-adverse-effect level (NOAEL) and lowest-observed-adverse-effect level (LOAEL) values for rat, mouse and rabbit models (oral) from the Cleaning Product Ingredient Safety Initiative database. Probabilistic distributions were subsequently constructed using data from several study durations for all available ingredients in all purpose cleaners. Based on data availability, product type-specific and chemical category-specific CTDs were also generated and compared. For each CTD, Cmax and AUC and their 95% confidence intervals were calculated using the log-normal model. To test whether the common default uncertainty factor (UF) approach (e.g., 10) in mammalian health risk assessment provides sufficient protection, we also derived UFs for acute (LD50) and chronic (reproductive/developmental NOAELs (ACRs) and reproductive/developmental LOAELs/NOAELs) via different models. In general, our novel analysis appears particularly useful for hazard and risk practitioners when identifying TTS for ingredients in all purpose cleaning products and other chemical classes. This approach can also support developmental data (e.g., maternal) for chemicals, such as cleaning product ingredients (e.g., read across) and screening-level health risk assessments when limited or no empirical toxicity information exists for specific chemicals.

2887 Probabilistic Health Hazard Assessment of Cleaning Product Ingredients in All-Purpose Cleaners
D. Dinh1, Z. Wang1, and B. W. Brooks1,2, Baylor University, Waco, TX, and 2Institute of Biomedical Studies, Waco, TX.

Though numerous chemical ingredients are used in cleaning products, empirical mammalian toxicology information is often limited for many substances. Such limited data inherently presents challenges to environmental health practitioners performing hazard and risk assessments. Probabilistic hazard assessment using chemical toxicity distributions (CTDs) is alternative approach for assessments of chemicals when toxicological information is lacking. The CTD concept allows for derivation of toxicological thresholds of concern (TTCs) to predict adverse effect thresholds for mammalian species, including humans. Unfortunately, health hazard assessment of cleaning product ingredients in different use categories has not been well studied. However, all purpose cleaners are used routinely for household and industrial applications, resulting in residential and industrial exposures. Therefore, we systematically examined and analyzed acute median lethal dose (LD50), and reproductive/developmental no-observed-adverse-effect level (NOAEL) and lowest-observed-adverse-effect level (LOAEL) values for rat, mouse and rabbit models (oral) from the Cleaning Product Ingredient Safety Initiative database. Probabilistic distributions were subsequently constructed using data from several study durations for all available ingredients in all purpose cleaners. Based on data availability, product type-specific and chemical category-specific CTDs were also generated and compared. For each CTD, Cmax and AUC and their 95% confidence intervals were calculated using the log-normal model. To test whether the common default uncertainty factor (UF) approach (e.g., 10) in mammalian health risk assessment provides sufficient protection, we also derived UFs for acute (LD50) and chronic (reproductive/developmental NOAELs (ACRs) and reproductive/developmental LOAELs/NOAELs) via different models. In general, our novel analysis appears particularly useful for hazard and risk practitioners when identifying TTS for ingredients in all purpose cleaning products and other chemical classes. This approach can also support developmental data (e.g., maternal) for chemicals, such as cleaning product ingredients (e.g., read across) and screening-level health risk assessments when limited or no empirical toxicity information exists for specific chemicals.

2888 Application of Quantitative Approaches to Assess Uncertainties in the Development of Toxicity Values: A Case Study Involving the Reference Dose (RfD) for 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD)
D. Wikoff1, P. Goodrum2, L. Haws3, and R. Budinsky4
1ToxStrategies, Asheville, NC; 2Integral, Fayetteville, NY, 3ToxStrategies, Austin, TX, and 4The Dow Chemical Company, Midland, MI.

Recent efforts to improve risk assessments include recommendations from The National Academy of Sciences (NAS) to incorporate quantitative uncertainty analysis to better inform risk decisions. However, there are relatively few examples where such has been applied in development of toxicity values. Using the RfD for TCDD as an example, we investigated the impact of uncertainty related to selection of critical studies, points of departure (PODs) from key datasets, and application of uncertainty factors (UFs) on the RfD. The current TCDD RfD is based on equivalent PODs (20 pg/kg/day) for sperm concentration in males and neonatal TSH screening levels from two human studies, with a 30x UF applied to arrive at an RfD=0.7 pg/kg/day. Significant limitations in internal validity (e.g., high risk of bias in key domains including exposure and outcome assessment) of each of the critical studies were identified but could not be evaluated quantitatively (though the potential impact is described qualitatively). With respect to identification of a POD, multiple aspects of uncertainty were assessed quantitatively: addition of TEQ, kinetic model uncertainties (estimation of daily intake associated with serum concentration in children), clinically relevant thresholds (e.g., TSH screening levels of 10 µU/ml) and designations of such as no- or low-effect levels, and dose-response information for neonatal TSH and risk of congenital hypothyroidism from multiple study populations was combined using Bayesian statistics to develop PODs for specified risk levels. Due to lack of statistical significance and/or clinical significance, alternative UFs were also applied (e.g., elimination of 10x for LOAEL to NOAEL). This assessment, including consideration of study quality, dose-response, magnitude, and clinical relevance, supports RfD values ranging from <0.7 to >70 pg/kg/day. This range of plausible RfD values informs risk management decisions and highlights key uncertainties, as well as demonstrates the utility of evidence-based approaches in deriving health-based guidance values.
Reducing the number of laboratory animals and refining experimental procedures to enhance animal welfare are fundamental questions to be considered in connection with toxicology testing. However, it is not obvious how the number of animals and the degree of distress should be weighed against each other, and there is a lack of guidance on prioritizing between the 3Rs when they are in conflict. In other words, would it be better to use fewer animals in order to reduce the distress of the few animals that experience more distress? Here, we first explored the use of cardinal ethical weights for clinical signs and symptoms in rodents by conducting trade-off interviews with members of Swedish Animal Ethics Committees in order to derive such weights for nine typical clinical signs of toxicity (i.e., the number of non-responding animals with an equal weight as one responding animal). The mild examples of signs, such as 30 minutes of decreased motor activity or 5% weight loss during one week, had median ethical weight between 2 and 4 whereas more severe examples of the signs such as 4 hours of decreased motor activity or 10% weight loss during one week had median ethical weights between 5 and 20. However, some interviewees assigned considerably higher ethical weights, as indicated by 75th percentiles for the ethical weights of 15 and 220, respectively. A similar range of ethical weights was then used to examine designs with four dose groups, varying the total number of animals, keeping the ethically weighted dose level constant between the 3 present chemicals. Two sets of quantal dose-response data (with and without background incidence) were generated by Monte-Carlo simulation. The informative value of the simulated data was estimated in terms of accuracy of benchmark dose (BMD) estimates. Our simulations suggest that if animal distress is given an ethical weight, it is preferable, in terms of BMD quality, to use high dose placements but increase the total number of animals. In conclusion, BMD data of higher quality may be obtained without higher ethical cost as long as the top dose shows a clear response rate, as compared to the background incidence. Conversely, a similar BMD quality as with a standard design may be possible to obtain at a lower ethical cost.

We have recently developed the subacute reference doses (saRfDs) of the 19 drinking water quality standards (DWSQs) in Japan) for emerging short-term exposure period. The DWSQs are required to monitor as legally-binding standards by water suppliers in Japan, because most of the DWSQs chemicals are often detected on the level of over 10% of its limit. For each DWSQ, the “Complementary Chemicals”. Additionally, about 50 chemicals are listed as the “Items for Further Study”, because of provisional risk assessment. The exposure levels of these chemicals are usually low, but are still highly concerned in public health. As the next step, we simulated 16 chemicals and two sets of the “Complementary Items” and “Items for Further Study”, and evaluated the toxicological profile of the chemicals for short-term exposure. After estimating the saRfDs, we calculated the health advisory subacute exposure levels of these chemicals in drinking water as one of the risk management tools. In order to estimate the saRfD, in principle, the NOAEL of a one to three-month rodent oral study was used as a Point of Departure (PbD), and a total uncertainty factors of 100 was generally applied to the PbD. The saRfD of about half of 16 chemicals were calculated according in this manner. As for four genotoxic chemicals, 10 times the Virtual Safe Level was defined as a saRfD. However, saRfDs of phthalate esters were evaluated as same as TDIs, because the most sensitive toxicological endpoints of developmental toxicity are independent from the exposure periods. Finally, most of the health advisory values of concentrations in drinking water for sub-acute exposure were determined by the monitoring values for lifetime exposure. We are going to make further evaluations for rest of the listed chemicals. This study was supported by a Health and Labour Sciences Research Grant (H28-Kenki-Ippan-005) from the Ministry of Health, Labour and Welfare, Japan.
We have described a tiered approach that moves from lower tiers focused on rapid decision making and prioritization to Tier 0–1 to higher tiers (Tier 2) that incorporate biologically relevant in vitro models to provide necessary dose-response information for making risk-based chemical safety decisions. Here, we used estrogenic chemicals in a case study for this tiered approach. Using published QSAR models for estrogen receptor (ER) binding (Collaborative Estrogen Receptor Activity Prediction Project; CERAPP) and high-throughput assays for parent chemical activity (ToxCast), 45,000 chemicals can be screened quickly for parent chemical activity and prioritized for further testing in a Tier 2 biologically relevant fit-for-purpose assay. To comprehensively evaluate chemical safety for prioritized chemicals, we used QSAR models of metabolism coupled with the estimates of ER binding to predict compounds likely to be bioactivated by metabolism and to develop a prioritization scheme based on parent and metabolite risk. Potential metabolite structures and bioavailability of 1,677 parent chemicals and related metabolites from the ToxCast library as well as an additional list of 593 purchasable metabolites. We are currently testing the top ranked parent and metabolite compounds using phenotypic cell based assays for the breast and uterus to determine a point of departure for parent and metabolite activity. We will then use IVIVE to determine a region of safety for estrogenic compounds that accounts for both activity and exposure to the parent chemicals and their metabolites.

**2895** Assessment of Risk Associated with Drug Treatment Coupled with Procedural Intervention for Non-Traumatic Neurological Events

A. Mayo-Perez, G. Johnson, M. Bourgeois, J. Wolfson, and R. Harbison, University of South Florida College of Public Health, Tampa, FL.

Cerebrovascular disease is a leading cause of death in the United States. Acute neurological events are a result of cerebrovascular disease. Acute neurological events comprise a large array of conditions that include acute ischemic attacks (strokes), transient ischemic attacks, hemorrhages, and un-ruptured aneurysms. Stroke is the leading cause of long-term disability. We estimated the associations between treatment methods and discharge rates and the prevalence of non-traumatic cerebrovascular events using the database from Florida’s Healthcare Administration (FLAHCMA). Drug therapy, commonly tissue plasminogen activator (t-PA), has been the cornerstone of treatment for stroke patients. The advent of new technologies (mechanical thrombectomy) has allowed surgeons to use intraluminal devices to repair damaged vessels and alleviate symptoms resulting from these events. The focus of this study is to assess the risks associated with the treatment based on discharge outcomes of visits to three hospital departments. Discharge outcomes are considered unfavorable when a patient is discharged into hospice care or dies. Patient outcomes for stroke patients regardless of treatment type were determined. Morbidity is common in stroke survivors, intermediate care that requires skilled medical staff is required after hospital discharge. A cross-sectional analysis of FLAHCMA databases explored the risk between treatment method and discharge rates using logistic regression. The step of length for each treatment was compared using the F-test. We identified 2142 cases of treatment with drug and 375 cases of treatment with mechanical thrombectomy (MT) in 2013. There were 41,033 cases of stroke, 45.8% of those who underwent treatment were discharged home while 7.8% died or entered hospice care. Stroke mortality for MT patients was 105 deaths per 100,000 while drug treatment patients was 251 deaths per 100,000. Stroke patients treated with MT were 3 times (OR = 0.32; 95% CI: 0.25-0.40) less likely to die or enter hospice care than drug treated stroke patients. Stroke patients treated with MT were 5 times (OR = 0.20; 95% CI: 0.13-0.29) less likely to require intermediate care than drug treated stroke patients. Although, stroke patients received drug therapy as the primary treatment approximately 6 times more often than MT, the risk of an unfavorable outcome was greater among drug treated patients.
were collected from 5 animals of each species and assayed in 5 replicates as soon as possible after collection (Time 0). Hematopathology analysis was performed using an Advia® 2120 and samples stored at ambient temperature were run at multiple times within the first 12 hours after Time 0, and, following storage at 2-8°C, at 24, 48, and 72 hours after Time 0. Coagulation and clinical chemistry analyses were performed using a Stago STA Coagu巣 and Olympus AU 5800, respectively. Samples for coagulation and clinical chemistry were analyzed at multiple time points following storage at ambient temperature, refrigeration at 2-8°C, and up to 84 days at -80°C with 3 freeze/thaw cycles. Additionally, coagulation samples were analyzed after storage on wet ice. Values from all analyses were compared to Time 0 to calculate the percent difference. Samples were considered to be stable when the mean percent difference was less than or equal to the established Testing Facility acceptance criteria, which was 25% for hematopathology parameters, 20% for coagulation parameters, and between 5% and 30% for clinical chemistry parameters. For hematopathology parameters at low physiologic levels, the absolute difference between the mean Time 0 value and the mean obtained value was evaluated. All clinical pathology parameters at all time points and storage conditions evaluated were stable for rats and NHP. Mean platelet volume in canines was only stable up to 12 hours at ambient temperature. Although changes in clinical pathology parameters were minimal, timely processing and analysis of samples is recommended to ensure integrity of the data and to avoid misinterpretation due to artifactual changes.

2898 Bolstering the Existing Database Supporting the Non-Cancer Threshold of Toxicological Concern Values with Toxicity Data for Fragrance-Related Compounds

A. Patel1, A. Api1, J. Rose2, K. Josh3, M. Francis1, and M. Laufersewiler1. 1Research Institute for Fragrance Materials, Woodcliff Lake, NJ; and 2Procter & Gamble, Cincinnati, OH.

The concept of threshold of toxicological concern (TTC) supports safety assessment of exposure to low levels of chemicals when toxicity data is limited. The TTC concept proposes that de minimis exposure values can be established for chemicals, including those of unknown toxicity, based on comparison with known toxicity of a wide range of chemicals. RIFM delivers safety assessments for fragrance materials that result in safe products for the consumer. The TTC safety assessment is based on exposure information on fragrance materials from oral, inhalation and dermal routes. A major goal of the TTC safety assessment program is to invest in alternative methods to animal testing for use in assessment of fragrance chemicals. The TTC concept provides a pragmatic approach for safety evaluation of fragrance materials of known chemical structure in the absence of chemical-specific toxicity data. The RIFM database provides the largest available inventory of fragrance and flavor materials classifying more than 6000 materials of which there are over 2600 discrepancy fragrance materials. The TTC database was used to identify TCT chemicals with at least a single dose, reproducibility or developmental toxicity studies. This database was refined to identify over 540 chemicals (TCT-TTC dataset) that are currently used in the fragrance industry to develop fragrance related non-cancer thresholds (i.e., NOAELs). These fragrance chemicals were individually assigned a Cramer Class via expert judgment and a threshold concentration derived from the organic functional group profiler from OECD toolbox v3.4. The chemical space comparisons were made with the Munro-TTC dataset. The toxicity studies associated with each chemical were then carefully evaluated to identify a NOAEL/NOAEL associated with associated chemical specific toxicity information. This information was used to generate a TTC-TTC dataset that is referenced with several toxicity databases, including some that provide robust safety/risk assessments (FEMA, EPA, OECD, EFSFA, SCCS, JECFA, CPDB among others). The ultimate goal is to enhance the existing TTC database with risk values for fragrance chemicals, similar to the work done on Carcinogenicity chemicals (COSMOS: Yang et al., 2017). This work will provide further support for the use of TTC as a tool to conduct safety assessments for fragrance chemicals.

2899 Toxic Load Exponents for Select Priority Chemicals on the ERPG List

Estimates of health outcomes resulting from inhalation exposures to hazardous chemicals (HCs) are needed for emergency response and preparedness. For short-term exposures, the National Academy of Sciences (NAS) recommends that estimates be derived from the toxic load equation, C = n * T * L. It states that both the exposure concentration, C, and duration, T, contribute to a toxic load, TL, that causes an equal level of injury at different levels of a steady-state concentration and duration. The empirical parameter n, the toxic load exponent (TLE), is chemical-specific. For each HC and health effect, a TLE can be extracted from appropriate in vivo toxicological studies. In the present work, TLEs for select HCs reviewed by the American Industrial Hygiene Association (AIHA) were derived. These HCs have publicly available health guidance values (HGVs) for only one duration but sufficient information for bivariate probit modeling to derive TLE estimates that make extrapolation to other durations possible. TLEs and their 95% confidence intervals were derived using animal mortality data from AIHA-cited studies for the following chemicals: benzyl chloride, 1.55 (0.29-2.81); hexachlorobutadiene, 1.16 (0.57-1.75); hexafluoracetone, 0.79 (0.52-1.05); hydrogen peroxide, 0.77 (0.69-0.85); 2-isocyanoethyl methacrylate, 0.97 (0.84-1.11); and 1-octene, 2.21 (1.46-2.96). Cobalt hydrocarbonyl, dimethyl disulfide, n-butyl acetate, tetraethoxysilane, and toluene disocyanate were also considered for probit modeling; however, data presented in the AIHA-cited documents were insufficient for derivation of a statistically significant model for these HCs. These chemical-specific TLEs (aka n-values) can be considered for extrapolation of HGVs available for the aforementioned HCs to other short-term durations instead of general-use default n-values recommended by NAS in the absence of empirical TLEs. Disclosure: The findings and conclusions in this presentation have not been formally disseminated by CDC/ATSDR and should not be construed to represent any agency determination or policy.

2900 The Use of Standard Toxicology Data to Substantiate the Safety of Feed Additives

W. Ng, and B. Walters. Intertek, Mississauga, ON, Canada.

A core component to regulatory approval of any new feed additive is that it is safe and suitable for the intended feed use. The typical process to establish safety of a feed additive is based on studies in the specific species of interest; however, target species studies remain a significant impediment to the approval of new feed additives given the time and resources invested to conduct these studies. The extent that toxicity data from common laboratory species may be useful in extrapolating to safety in target species has been considered. The purpose of the current work was to evaluate whether standard toxicology studies are a good alternative to target species studies for establishing a safe use level for feed additives and identify any methodological limitations. The initial proof-of-concept study was conducted using examples of simple chemical compounds (potassium diformate, propionic acid, fumaric acid and formic acid) that have been approved as feed additives in the EU based on target species studies. Relevant toxicology data were systematically identified for these compounds within the best available and appropriate uncertainty factors and species-specific risk factors were applied to determine whether there were any differences in the safe use concentrations on the basis of laboratory animal data relative to that determined from target animal studies. In all additives examined, while the safe use level derived from laboratory species data were within the levels of use that are currently approved, the observed trend was that levels were at least an order of magnitude below the presently established use level derived on the basis of target species studies. The safe use concentration derived from standard toxicology studies uses safety factors which give an adequate safety margin for target species and may be a useful tool in the preliminary assessment of feed additives. The differences between laboratory and target animal species is likely related to practical limitations regarding feed additive levels which can be included in laboratory species diets. In practice, these could limit the utility of certain feed additives in target species and as such target species studies will continue to be the animal model of choice despite the improved margin of safety afforded by the derived safe use concentration. Further investigations should be conducted to determine whether this process can be extended to more complex feed additives.

2901 Decision Tree Approach for Cosmetic Ingredient Safety Evaluation with Botanical Biofunctionalss: Case Study with Baobab Seed Extract Rich in Plant Small RNAs

S. Kim1, E. Oger1, E. Bauza2, K. Gondran2, K. Cucumel2, C. Choi3, and A. Schatz2. 1Ashland LLC, Lincoln, CA; 2Ashland Global Skin Research Center, Sophia-Antipolis, France; and 3Ashland LLC, Bridgewater, NJ.

Today, there is a growing consumer demand for cosmetics containing sustainable botanical ingredients, with a wide range of biofunctional activities that contribute to skin wellness. However, there is a dearth of information on approaches in addressing the consumer safety of these ingredients. To address the concerns with assessing botanical ingredients in personal care products, Ashland has developed a decision tree approach to regulatory approval of any new feed additive is that it is safe and suitable for the intended feed use. The typical process to establish safety of a feed additive is based on studies in the specific species of interest; however, target species studies remain a significant impediment to the approval of new feed additives given the time and resources invested to conduct these studies. The extent that toxicity data from common laboratory species may be useful in extrapolating to safety in target species has been considered. The purpose of the current work was to evaluate whether standard toxicology studies are a good alternative to target species studies for establishing a safe use level for feed additives and identify any methodological limitations. The initial proof-of-concept study was conducted using examples of simple chemical compounds (potassium diformate, propionic acid, fumaric acid and formic acid) that have been approved as feed additives in the EU based on target species studies. Relevant toxicology data were systematically identified for these compounds within the best available and appropriate uncertainty factors and species-specific risk factors were applied to determine whether there were any differences in the safe use concentrations on the basis of laboratory animal data relative to that determined from target animal studies. In all additives examined, while the safe use level derived from laboratory species data were within the levels of use that are currently approved, the observed trend was that levels were at least an order of magnitude below the presently established use level derived on the basis of target species studies. The safe use concentration derived from standard toxicology studies uses safety factors which give an adequate safety margin for target species and may be a useful tool in the preliminary assessment of feed additives. The differences between laboratory and target animal species is likely related to practical limitations regarding feed additive levels which can be included in laboratory species diets. In practice, these could limit the utility of certain feed additives in target species and as such target species studies will continue to be the animal model of choice despite the improved margin of safety afforded by the derived safe use concentration. Further investigations should be conducted to determine whether this process can be extended to more complex feed additives.

2902 Decision Tree Approach for Cosmetic Ingredient Safety Evaluation with Botanical Biofunctionalss: Case Study with Baobab Seed Extract Rich in Plant Small RNAs

S. Kim1, E. Oger1, E. Bauza2, K. Gondran2, K. Cucumel2, C. Choi3, and A. Schatz2. 1Ashland LLC, Lincoln, CA; 2Ashland Global Skin Research Center, Sophia-Antipolis, France; and 3Ashland LLC, Bridgewater, NJ.

Today, there is a growing consumer demand for cosmetics containing sustainable botanical ingredients, with a wide range of biofunctional activities that contribute to skin wellness. However, there is a dearth of information on approaches in addressing the consumer safety of these ingredients. To address the concerns with assessing botanical ingredients in personal care products, Ashland has developed a decision tree...
approach to conduct a safety evaluation and used a Baobab seed extract (CASRN 91745-12-9) as a case study. The decision tree involves the following aspects: (1) botanical source identification and biological activities assessment, (2) intended use application and usage concentration assessment, (3) literature-based demonstrated safety or toxicological review, (4) potential safety concern identification, analysis, and mitigation, and (5) confirmatory safety testing. A Baobab seed extract from *Adansonia digitata* species was obtained by valorizing oil by-product to retain the richness of cold pressing seeds and particularly to preserve small RNAs. Rich in small RNAs, this Baobab seed extract has been shown to have positive effects on microRNA maturation machinery dysregulation that may limit the appearance of skin aging and the presence of enzymes associated with skin hydration level, based on in vitro assays with fibroblast cells. Baobab seed extracts are not known to contain chemicals of toxicological concern. In *in vitro* dermal/eye irritation studies, the Baobab seed extract was not irritating (Reconstituted Human Epidermis, 24 hour contact). The oral dermal and Epithelium of Hen’s Eye Test-Chorioallantoic Membrane, Neutral Red Release Uptake Assays). It was also non-mutagenic (Ames assay) and non-phototoxic (3T3 Neutral Red Uptake Phototoxicity assay). In clinical studies, the Baobab seed extract was not irritating (48-Hr Human Patch Testing, N = 10) or a sensitizer (Human Repeat Insult Patch Testing, N >200). Our scientific and systematic decision tree approach, as exemplified with this Baobab seed extract, provides a sufficient margin for consumer safety while minimizing the need for extensive physicochemical and toxicological characterization of botanical biofunctional ingredients intended to be used in cosmetics.

**2902 An Approach for Evaluating the Skin Sensitization of Cosmetic Ingredients Using Non-Animal Safety Assessment Methods**

Development of non-animal safety evaluation method for cosmetic ingredients is essential from the viewpoint of animal welfare and to meet the 7th amendment of the European cosmetics directive. Recently, many non-animal skin sensitization evaluation models are developed based on *in vitro* assays and *in silico* approaches (quantitative structure-activity relationship (QSAR) and Read-across). In this study, we developed a skin sensitization evaluation system based on the *in vitro* or *in silico* quantitative risk assessment models and read-across approach. Using an artificial neural network (ANN) based on several *in vitro* assays (h-CLAT, DPRA and Keratinosens™) and *in silico* QSAR approach (using MOPAC2002) to predict stimulation index of 3 (EC3) of the local lymph node assay (LLNA) followed by Read-across approach. *In vitro* or *in silico* artificial neural network (ANN) models predicting the EC3 value of the local lymph node assay (LLNA) were constructed with a dataset (a training dataset) of 134 and 206 general compounds respectively. Read-across approach was composited by structure, chemical structure, physical properties and toxicological concerns (ex. protein binding, structural alert, Cramer classification) using OECD QSAR Toolbox and DEREK. The correlation coefficient of *in vitro* and *in silico* ANN prediction models were 0.89 (RRM error = 0.51) and 0.73 (RRM error = 0.64), respectively. If predicted EC3 value of each chemical is decided by adopting a lower value of both models. The differences between actual and predicted EC3 values were less than 10 times in approximately 80% of the chemicals. To avoid misjudgment of strong and extremely sensitive, chemicals which evaluated strong or extremely sensitive by read-across approach are imposed safety margin to the predicted EC3 value. We concluded that this integrated evaluation system was useful for evaluating cosmetic ingredients in terms of risk assessment of skin sensitization. Reference: Hirata et al., SOT, PS 2735, 2017.

**2903 Derivation of Maximum Allowable Dose Levels for Bisphenol A**

J. E. Goodman1, M. K. Peterson2, M. L. Hixon1, and S. Pacheco Shubin2. *Gradient, Cambridge, MA; and* *Gradient, Seattle, WA.*

In 2015, California’s Office of Environmental Health Hazard Assessment (OEHHA) added Bisphenol A (BPA) to the State’s Proposition 65 list of chemicals “known to cause reproductive toxicity.” OEHHA based its decision on the conclusion of its Developmental and Reproductive Toxicant Identification Committee (DART-IC) that BPA has been shown to cause female reproductive toxicity. A critical factor in determining compliance with Proposition 65 is evaluating whether the reasonably anticipated use of a product could result in an exposure above a Maximum Allowable Dose Level (MADL). However, OEHHA has not derived oral BPA MADL. Thus, we independently derived an oral BPA MADL, based on many factors, including study selection and metabolism considerations. More specifically, the oral BPA MADL is based on Delclos et al. (2014), a 90-day subchronic study that evaluated the effects of BPA exposure on rat dam and their offspring, which was identified as the most appropriate study among the many peer-reviewed studies available. It is of sufficient quality, has the lowest no observed effect level (NOEL), and results in the most conservative oral BPA MADL of 157 mg/day. This oral BPA MADL is generally supported by other studies, including those that are considered by DART-IC in its evaluation of BPA toxicity. Also, the oral MADL for BPA provides a similar margin of safety as OOHHAA’s dermal MADL and other BPA regulatory guidelines.

**2904 Integration of 2D and 3D In Vitro Cytotoxicity and In Silico Models for Predictive Toxicology**

J. LaRocca, Z. Zhang, J. Xiong, A. Lehman, B. J. Rasoulpour, and S. Gehren, Dow AgroSciences, Indianapolis, IN.

The development of new crop protection products (i.e. pesticides) is a complex process that requires large expenditures in time and cost. Embracing high throughput predictive models for assessment of potential hazards of a database early in the development phase can aid in analog selection with the ultimate goal of generating studies with a more favorable human health profile. We assessed the predictive utility of two cytotoxicity endpoints by comparing *in vitro* IC50 values to reported rat 90-day *in vivo* NOAEL and LOAELs. Human hepatocellular carcinoma HepG2 cells (20 μM) were exposed to a set of 23 pesticides for 24 hours at 6 different concentrations, and cytotoxicity was assessed by calculating IC50 values for mitochondrial membrane potential (MMP) and adenosine triphosphate (ATP) content. Using a linear mixed-effects model accounting for a grouping structure of pesticidal use (fungicide, insecticide or herbicide), as random effect increased prediction accuracy comparing to a simple regression model, *2D in vitro* cytotoxicity and *in vivo* NOAEL and LOAELs were correlated (e.g. the predictive relationship of *in vitro* 2D MMP IC50 to *in vivo* LOAELs was r = 0.407). To determine if *3D* cell culture conditions increased predictivity, 21-day HepG2 3D spheroids were exposed to the same set of pesticides for 24 hours for assessment of ATP content. The predictive relationship for *in vitro* ATP IC50 and *in vivo* LOAEL was strengthened with 3D compared to 2D cultures (r = 0.528 and r = 0.348, respectively) but was similar for predicting the NOAEL. Given that molecules can have varying absorption and bioavailability profiles, which can impact *in vivo* points of departure but are accounted for in *in silico* approaches, we in-house developed a GastroPlus to estimate the plasma Cmax of a molecule at the 90-day LOAEL applied dose and compared these Cmax values to *in vitro* cytotoxicity IC50 values. Utilizing the Cmax at the LOAEL increased the predictive relationship of *2D* ATP IC50 (r = 0.54) and *2D* MMP IC50 (r = 0.534) compared to NOAEL based upon *in vitro* IC50 (r = 0.448 and 0.348, respectively) and *2D* ATP (r = 0.407 (2D MMP)), but remained similar for ATP in 3D spheroid culture (r = 0.522 (3D) and 0.528 (2D)). These data demonstrate that harnessing in *vitro* cytotoxicity and *in silico* BPBK models can predict in *in vivo* points of departure, which can aid in new molecule prioritization decisions.

**2905 An Interdisciplinary Approach to Setting Science-Based Occupational Exposure Levels (OELs)**

J. J. Freeman1, J. Foreman1, and M. Adenuga2. Exxon Mobil Biomedical Sciences, Inc., Annandale, NJ; and ExxonMobil Biomedical Sciences, Inc., Annandale, NJ.

OELs are generally established to assure adequate protection of workers in the workplace. Typically, such values are expressed as an 8-hr time weighted average (TWA), Short-term Exposure Limit (STEL) or a ceiling value. While there are numerous OEL setting bodies, there is no common approach. At ExxonMobil, we extensively make use of the AGICH TLVs and the OARS WEELs. In cases where an exposure limit is needed and there is no TLV or WEEL, or if the scientific derivation of those limits does not appear to be aligned with current scientific evidence, an internal OEL may be established. ExxonMobil has been setting internal science-based OELs for several decades, and under the formal guidance of a senior science, staffed OEL Committee since the late 1970s. A number of learnings about the process are shared here. OEL-
setting benefits from an interdisciplinary approach. The available health data come from across the fields of epidemiology and/or toxicology, and always exposure. EM OEL teams always include scientists from all of these disciplines. Value is enhanced through development of OEL recommendations by working level scientists, followed by expert review by an interdisciplinary group of senior scientists. In this way, balance is achieved between novel approaches and evolving technology with historical perspective and broad experience. Well-articulated rationale for applying assessment factors improves transparency and consistency across time and between periodic OEL reviews. Integrating information across all evidence streams informs assessment factor selection rationale. Judgment remains critical to address either database insufficiency or unaccounted uncertainty. Consideration should be given to establishing OELs as STEL or ceiling values when the primary or initial occupational hazard is upper respiratory irritation. Special notations, e.g., for skin absorption, sensitizers, cancer potential, etc are informative to Occupational health staff. Regarding notation of potential skin absorption, skin penetration modeling, e.g, with SkinPerm, informs decision making. For complex mixtures, e.g., hydrocarbons, the Reciprocal Calculation Procedure, which is addressed in the TLV booklet, is a useful approach.OELs are not particularly useful without appropriately sensitive methods for measurement; at EM, the analytical methods are updated or developed as needed. Science is dynamic; hence, OEL re-reviews on a regular basis are recommended.

2906 An Exposure-Led Safety Assessment Framework for Systemic Toxicity: Initial Case Studies from Cosmetics Europe

G. Ouedraogo1, B. Van der Burg2, D. Bury1, S. Grégoire1, J. Eilstein1, C. Mahony1, S. Tozer1, A. Roe1, E. Ellison1, M. Dent1, B. Nico1, R. Cubberley1, H. Duplan2, C. Jacques2, A. Schepky1, D. Lange2, H. Rothé3, D. Kellar1, M. Hewitt10, M. Klairi10, and D. Desprez10. 1 Pierre Fabre Dermo Cosmétique, Toulouse, France; 2 Polyalphaolefin (PAO) Fluid in the 2-week Inhalation Toxicity Studies Two-Week Inhalation Toxicity Studies. AIBMR Life Sciences, Inc, Seattle, WA; and 3Toxi-Coop, Budapest, Hungary.

A battery of toxicological studies was conducted on a proprietary hemp oil (ca. 25% cannabinoids) extracted from the aerial parts of the Cannabis sativa plant. No evidence of genotoxicity was found in a bacterial reverse mutation test (Ames), an in vitro mammalian chromosomal aberration test, and an in vivo mutagenicity/carcinogenicity study. Based on the results of a 14-day repeated dose range finding study, a 90-day repeated dose oral toxicity study was conducted in rats using doses of 100, 360 and 720 mg/kg bw/day, followed by a 28-day recovery period for two satellite groups (control and high-dose). No deaths occurred. Significantly decreased body weight and body weight gain were noted in males in the 360 mg/kg bw/day group and in both sexes in the 720 mg/kg bw/day group. Various significant differences in organ weights compared to controls were found in all groups; however, only elevated liver (360 and 720 mg/kg bw/day for males and females) and adrenal mass weights (720 mg/kg bw/day males and females) were considered to be test article related. There were no histopathological variations in the livers of these animals and related histopathological findings in the adrenals were only noted in the 720 mg/kg bw/day group. In addition, at the end of the recovery period, both male and female high-dose sat-ellite groups’ organ weight results were trending toward normal; thus, the changes appeared reversible. No toxicologically relevant test item related changes were observed in animals administered 100 mg/kg bw/day. The NOAEL for this hemp oil in Hsd. Han: Wistar rats was considered to be 100 mg/kg bw/day for males and 360 mg/kg bw/day for females.

2908 Potential Utility of Juvenile Animal Study Protocols for Infant Food-Contact Safety Assessment

Q. Nartey1, J. Aungst2, F. Basso3, I. Elayan3, J. Liu1, Y. Wu1, and A. Neal-Kluever3. 1Oak Ridge Institute for Science and Education, Oak Ridge, TN; 2USFDA, College Park, MD; and 3USFDA, Silver Spring, MD.

The US FDA Center for Food Safety and Applied Nutrition (CFSAN), Division of Food Contact Notifications (DFCN) performs infant lifestyle-specific safety assessments for food contact materials intended to contact human milk or infant formula. DFCN reviews developmental and reproductive toxicity (DART) studies conducted in laboratory animals to identify potential hazards for the infant population. DFCN examined the potential utility of the juvenile animal study (JAS) protocol for use in the OFAS infant food contact safety paradigm. We previously shared the study characteristics and common outcomes in our JAS library and factors that enhanced JAS dose selection (Neal-Kluever et al., SOT 2017; Wu et al., SOT 2017). In the present analysis, we evaluated how the JAS compared to the sub-chronic (SC) toxicity protocol as well as other DART studies that measured postnatal toxicity (PN: generational DART protocol and pre- and post-natal toxicity protocol). For each study type, we harvested metrics associated with protocol design, endpoints measured, and dosage prepar-ation (POD), test-article related effects, toxicokinetics, and affected biological systems. Our database had 11 drugs with concordant SC and PN studies for comparison. We observed that 1) the JAS and PN studies performed similarly by providing the lowest LOAEL in 4/11 drugs (36%) and 2) PN studies identified more drugs (48%) compared to PN studies (22%), or similar internal exposure (3/9 drugs, 33%) compared to adult rats, as measured by blood AUC or Cmax; 3) the most common toxicological effects in the JAS were target organ and behavioral in SC studies and target organs and behavioral in PN studies; 4) the most common effects were reproductive effects and body weight, and 4) the PN and SC studies identified potential hazards for developing systems that were largely confirmed in the JAS. The JAS provided unique results in 7/9 drugs (78%) and was more sensitive than the PN and SC studies in 2/9 drugs (67%). The SC and PN studies predicted similar toxicity as the JAS in 7/9 drugs (78%) and 4/9 drugs (44%), respectively. In the DFCN paradigm, our analyses suggest that the PN and SC studies may be helpful to design a targeted JAS in cases with an outstanding question regarding infant safety.
2910 Evaluation of FXR-Active Chemicals Identified from Tox21 Screening

J. Hamm1, P. Ceger1, X. Chang1, E. Maull1, D. Mahapatra1, M. Knuth2, M. A. Lingerfelt3, S. Ekins4, M. Xia5, and S. W. Kullman6.

Nuclear receptors play a key role in physiological functions. Assessing how chemicals interact with this superfamily of proteins can provide mechanistic data that supports the construction of toxicity pathways related to human disease. Farnesoid X receptor alpha (FXRa, NR1H4) is a member of the nuclear receptor superfamily with demonstrated importance in bile acid homeostasis, glucose metabolism, lipid homeostasis, and immune system generation. In this study, we screened two sets of compounds previously identified in Tox21 qHTS in vitro screens as FXRa agonists and antagonists using four experimental approaches. Transactivation studies were conducted to validate potency and efficacy of putative FXRa agonists and antagonists using four experimental approaches. Transactivation studies were conducted to validate potency and efficacy of putative FXRa agonists and antagonists using four experimental approaches. Transactivation studies were conducted to validate potency and efficacy of putative FXRa agonists and antagonists using four experimental approaches. Transactivation studies were conducted to validate potency and efficacy of putative FXRa agonists and antagonists using four experimental approaches. Transactivation studies were conducted to validate potency and efficacy of putative FXRa agonists and antagonists using four experimental approaches.

2911 Chemical Stability of a Cleansing Conditioner Product under High-Heat Conditions Experienced during Consumer Use

Chemical stability is a key component of ensuring that a cosmetic personal care product is safe for consumer use. Current industry guidance for stability testing of products considers whether foreseen transport, storage or handling impacts the integrity of the product. Typical testing conditions include evaluations of thermal stability at temperatures up to 40 °C for several months. However, such testing protocols may not reflect specific stress conditions experienced during the actual use of the product. For example, hair care products may be exposed to high-heat stresses during the styling process, including blow-drying and hair straightening. In this study, a hair cleansing conditioner product was subjected to temperatures of 60 and 185 °C to simulate the use of a hair dryer and flatiron hair straightener, respectively. Matched heated and unheated samples were analyzed via GC-MS HPLC, and FT-IR to capture a widespread profile of the product which included volatile and non-volatile organic and non-organic chemicals. The resulting spectra from matched heated and unheated product samples were analyzed to identify any changes in chemical composition or generation of degradation product(s). Together, no differences in the spectra were observed between the heated and unheated samples. Individual chemicals identified during GC-MS were all known ingredients of the cleansing conditioning changes. In addition, no alteration of the active preservative ingredients, methylisothiazolone and methylchloroisothiazolone, upon heating. Therefore, no changes in chemical composition are expected to occur under high-heat conditions associated with the use of the product. Therefore, the potential health risk of this product would not be impacted by heat modulation during use.

2912 Four-Week Continuous Nicotine Treatment of Immortalized Bronchial Epithelial Cells Does Not Contribute to Tumorigenesis

M. van der Toorn, K. Baumer, D. Peric, D. Bordon, R. Dulize, E. Guedj, A. Sewer, K. Luettich, N. Ivanov, M. Peitsch, and J. Hoeng, PMI, Neuchatel, Switzerland.

Cigarette smoking is one of the major risk factors for the development of lung cancer, but relatively little is known about the effects of nicotine, a major constituent of cigarette smoke, on lung epithelial cells in the context of lung tumorigenesis. In order to investigate whether nicotine elicits differential effects on mechanisms promoting or leading to carcinogenesis, immortalized non-tumorigenic BEAS-2B and tumorigenic (BZR) human bronchial epithelial cells were continuously exposed to low, medium and high concentrations of nicotine (10, 100 and 1000 nM) for 4 weeks. Proliferation, apoptosis and expression of metalloprotease-1, -3 and -9 were evaluated using western blot and qRT-PCR and compared to untreated control cells. In addition, tumorigenicity of the cell lines was assessed using the xCELLigence platform, high-content imaging and Lumexin technology. Gene expression analysis was performed on nicotine-treated and untreated cells collected weekly during microarray experiments with a computational network approach. In summary, nicotine treatment did not increase the proliferation of immortalized BEAS-2B or BZR cells as determined by cell counting. Real-time impedance data indicate a small, but transient pro-proliferative effect on BEAS-2B cells at week 3. Nicotine treatment had no impact on stauroporine-induced apoptosis of BEAS-2B and BZR cells. Furthermore, nicotine treatment did not increase the levels and activity of metalloproteases. Systems toxicological analysis indicated a small, but non-consistent impact when treating BEAS-2B cells with nicotine, while BZR cells seemed to be more responsive to nicotine than BEAS-2B cells. Finally, anchorage-independent growth was not observed in BEAS-2B or BZR cells when treated for four weeks with nicotine. Chronic nicotine treatment of immortalized non-tumorigenic BEAS-2B and tumorigenic BZR cells did not promote cell proliferation, suppress apoptosis or initiate any mechanisms that favor tumorigenesis. Longer exposures might be necessary to elucidate the contribution of nicotine to cancer promotion and progression.

2913 Microsampling Method That Does Not Cause Anemia or Hematopoiesis in Rats

Microsampling improves animal welfare (refinement and reduction) and enables to evaluate the relationship between safety profile and drug exposure in the same animal. Many facilities have reported the relationship between microsampling and anemia, but that between microsampling and hematopoiesis caused by anemia has little been evaluated. We examined anemia- and hematopoiesis-related changes at endpoints of 1, 3, and 7 days after blood sampling by clinical pathology and histopathology. Seven-day oral dosing with microsampling was also conducted to mimic a 1-week screening toxicity study with toxicokinetics. Six-week-old female Crl:CD(SD) rats (5 animals/group) were used, and microsampling was conducted via the jugular vein without anesthesia. Experiment 1: Blood was collected by serial sampling (6 × 0.05 mL, 0.10, and 0.15 mL of blood; approximately 3, 6, and 9% of the circulating blood volume, respectively. Sampling points were 0, 1, 2, 4, 8, 24 h) on Day 1, and the animals were necropsied on Day 2 or Day 4. Untreated control and sham groups (restraint and needle puncture) were also set. Experiment 1: Animals received 10 mL/kg of water orally, once daily for 7 days. Animals underwent serial microsampling (6 × 0.05 mL at 0.5, 1, 2, 4, 8, 24 h on Day 1 and 7 × 0.05 mL on Day 7). Untreated control and sham groups were also set. Experiment 1: The 0.05 mL sampling at 6 points did not affect results in any examination. Anemia and hematopoiesis...
and extramedullary hematopoiesis in the spleen and liver on Day 4. The thymic hemorrhage. Microsampling with 6% and 9% of the circulating blood volume caused anemia and/or hematopoiesis, but 3% did not. Microsampling within 3% of circulating blood volume enabled toxicity to be appropriately evaluated.

**2915 Marijuana-Induced Hepatic and Renal Mitochondrial Lipotoxic and Non-Lipotoxic Dyslipidemia in Female Albino Rats**

O. Ademuyiwa, Federal University of Agriculture, Abeokuta, Nigeria; and Landmark University, Omu-aran, Nigeria.

Intake of marijuana has been associated with debilitating outcomes. Various reports have appeared in the literature suggesting a role for mitochondrial dysfunction in the pathophysiology of several diseases. To investigate the effects of marijuana on mitochondrial function, female albino rats (n=36) were exposed orally to marijuana (25 and 50 mg/kg body weight) (extracted with petroleum ether and suspended in olive oil) for 2, 4 and 6 weeks. Control animals (n=18) received the vehicle for the same period. Mitochondria were isolated from the kidney and liver of the animals and analysed for their lipid profile. Both lipotoxicity and non-lipotoxicity characterised the effects of marijuana on renal and hepatic mitochondria. Induction of both cholestero genesis and phospholipidosis in hepatic and renal mitochondria at the highest dose characterised the lipotoxic effects of marijuana at the end of 6 weeks. Comparatively, while cholestero genesis was more pronounced in the kidney, phospholipidosis was more pronounced in the liver. Triglyceride constipation was the hallmark of the highest dose of marijuana exposure at the end of 4 weeks in both renal and hepatic mitochondria. Reduced hepatic and renal mitochondrial triglyceride (2 weeks), as well as a dose-dependent reduction of renal mitochondrial cholesterol (2 weeks), were the hallmarks of non-lipotoxicity of marijuana. These findings suggest that marijuana-induced mitochondrial dysfunction characterised by dyslipidemia might mediate its disease endpoints.

**2916 Challenges in Assessing Health Risk from Exposure to Bisphenol A (BPA) in Consumer Products**

P. Sheehan, R. Kalmes, M. Posson, A. Singhal, R. Lewis, and A. Gauthier. Exponent, Oakland, CA.

BPA is regulated differently by various national and international agencies due to discrepancies in the characterization of health risks posed by BPA. For example, current "safe harbor level" estimates for BPA from different sources range from 3 to 290 µg/day, nearly a 100-fold dose range. The recent State of California Proposition 65 listing of BPA was accompanied by a yet-to-dermal route-specific maximum allowable dose level, but not yet a new challenge for assessing health risk for BPA-containing consumer products. This challenge is further compounded by the absence of well-accepted methods for estimating BPA transfer from products to skin or from packaging to foods. This presentation describes our experience in assessing BPA transfer from a variety of consumer products and food for estimating potential BPA dermal and oral exposures. Most of our dermal transfer testing to date is based on either wiping the product with a cotton pad or rolling the product, indicating minimal potential dermal exposure. Similarly, model evaluations of several paper packaging and food combinations, including long-term storage and heated preparation scenarios, produced BPA daily dose estimates from packaged food consumption substantially less than 0.1 µg/day. We will present our understanding of the relationship between BPA transfer and the characteristics of material, BPA content, time of contact, receptor media and environmental variables, and discuss uncertainties in current BPA health risk assessments of consumer products and their effects on evaluating product compliance with health-based criteria.

**2917 Tier-Based Safety Testing of Common Personal Care Products and Their Constituents**

E. S. Fung1, R. Novick2, D. Drechsel3, K. Towle2, D. Paustenbach2, and A. Monnot1. 1Cardno ChemRisk, Aliso Viejo, CA; 2Cardno ChemRisk, San Francisco, CA; and 3Cardno ChemRisk, Boulder, CO.

The Food and Drug Administration (FDA) does not require testing of personal care products or their individual constituents before the products enter the market. Various trade associations such as the Scientific Committee on Consumer Safety and the Personal Care Product Council recommend tier-based assessments to evaluate the safety of personal care products and their individual constituents. The goal of this study is to evaluate the dermal irritation and sensitation potential of several commercially available hair care products using the methodology recommended by personal care product and consumer product trade associations. The first tier of testing utilized the OECD Toolbox to execute an in silico evaluation of the 30 identified ingredients in the hair care products for potential dermal irritation and sensitation potential of each of the identified constituents was evaluated using this tool. Subsequently, two OECD in vitro guideline tests were executed to evaluate the dermal irritation and sensitation potential of the commercially available hair care products. The OECD 439, EpiDerm Skin Irritation Test (SIT), utilizes a reconstructed human epidermis (RHE) to evaluate the irritation potential of a test article. The OECD 442C, Direct Peptide Reactivity Assay (DPRA), utilizes high-performance liquid chromatography (HPLC) to evaluate test article-peptide reactivity to evaluate the sensitation potential of a test article. The results from tier one in silico testing showed that 6 of the 30 ingredients for dermal irritation and sensitation testing included: behentrimonium methosulfate, dicetyldimonium chloride, methylchloroisothiazolinone, methylisothiazolinone, panthenol, and stearamidopropyl dimethylamine. However, tier two in vitro testing showed that all of the commercially available hair care products tested were non-irritants and non-sensitizers. The results of this study demonstrate that although several constituents had structural alerts from in silico testing, subsequent in vitro testing showed that the products of interest were non-irritants and non-sensitizers. Therefore, the presence of potential irritants or sensitizers alone does not determine the safety of personal care products.

**2918 Does Raising E-Liquid pH Increase Saliva Nicotine Absorption?**

J. H. Lauterbach. Lauterbach & Associates, LLC, Macon, GA.

Recent journal articles have suggested that unprotonated nicotine in e-liquids, when vaporized, can partition between the gas-vapor phase (GVP) and the particulate phase (PP) of the aerosol, potentially increasing the addictiveness of use of e-vapor products. However, the research reported to date has used toluene-extracted nicotine from water-diluted e-liquids or PP of the aerosol to estimate the fraction of nicotine that is not protonated. Consequently, a series of experiments were set up containing artificial saliva. Experimental e-liquids were formulated using commercial 50 mg/mL nicotine in propylene glycol and additions of propionic acid to make it acidic and ammonium carbonate to make it basic. The amounts of propionic acid (PA) and ammonium carbonate (AC) added, respectively, were equimolar with the theoretical amount of nicotine (3.08 millimoles per 10 mL).

Two samples of each formulation were prepared. Apparent pH-values (Hanna 1083B microelectrode with IQ150 pH meter) were PA1 6.61, PA2 6.77, AC1 9.28, and AC2 9.29. For comparison, the apparent pH-values for major-brand red 2.4 was 7.03; major-brand green 2.4 was 8.49; and 50 mg/mL nicotine was 9.19. The term apparent pH-value is used here as samples were not diluted with water, and no water was added to the PA and AC formulations. The e-liquids (about 500 mg) were loaded into 2 blank cartomizers and allowed to age at RT for at least 24 hours prior to use. Each cartomizer was affixed to a V2 battery, and the device was inserted into the mouth end of a glassmouth using a latex tubing sleeve to seal the connection. The glassmouth was filled with artificial saliva (10 mL), a HI-1053 pH electrode inserted in the aerosol sampling port and
the device puffed using a 55/3/30 sequence for 50 puffs. The saliva was removed and nicotine content determined by HPLC using a C18 column and UV detection at 259 nm. Although the final pH-values of the saliva ranged from 6.6 to 8.6, the nicotine content of those saliva samples did not change by more than 4%. These findings do not support partitioning of nicotine between the GVP and PP.

2919 The Future of Agrochemical Risk Assessment: Establishing a Platform for Early Estimation of Chronic Dietary Exposure for Agrochemicals

Z. Zhang, P. Geurs, and Z. Yan. Dow AgroSciences, Indianapolis, IN.

Human health assessment of agrochemicals requires a comprehensive battery of toxicological animal studies as well as estimations of human exposure, culminating in risk assessment(s). Among the necessary exposure data, chronic dietary exposures are primarily based on results from extensive residue trials on multiple crops. Given the potentially multi-year study durations and significant number of studies, adequate information for assessments is not usually available until late stages of new agrochemical Research & Development. Thus, it is important to provide a tool that could minimize the residue trials needed to provide exposure estimations to inform safety and enable early decision-making. This study used Clopyralid as a case study to demonstrate a platform for chronic exposure prediction with minimal field residue trials. In the first step, residue predictions were generated using DynamicCROP Model. Available Good Agricultural Practices (GAPs) used for 67 crops were collected. Calculated chemical-specific DT50s from decline trials were used for representative and closely-related crops. Residue predictions were made for different portions of crops based on different application methods, application rates and pre-harvest intervals. The summation of different portions was calculated for each crop. The predicted worst-case scenario (highest value) for each crop was compared with actual data from appropriate field residue trials. Using the default model, the predicted and observed residues were similar for stem, foliar and root crops with correlations of 0.64 and 0.53, 0.32 and 0.28, respectively. However, when a meta-modeling approach was incorporated as a remedy for overcoming model limitations (e.g. underestimation of stem and root), substantially improved predictive performance (R² = 0.79-0.94) for all crop portions was achieved. The second step used the predicted residues from step 1 as inputs for Dietary Exposure Evaluation Model (DEEM) for chronic exposure estimations. The average estimated exposure using predicted residues was within 5% relative to that from measured residues for all subpopulations. In summary, the established platform could significantly improve residue prediction for multiple crops and provide a basis for human exposure-based toxicity testing and early decision making for novel agrochemicals.

Good Agricultural Practices, physicochemical-chemical properties, and crop DT50s from limited field residue trials, residue levels of all crops for a specific agrochemical can be predicted by the modified DynamicCROP model, which can then be used for estimating chronic exposures for different subpopulations. Finally, chronic risk characterization can be performed based on results from step 1 and 2, as well as other relevant toxicological animal studies, such as those from developmental and subchronic studies. Overall, this 3R-focused framework provides a practical tool for conducting chronic risk assessment using data from enhanced subchronic studies and limited residue data to enable agrochemical product development and, potentially, regulatory decision-making.

2920 The Future of Agrochemical Risk Assessment: Framework for Conducting Chronic Risk Assessment with Enhanced Short-Term Toxicological Studies and Significantly Reduced Residue Trial Studies

Z. Yan¹, K. Johnson², C. Terry³, X. Wang¹, L. Murphy¹, P. Geurs¹, Z. Zhang¹, and R. Rasoupour¹. ¹Dow AgroSciences, Indianapolis, IN; and ²The Dow Chemical Company, Midland, MI.

Human health assessment of agrochemicals requires a comprehensive battery of toxicological animal studies as well as estimations of human exposure, culminating in risk assessment(s). Within the required animal studies, chronic rat and mouse studies and potentially multi-year residue studies are amongst the most time- and resource-intensive. Given the significant animal use, an increased body of evidence indicating many rodent tumors are not relevant to humans, and advances in computational tools, it is important to consider alternative approaches for conducting chronic human health assessment. A framework has been developed for conducting a chronic risk assessment using data from enhanced short-term toxicological studies and significantly reduced residue trial levels. In this framework, four steps of the risk assessment paradigm were addressed. First, for hazard identification and dose-response assessment, data-driven retrospective analyses that investigated correlations between rat short-term and long-term critical toxicological points of departure (PODs) at the levels of apical effects (for 143 agrochemicals) and transcriptional effects (for 7 phenoxyacetates) were conducted. These results demonstrated that chronic PODs can be reasonably estimated using apical and transcriptome data from subchronic studies by applying an extrapolation factor of 2-10. Second, for exposure assessment, a platform was established by integrating a modified DynamICROP and DEEM models. Using agrochemical-specific computational tools, it is important to consider alternative approaches to early decision making for novel agrochemicals.

2921 The Future of Agrochemical Risk Assessment: Benefits, Challenges, and the Evolution of Integrated Endpoints for the Rat 90-Day Toxicity Study

L. Murphy¹, S. Papineni², M. Corvaro³, M. Aggarwal¹, J. Mehta³, K. Johnson¹, Z. Yan², and C. Terry³. ¹The Dow Chemical Company, Midland, MI; ²Dow AgroSciences, Indianapolis, IN; and ³Dow AgroSciences, Oxfordshire, United Kingdom.

The basis of human health assessment of agrochemicals is hazard identification via regulatory guideline toxicity studies. Traditionally, endpoints such as immunotoxicity, genotoxicity, neurotoxicity, toxicokinetics (TK), Mode of Action (MoA) and toxicogenomics (TxG) were evaluated in separate studies. While these endpoints are critical to establish toxicity endpoints and human safety margins, separate endpoints for an adverse effect are animal-, labor-, time- and cost-intensive. There has been considerable effort to adapt testing strategies incorporating 3R principles of animal welfare, and integration of testing endpoints in a single study design. An integrated 90-day study, using 120 rats, reduces total animal use by more than 70% compared to 440 animals used in separate studies. Here we discuss the evolution of integrated testing strategies for rat 28- and 90-day dietary toxicity studies for the herbicides, haloxfen-methyl and florpyptrauxfen benzyl, and the insecticides, sulfoxaflor and a bis-heterocyclic amide. TK data to assess systemic exposure relative to observed toxicity were critical for dose selection and use of KMD approaches resulting in definitive rat and dog studies for florpyptrauxfen benzyl conducted at a high dose of 300 mg/kg/day, as opposed to the limit dose, in the absence of toxicity. Liver MoA and TxG have proven critical for early decision making and prediction of carcinogenic effects for the long-term studies as data were available earlier and were utilized to test sulfoxaflor, haloxfen-methyl, and a bis-heterocyclic amide. Adding the mammalian erythrocyte micronucleus test for the bis-heterocyclic amide and florpyptrauxfen benzyl revealed potential new challenges to address for integrated studies such as dose level, blood or bone marrow, and demonstration of adequate test substance exposure to the target tissue. These innovative testing approaches can provide a comprehensive evaluation of regulatory required toxicity endpoints in a single study using a route of exposure relevant to human health risk assessments. As toxicity testing continues to evolve, the rat 90-day toxicity study should be considered for use as the definitive study for toxicity endpoint evaluation and human health risk assessments, including potentially chronic effects.

2922 The Future of Agrochemical Risk Assessment: Predicting Toxicity Point of Departure with Transcriptome Data

K. Johnson¹, Z. Yan², E. Costa³, C. Terry³, and X. Wang³. ¹The Dow Chemical Company, Midland, MI; ²Dow AgroSciences, Indianapolis, IN; and ³Dow AgroSciences, Caieiras, Brazil.

Human health assessment of agrochemicals requires identification of a toxicity point of departure (POD) from the comprehensive battery of regulatory, guideline toxicity studies conducted when developing a new agrochemical. Currently, the toxicity POD is determined from developmental and subchronic studies, chronic dietary exposures are primarily based on results from enhanced short-term toxicological studies and significantly reduced residue trial levels. In this framework, four steps of the risk assessment paradigm were addressed. First, for hazard identification and dose-response assessment, data-driven retrospective analyses that investigated correlations between rat short-term and long-term critical toxicological points of departure (PODs) at the levels of apical effects (for 143 agrochemicals) and transcriptional effects (for 7 phenoxyacetates) were conducted. These results demonstrated that chronic PODs can be reasonably estimated using apical and transcriptome data from subchronic studies by applying an extrapolation factor of 2-10. Second, for exposure assessment, a platform was established by integrating a modified DynamICROP and DEEM models. Using agrochemical-specific computational tools, it is important to consider alternative approaches to early decision making for novel agrochemicals.

Good Agricultural Practices, physicochemical-chemical properties, and crop DT50s from limited field residue trials, residue levels of all crops for a specific agrochemical can be predicted by the modified DynamicCROP model, which can then be used for estimating chronic exposures for different subpopulations. Finally, chronic risk characterization can be performed based on results from step 1 and 2, as well as other relevant toxicological animal studies, such as those from developmental and subchronic studies. Overall, this 3R-focused framework provides a practical tool for conducting chronic risk assessment using data from enhanced subchronic studies and limited residue data to enable agrochemical product development and, potentially, regulatory decision-making.
agrochemicals. To examine the utility of rat liver microarray data from a subchronic study to predict an apical endpoint POD from a chronic study, data from 7 drugs in the TG-GATES database were examined. The rat liveromic POD was determined from TG-GATES microarray data following 29 days of exposure using BMDExpress. BMDs was used to identify the apical POD from publicly available cancer bioassay data. For 6/7 molecules, the chronic omic-biomarker (O-B) was within 20% of the chronic study apical POD. For acetaminophen, the rat liver omic-based POD was nearly identical to the chronic study apical POD, which was based upon effects in the kidney. These data suggest an omic-based POD derived from subchronic studies approximates a chronic study apical POD. Further, liver omics data may have the potential to be surrogate measures to derive an apical POD in non-liver organs. With additional research and refinement, a transcriptome-based POD from a subchronic study can be considered for determining an apical endpoint POD for both subchronic and chronic study designs.

2923 An Approach to Evaluate Chemical-Induced Biological Response Similarities across Multiple Echinacea purpurea Extracts

K. Ryan1, S. Ferguson1, S. Ramaiahgari1, J. Rice1, P. Dunlap1, M. DeVito1, S. Auerbach1, J. Pielerfelce1, T. Cristy1, E. Mutlu1, S. Waidyanatha1, and C. Rider1. 1NIEHS, Research Triangle Park, NC, and 2Battelle Memorial Institute, Columbus, OH.

Botanical dietary supplements are complex mixtures that can display significant variability depending on raw plant material and manufacturing processes. *Echinacea purpurea* (EP) is consistently one of the top 10 best-selling supplements in the market. As such, the National Toxicology Program (NTP) is exploring the potential for it to cause toxicity. To probe the extent of variability of representative species, rat liver microarray analysis was performed on 15 samples from the selected EP root extract to other *Echinacea* products available in the marketplace. The NTP developed a case study to assess the chemical-induced biological response similarity of 23 purchased samples, including standard reference materials, to the NTP EP root extract. All samples were extracted with a mixture of ethanol/water and HPLC profiles were generated. The peaks were aligned using standards of known *Echinacea* constituents and evaluated for similarity to the selected EP root extract by hierarchical clustering. By this approach, 9 samples including the standard reference material for EP were highly correlated (Pearson correlation coefficient > 0.9) to the NTP selected EP root extract, while 8 samples, including standard reference materials for other *Echinacea* species had correlation coefficients < 0.5. Next, biological-response similarity of 15 *Echinacea* samples, including the NTP selected EP root extract, were evaluated in organotypic cultures of primary human hepatocytes for liver enzyme induction/receptor activation. Concentration-response data were fit to sigmoidal concentration-response models to determine their respective impacts on target gene expression for major hepatic receptor pathways. Eight out of 15 samples demonstrated marked (10-30-fold) induction of CYP2B6 mRNA consistent with activation of the constitutive androstane receptor (CAR). Interestingly, CYP3A4 mRNA content (along with HMGCS2 and ABCB11) appeared to be suppressed in the majority of samples examined (12 out of 15), and modestly induced in 3 samples consistent with competing dynamics in these complex mixtures. Hierarchical clustering revealed biological-response similarities which were mapped to chemical compositions to characterize lot similarities and identify effector constituents.

2924 Evaluation of Heat-Treated Aqueous Extracts of Hibiscus sabdariffa Calyces for Phytochemicals, Cytotoxicity, Antioxidant, and Anti-Inflammatory Activity

O. O. Olakun, N. M. Mkolo, and P. H. King. Sefako Makgatho Health Sciences University, Pretoria, South Africa.

The extract of *Hibiscus sabdariffa* calyx is widely consumed as beverage and is used in folk medicine to treat diseases. Due to its low cost, the demand for the drink is high and many individuals are involved in its production and sales. The choice of using a water extraction method depends on processor’s preference and safety of product is of great concern. The safety or potential toxicity of regularly consumed medicinal remedies needs to be carefully considered, investigated and validated, more especially when traditional use of plant extracts has been reported to cause deaths due to toxic effects. Hot water extraction of dried and ground *H. sabdariffa* calyx was performed with and without additional heat treatment at 60°C for 0, 10, 20 and 40 min, respectively were prepared. After centrifuged and filtration, clear extract supernatants were used for assays. Cytotoxicity against Vero kidney cell lines was evaluated by MTT, anti-oxidant activity by trolox equivalent antioxidant capacity, total phenolic by gallic acid equivalent and flavonoid by quercetin equivalent. Heat treatment time had no significant effect on parameters investigated in comparison to extracts without additional heat treatment. However with increasing heating time there was a trend of a decrease in the total phenolic content. Extract without additional heat treatment had the highest phenolic content (88.1 ± 0.62 mg/ml) was with heat treatment POD and 40 min (73.5 ± 0.28). Irrespective of the extraction method, all extracts exerted anti-inflammatory activity by the inhibition of 5-lipoxygenase enzyme (58.97 ± 1.17 to 78.77 ± 3.47 μg/ml) although to a moderate extent. This was the first study to demonstrate the anti-inflammatory activity of *H. sabdariffa* extract by inhibition of 5-lipoxygenase activity. Also all extracts were relatively cytotoxic to Vero cells in a dose dependent manner with LD₅₀ ranging from 257.77 ± 1.73 to 280.37 ± 1.52 μg/ml. The aqueous extract of *H. sabdariffa* calyx possesses health benefits but with moderate cytotoxicity. Although there has been no reports of the suspected toxicity of this plant since its long traditional use in folk medicine caution should be exercised in using this extract especially at high concentration and for long periods which could be detrimental to health.

2925 Green Tea Extract and Hepatotoxicity: An Extensive Review by the US Pharmacopeia

Following routine review of literature on hepatotoxicity of green tea extract (GTE), the USP Dietary Supplements Admission Evaluations J3 recommended that USP seek the assistance of toxicologists, to conduct a risk assessment Panel to GTE. The Expert Panel was convened to review toxicity and safety data related to GTE, and to define a label cautionary statement for inclusion in the USP Powdered Decaffeinated Green Tea Extract (PDGTE) monograph. The panel considered three topics relevant to potential hepatotoxicity of GTE: 1) chemistry, manufacturing and control (CMC) pharmacokinetics/pharmaco-dynamics, and clinical/non-clinical data and adverse event reports for risk assessment. A review of information on these topics suggest that constituents, particularly epigallocatechin gallate (EGCG) and other catechins of GTE may be involved in hepatotoxicity, not contaminants, and suggest that fasting increases the absorption of GTE constituents which can lead to hepatotoxic levels in rodents and humans. To evaluate safety data, a comprehensive literature search was performed for clinical and nonclinical studies on GTE and major constituents published since the USP assessment in 2008. All studies were categorized for relevance based on pre-established criteria. We also obtained human case reports, and FDA MedWatch Adverse Event Reports (AERs) related to the use of dietary supplement products containing GTE for the period January 1, 2008 to October 31, 2016. The non-clinical data demonstrated dose-dependent hepatotoxicity in rodents and dogs, with fasted dogs being the most sensitive model (NOAEL of 40 mg/kg EGCG content). In nine clinical studies reviewed, one reported clear evidence of hepatic toxicity in 4 out of 44 participants, and the panel recommended that it be added to the list of potential GTE adverse effects. The GTE monograph currently recommends that USP seek the assistance of toxicologists, to conduct a risk assessment on GTE. An Expert Panel was convened to review toxicology studies and a risk assessment on GTE. An Expert Panel was convened to review toxicology studies and a risk assessment on GTE. An Expert Panel was convened to review toxicology studies and a risk assessment on GTE. An Expert Panel was convened to review toxicology studies and a risk assessment on GTE. An Expert Panel was convened to review toxicology studies and a risk assessment on GTE. An Expert Panel was convened to review toxicology studies and a risk assessment on GTE. An Expert Panel was convened to review toxicology studies and a risk assessment on GTE.

2926 Therapeutic Effects of Astilbin from Smilax glabra Roxb. Targeting Inflammatory Mediators in Rheumatoid Arthritis Disease

L. Dong1, J. Chen1, and J. Zhu2. 1School of Pharmacy, Guiyang College of Traditional Chinese Medicine, Gui Yang, China; 2School of Chinese Medicine, Hong Kong Baptist University, Hong Kong, Hong Kong; and 3The State University of New York Buffalo, Buffalo, NY.

Astilbin, a flavonoid compound, was isolated from the rhizome of *Smilax glabra* Roxb. (with red cross section) grown in Guizhou province, China. We assessed its effect and potential mechanism on attenuation of the inflammatory response in adjuvant-induced arthritic rats. Our results showed that daily oral administration of astilbin at 5.3 mg/kg reduced joint damage in the hind paw of rats with adjuvant arthritis (AA) induced by complete Freund’s adjuvant (CFA), as assessed by radiographic analysis and histopathological evaluation. Accordingly, astilbin exhibited remarkable inhibitory effects on tumor necrosis factor (TNF)-α, -
interleukin (IL)-1β, and IL-6 mRNA expression. Significant decrease of serum cytokine levels of TNF-α, IL-1β, and IL-6 was also observed in astilbin-treated AA rats compared to the vehicle-treated AA rats. The reduced expression of these cytokines was associated with protein activity suppression of three key molecular targets in the pathogenesis of rheumatoid arthritis: inhibitory protein kappa B (IkBκ), nuclear factor kappa B (NF-κB) subunit p65, and toll-like receptor (TLR) adaptor MyD88. Furthermore, the therapeutic effects of astilbin on the inhibition of cytokines production as well as the reduction of inflammatory response in AA rats are close to a commonly used disease-modifying antirheumatic drug, leflunomide (LEF). Collectively, our data suggest the action mechanism of astilbin, as an anti-inflammatory agent, for rheumatoid arthritis treatment, is associated with modulating the production of pro-inflammatory cytokines and inhibiting the expression of key elements in NF-κB signaling pathway mediated by TLR.

**2927** 'H-NMR-Based Chemometric Analysis of Myelostimulatory Activity Exhibited by Echinacea

S. K. Nagamalli1, J. D. Carstens2, K. ElSayed1, and S. A. Meyer2.

1University of Louisiana at Monroe, Monroe, LA; and 2North Central Region Plant Introductory Station, Ames, IA.

The three medicinal species of Echinacea that are widely used are E. purpurea, E. angustifolia, and E. pallida. We previously described myelostimulatory activity of aerial parts of Echinacea. In present study, we evaluated myelostimulation by 8 different accessions of Echinacea spp. We employed chemometrics to identify regions of 'H-NMR spectra associated with activity. We also performed concurrent studies to monitor toxicity of accessions. We obtained aerial parts of accessions E. purpurea PI-631307, PI-63668, PI-649040, E. angustifolia PI-649029, and E. pallida PI-631300 and PI-597603 from the USDA-ARS NCRPS. Female Sprague-Dawley rats (n=6) were dosed with ethanol extract (75% v/v) at 0, 25, 50, 100, 200 mg/kg for 7 days. After 24hrs, rats were euthanized and Dawley rats (n=6) were dosed with ethanol extract (75% v/v) at 0, 25, 50, 100, 200 mg/kg for 7 days. After 24hrs, rats were euthanized and cell number was cultured in methylcellulose with csf2, IL-3 and SCF and cell number was determined. Myeloid progenitors, i.e., CFU-GMs, from femur bone marrow were cultured in methylcellulose with csf2, IL-3 and SCF and cell number was determined. Cell number was evaluated in methylcellulose with csf2, IL-3 and SCF and cell number was determined. Myeloid progenitors, i.e., CFU-GMs, from femur bone marrow were cultured in methylcellulose with csf2, IL-3 and SCF and cell number was determined.

**2928** Anti-Inflammatory Activity of Cranberry (Vaccinium macrocarpon) Polyphenols and Oligosaccharides in Intestinal Fibroblasts

V. P. Venancio, M. A. Sirven, S. Talcott, and S. U. Mertens-Talcott.

Texas A&M University, College Station, TX.

Cranberries (Vaccinium macrocarpon) are a rich source of polyphenols, including A-type proanthocyanidins, which have been described to exert antioxidant and antibacterial effects. Although the anti-inflammatory activity of polyphenols from cranberry and other fruits have been previously described, the effects of oligosaccharides are less elucidated. Therefore, this study compared the anti-inflammatory activity of a high-tannin cranberry whole extract and subfractions (anthocyanins, flavonols/tannins, and oligosaccharides) in lipopolysaccharide (LPS)-challenged human non-malignant intestinal fibroblasts (CCD-18Co). Cells were treated with the extract or each fraction for four hours, and LPS was used as inflammation inducer. The mRNA expression of the inflammatory targets tumor necrosis factor alpha (TNF-α), interleukin 1 beta (IL-1β), interleukin 6 (IL-6), and nuclear factor kappa B (NF-κB) was evaluated using real-time quantitative PCR. Results show that whole cranberry extract and fractions decreased the expression of inflammatory markers. This study describes for the first time the anti-inflammatory activity of cranberry oligosaccharides. These compounds reduced NF-κB and TNF-α by 45% compared to the LPS-control at 25 mg/L. The anthocyanin-rich fraction proved to exert the highest anti-inflammatory activity starting at 3.12 mg/L, restoring the expression of NF-κB back to levels observed in the control group. Further studies will be performed using microbial metabolites of the fractions based on their physiological relevance in an intestinal environment.

**2929** Effect of pH and Gastro-Intestinal Conditions on the Fibrinolytic Activity of Nattokinase and Lumbrokinase In Vitro

L. Camacho1, P. Porter-Gill1, S. Swift2, A. Abdel-Rahman3, C. Welch2, and S. Fitzpatrick4.

1US FDA/NCTR, Jefferson, AR; and 2US FDA, College Park, MD.

Nattokinase (produced by Bacillus subtilis var. natto) and lumbrokinase (from earthworms) are promoted as health supplements for their claimed support of cardiovascular and circulation health in humans. The mechanism for such claimed effects is, at least in part, mediated by their fibrinolytic activity. The possibility exists that consumption of fibrinolytic enzymes may increase the risk of bleeding, especially when taken together with other clot-modifying compounds. Using a validated semi-quantitative fibrin plate method, we assessed the fibrinolytic activity of nattokinase and lumbrokinase over a range of pHs and upon incubation with simulated and rat gastric and intestinal fluids. The effect of adding pepsin and pancreatin to the gastric and intestinal fluids, respectively, was also tested. Our data indicate that nattokinase is inactivated at pH < 5.5, while lumbrokinase is inactivated at pH < 3.5, upon incubation at 37°C for 2 h. Consistent with this, incubation in simulated gastric fluid (pH < 1.5) inactivated both enzymes in as little as 5 min. Lumbrokinase was highly resistant to an incubation in simulated intestinal fluid (pH = 6.5) up to 3 h, and did not. Rat gastric fluid (pH = 4.5) inhibited the fibrinolytic activity of nattokinase over time, while it had no or little effect on lumbrokinase activity. The effect of the rat intestinal fluid on the fibrinolytic activity of the enzymes could not be assessed in a fibrin plate because this fluid cleaved fibrin. Pepsin and lumbrokinase digested nattokinase and lumbrokinase, while some enzymes in the pancreatin mixture appeared to be hydrolyzed by nattokinase and lumbrokinase, as assessed by SDS-PAGE. The systematic characterization of the conditions in which nattokinase and lumbrokinase are fibrinolytically active in vitro may contribute to a better understanding of their potential effects in vivo. This work was sponsored under an interagency agreement between the FDA/NCTR and the NIH/NTP (FDA IAG # 224-12-0003/NIEHS IAG # AES12013).

**2930** Effects of Sub-Acute Exposure of Wistar Rats to Ethanolic Leaf Extract of Byrsocarpus coccineus on Some Haematological and Serum Biochemical Parameters

Byrsocarpus coccineus is an indigenous herb widely dispersed in tropical Africa and commonly known as Crimson thyme. The leaf and root of the plant is noted to possess medicinal benefits in traditional medicine of the Western part of Nigeria. The plant has been reported for its analgesic, anti-inflammatory, antidiarrhoeal and antipyretic activities. Its antiplasmodial properties have also been reported by researchers. In the light of these medicinal properties, the plant can be represented as a valuable source of medicinal compounds and the present study was therefore aimed at determining the sub-acute toxicity of the leaf extract of the plant. The ethnolthic leaf extract of the plant was administered orally at 250, 500, and 1000 mg/kg to three groups A, B and C of Wistar rats respectively for 14 days while the control group D was administered orally with 3ml/kg of distilled water. Blood samples were then obtained from the anaesthetized rats for haematology and serum biochemistry analyses. The result obtained from serum analyses showed a significant increase (p<0.05) in the levels of blood urea nitrogen and creatinine while the increase in alkaline phosphatase is not significant for the treated groups B and C. It was therefore concluded that high doses of the extract may have untoward effects especially on the kidney and therefore care must be taken when using the plant in high concentration. Further research is on to determine the level and the mode of the toxicity.
2931 Cytotoxic and Anti-Prosiferative Activities of Methanol Extract of Adansonia digitata on Breast Cancer (MCF-7) Cells
A. M. Adegoke1,2, S. Prince3, M. A. Gbadegesin1, and O. A. Odunola1,3
1University of Ibadan, Ibadan, Nigeria; and 1University of Cape Town, Cape Town, South Africa.

There is a notable dependence on the use of herbal medicinal products as anticancer agents in contrast to synthetic drugs in developing countries due to their cost, availability and associated toxicity. In addition, there is upsurge in research towards the identification of active ingredients in plant extracts and their mechanism of action. Adansonia digitata is a referenced medicinal forest tree and its stem bark (SBAD) has many traditional medicinal uses, including for the treatment of cancer. There is a dearth of scientific information about the anticancer potential of SBAD and its mechanism of action. The aim of this study therefore, was to assess the cytotoxic and long term antiproliferative effects of methanol extract of SBAD (MESBAD) on breast cancer (MCF-7) cells using the MTT, clonogenic assay and western blotting. Adansonia digitata was identified/authenticated with voucher number FHI NO. 109859. Cold extraction was carried out on SBAD by soaking in 7% methanol for 72 hrs at room temperature to obtain MESBAD. The extract was filtered and concentrated using a rotary evaporator and then lyophilized. Cells were cultured according to established procedure, while cytotoxicity and clonogenic assays were performed in accordance with standard protocols. Western blotting analysis was performed with antibodies to p21 and p53. In all the experiments, cells were treated with MESBAD or DMSO (vehicle control). MESBAD was shown to have a dose dependent cytotoxicity as compared with the control, with IC50 value of 100µg/ml. MESBAD also demonstrated a dose dependent inhibition of long term (13 to 15 days) survival of MCF-7 cells. Indeed, when MCF-7 cells were treated with ½ IC50, IC50, 2X IC50 and 4X IC50 of MESBAD their abilities to form colonies were reduced in a dose dependent manner. Western blotting indicated that MESBAD activated the p38 stress signaling pathway and the p53/p21 response in MCF7 cells. We propose that MESBAD reduces short- and long-term viability of MCF-7 breast cancer cells in a concentration dependent manner. Further work is needed to fully characterize its mechanism of action.

2932 Thymoquinone Attenuates Maneb and Mancozeb-Induced Cytotoxicity

The ethylene-bis-dithiocarbamate (EBDC) fungicides, manebe (MB) and mancozeb (MZ), are widely used in the agricultural industry to control various crop diseases such as the infamous potato blight. However, recent studies have linked these pesticides to neurodegenerative diseases such as Parkinson’s and have raised a major toxicological concern. Acute exposure to EBDCs has shown low toxic effects in mammals but chronic exposure is linked to neurodegeneration. MB and MZ increase apoptosis pathway and leading to cell death. Antioxidant compounds can hinder the activity of ROS and other free radicals. Thymoquinone (TQ), the active compound present in black cumin seed, is known for its antioxidant and neuroprotective properties among many others. This study examines the protective effect of TQ on PC12 cells treated with MB and MZ. Neutral red uptake assays for cell viability analysis and CellROX Green reagent for oxidative stress detection were carried out. The results have shown a decrease (about 55-58% cell death) in cell viability after MB and MZ treatment at 5µM for 24 hours and an increase (only about 25-28% cell death) when pretreated with 10 µM TQ for 24 hours. The results indicate that TQ can act as a potential treatment agent against EBDCs-induced cell death. TQ also attenuated ROS generation by about 10-30% in PC12 cells treated with 5 and 10 µM MB and MZ for 2 hours. Our future research goal is to study the mechanism of this attenuation triggered by TQ. The expression levels of oxidative stress regulator genes, such as p53, in cells treated with TQ and pesticides MB and MZ will be determined by Western blot analysis.

2933 Toxicological Assessment of Bryophyllum pinnatum Leaf Extract in Rodents
O. K. Yemitan. Lagos State University College of Medicine, Ikeja, Nigeria.

The aqueous leaf extract of Bryophyllum pinnatum (ALBP) is used in Alternative Medicines in the management of acute and chronic diseases such as hypertension, diabetes, arthritis, asthma and weight management; and it is believed that it is devoid of any form of toxicities. Various toxicological end-points were investigated for effects of ALBP in rodents, with a view to ascertaining and predicting its safety claims. For acute toxicity test, mice were administered 10mg/kg – 5000mg/kg (p.o.) of ALBP for toxicity end-points up to 14 days. For subchronic study, rats were given daily doses of ALBP (10, 100 or 1000 mg/kg) for 90 days, during which the body weights were measured. After 90 days, weights of vital organs and serum metabolites- alkaline phosphatase (ALP), aspartate amino transferase (AST), alanine amino transferase (ALT), bilirubin and uric acid were measured; and oxidative stress markers- catalase (CAT), superoxide dismutase (SOD), reduced glutathione (GSH), and malondialdehyde (MDA) were determined from tissues. Hematologic and spermatologic functions, and lastly, histopathologic assessment of the organs were also assessed. These were followed by 21 days reversibility tests. Acutely, orally administered ALBP did not cause mortality, but dose-dependent drowsiness, reversed within 48h. In the subchronic test, significant (p<0.05) reduction in body weight; increases in weights of liver, kidneys & spleen, but weight reduction of the lungs. Also, there was weight reduction of the testis. The weights of liver & spleen, but not those of lungs & testes were reversed. Furthermore, there was an increase in PCV%, but reduction in RBC, Hb & platelet concentrations. There was elevated WBC level which was not reversed. At 1000 mg/kg there were significant increases in ALP, AST, ALT, LDH, Uric acid and creatinine whereas, bilirubin and uric acid were reversed after 21 days. There was reduction in CAT & SOD, but increase in MDA level for all the vital organs; but effects were reversed except for the lungs and testes at 1000mg/kg. The results suggest that the ALBP might exhibit haematological, renal, hepatic and specific organ (lungs and testes) toxicities following chronic oral use, at high doses.

2934 Assessment of In Vitro Anti-Influenza Potential and Cytotoxicity of Crude Extract and Fractions of Loxostylis alata
D. A. Gado1,2, P. Mehrbod1,2,3, M. Ali Abdalla1, A. S. Ahmed1, F. O. Fasina1, F. Fotouhi3, and J. McCaw1
1University of Pretoria, Pretoria, South Africa; 2National Veterinary Research Institute, Plateau State, Nigeria; 3Pasteur Institute of Iran, Tehran, Iran, Islamic Republic of; and 4Food and Agriculture Organization of the United Nations (FAO), Nairobi, Kenya.

Loxostylis alata A. Spreng. ex Rchb. (Anacardiaceae) is a small tree distributed in the Eastern Cape and Kwazulu-Natal provinces of South Africa. The antifungal and antibacterial properties of this plant have been previously investigated but no antiviral property documented. The aim of this study was to investigate in vitro anti-influenza activity of the methanol extract of L. alata and its hexane, butanol, chloroform, ethyl acetate and water fractions. The 50% cytotoxic concentration (CC50) of the extracts was determined using MDCK cells, revealing only mild toxicity against MDCK cells for all the extracts. Cells were subsequently treated with effective concentration (EC50) of the extracts with approximately 100 tissue culture infectious dose (100TCID50) of the virus at varying exposure times: simultaneous, pre-penetration and post-penetration combined treatments with an incubation time of one hour. The antiviral potential of the extracts was tested by standard haemagglutination (HA) and haemadsorption (HA) inhibition assays. A dose-dependent HI pattern of the extracts’ test results was observed. Methanol and butanol extracts were the most promising against influenza A virus (IAV) in all types of combination treatments which confirms the extracts’ efficacy in all steps of viral attachment, entry and life cycle. However, the MTT assay, which provided the EC50 value of 77.00 µg/ml, could be considered as effective extracts against IAV. This study represents the first report of L. alata extracts as a potential source of new anti-IAV drugs or preparations.

2935 In Vitro Cytotoxic Activities of Dianthus thunbergii S.S. Hooper (Caryophyllaceae)
A. S. Akinrinde1, T. Koekemoer2, M. Van de Venter3, and G. Bradley4
1University of Ibadan, Nigeria, Ibadan, Nigeria; 2National Veterinary Research Institute, Plateau State, Nigeria; 3University of Pretoria, Pretoria, South Africa; and 4University of Fort Hare, Alice, South Africa.

The roots of Dianthus thunbergii SS Hooper are used traditionally in South Africa for the treatment of diabetes, wounds, colic, chest complaints and cancer. The potential cytotoxic and/or anti-proliferative activities of the aqueous and ethanol root extracts of D. thunbergii were evaluated in vitro on two cancer cell lines- human hepatocellular carcinoma (HepG2) cells and murine insuloma (INS-1) cells using the 3-(4,5-Dimethylthiazol-2-yl) 2,5-diphenyltetrazolium bromide (MTT) and crystal violet cell viability assays, as well as live-cell fluorescence imaging microscopy. The aqueous extract (50-200µg/ml) exhibited sig-
nificant (p<0.05) cytotoxicity in HepG2 cells (IC50=50 µg/ml), while also significantly (p<0.05) decreasing the viability of INS-1 cells (IC50=36.0 µg/ml), although no toxicity was evident in L6 myotubes. Hoechst 33342 and propidium iodide staining of INS-1 cells further revealed significant growth inhibition (p<0.001) of INS-1 cells by the aqueous extract. No meaningful toxicity was, however, obtained with the ethanol extract (IC50 = 39.0 µg/ml) and nor with the LcE50/MS analysis of the aqueous extract revealing the putative identities of main compounds present in the aqueous root extracts, including some that may contribute to its anti-proliferative action. Taken together, the results showed that the roots of D. thunbergii may represent a potential plant-based source of agents with anti-proliferative efficacy.

2936 Potency and Safety of Eight Under-Investigated South African Plants from the Myrtaceae Family for Activity against Bacillus anthracis Sterne Vaccine Strain

I. M. Famuyide1, O. A. Aro1, F. O. Fasina2, J. N. Ellof2, and L. McGaw1. 1University of Pretoria, Pretoria, South Africa; and 2Emergency Centre for Transboundary Animal Diseases-Food and Agriculture Organisation of the United Nations, UN Avenue, Ggigiri, Kenya.

Anthrax, caused by Bacillus anthracis infection is a severe acute disease. Apart from its zoonotic importance and potential as a bioterrorism agent, the economic losses associated with morbidity and mortality of animals. It is transmitted through the control of the carrier state, which has a high priority globally. Against the backdrop of antimicrobial resistance, there is motivation to develop new anti-B. anthracis products especially from natural sources to provide alternative or complementary remedies. Recent empirical evidences show that plants hold potential for anthrax control in South African plants have been tested for their efficacies against B. anthracis. This study reports the growth inhibitory activity of crude leaf extracts of plants from the myrtaceae family against B. anthracis Sterne vaccine strain. A two-fold serial microdilution assay was used to determine the minimum inhibitory concentration (MIC) of the extracts against B. anthracis. Cytotoxicity (LC50) was determined by a tetrazolium-based colorimetric assay against Vero kidney cells and selectivity indices (LC50/MIC) which gives an indication of the safety of the crude extracts were obtained. The MIC of the plant extracts ranged from 39µg/ml to 156µg/ml. Excellent MIC values were observed for the active extracts.

2937 Nematicide Activity of Chenopodium ambrosioides L. and Ambrosia cumanensis kunth

Chenopodium ambrosioides L. and Ambrosia cumanensis Kunth are shrubs that grow in some regions of South America, whose leaves have traditionally been used for therapeutic purposes such as anthelmintics, anthelmintics, anti-inflammatories and against colds. In this work the anthelmintic activity of different leaf fractions of these two plants was evaluated. Extracts of these plants were obtained by maceration of the crushed vegetable material with 96% ethanol as solvent, and concentration in the rotovaporator at 45 °C and vacuum of 172 mbar pressure, monitoring the process by thin layer chromatography. The concentrated extract was incubated at 40 °C for 48 h. It was then mixed with silica gel powder and allowed to dry for 12 h. Extracts of different polarities were obtained by eluting hexane, chloroform, ethyl acetate and methanol through column chromatography. Phytochemical screening of the major groups of secondary metabolites in the extracts of the plants studied was performed to identify the presence of alkaloids, tannins, coumarins, flavonoids, triterpenes, saponins, quinones and cardiotonic glucosides. The nematicidal effect was carried out using a tetrazolium-based colorimetric assay against Vero kidney cells and selectivity indices (LC50/MIC) which gives an indication of the safety of the crude extracts. We found that the extracts had high selectivity against the bacteria than to normal body cells. The extracts were relatively safe (S.1>1). This shows that the extracts have higher toxicity against the bacteria than to normal body cells. Further research is on-going to isolate the compounds responsible for anti-B. anthracis activity and determine the mechanism of action of the active extracts.

2938 Toxicological Evaluation of Annona muricata Methanolic Extract in Rodents

T. A. Oladipo1, A. A. Adebjii1, A. O. Morakinyo1, J. Olorode1, E. Popoola2, and J. O. Olukunle2. 1Federal College of Animal Health and Production, Technology, Moor Plantation, Ibadan, Nigeria; and 2Federal University of Agriculture, Abeokuta, Abeokuta, Nigeria.

Due to large growth in the use of herbs as alternative to conventional drugs, its becomes imperative for researchers worldwide to intensify effort in screening for safe dose and the likely toxicological effects that may be associated with the use of these herbs. Hence, this work focussed on the toxicological evaluation of Annona muricata methanolic bark extract (AMMBE) also known as soursop. Twelve 12 mice and 16 rats were used for the toxicological study consisting of four groups and 4 animals per group per study. Annona muricata bark was soaked in methanol for 72 hours and processed to obtain the brownish semi-solid extract used for the study. The acute toxicity test revealed that clinical signs of paw-licking, writhing, incoordination etc were observed at a dose of 2600mg/kg while mortality was recorded at 3200mg/kg body weight and L90 was calculated to be 2884.4mg/kg. The sub-chronic study showed dose dependent mild reductions in PCV, RBC and Haemoglobin, there were no significant changes in the serum chemistry and organs histopathology when compared to the control.

2939 Potential Effects of 4-O-Methylhonokiol on Japanese Medaka Embryos

Since the potential toxic effects of 4-O-Methylhonokiol (MH), a major bioactive constituent of Magnolia grandiflora seeds or Magnolia officinalis bark for clinical trials remain elusive, toxicity assessment of MH was assessed with Japanese Medaka (Oryzias latipes) embryos in vivo. Fertilized medaka eggs (Iwamatsu stage 10) were exposed to various concentrations of MH in embryo rearing medium (ERM) in a 48 well culture plate (one embryo/well/ml) and maintained at 25±1°C with 16L:8D light cycle. The treatment continued for 0-6 day post-fertilization (dpf) to explore whether MH induces developmental defects in medaka and how it contributes to their survival. Embryos were evaluated for heart rate, vessel circulation, thrombus formation, hatching efficiency and mortality. Embryos exposed to 5, and 10 µM MH caused suppression of heart rate and a reduction of blood flow in lower trunk vessels in 5dpf with a median effective concentration of 3.53 µM. Since blood coagulation factors are concomitantly also activated by the lesion on the lining of blood vessel, we initially examined the procoagulant action of MH on the components of the plasma kalikrein-kinin system. MH was ineffective to activate prekallikrein (Fletcher factor), factor XI (plasma thromboplastin antecedent), or factor VIII (von Willebrand factor). The lowest concentration of MH to induce tail malformation was 5 µM. The embryos exposed to 5 and 10 µM MH 0-6 dpf significantly reduced hatching efficiency and caused mortality in comparison with other groups. Their findings indicate that MH affects the normal development of the medaka embryo in low µM concentrations.

2940 Ethyl Acetate Fraction of Acacia ataxacantha Leaf Extract Inhibits Escherichia coli O157:H7

Escherichia coli O157:H7 is a well-recognized food-borne bacterial pathogen of high public health importance. Globally, cattle serve as major reservoirs of the organism. Most case fatalities and episodes of the infection result from the effects of enterotoxins, cytotoxins, shiga-toxin production and other virulence factors. Infants, elderly and immune-compromised individuals are particularly at high risk. Complications that often accompany conventional antibiotic therapy and the persistence of multiple resistant mechanisms of the pathogen were negative controls. In A. cumanensis the presence of cardiotonic glycosides was determined in the ethanolic, hexanolic and chloroform extracts; saponins in ethyl acetate and methanolic extracts, triterpenes and sterols for ethanolic, hexanolic and chloroform extracts. In C. ambrosioides, flavonoids and tannins were identified in total extract, ethyl acetate and methanol and triterpenes and steroids in all extracts. The hexanoic extract of A. cumanensis contained the highest morality in C. elegans, while all extracts of C. ambrosioides showed nematicidal effect at 150 µg/mL. In conclusion, the compounds present in leaf extracts of both plants can be used as anthelmintics.
present obvious challenges to effective treatment. Extract of Acacia ataxacantha leaves (EAA) is a popular herbal remedy for digestive disorders in Nigeria. The study evaluated EAA for bioactivity against E. coli O157:H7. The crude EAA was prepared by cold maceration in 98% methanol and concentrated in a rotary evaporator. Solvent partitioning of the crude extract was done with N-hexane, ethyl acetate and distilled water. Tests using E. coli O157:H7 and H7 flagellar antigens, respectively. Antimicrobial susceptibility tests were carried out on the isolates using the agar disc diffusion method; the minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) of the extract were evaluated. Eighteen isolates from the 515 samples were identified as non-sorbitol fermenters with two isolates each for E. coli O157 and E. coli O157:H7 respectively. The crude extract (300-600 mg/ml) exhibited a comparable antibacterial activity (zones of growth inhibition) to that of tetracycline (30 μg/ml), gentamicin (10 μg/ml) and ciprofloxacin (5 μg/ml). Ethyl acetate fraction with MIC of 200 mg/ml was the most potent. Culture from MIC tubes on fresh seeded media showed growth of the isolates following 24 h incubation indicating a bacteriostatic activity. The findings demonstrated that ethyl acetate fraction of A. ataxacantha leaf extract possessed a bacteriostatic activity and this could be explored to complement therapy against E. coli O157:H7 infection.

**2941 The Effect of Sesamin on Endothelial Nitric Oxide Synthase Activation through Calcium-Dependent Signaling Pathways**

T. Pham¹, T. Ngań¹, G. Lee¹, S. Jin¹, S. Kim², H. Kim², and H. Jeong¹.

¹Chungnam National University, Daejeon, Korea, Republic of; and²Mokpo Marine Food-Industry Research Center, Mokpo, Korea, Republic of.

Sesamin is a major lignin in sesame seeds (Sesamum indicum) and has been known to act as a potent antioxidant and enhance endothelial function which contributes in protecting and preventing or reducing cardiovascular diseases. However, the mechanism involved to the cardioprotective effect by activation endothelial nitric oxide synthase (eNOS) of sesamin remains unclear. In this study, we identified the intracellular pathways underlying eNOS activation by sesamin. Sesamin induced the activating phosphorylation of eNOS on Ser1177 in EA.hy926 cells. Sesamin-induced eNOS phosphorylation required adenosine receptor (ADORA2B)-mediated PI3K/Akt and MAPK signaling and was reversed by AMPK and CaMKII inhibition. These results indicate that sesamin stimulates eNOS phosphorylation via activation of ADORA2B-mediated PI3K/Akt, MAPK, CaMKII/AMPK-dependent pathway. Sesamin may be useful for the treatment or prevention of endothelial dysfunction associated with diabetes and cardiovascular disease.

**2944 Phillyrin Suppresses Hepatic Gluconeogenesis Via Phosphorylation of CRTC2 and HDAC5 in HepG2 Cells**

G. Lee¹, T. Ngań¹, S. Kim¹, S. Jin¹, E. Han², and H. Jeong¹. ¹Chungnam National University, Daejeon, Korea, Republic of; and²Korea Basic Science Institute, Cheongju, Korea, Republic of.

Type II diabetes mellitus (T2DM) is a chronic metabolic disease caused by insulin resistance, and its worldwide prevalence has dramatically increased over the past few decades. Increased glucose production through hyperglycaemia is dysregulated and results in the manifestation of hyperglycaemia in T2DM. Phillyrin, one of the major active constituents of F. suspensa and F. koreana, was known to possess the anti-inflammatory and anti-oxidant effects. An in vivo study showed that phillyrin exerted anti-obesity effects in nutritive obesity mice. However, the anti-diabetes mellitus effect of phillyrin and its underlying molecular mechanisms have not been elucidated. In this study, we investigated the inhibitory effects of phillyrin on hepatic gluconeogenesis in HepG2 cells. Phillyrin reduced the mRNA expression of glucose-6-phosphatase (G6Pase), major genes in hepatic gluconeogenesis. Also, Activated AMPK by phillyrin suppresses hepatic gluconeogenesis through phosphorylation of CRTC2 Regulated Transcription Coactivator 2 (CRTC2) and Histone deacetylases (HDAC5). These phosphorylation events induce the sequestration of CRTC2 and HDAC5 in the cytoplasm, which leads to suppression of CREB and FoxO1 transactivation activities. Together, these results suggest that phillyrin inhibited hepatic gluconeogenesis via phosphorylation of CRTC2 and HDAC5 by activated AMPK in HepG2 cells.

**2944a Interaction of Quercetin with Different Flavonoids and Induction of Phase-II Enzymes in Hepa-1c1c7 Cells**

B. Benavides¹, and H. Ahmad². ¹University of Texas San Antonio, San Antonio, TX; and²University of Texas Rio Grande Valley, Edinburg, TX. Sponsor: M. Mumtaz.

For more than four decades epidemiologic studies correlate that consumption of diets rich in fruits and vegetables are associated with lower risks of cancers. A persuasive body of evidence indicates that protection against chemical carcinogenesis can be achieved by non-nutrient components of vegetables and fruits capable of inducing phase II enzymes that are involved in carcinogen metabolisms. These enzymes include Glutathione S-transferase (GST), which inactivates toxic electrophiles, and NAD(P)H:quinone reductase (QR), which catalyzes two-electron reductions of quinones to hydroquinones. The flavonoids are an important class of naturally occurring compounds and represent parts of the human diet found in edible plants. This study investigated the synergetic effect of hesperidin with other flavonoids/biomolecules on the induction of GST and QR activity in a murine hepatoma line. The cells were incubated with appropriate concentrations of flavonoids
individuals and with mixtures of flavonoids/biomolecules for 48 hours in CO2 incubator, maintained at 37°C. For the synergistic effects, the concentration of quercetin is kept constant whereas the concentrations of the second and third flavonoid/biomolecule were varied. The cells were sonicated, the content centrifuged and the supernatant was used to determine enzyme activities and proteins. GST activities were determined against two substrates: 1-chloro-2, 4-dinitrobenzene (CDNB) and 4-nitroquinoline 1-oxide (4NQO), whereas QR activities were determined by the reduction of 2, 6-dichlorophenolindophenol (DCPIP). Quercetin in combination of caffeine and hesperidin exhibited no significant change in GST or QR activities whereas individually they showed induction. Also, no significant change in GST activities was observed when quercetin was incubated with caffeine and ginger extract but QR activities were induced. In the third group, where quercetin, caffeine, and resveratrol were mixed, both GST and QR activities showed significant induction against the control. In the group where quercetin, cafe- feine, and β-carotene were varied, no changes were observed although individually they caused induction. These results suggest that induction of phase-II enzymes by flavonoids in combina- tion may be important in achieving of a meaningful effect in order to formulate imminent cancer prevention strategies. A more in depth in vivo study may be needed to further corroborate results of this study.

**2945 Advancing Toxicology Education in Consumer Products Safety and Sustainability through a Corporate Partnership**

K. W. Fried1, M. C. Fortin2, L. M. Aleksunes2, M. Capdevielle1, and D. M. Bagley1, 1Colgate-Palmolive Company, Piscataway, NJ; and 2Rutgers, The State University of New Jersey, Piscataway, NJ.

The importance of investigating, documenting, and supporting the safety of consumer products for consumers, workers, and the planet cannot be overstated. It is the basis of consumers’ trust in the products they use. However, this topic is not typically offered in toxicology training programs and requires a specialized skill set, which is often acquired on the job. In close partnership, Rutgers University (RU) faculty and Colgate-Palmolive Company (CP) scientists designed and imple- mented a two-credit elective course in “Consumer Products Safety and Sustainability”. During this course, students and postdoctoral fellows acquired specialized skills in assessing ingredients for use in specific product types, in regulatory compliance, addressing consumer and worker safety, as well as environmental exposures, biodegradability, and sustainability. Course content was built on the strong founda- tional curriculum at RU, and went beyond the traditional risk assessment framework to teach real-world application-based skills. Students worked through case studies at the end of each session. Interaction and assessment of real-time comprehension were enabled by using a clicker response system. Course participants were evaluated based on attendance and participation (10%), team-based mid-term oral presentations evaluated by a panel of CP scientists (45%), and a final examination composed of multiple choice and written answers (45%). Students completed a course evaluation including a five-level rating scale (from disagree strongly to agree strongly), word attributes, and open-ended questions. 100% of the participants “would recommend this course to a friend”. The students’ rating of the course overall was a 4/5 (with 5 being the best). A benchmarking quiz was completed by the students at the beginning and the end of the semester, showing quantitative and qualitative improvements in understanding. In con- clusion, a team-taught elective course as part of a private-public part- nership provides graduate and postdoctoral students with real-world, application-based training that prepares them for careers in all areas of corporate toxicology in the consumer goods industry. **Supported by T32 ES007148.**

**2946 Exploring Careers in Toxicology through an Interactive Summer Program for High School Students: A Five-Year Perspective**

Introducing students early in their education to the fields of toxicology and environmental health sciences is critical to developing the next generation of talented and dedicated scientists. Towards this effort, the Toxicology, Health and Environmental Disease (THED) program was established to engage high school students interested in pursuing sci- entific careers in toxicology. A critical goal of THED is to provide the basic concepts and skills of designing and conducting a toxicology study: study design, dose-response relationships, necropsy, pharmacokinetics, histopathology, molecular biology and immunohistochemistry. This was accomplished with hands-on, team-based laboratory experiments and lectures from graduate students and postdoctoral fellows. In addition, participants met with speakers in careers in medicine, pharmacy, gov- ernment, pharmaceutical industry, and academia, to receive guidance on career paths. In 2017, we marked the fifth year of the THED program with engagement of 240 students. Each year, the program was assessed through post and post-survey by parents. Based on survey feedback, the THED program has evolved to align the goals of the program with those of the students and parents. In response to parental feedback, more time and a greater emphasis were placed on introducing participants to prospective career tracks. Moreover, the selection and conduct of the hands-on laboratory activi- ties were refined to enhance the program’s effectiveness of teaching the desired laboratory based skills and key concepts of toxicology. By centering each laboratory activity on the overarching question, “How would one develop countermeasures against chemical warfare agents?”, instructors demonstrated how experiments should approach a contemporary toxicologic problem. With the added focus on career development, when parents were asked to grade on a 7-point Likert scale how effective the program was in exposing their children to different scientific careers, we received an average score of 6.65 (SD = 0.81). In conclusion, a one-week interactive, laboratory-based, edu- cational program contributes to the training pipeline in toxicology by advancing the research skills of high school students and exposing them to career paths in toxicology. **Supported by NIEHS T2ES007148, P30ES005022, and U54AR055073.**

**2947 Mentor Perceptions and Motivations in a Ten Week Summer Undergraduate Research Fellowship in Toxicology**

D. L. Laskin, and L. M. Aleksunes, Rutgers, The State University of New Jersey, Piscataway, NJ.

Intensive laboratory training during the summer provides undergradu- ate students with the opportunity to gain research skills, explore post-graduate training options, and develop interpersonal skills. Most assessments of summer fellowships focus largely on student percep- tions and outcomes. The purpose of the present study was to assess the motivations, satisfaction, and perceptions of mentors who supervised undergraduate students in a 10-week summer research fellowship at Rutgers University. Students spent 40 h per week in individual labora- tories or clinical sites and 2 h per week in career development activi- ties such as toxicology research seminars, field trip, and LinkedIn profile development. The fellowship culminated in student research presen- tations. Each student submitted a scientific abstract and presented their major research findings during symposiums held in the last two weeks of the fellowship. All co-authors on the abstracts (N=25) were emailed an 11 question online survey upon completion of the program. Responses were received from 32 individuals (24 faculty members and 8 graduate students/postdocs/technicians). All respondents had previously mentored summer interns with 68% of mentors having supervised between 1 and 5 students in the past 5 summers. The remaining 32% of respondents reported mentoring between 6 and 10 students in the past 5 summers. Respondents spent an average of 13.3 h (± 1.10 h SD, 1.5-37 h range) with their student each week. Using a 5-point system, the student fellows received the highest ratings for their work ethic and scientific curiosity followed by the quality of their presentation and technical skills. The majority of mentors would definitely recommend (score of 5) the summer fellowship program to a student (85%) and to another mentor (72%) and would serve as a mentor in a subsequent summer (77%). Motivations for serving as a mentor included another mentor (72%) and would serve as a mentor in a subsequent summer (77%). Motivations for serving as a mentor included another mentor (72%) and would serve as a mentor in a subsequent summer (77%). The remaining 32% of mentors were motivated to serve as a mentor because of their enjoyment of teaching students. Periodic assessment of mentor per- ceptions and motivations is important for the continual evaluation and improvement of a summer undergraduate research program. **Supported by NIEHS R25ES007271, P30ES005022, ASAP, and the SOT Intern Program.**

**2948 Creating Scientific and Graphical Abstracts as an Interactive Session in a Summer Research Fellowship**

L. M. Aleksunes, and D. L. Laskin, Rutgers, The State University of New Jersey, Piscataway, NJ.

Short-term research experiences such as summer fellowship programs provide students with an opportunity to develop their research skills, explore career options, and improve written and oral communication skills. Most summer research programs for undergraduate students require a final poster or podium presentation. At Rutgers University, we emphasize interactive, hands-on training for undergraduate students to conceptually and draft written and graphical abstracts that would sum- marize the major findings of their research and be distributed at our
research symposium. During week 7 of a 10-week summer undergraduate research fellowship, students learned about the major components of an abstract using a variety of examples. Students were also taught common pitfalls to avoid in communicating research findings. After the discussion of each of the opening sections (title, introduction, hypothesis, and methods), students were provided 5-minutes for writing. After each portion of the abstract was composed, students volunteered to share their writings with the group, and the moderator provided constructive comments. Different examples of graphical abstracts were also presented to the students. Twenty seven students submitted abstracts during week 9 of the summer fellowship program which were assembled into booklets for the final research presentations. This interactive activity received the highest programmatic rating of the summer fellowship with a mean score of 4.39 (±0.71 SD) on a Likert scale of 1 to 5 with 5 representing the highest possible rating. Other weekly activities were also well-received with mean scores ranging from 3.57 to 4.32. Taken together, all interactive sessions included didactic instruction and student responses allows undergraduate students to begin writing and designing their written and graphical abstracts as part of a summer research fellowship. Supported by NEIHS R25ES020721, P30ES005022, ASPET, and the SOT Intern Program.

2949 Initial Assessment of a Summer Undergraduate Research Program

H. Swanson1, and L. Xiang2. 1University of Kentucky, Lexington, KY; and 2Weber State University, Ogden, UT.

Undergraduate research experiences are closely correlated with enhanced student learning and student success. Summer research programs are of particular interest as they offer unique opportunities for incorporating hands-on research with additional activities designed to enhance students’ scientific skills and career readiness. They also can be invaluable for developing a diverse scientific and professional workforce. The Summer Undergraduate Research in Environmental Health Sciences (SUREs) program is a 10-week program involving upper-level undergraduates and near-peer as well as faculty mentors. Student participants were matched with their faculty mentors by ranking their interests and were matched with near-peer mentors using a “speed-dating” approach. The goal of this study was to determine the most effective aspects of the program. Assessment using a pre/post survey instrument revealed that program participation increased student interest (from 9.1% to 100% of respondents) in teaching at the post-secondary level. In addition, student respondents reported gains in 39 of the 40 items adopted from the Undergraduate Research Student Self-Assessment, with statistically significant gains in students’ research skills and attitudes toward research. Survey respondents reported an overall increase in confidence, in particular, in their ability to participate in research. With respect to program activities, creating and presenting posters was the most highly ranked amongst the respondents in helping them understand environmental health sciences. Students also indicated that program components related to career skills and pathway were very helpful. Time spent with faculty mentors focused on research related activities and discussions on careers. Respondents indicated that the near-peer mentors provided emotional support and opportunities to ask for help and discuss difficulties. The results from this study provided insights into particular aspects of the SUREs program that best contribute to student learning and prepare students for careers in environmental health sciences.

2950 A Novel Toxicology Mentoring and Training Program Targeting Underrepresented Undergraduate Students in STEM Disciplines

W. K. Rumbeia1, J. D. Wolt1, A. Correia1, E. Gilbreath1, D. Alexander2, and R. Whittington1. 1Iowa State University, Ames, IA; 2The Ohio State University, Columbus, OH; and 3Tuskegee University, Tuskegee, AL.

Exposure of undergraduate students to toxicology as a career choice is not coupled with increased diversity in the field. Thus understanding how the pool of undergraduates applying to graduate programs or entering careers in toxicology may be limited because students who are otherwise interested may not be aware of toxicology as a career option. This is particularly true for underrepresented students who are critical to a more diverse and representative future workforce in toxicology. A diverse workforce is critical for new scientific discoveries and human health care. The Toxicology Mentoring and Skills Development Training Program (ToxMSDT) - a collaboration amongst educators at Iowa State University, Tuskegee University and The Ohio State University - seeks to acquaint promising undergraduates with knowledge about toxicology careers and to provide training that equips students with toxicology fundamentals and skills that will aid their entry into graduate programs or careers in STEM disciplines. This is a year-long training and mentoring program. The public face of this program is ToxMSDT, a web resource comprised of learning e-modules and supplemental resources targeted to student learning as well as the general public to the discipline of toxicology. The learning e-modules and associated activities reflect key core competencies for training of the total toxicologist as identified through the 2012 SOT Toxicology Education Summit, namely (1) fundamentals of toxicology; (2) pathophysiology; (3) applied systems biology; (3) biochemistry; (4) molecular genetics; (5) regulatory frameworks; (6) communication skills; and (7) critical thinking skills. The second cohort of students will complete all required elements of the ToxMSDT program by June 30th 2018. This mentoring program advances the goals of National Institute of General Medical Sciences by creating an inclusive workforce to achieve the NIH mission.

2951 Foundational Concepts in Undergraduate Toxicology: Applying Vision and Change to the Development of Core Concepts and Learning Objectives for an Undergraduate Toxicology Course

J. P. Gray1, C. P. Curran2, V. A. Fitsanakis3, S. D. Ray4, K. E. Stine5, and B. Eidemiller6. 1US Coast Guard Academy, New London, CT; 2Northern Kentucky University, Highland Heights, KY; 3Northeast Ohio Medical University, Rootstown, OH; 4Manchester University College of Pharmacy, Fort Wayne, IN; 5Auburn University at Montgomery, Montgomery, AL; and 6Society of Toxicology, Reston, VA.

In 2011, the National Science Foundation and American Association for the Advancement of Science produced the “Vision and Change Report” (visionandchange.org) which sought to improve education in undergraduate biology for all students by defining Core Concepts: Evolution; Structure and Function; Information Flow, Exchange, and Storage; Pathways and Transformations of Energy and Matter; and Systems. Vision & Change has had a major impact on undergraduate biology education; scientific societies have created and adopted their own Core Concepts for their undergraduate courses and communicated them via peer reviewed publication. Appointed by the Undergraduate Education Subcommittee of the Five Core Concept Themes Committee, under the direction of the undergradate educators, the goal of the Learning Objectives ad hoc committee is to implement Vision & Change for undergraduates toxicology and to communicate its findings internally within the Society of Toxicology and externally via collaborations with multidisciplinary organizations including Course Source (coursesource.org), the Life Science Teaching Resource Collection (lifesciencetr.org), and peer reviewed publication. Data were collected and analyzed from more than 20 undergraduate toxicology syllabi from across the United States together with several undergraduate textbooks to quantify themes taught in all toxicology-related courses. A Learning Framework with Five Core Concept themes compatible with Vision & Change was developed: Evolution; Pathways and Transformations of Energy and Matter; Systems Toxicology; Biological Information; and Risk Assessment. Society Learning Goals for these five Core Concepts and Learning Objectives associated with each Society Learning Goal were also created. The publication of the work alongside the other major life science disciplines will facilitate the development and sharing of evidenced-based teaching materials for toxicology educators throughout the world and expand toxicology’s impact to a broader audience.

2952 Problems and Promises with Collaborative Learning in the Field in an Urban Public College

Sandra Swenson. John Jay College of Criminal Justice, New York, NY. 10019. Problems and Promises with Collaborative Learning in the Field in an Urban Public College Many STEM disciplines require collaborative and cooperative learning because it supports social interdependence which is inherent in scientific research as well as civic responsibility. Many studies report positive outcomes for collaborative and cooperative learning environments because learners work together to support each other in a common learning goal and students learn about group dynamics as well as interpersonal skills such as communication, trust, and dealing with conflicts. However, collaborative & cooperative learning in the field has its problems and its promises. This study examines the weaknesses as well as the strengths of collaborative field and laboratory work. In our research, each year, approximately 90 students were instructed in the proposed new method; the remainder of students (upwards of 90 in the control group) attended the traditional class that had been taught at the college for 15 years. All students were divided into groups of 4 in a lab class of
nearly 24 students, whether they were traditional or treatment classes, but each treatment group of Environmental Science students went into the field to collect data while the traditional groups only completed labs in the laboratory. Pre- and post-Likert scale surveys and open ended questionnaires were given to student volunteers. The significant results were slightly more favorable for the treatment group as compared to the control group and this study drills down to examine those differences and proposes some possible explanations as to why the treatment group did not have better results.

2954 Interdisciplinary Emergency Crisis Drills: Toxicology Students as Technical Experts

D. Bianculli, I. Ban, A. Cummings, W. Murphy, and S. M. Ford. St. John’s University, Jamaica, NY.

St. John’s University has conducted Mock Crisis drills for the past three years in order to provide students with a career-focused, experiential learning opportunities in their various disciplines. Studies have shown that such practical learning increases student engagement. The Career Center at St. John’s has coordinated the Mock Crisis drills involving student volunteers from Criminal Justice, Homeland Security, Physician Assistant, Journalism, Public Relations, Legal Studies, and Toxicology. The past three crisis scenarios have involved potential exposure of “victims” (student actors) to a toxic chemical. The scenarios were constructed by faculty advisors. Student participants were involved as part of a required course assignment overseen by their faculty instructor or were recruited as volunteers. Toxicology graduate students served as technical experts to inform and communicate toxicological information to first responders and the “media,” played by students in the appropriate majors. The role of the toxicology students was to communicate toxicological information to students of multiple backgrounds. This was most challenging for the toxicology students when conveying information to the journalism and public relations students, who possessed no background in science. The information provided to them not only had to be easy to understand, but consistent as well. The toxicology students were also present at the mock press conferences. After the conference, professors commented on the performance of the students involved. The result was that the interdisciplinary team operated effectively in resolving the crisis. These drills have proved extremely useful, as they emphasize skills that aren’t traditionally taught, such as effective communication and operating with others outside of toxicology. Program outcomes were assessed by the Career Center. These drills have been recognized for their effectiveness as well, winning two awards in 2015. One was an honorable mention from the Student Affairs Professionals Association and the other was first place in the Alva C. Cooper Award for Best Practices in Career Development.

2955 Integrating Bioinformatics and Neurotoxicology into a Research-Based Course for Undergraduates

V. A. Fitsanakis1,2, and L. K. Vaughan1,2. Northeast Ohio Medical University, Rootstown, OH; and King University, Bristol, TN.

As the ease with which “big data” can be generated increases, it is becoming more important for undergraduate educators to find ways to integrate this type of application and analysis into the curriculum. One way is to combine topics from multiple courses and teach these concepts “across the curriculum,” a process emphasized in the “Vision and Change” document. The biological database of Caenorhabditis elegans, produced by the National Science Foundation for the Advancement of Science. In a pilot study, we integrated concepts from a course in bioinformatics with a research-based class intended to provide students with opportunities to conduct original research. In this project, a student interested in nicotine addiction and metabolism was tasked with data-mining the literature for associated genes. Following nearest-neighbor analysis to determine the strongest links among the various genes, the student identified links connecting genes involved in nicotine addiction and metabolism to neurodegenerative diseases, nicotine metabolic pathways, and cancer. In light of the protective effect of nicotine, we then hypothesized that knocking down related genes from the bioinformatics analysis would increase the nicotine protection. Although the student did not complete the last part of the study, we learned better ways to (1) incorporate relevant bioinformatic questions into student research, (2) move bioinformatic results obtained from human data into a model system that is easily accessible to undergraduates, and (3) alter the scope of the overall research project so that is should be possible to complete within a 12-month period. Current revisions are underway to better refine the process, and to scale it so that a similar project could be used for a small upper-division course rather than a single student.

2956 Using C. elegans to Teach Genetics, Bioinformatics, and Neurotoxicology at Underfunded Undergraduate Institutions

L. K. Vaughan1, D. C. Williams2, and V. A. Fitsanakis1,3. King University, Bristol, TN; 2Coastal Carolina University, Conway, SC; and 3Northeast Ohio Medical University, Rootstown, OH.

One of the difficulties of teaching complex concepts associated with genetics, bioinformatics, and toxicology to undergraduates is the lack of resources and infrastructure. Furthermore, it can be challenging to put together lab activities that are relatively cheap, build on concepts presented in potentially unrelated courses, and engage the student in individual and novel research. As universities around the country struggle with how to implement best practices, such as those outlined in the “Vision and Change” document endorsed by the American Association for the Advancement of Science and the National Science Foundation, we sought not only to create a unique learning environment on our respective campuses, but to also integrate a collaboration among universities to model for students how the enterprise of science can work. Thus, we have started working on a project that integrates the ease with which Caenorhabditis elegans (C. elegans) can be genetically manipulated with the information that came from the sequencing of this worm’s genome. In our curriculum, student enrolled in “Genetics” use C. elegans to phenotype and map genetic mutants using basic genetic and linkage analysis techniques. This information is used towards the end of the semester to help students learn how to use basic bioinformatics tools to identify candidate genes for further analysis in advanced courses or in the research laboratory. In some cases, where a bioinformatics course is available, the students can then learn to analyze more advanced “omic” level data (epigenetic, sequencing, gene expression, etc.) generated from the research lab. Ultimately, the goal of this
endeavor is to provide students with the basis of an individual research project that allows them to use the worms to evaluate the effect various genetic backgrounds have on exposure to environmental chemicals, such as pesticides. As such, we are progressing towards a model whereby undergraduates are able to study important gene-environment interactions. Although in its early stages, we ultimately anticipate that this process can be used as a model for collaboration for other small undergraduate universities who want to provide a rich lab experience that leads students towards a career in research.

2957 Using the Exposome and a Graph Theoretical Toolchain to Analyze Disparities

D. B. Hood1, P. D. Juarez2, G. Rogers3, S. H. Baktash1, A. M. Saxton1, P. Matthew-Juarez2, W. Im2, M. P. Cifuentes3, C. A. Phillips3, M. L. Lichtveld1, and M. A. Langston4. 1The Ohio State University, Columbus, OH; 2Meharry Medical College, Nashville, TN; 3University of Tennessee, Knoxville, TN; and 4Tulane University, New Orleans, LA.

To identify exposures associated with lung cancer mortality and mortality disparities by race and gender using an exposome database comprising of county-level heterogeneous data coupled to a graph-theoretical toolchain. Graph-theoretical algorithms were employed to extract paracilies (noise resilient dense subgraphs) from correlation graphs built using associations between 2,162 environmental exposures and lung cancer mortality rates in 2,067 counties, with clique-doubling applied to compute an absolute threshold of significance. Factor analysis and multiple linear regression were then used to analyze differences in exposures associated with lung cancer mortality and mortality disparities by race and gender. While smoking was highly correlated with rates of lung cancer mortality for white men and women, previously unidentified exposures were mostly associated with lung cancer mortality and mortality disparities for Blacks. Exposures beyond smoking are moderators of lung cancer mortality and mortality disparities by race and gender. An exposome database coupled with scalable combinatorial analytics provides a powerful new approach for analyzing relationships between multiple environmental exposures, mortality and mortality disparities. The impact of which will translate to other disparate health outcomes to inform environmental public health research, practice, and policy.

2958 Application of Collaborative Analysis Methods to Address Human Health Risk Assessment Decisions

A. Maier, J. Patterson, and O. Ogbonnaya. University of Cincinnati, Cincinnati, OH.

In the practice of human health risk assessment there is frequently tension between stakeholder groups (e.g., government, industry, advocacy groups, academia) regarding interpretation and confidence in results of toxicology and epidemiology data. In the application of toxicology for assessing risks, data gaps and uncertainties are common, with conclusions highly dependent upon scientific judgments and weight of evidence. When the decisions are controversial, opposing parties often form subcultural alliances in adversarial analysis or whether their position is justified by public or regulators. Such competing analyses without efforts to define the bases for areas of commonality and differences can result in confusion among decision makers regarding the current state of science. We explored the hypothesis that pursuit of high quality risk science is best served by actively involving a diversity of scientists from relevant disciplines and affiliations to identify and discuss data and judgments. Data drawn from the literature on chemical exposure health assessments and personal experience in developing over 50 multi-stakeholder peer reviews were evaluated to identify key variables that impact the successful application of collaborative analyses. Published case studies and best practices were evaluated. Little empirical research related to best practices for collaborative working groups and measurement of the quality, validity, and reliability of their results was found. The absence of published cases was confirmed through a benchmarking effort with experts leading to a finding that additional case studies are needed to build a robust basis for comparing adversarial and collaborative analytic techniques. An analysis of over 50 independent peer review meetings on health risk assessments illustrates that multi-disciplined groups of scientists can perform careful and detailed evaluations of assessments and reach conclusions on the scientific validity of the findings and results. A structured comparative approach, using panels of scientists inclusive of the range of stakeholders and scientific opinions to evaluate the data as a group and reach mutually agreeable conclusions, may be an option for controversial risk issues involving toxicology interpretation. Based on the resulting analysis a framework is proposed for the active application of methods of collaborative analysis to risk informed decision-making.

2959 The Write Way to a Successful Career: SOT Efforts to Fill Professional Writing Skills Gaps

A. B. Bowman1, A. L. Roe2, V. S. Bhat1, P. Lawrence1, and B. Eidemiller3. 1Vanderbilt University Medical Center, Nashville, TN; 2Procter & Gamble, Cincinnati, OH; 3NSF International, Ann Arbor, MI; 4University of Rochester, Rochester, NY; and 5Society of Toxicology, Reston, VA.

The SOT Graduate Education Subcommittee goals are to develop and implement initiatives within SOT and through academia, industry, and gov’t. partnerships to better equip graduate students for productive and successful careers, including opportunities for toxicology training and research. To address these gaps, the Subcommitte, along with the SOT Career Resources and Development Committee (CRAD), is considering ways to augment technical writing skills to facilitate career success. An anonymous survey was distributed to SOT graduate student members in Fall 2017 and 167 students responded. Many respondents primarily obtain technical writing skills through writing research proposals/dissertations (97%), while only half included skills related to chemical risk/safety assessments (52%) or study reports (49%). Half of respondents (50%) listed study director/monitor, gov’t. regulator or safety/risk assessor as their top career choice, versus academic or lab researcher. The most popular first choice for next training step was a postdoc in academia (41%) with govt. (28%) and industry (27% postdocs) well represented. While limited in sample size, the survey results suggest a need to educate current toxicology graduate students that professional writing skills often need to be tailored toward specific career paths or audiences, and can be distinct from skills obtained while conducting experimental research. We are now considering ways to facilitate the attainment of diverse types of technical writing skills to ultimately reduce professional skill gaps and better equip toxicology graduate students for future career success.

2960 Evaluating the Utility, Diversity, and Effectiveness of the SOT Mentor Match Database

V. S. Bhat1, J. C. Fortin2, and S. D. McCullough1,2. 1NSF International, Ann Arbor, MI; 2SOT Career Resources & Development Committee, Reston, VA; 3Alcami Corporation, Edison, NJ; and 4US EPA, Research Triangle Park, NC.

Mentor Match (MM), the SOT online mentoring resource is designed to help matching SOT members with members expressing interest in being a mentor. The MM database, at https://www.toxicology.org/application/jobbank/mentormatch.asp, was reviewed to examine whether it reflects SOT’s commitment to diversity and inclusiveness in all activities as stated in the SOT mission and policies. This review also considered whether the current MM structure (e.g., stand-alone database) is an effective format and what potential improvements and/or alternate formats(s) might better foster inclusiveness and diversity and facilitate mentor-mentee matches and interaction. Based on mentee (n=327) and mentor (n=184) data currently housed in MM, mentees outnumber mentors almost 2 to 1 and 20% of mentees are mid-career professionals (i.e. no longer students or post-docs), while 11% of mentors are grad students or post-docs. Whereas, 95% of mentors reside in N. America (93% within the US), 15% of mentees reside outside N. America. While mentee gender was near balanced, 55% of mentors are male. These data suggest that geographic diversity may be lacking. Conclusions related to other metrics of inclusiveness and diversity, such as (but not limited to) ethnicity, socioeconomics, role (e.g., manager, bench scientist) cannot be drawn, since these data are not collected. Similarly, website tracking data (e.g. number of hits/day) duration of browsing) may have also informed the success. Most respondents viewed necessary professional writing skills as encompassing grants for research funding (89%) or authorship of manuscripts (97%), while only half included skills related to chemical risk/safety assessments (52%) or study reports (49%). Half of respondents (50%) listed study director/monitor, gov’t. regulator or safety/risk assessor as their top career choice, versus academic or lab researcher. The most popular first choice for next training step was a postdoc in academia (41%) with govt. (28%) and industry (27% postdocs) well represented. While limited in sample size, the survey results suggest a need to educate current toxicology graduate students that professional writing skills often need to be tailored toward specific career paths or audiences, and can be distinct from skills obtained while conducting experimental research. We are now considering ways to facilitate the attainment of diverse types of technical writing skills to ultimately reduce professional skill gaps and better equip toxicology graduate students for future career success.
Chapter 2961

**International ToxScholar: Increasing Awareness in Toxicology Globally**

A. K. Cuevas1, R. J. Dearman2, and B. Eidemiller3. 1Henkel Corp., Trumbull, CT; 2The University of Manchester, Manchester, United Kingdom; and 3Society of Toxicology, Reston, VA.

The political situation in many developing countries is often complex, but science can be a vehicle to break down barriers. The goal of the SOT Education Committee’s International ToxScholar Award (ITS) is to increase awareness, breadth, and depth of toxicology in such countries. ITS awards up to $1250 for toxicologists to travel to 139 eligible countries. Since 2010, 24 scholars have completed visits to 35 host institutions. Some scholars incorporated multiple institutions in their itinerary, with one visiting 12 institutions in a single ITS visit. Following their visit scholars submit a final report and share their experiences via the SOT Communique. Examining case studies over the duration of the ITS program has demonstrated the program’s value. Dr. Blas Ramirez, a 2018 ITS scholar, visited 12 institutions in Mexico and Moldova to pharmacy/clinical lab science students. An audience survey indicated the following: 21-25yrs; 90% female; 89% found value in the symposium; and 100% support continuing the ITS program. Students also indicated an increase in knowledge about toxicology, toxicology careers, and interest in pursuing advanced education. Some scholars, like Dr. Blas Ramirez and Dr. Velez utilized key contacts in Cuba to understand how best to focus toxicology outreach and was awarded ITS funding to present his work on Air Pollution and Genetic Susceptibility. Continuing the momentum of this ITS visit he worked with the Hispanic Organization of Toxicology (HOT) and Dr. Wallace Hayes, to receive the SOT Global Strategies award for the development a 2-day course on current trends in toxicology and food safety in Havana Cuba. The 150 participants learned about the state of the science in key toxicology topics, were introduced to the benefits of SOT membership, SOT international programs (GSSEP) and Special Interest Groups (i.e. HOT). Subsequently, 100 participants requested free HOT membership to stay connected to SOT. To date SOT has received 125 membership fee waivers which is an indirect testament to the value of the program and the impetus given to host institution members to join SOT. Together this demonstrates that the ITS program facilitates ongoing collaborations and networking which are key to promoting toxicology globally. The continued success of this program is dependent on attracting applicants who request visits to institutions in a wider array of target countries.

Chapter 2962

**Identification of Cytotoxicity-Inducing Factors That Are Released from Cells by Methylmercury**

T. Toyama, G. Hwang, and A. Naganuma. Tohoku University, Sendai, Japan.

Methylmercury is a common environmental pollutant. Methylmercury crosses the blood-brain barrier and accumulates in the brain, causing neuronal cell death and leading to central nervous system disorders. However, the underlying molecular mechanisms that result in neuronal toxicity are almost unknown. It has been reported that increased levels of extracellular glutamate, aspartic acid, and serotonin, among others, are involved in methylmercury-induced neuronal cell death. However, little is known about extracellular factors involved in methylmercury toxicity. Using cultured cell lines, in this study, we examined the possible existence of a factor that is driven out of the cell by methylmercury and that subsequently shows cytostatic activity (cytotoxicity-inducing extracellular factor, CIEF). To confirm the existence of CIEF, which is driven out of the cell by methylmercury, we prepared methylmercury preconditioning medium (MeHg-PM) according to the following method. Human embryonic kidney HEK293 cells were cultured in medium containing methylmercury for 2 hr. After washing with PBS, the cells were further cultured for 6 hr in methylmercury-free medium. The resulting culture medium was used as MeHg-PM. Untreated HEK293 cells and C17.2 cells (mouse neural stem cells) were placed in the obtained medium and, as a result, showed growth inhibition, which resulted in significantly inhibited cell growth. This cell growth inhibition was not affected by heating or proteinase K treatment, suggesting that neither proteins nor peptides caused the growth inhibition. We next performed a metabolic analysis for MeHg-PM, and identified 3-phenylpropionic acid, lactic acid, ornithine, proline, and beta-alanine were increased compared with control-PM. Treating HEK293 and C17.2 cells with each of the six substances minimally affected the proliferation of both cell lines. Among these six substances, however, only citrulline slightly but significantly increased the sensitivity of C17.2 and HEK293 cells to low levels of methylmercury. Citrulline is thought to be a methylmercury toxicity-enhancing factor whose extracellular release is enhanced by methylmercury.

Chapter 2963

**Potential Mechanisms of Inorganic Mercury Intoxication in Rat Kidney Cells**

S. E. Orr, L. Joshee, O. Uchakina, R. McKallip, and C. Bridges. Mercer University School of Medicine, Macon, GA.

Mercury is one of the ubiquitous toxic metals that is found in the environment and humans are exposed mostly via occupational and dietary sources. In the body, the primary site of accumulation and toxicity of inorganic mercury (Hg<sup>2+</sup>) is the kidney. The mechanism of Hg<sup>2+</sup>-induced toxicity of target cells. Normal rat kidney (NRK) cells were exposed to several concentrations of Hg<sup>2+</sup> for various times. Using imaging and biochemical techniques, Hg<sup>2+</sup>-treated cells showed significant alterations in cytoskeletal structure, oxidative stress, and calcium availability. After Hg<sup>2+</sup> exposure, NRK cells experienced actin disorganization and loss of cytoskeleton integrity. Additionally, intracellular levels of hydrogen peroxide and superoxide increased, which led to a rise in the amount of oxidative stress. Interestingly, levels of calcium, a vital and strictly regulated second messenger in cells, were elevated in the cytosol immediately following exposure. It is likely that intracellular Hg<sup>2+</sup> leads to an increase in IP<sub>3</sub> levels, which induces calcium release from the endoplasmic reticulum. Overall, Hg<sup>2+</sup>-treated cells experience many adverse changes including cytoskeleton collapse, reactive oxygen species accumulation, and elevated calcium levels. Although further studies are required for a complete understanding, a more definite explanation for the mechanisms of intracellular Hg<sup>2+</sup> intoxication and cellular injury has been established.

Chapter 2964

**Elucidation of Mechanisms Underlying Induction of Tumor Necrosis Factor-α by Methylmercury in Mouse Brain**

S. Murakami, T. Toyama, N. Hoshi, A. Naganuma, and G. Hwang. Tohoku University, Sendai, Japan.

Methylmercury is an environmental pollutant that causes neurotoxicity. We recently found that expression of the inflammatory cytokine tumor necrosis factor-α (TNF-α) is induced in brains of mice treated with methylmercury. Although TNF-α may be involved in the neurotoxicity caused by methylmercury, the mechanisms involved in the induction of TNF-α expression by methylmercury are unknown. In this study, we aimed to identify cells involved in the induction of TNF-α expression by methylmercury in mouse brain, to elucidate the underlying molecular mechanisms. Seven days after subcutaneous injection of C57BL6 mice with saline or methylmercuric chloride (25 mg/kg), TNF-α mRNA levels were determined in the brain tissues by in situ hybridization. We found that TNF-α was hardly expressed in the saline-administered group, whereas TNF-α-expressing cells were observed in the whole area of the brain in the methylmercury-treated group. It was reported that astrocytes and microglial cells are involved in the induction of TNF-α expression. Therefore, we performed immunostaining using antibodies specific for GFAP or IBA1, which are specifically expressed in astrocytes and microglial cells, respectively. The TNF-α-expressing cells did not colocalize with GFAP-positive cells, but with IBA1-positive cells. The results suggest that microglial cells are mainly involved in the induction of TNF-α expression by methylmercury in the mouse brain. In addition, methylmercury induced TNF-α expression in mouse microglial cell line BV2. Pretreatment with the RNA synthesis inhibitor, actinomycin D, mostly suppressed the elevation of TNF-α mRNA level by methylmercury, suggesting that transcriptional activation is involved in methylmercury-induced expression of TNF-α. MAP kinases such as JNK, ERK, and p38 are known to be involved in the induction of TNF-α transcription in microglial cells. We found that JNK, ERK and p38 were phosphorylated by methylmercury treatment in BV2 cells. Moreover, when the cells were pretreated with specific inhibitors, only the p38 inhibitor suppressed the induction of TNF-α expression by methylmercury. These results indicate that methylmercury may induce TNF-α expression via activation of p38 in microglial cells. We are examining the detailed molecular mechanisms involved in the induction of TNF-α expression by methylmercury.
Methylmercury (MeHg) is a neurotoxicant that exists widely in the natural environment. Because of fears regarding the adverse effect of MeHg contained in seafood on the developing fetus brain, pregnant women have been cautioned against consuming fish and shellfish in several countries. So far it has been reported that some food ingredients have effects on tissue concentration of Hg. In this study, we investigated the effect of co-administration of wheat bran and MeHg on tissue concentration of Hg in MeHg-exposed mice. Female BALB/c mice (age 3 weeks) were fed with the basal diet (AIN-76) containing no Hg for 6 weeks. Then after a single administration of MeHg (5 mg MeHgCl/kg), mice were housed in metabolic cages and fed with the same basal diet supplemented with or without wheat bran (300g/kg) for 2 weeks. Daily urine and feces were collected from wheat bran-treated and non-treated groups for 2 weeks. The accumulative amount of urinary Hg was higher in wheat bran-treated group than in control group. After the daily accumulation of urine and feces for two weeks, mice were deeply anesthetized with isoflurane, given by transcardiac perfusion with 0.9% ice-cold saline, and blood, brain, liver and kidney were obtained. Total Hg levels of blood, brain and kidney were lower in wheat bran-treated group than in control group. However, liver showed similar total Hg levels among both groups. These results were the same as our previous studies on mice fed with 30% wheat bran diet for 3 months before MeHg exposure which showed acceleration of Hg excretion into the urine, suggesting excretion of Hg from tissues was not caused by enhanced metabolism of MeHg by gut bacteria. Although total Hg concentration in feces is currently being measured, the results suggest that wheat bran is effective to accelerate Hg excretion into urine. It remains to be solved the reason why both pre- and co-administration of wheat bran have no effect on the excretion of Hg from liver. All experiments were carried out in accordance with guidelines for the care and use of laboratory animals established by the National Institute for Minamata Disease.
Cystathionine Gamma-Lyase is a Key Protein Repressing Methylmercury Poisoning Symptoms in Mice

M. Akiyama1, Y. Shinkai1, I. Ishii2, T. Akaike1, and Y. Kumagai1. 1University of Tsukuba, Tsukuba, Japan; 2Showa Pharmaceutical University, Tokyo, Japan; and 3Tohoku University, Sendai, Japan.

Methylmercury (MeHg) is an environmental electrophile that readily modifies protein thiols, causing toxicity. MeHg is inactivated by sulfur nucleophiles such as cysteine (CysSH), glutathione (GSH) and its related reactive persulfides through the formation of GSH adduct (MeHg-SG) and bismethylmercury sulfide ((MeHg)2S), respectively. Cystathionine gamma-lyase (CSE) catalyzes production of CysSH and its persulfides (CysSSH). Previously, we reported that CSE was required for in vivo formation of (MeHg)2S, suggesting that CSE is a key protein for protection against MeHg toxicity. To address this issue, we used CSE knockout (KO) mice. CSE KO and Wild-type (WT) mice were orally administered with MeHg. Loss of coordinated movement, body weights, survival rates and pathological changes in the brain were monitored to assess sensitivity to MeHg. Levels of mercury and sulfur nucleophiles in the organs were measured with an atomic absorption mercury detector and a mass spectrometer, respectively. We found that CSE KO mice were more sensitive to MeHg than WT mice and, concomitantly, had higher mercury accumulation in the brain. Levels of CysSH, GSH, and their persulfide derivatives were lower in the liver and kidney of CSE KO mice than in those of WT mice. These results suggest that CSE deletion in mice caused decreased levels of sulfur nucleophiles due to the disruption of CysH metabolism, resulting in increased sensitivity to MeHg.

Methylmercury Induces Metabolic Alterations in C. elegans: Role for C/EBP Transcription Factor

S. W. Caiot1, J. Newell-Caiot2, and M. Aschner3. 1Husson University, Bangor, ME; 2University of Maine, Orono, ME; and 3Albert Einstein College of Medicine, Bronx, NY.

Methylmercury (MeHg) is a well-known neurotoxicant; however, its role in metabolic diseases have been gaining wider attention. Chronic exposure to MeHg (measured by hair and toenail Hg levels) shows an association with diabetes mellitus (DM) and metabolic syndrome (MS). MS is a multifactorial condition that includes obesity, insulin resistance, dyslipidemia, and systemic oxidative stress. As incidences of both MS and DM increase on the rise globally, it is important to understand the potential role of MeHg in the development of the disease. In vitro experiments using the transgenic worm Caenorhabditis elegans can aid in identifying gene-environment interactions upon MeHg exposure and MS. We hypothesized that MeHg exposure in C. elegans would alter transcription of genes involved in the development of MS. RNA from wild-type worms exposed to MeHg was collected immediately after treatment, and used for gene expression analysis by DNA microarray. MeHg differentially regulated 215 genes, 46 were metabolic genes, 10 genes involved in lipid homeostasis, and 12 genes involved in carbohydrate homeostasis. Of particular interest was cebp-1, the worm homolog to human C/EBP, a pro-adipogenic transcription factor implicated in MS. MeHg increased the RNA levels of cebp-1 and conserved molecular signaling pathways. We hypothesize that C. elegans lacking src-1 or src-2 (homologs of C-Src and Fyn, respectively) would show persistent skn-1 (Nrf2 homolog) activity, leading to greater resistance against MeHg toxicity. L1 stage worms were treated for 1 hr with doses of MeHg ranging from 0 - 100 µM to determine a lethal dose curve. LD₅₀ values were established for each strain (WT: 46.61 µM, skn-1 KO: 39 µM, src-1 KO: 35.68 µM). A significant 2.4 fold increase in src-1 expression in src-2 KO treated worms compared to untreated worms was also noted, supporting the notion that src-2 may act as an inhibitor of skn-1 (2-tailed t-test, n=3, p<0.05). A significant 2.2 fold increase in skn-1 expression in src-2 KO treated worms compared to untreated worms was also noted, supporting the notion that src-2 may act as an inhibitor of skn-1 (2-tailed t-test, n=3, p<0.001). It is also conceivable that knockdown of src-1 or src-2 led to compensatory upregulation of src-2 or src-1, respectively. The current data suggest that src-2, the homolog to Fyn, is likely the stronger src family inhibitor of skn-1.
double positive CD133+24+ cells are more resistant to cadmium expo-
sure when compared to the CD24+ only cells. In addition, there is no
change in the number of double positive cells in response to cadmium
treatment, whereas the number of CD24+ cells significantly decrease.
Both the populations of cells form domes in culture indicative of vec-
torial active transport. In addition, the double positive CD133+CD24+
cells separated from the CD133+CD24- cells. In conclusion, our data suggests that the CD133+CD24+ cells are likely the progenitor
cells present in the kidney involved in tubular regeneration whereas the
CD24+ cells are the differentiated cells which are more sensitive to toxic
insults and are replaced by the stem/progenitor cells upon toxic insult.

2974 Effects of Calcium Disodium EDTA Nanoparticles against Cadmium Toxicity in Rats

S. Saleh1, E. El-Saied1, M. Mahmoud2, and O. El-Tawil1. 1Cairo University, Giza, Egypt; and 2Research Institute for Animal Reproduction, Giza, Egypt.

Cadmium is one of the most important environmental and industrial pol-
lutants that adversely affect human and animal health. Nanoparticulate
drug delivery systems are being used to alter the drug's biopharmaceu-
tics and pharmacokinetics such as drug absorption, distribution, metab-
olism, and elimination. In this study the toxic effects of cadmium sulfate
on adult female Sprague Dawley rats as well as the ameliorating effects of
CaNa2EDTA nanoparticles against such toxicity were investigated. The
predictive protective effect was compared with CaNa2EDTA micro-
particles. For toxicological assessment of cadmium toxicity, animals
were classified into a control and three experimental groups; the three
experimental groups received 60 ppm cadmium sulfate in drinking
water for 10 weeks. At the end of the 6th week of the experiment, the
second and third experimental groups were injected intraperitone-
ally with 50 mg/kg/day CaNa2EDTA microparticles and nanoparticles
respectively for 4 courses (4 days each) with an interval of 3 days. The
result showed that treatment with CaNa2EDTA nanoparticles exerted
marked protective effect against cadmium toxicity, which was indicated by
increasing body weight gain and food and water consumption and reducing
desired liver, kidney and bone cellular damage when compared to cadmium
treated group. Improvement in the bone mineral density was observed in
CaNa2EDTA nanoparticles treated group. Serum urea and creatinine con-
centrations as well as serum and urine metallothioneins levels were decreased by CaNa2EDTA nanoparticles treatment. Both
 cellular and humoral immune responses were increased in CaNa2EDTA
nanoparticles treated group. However, there is an increase in lym-
phocytes count and a decrease in neutrophils and monocytes counts. Serum IL-2 and IL-6 levels were increased by CaNa2EDTA nanoparticles
 treatment. CaNa2EDTA microparticles treatment induced mild protect-
ive effect against cadmium toxicity as compared to the nanoparticles
form. These findings suggested that CaNa2EDTA nanoparticles could be
effectively used as a chelating agent against cadmium toxicity as they
have a better affinity to chelate cadmium and lesser side effects than the
microparticles form.

2975 Cadmium-Mediated Activation of the HSP90/HSF1 Pathway Regulated by Reactive Persulfides and Polysulfides

Y. Shinkai1, A. Masuda1, M. Akiyama1, M. Xian2, and Y. Kumagai1. 1University of Tsukuba, Tsukuba, Japan; and 2Washington State University, Pullman, WA.

Cadmium is an environmental electrophile that modifies reactive thiols in proteins, indicating that this heavy metal may modulate redox-signa-
tion pathways. The current consensus is that reactive persulf-
ides and polysulfides produced by cystathionine γ-lyase (CSE) and
cystathionine β-synthase are highly nucleophilic and thus cadmium
may be captured by these reactive sulfur species. It has previously
been found that electrophile-mediated covalent modifications of the
heat shock protein (HSP) are involved in the activation of heat shock
factor 1 (HSF1) pathway. The effects of cadmium on the activation of
HSP/HSF1 pathway were investigated in this study. Exposure of bovine
aortic endothelial cells to cadmium resulted in modification of HSP90
and HSF1 activation, thereby up-regulating the downstream protein
HSP70. The siRNA-mediated knockdown of HSF1 enhanced the cyto-
toxicity induced by cadmium, suggesting that the HSP90/HSF1 pathway
contributes to protection against cadmium toxicity. The knockdown of
CSE and/or cystathionine β-synthase decreased the levels of reactive
sulfur species in the cells and increased the degree of HSP70 induction
and cytotoxicity caused by exposure to cadmium. Overexpression of
Diabetes mellitus (DM) is a growing worldwide epidemic. Impaired insulin release is a hallmark of type I DM and can have a role in the progression of type II DM. Epidemiological and experimental studies show that exposure to the metal cadmium (Cd), is associated with pre-DM, DM, and altered plasma insulin. How Cd disrupts pancreatic islet function and glucose-stimulated insulin release is not known. The objective of the current study was to begin to characterize the in vitro toxic effects of Cd on pancreatic beta cells. To do this, we used a model of pancreatic beta cells, the MIN6 cell line, and quantitated lactate dehydrogenase (LDH) release from cells exposed to Cd in serum-free physiological saline buffer. To begin to assess how Cd may alter glucose-stimulated insulin release MIN6 cells were exposed to 100 µM Cd in low (0.5 mg/ml) or high (3 mg/ml) glucose-containing buffer for 4 hours then LDLH was quantified. Initial results show that MIN6 cells incubated in low glucose buffer and exposed to 100 µM Cd caused 10.5 ± 0.6% of total LDLH release. Cd-exposed cells incubated in high glucose buffer had a statistically significant higher level of LDLH release at 21.2 ± 0.7%. There was no difference in LDLH release between cells incubated in low vs high glucose buffer in the saline-treated control groups. Cells were also treated with 5 µM nifedipine since L-type voltage-gated calcium channels play a fundamental role in beta cell function. Nifedipine treatment did not cause a statistically significant change in LDLH in release in cells exposed to 100µM Cd in either low or high glucose-containing buffer. These preliminary data indicate that glucose concentration is a significant factor in determining the toxicity of Cd in the MIN6 pancreatic beta cell line while L-type voltage-gated calcium channels apparently do not.
or down-regulation, p-value 0.005). Gene ontology (GO) analysis of the up-regulated genes showed the enrichment of biological process like response to oxygen containing compound and regulation of cell proliferation. Pathway analysis of up-regulated genes showed the enrichment of the axonal guidance, production of nitric oxide, reactive oxygen and acute phase response pathways. Transcriptional factor analysis of the up-regulated genes showed the enrichment of the estrogen receptor (55.5% genes). The findings strongly suggest that acute exposure of Cd on BEAS-2B cells can modulate the expression of the genes regulated by estrogen receptor and could contribute to the cadmium induced lung cancer.

**2983 Developmental Cadmium Exposure Disrupts Zebrafish Vestibular Development**

A. Planchart, C. J. Mattingly, and A. J. Green, North Carolina State University, Raleigh, NC.

The incidence of hyperactive behavioral disorders in the United States has risen by an average of 5% per year. Currently, 6.4 million children aged 4 to 17 years of age have received an ADHD diagnosis. The underlying causes are largely unknown though, like many disorders, it is likely a combination of genetic and environmental factors. One suspected environmental factor is cadmium (Cd), which has been shown to be nephro-, neuro-, and osteotoxic, and is a known carcinogen. Developmental studies have linked prenatal Cd exposure to reduced birth weight and hyperactivity. Our lab has shown that zebrafish exposed developmentally to 30 - 60 parts per billion (ppb) Cd from four hours post fertilization to seven days post-fertilization are hyperactive, have delayed otolith formation, and exhibit pronounced circling behavior. Radiotrace (109Cd) uptake analysis revealed that total body burden was 234 ng Cd/g body weight after seven days of exposure to 40 ppb Cd; human total body burden ranges from 45 - 775 ng Cd/g body weight. Furthermore, we have shown that developmental Cd exposure alters the timing of otolith appearance, likely due to vestibular calcium sensing, and transport. In light of the fact that otoliths are vital for vestibular function, these findings are interesting because they may explain why hyperactivity is observed in both children with inner ear dysfunction and those developmentally exposed to cadmium. While the mechanisms behind this Cd-induced ototoxicity remain unclear, their link to vestibular-based behavioral abnormalities merits further investigation.

**2983a Environmental Cadmium Exposure Disrupts Lung Fatty Acid Metabolism**

Y. Go, X. Hu, J. Chandler, J. Fernandes, C. Ma, and D. P. Jones, Emory University, Atlanta, GA.

Our previous studies showed that low dose cadmium (Cd) altered protein redox states resulting in inflammatory signaling, actin cytoskeleton disruption, and fibrosis. However, little is known about the effects of Cd at relatively low level on the metabolic regulation in pulmonary function and potential impact on pulmonary health. To address this issue, we performed ultra-high resolution mass spectrometry-based high resolution metabolomics (HRM) on lungs from mice exposed to Cd by drinking water (10 mg/L) for 20 weeks. The results show that abun-
dance of 426 metabolic features in mouse lung were changed by Cd exposure (p-value = 0.5, p = 0.03, n = 10) than females (r = 0.2, p = 0.09, n = 9). The results was associated with pack years of smoking and was higher in males (r = -0.4, p ≤< 0.01, n = 9), magnesium (r = -0.5, p = 0.001, n = 9) and copper (r = -0.4, p = 0.01, n = 9) in females. In males, Mn, Al, Ni, Co, Cu, Sn and Ba were correlated with Cd. Lung Cd level was associated with pack years of smoking and was higher in males (r = 0.5, p = 0.03, n = 10) than females (r = 0.2, p = 0.09, n = 9). The results suggest that the induction of metallothionein results in increased metal accumulation, and the increased burden potentiates cellular dysfunction and further contribute to lung diseases.

**2983b Characterization of the Effects of Selenium and Phenyl Mercuric Acetate Exposure on the Lipid Profiling of the Free Living Nematode Caenorhabditis elegans**

S. Jamadar, K. Anthony, D. Hlangothi, T. Nguyen, and F. Abdul-Rahman. Texas Southern University, Houston, TX.

Mercury (Hg) compounds exposure from environmental and food sources is a significant threat to public health. Organomercuro compounds such as phenyl mercuric acetate (PMA) can cause harmful damage to the nervous system. Caenorhabditis elegans studies showed that chronic exposure to mercury compounds induces neuron degeneration likely due to the increase in reactive oxygen species (ROS). Selenium (Se) is an essential trace element required for activation of many antioxidant enzymes. Accordingly, Se is capable of decreasing deposition of Hg during co-exposure possibly due to the high affinity between Hg and Se and reducing the ROS level by activating antioxidant enzymes. In this study, we evaluated the treatment of C. elegans with PMA, Se, and PMA + Se to determine the effect it could have on the fatty acid and the lipid profile. The nematode C. elegans was exposed to a sub-lethal concentration of PMA to investigate its toxic effect. Exposure to PMA + Se was used to determine if Se could minimize or counteract the effects of PMA. Fatty acids methyl esters (FAMES) of C. elegans were analyzed by gas chromatography/mass spectrometry (GC-MSD). Lipid profiling was analyzed using high-performance thin layer chromatography (HPTLC) and liquid chromatography-mass spectrometry (LC-MS). Microscopy and other biological results showed that exposure to PMA increased levels of ROS in C. elegans which could account for the change in the fatty acid content and lipid profile of the nematodes. Selenium showed the ability to partially counteract the effects of PMA. Elucidation and identification of fatty acid methyl esters from each treatment will be presented.

**2983c Cadmium Correlations with Other Metals in Diseased Human Lung**

D. Jones, J. Fernandes, R. Smith, M. Orr, and Y. Go, Emory University, Atlanta, GA.

Our recent research in mice shows that low cadmium (Cd) exposures by drinking water potentiate inflammation and fibrosis. In these studies, we found that Cd dosing resulted in changes in contents of other metals in lung. Multiple metals have been associated with lung pathologies, but understanding of metal-metal interactions in lung disease is limited. To gain an understanding of correlations of Cd with other metals in human lung, we used Inductively Coupled Plasma Mass Spectrometry (ICP-MS) to measure Cd (μg g⁻¹ SE, 38 ± 8.9 μg/g tissue, n = 19) and 13 other metals in human lungs from 10 males and 9 females with a range of lung diseases. Mean age was 59 ± 9 y. Nine males reported being smokers (37 ± 10 pack years) and 5 females reported being smokers (31 ± 9 pack years). Results showed that lung Cd level is negatively associated with 3 metals including manganese (r = -0.4, p ≤< 0.01, n = 9), magnesium (r = -0.5, p ≤< 0.001, n = 9), and copper (r = -0.4, p = 0.01, n = 9) in females. In males, Mn, Al, Ni, Co, Cu, Sn and Ba were correlated with Cd. Lung Cd was associated with pack years of smoking and was higher in males (r = 0.5, p = 0.03, n = 10) than females (r = 0.2, p = 0.09, n = 9). The results suggest that the induction of metallothionein results in increased metal accumulation, and the increased burden potentiates cellular dysfunction and further contribute to lung diseases.

**2984 Metabolism Reprogramming in Hexavalent Chromium-Induced Lung Carcinogenesis**

J. T. Wise, L. Wang, K. Schumann, J. A. Hitron, Z. Zhang, and X. Shi, University of Kentucky, Lexington, KY.

Hexavalent chromium, Cr(VI), is a known human carcinogen that is a worldwide environmental health concern. It is well understood that reactive oxygen species, genomic instability, and DNA repair deficiency are important contributors to Cr(VI)-induced carcinogenesis. However, some cancer hallmarks remain understudied for the mechanism of Cr(VI) carcinogenesis. Specifically, increased de novo lipid synthesis is an important mechanism of carcinogenesis and tumorigenesis in multiple types of cancers, but it is still unclear the role metabolic reprogramming plays in Cr(VI) carcinogenesis. It has previously been reported that acute exposure to Cr(VI) can increase glycolysis and decrease mitochondrial respiration in human lung cells. Here, we report that Cr(VI) is able to induce expression of lipogenesis proteins. Specifically, our data show prolonged exposure (1 month) of human lung epithelial cells (BEAS-2B
cells) to sodium chromate increases ATP citrate lyase (ACL), and fatty acid synthase (FASN) expressions. Interestingly, we also found that chromium-transformed BEAS-2B cells and human lung fibroblasts (WTHBF-6 cells) had no major changes in their glycolytic function as measured by the Seahorse Analyzer when compared to their passage-matched control cells. Future work is aimed at continuing to investigate changes in lipid metabolism and the mechanisms that regulate lipid metabolism in Cr(VI)-induced lung carcinogenesis.

---

### 2985 Cytotoxicity and Morphological Transformation in C3H/10T1/2 CI Mouse Embryo Cells by Sodium Chromate: Enhancement by Ascorbate

Soluble/insoluble hexavalent chromium (Cr(VI)) compounds are animal and human carcinogens. They induce respiratory cancers in humans when inhaled, and stomach, liver, kidney, and G. I. tract when given in drinking water. Soluble/insoluble Cr(VI) compounds induce mutations, DNA-DNA cross links, and DNA-protein cross-links in cultured mammalian cells. We found weak, dose-dependent induction of foci by PbcCrO₄, but no induction of foci by CaCrO₄, K₂CrO₄, and Na₂CrO₄. The reductants ascorbate, glutathione (GSH) and cysteine (CySH), convert intracellular Cr(VI) to Cr(III) and induce foci in lung and breast carcinoma tissue culture cells in mammalian cells, by reducing it to Cr(VI), Cr(III), and Cr(II) with generation of hydrogen peroxide and hydroxyl radicals, causing mutation. We hypothesized weak/no induction of morphological transformation of 10T1/2 cells by Cr(VI) compounds in Basal Medium Eagle (BME), were due to low concentrations of ascorbate, GSH, and/or CySH in BME. Ascorbate is present in human serum at μM concentrations but only at μM concentrations in BME. We studied effects of the highest non-cytotoxic concentrations of ascorbate, GSH, and CySH on Cr(VI)-induced cytotoxicity in 10T1/2 cells. When 10T1/2 cells were treated with Cr(VI), ascorbate enhanced the cytotoxicity of Cr(VI) at concentrations up to 0.1 mM, and reduced the cytotoxicity of Cr(VI) at concentrations of 0.25 mM and higher. One non-cytotoxic concentration of ascorbate, 0.00625 mM, caused dose-dependent induction of cytotoxicity/morphological transformation when added to various concentrations of sodium chromate in 3 experiments. Our findings indicate ascorbate enhanced cytotoxicity/morphological transformation of 10T1/2 cells treated with sodium chromate, likely by enhancing reduction of intracellular Cr(VI) with ascorbate to generate Cr(III) and ROS. GSH or CySH, separately/together, did not enhance Cr(VI)-induced cytotoxicity to 10T1/2 cells. Supported by undergraduate fellowships from Provost’s Office at USC, funding from the S. Program, Dept. of Mol. Micro.,/m., discretionary funding, and grant ES03341, from NIEHS/NIH, to JRL.

### 2986 Chromate-Induced Suppression of E2F1 and RAD51 in the Homologous Recombination Response

R. M. Speer¹, C. L. Browning², and J. P. Wise³. University of Louisville, Louisville, KY; and "Brown University, Providence, RI.

Hexavalent chromium [Cr(VI)] is a global environmental contaminant and known human lung carcinogen. Specifically, particulate Cr(VI) is considered to have the highest carcinogenic potential as it lodges at bifurcation sites in the lung and slowly dissolves over time. While Cr(VI) is known to have many intracellular effects, the mechanism of Cr(VI) carcinogenicity is currently unknown. Maintaining a functional homologous recombination (HR) pathway is crucial in preserving genomic stability and preventing carcinogenesis. Studies show that Cr(VI) induces DNA double strand breaks (DSBs) and also inhibits HR repair resulting in chromosome instability (CIN), a hallmark event in lung cancer. Data on our human lung cell model show longer exposures to particulate Cr(VI) lead to loss of the critical effector step in the HR pathway through impaired RAD51 function while preceding steps remain functional. However, it is currently unknown how Cr(VI) is impairing RAD51 function. The transcription factor E2F1 has previously been shown to be involved in HR through transcription of DNA repair proteins and it plays a role in the HR response to DSBs. Furthermore, research shows Cr(VI) modulates epigenetic changes, however, only a few studies have investigated these effects in the context of DNA repair and lung cancer. We found exposure to particulate Cr(VI) reduced RAD51 and E2F1 mRNA at all exposure times. Protein levels were also reduced following a similar pattern to the one observed in the mRNA results. We also observed inhibited protein foci formation in response to prolonged particulate Cr(VI) exposure. Finally, we investigated how miRNAs may be involved in Cr(VI)-impaired HR. These results provide mechanistic insight into the carcinogenesis of particulate Cr(VI) in human lung cancer and suggest a role of the transcription factor E2F1 in the HR response. This work was supported by NIEHS grant ES016893 (J.P.W.) and the Jewish Heritage Fund for Excellence Research Enhancement Grant Program at the University of Louisville School of Medicine.

### 2987 Chronic Exposure to Particulate Hexavalent Chromium Induces Centrosome Abnormalities and Disrupts Mitosis in Both Sea Turtle and Alligator Primary Lung Cells

Hexavalent chromium (Cr(VI)) is a well-established human lung carcinogen. Tumors in the lung are often characterized by numerical chromosome instability (CIN). One way CIN can be established is through abnormal centrosome function. Specifically, centrosome amplification has been associated with numerical CIN. Previous studies in our lab established that Cr(VI) induces premature centrosome separation and disengagement in human lung cells; events that could underlie Cr(VI) induced centrosome amplification. We also showed Cr(VI) exposure induces a decrease in mitotic index and prolonged G2 arrest; events hypothesized to lead to centrosome amplification in human lung cells. These findings have given insight into the mechanism for Cr(VI) induced centrosome amplification. Using a One Health approach, this study extends the previous analyses into wildlife cell cultures. Primary lung cell lines from both Dermochelys coriacea and Alligator mississippiensis were used to determine what effects Cr(VI) exposure has on mitotic index, centrosome separation, and centrosome disengagement in cells from these species. We found results in wildlife cell culture that are consistent with human lung cells. Cr(VI) exposure resulted in a statistically significant decrease in mitotic index that correlated with time and concentration of Cr(VI) exposure. Cr(VI) also induced centrosome amplification and premature centriole disengagement in the wildlife cultures. These findings have given insight into the centrosome amplification in human lung cells, and help to understand how Cr(VI) induces centrosome amplification; information that can ultimately lead toward a more mechanistic understanding of Cr(VI) carcinogenesis. This study is an example of a One Health approach that recognizes the health of humans, animals and the environment are connected.

### 2988 NAD-Dependent Sirtuin 3 Negatively Regulates Mitophagy of Chromium(VI) Transformed Cells

M. Clementino, D. Kim, and Z. Zhang. University of Kentucky, Lexington, KY.

Chronic exposure of human bronchial epithelial BEAS-2B cells to hexavalent chromium (Cr(VI)) induces malignant cell transformation and these Cr(VI)-transformed cells are tumorigenic. The present study investigated the role of NAD- dependent sirtuin 3 (SIRT3) in mitophagy of Cr(VI)-transformed cells. Our results showed that expression of SIRT3 at both mRNA and protein level was elevated in Cr(VI)-transformed cells compared to that in passage-matched normal cells. The results from Seahorse analysis showed that mitochondrial ATP production and proton leak were reduced in Cr(VI)-transformed cells. Inhibition of SIRT3 by its shRNA further reduced mitochondrial ATP-production and proton leak in Cr(VI)-transformed cells. Similarly, in Cr(VI)-transformed cells the p62 less available to bind to KEAP1, resulting in increased binding of Nrf2 and Parkin and Pink1, two mitophagy proteins, were elevated in Cr(VI)-transformed cells, Nrf2 is constitutive activated. Inhibition of Nrf2 by its shRNA decreased SIRT3 expression. These results suggest that Nrf2 is a positive regulator of SIRT3. The results from CHIP assay showed that Nrf2 binds to antioxidant response element (ARE) of SIRT3 gene promoter. The present study demonstrates that SIRT3 negatively regulate mitophagy of Cr(VI)-transformed cells.
Bone is a known long-term storage compartment for Uranium (U); there is growing evidence for natural U inducing adverse effects in bone function and development, including delayed growth, increased bone resorption rates, reduced bone volume and fragility in laboratory animals. This effect has not yet been demonstrated in epidemiologic studies due to exposure to Depleted Uranium (DU), isotopically different from but chemically identical to natural U. Our longitudinal clinical surveillance of a cohort of Gulf War Veterans exposed to DU in friendly fire events in 1991 is designed to identify potential long-term health effects from embedded DU fragments and includes using DEXA scans to measure mild (osteopenia) or severe (osteoporosis) bone loss. The cohort was divided into high vs. low urine U (uU) exposure groups based on creatinine-adjusted uU levels, which correlate generally with embedded DU fragment presence (high) vs. exposure limited to inhalation (no fragments) (low). Based on the Endocrine Society’s recommendation to screen men with osteoporosis risk factors at age 50, we performed DEXA scans in cohort members who have reached this age. Of these 23 Veterans, six fell into the high uU group (uU ≥ 0.1μg/cre) and 17 were in the low uU group (uU < 0.1μg/cre). Using Fisher’s exact test we investigated associations between bone density via DEXA scans and uranium exposure status. Five of the six (83%) in the high uU group had abnormal DEXA results, with osteopenia, compared to five of the 17 (29%) in the low uU group (p = 0.052). A low Vitamin D level was not significantly associated with abnormal DEXA results (p = 0.669). Although limited by the small number of Veterans assessed, we have shown a significant association between U burden and osteopenia as demonstrated by DEXA results. Our biologically plausible preliminary findings, combined with increasing evidence supporting adverse effects of U on bone, advocate for continued surveillance of this health outcome in U-exposed populations. As we accumulate more clinical data from this aging cohort, we will be able to assess our preliminary findings and explore potential effect modifiers (such as medications) more fully. If confirmed, this association has significant implications for the medical management of U-exposed populations, to preserve bone health.

High levels of uranium and arsenic exist in air, water, and soil in the Navajo Nation, due to >500 abandoned uranium mines in the rural southwestern United States. Human exposures in the Navajo Nation are associated with increased prevalence of metal-associated diseases, as demonstrated by DEXA results. Our biologically plausible preliminary findings, combined with increasing evidence supporting adverse effects of U on bone, advocate for continued surveillance of this health outcome in U-exposed populations. As we accumulate more clinical data from this aging cohort, we will be able to assess our preliminary findings and explore potential effect modifiers (such as medications) more fully. If confirmed, this association has significant implications for the medical management of U-exposed populations, to preserve bone health.

The circadian rhythm is an essential system for maintaining homeostasis of life. The main disruptor of this system is light at night (LAN), continually and frequently induced in an environment like shift work. Chronic circadian disruption causes various health problems including lifestyle diseases such as hypertension, diabetes and obesity. Furthermore, the relationship between circadian disruption and carcinogenesis is also being clarified recently. In the present study, we report that the circadian rhythm disruption showed inhibitory effect on testicular function using mouse model. Male C57BL/6J mice (7 weeks old) were raised for 1, 3, 9 and 12 weeks under normal lighting conditions (12 hours light and dark) and light and dark shift conditions (every 2 days, reversed 12 hours the light and dark). The testicular function was analyzed using the CASA system. Plasma concentrations of zinc and calcium were measured using Metalloassay kit. The behavioral activity of the mice in the normal light and dark condition group was high in the dark period and showed a definite circadian rhythm, but it was confirmed that the circadian rhythm was disturbed in the light/dark shift condition group. The sperm numbers in the testis and cauda epididymides decreased significantly from 6 weeks after the onset of light/dark shift, and continued until after 12 weeks. Similarly, the sperm motility was also significantly decreased after 6 weeks. The decrease was sustained until after 12 weeks. Plasma zinc concentration showed transient decrease after 1 week of light/dark shift condition. It is well known that spermatogenesis is suppressed in low concentration of zinc. The circadian rhythm of zinc secretion is disturbed by light/dark shift condition, possibly causing testicular dysfunction.
Tungsten dioxide nanoparticles (TiNPs) are manufactured worldwide in large quantities for use in a broad range of applications such as cosmetics, pigments, and antibacterial agent. Recently, reports on TiNPs-induced toxicity in organs such as the liver, lung, and intestine are increasing. We also reported that TiNPs-induced testicular toxicity, i.e., testis was highly sensitive to TiNPs as compared to the liver. In this presentation, we examined the acute effect of TiO2 on testicular function in mice. TiNPs (Aerioxide P25) were dispersed in disoside phosphate solution (DSP) by sonication. Male C57BL/6J mice were orally administrated with titanium dioxide (10, 20 or 100 mg/kg body weight) once per week for 4 weeks. Mice were sacrificed 3 days after the last administration. Although the sperm numbers in the cauda epididymides were not changed by TiNPs administration, the sperm motility at 3 days after the last injection was significantly inhibited. Plasma testosterone concentrations were not different between control group and TiNPs administered groups. Further, we observed no significant histological change in testes among control group and TiNPs administration groups. Our results indicated that TiNPs possesses acute adverse effect on testicular function, especially on the matured sperm existed in the cauda epididymides.

Tungsten's increasing presence in electronics and medical devices positions it as an emerging environmental toxicant, yet its potential health consequences are not well understood. Like many metals, tungsten accumulates in the bone, dose-dependently, with a faster rate of accumulation than removal. This makes bone a long-term storage site and a source of chronic exposure. The bone is a dynamic organ that constantly undergoes an intricate remodeling processes to balance bone formation, driven by the osteoblasts, and bone resorption, driven by the osteoclasts. Osteoblasts, like many other cell types, are derived from mesenchymal stromal cells. We have previously shown that sodium tungstate skews mesenchymal stromal cell differentiation by promoting adipogenesis and inhibiting osteogenesis. Here, we evaluated the effects of tungsten exposure on the other face of bone remodeling: osteoclast differentiation. We have previously shown that sodium tungstate exposure for 4 weeks increased the amount of TRAP positive osteoclasts within the bone marrow. In vitro, tungsten by itself was able to induce the expression of osteoclastogenic genes Acsp5 and Ctsk in pre-osteoclasts, but not to the same extent as RANKL, the known inducer of osteoclast differentiation. However, sodium tungstate did not significantly enhance osteoclastogenesis, alone or in combination with RANKL. In addition, tungsten treated pre-osteoclasts demonstrated increased adhesion to vitronectin surfaces. We also observed an increase in mRNA expression levels of integrin-αv in sodium tungstate-treated osteoclast precursors. We suspect that tungsten may enhance adhesion of osteoclast precursors to the bone matrix causing the increased TRAP positive osteoclasts observed in vivo. To fully assess the relevance of increased osteoclasts in the bone, activity assays will be carried out in the future.

Tungsten (W) is a refractory metal that is being used in alloy manufacturing, high speed tools, light filaments, x-ray shielding, welding electrodes, solar energy devices, and pigment production. W is historically considered a non-toxic metal and as such W alloy replaced lead in ammunition in the 1990s. Recent reports indicate a greater risk than originally assumed for the mobility and presence of W in the environment, increasing the likelihood of an environmental exposure. In addition, an association of W with a childhood cancer cluster in Nevada located near tungsten mining sites and military bases was indicated. As a result, there are returning questions on the toxicity of W alone and/or in mixtures similar to the composition of tungsten alloy. Current hypotheses support a toxicity mixture interaction with W and other metal(s) present in the W alloy, but further research is needed to define the mixture toxicity. In this study, the zebrafish model was used to assess the influence of cobalt (Co) and/or nickel (Ni) on tungsten toxicity. Zebrafish embryos were first exposed to each metal (W, Co, or Ni) alone beginning immediately after fertilization and survivability was monitored every 6 hours through 120 hours post fertilization (hpf). The results revealed that 10000 parts per million (ppm; mg/L) W, 100 ppm Ni, and 100 ppm Co caused a decrease in survivability. Non-lethal concentrations were then chosen to assess the toxicity interaction of the mixture. Three concentrations of each metal were included: 0, 100 and 1000 ppm W; 0, 1 or 1 ppm Ni; and 0, 1, or 10 ppm Co. Zebrafish embryos were exposed to one of the 27 metal treatments beginning immediately after fertilization. The toxicity of the mixtures was assessed by monitoring the survivability and hatching rates every 6 hours through 120 hpf. In addition, behavioral analysis using a visual motor response test was performed at 120 hpf. No significant difference in survival or hatching rate was observed between treatments. A decrease in velocity, time spent moving, and distance swam in all treatment groups that contained 10 ppm Co was observed (p<0.05). These results showed that only 10 ppm Co controls the change in locomotor activity of the zebrafish larvae and W alone had no effect on survivability or locomotor activity at the tested concentrations. Future work is now characterizing morphological outcomes of the metal mixtures at non-lethal concentrations.
Predicting Oral Repeated-Dose Toxicity of Cobalt Substances Using a Read-Across Approach

A. Burzlaff1, V. Viegas2, and R. Danzeisen2. 1Exponent, Inc., Maynard, MA; 2Exponent, Inc., Alexandria, VA; and 4Red Cap Consulting, Lake Point, UT.

Cobalt in the form of vitamin B12 is essential for the maintenance of human health, and inorganic cobalt is essential for bacteria living in the marine environment. The indiscriminate release of potential toxic metals (PTMs) into the environment by the industries is at an alarming rate, hence the need for the use of agricultural waste materials (AWMs) as an adsorbent for the removal of PTMs from wastewater. The point of zero charge (PZC) of AWMs is one of the factors that contributes to the adsorption of copper ion (Cu2+) in aqueous solution. The indiscriminate release of PTMs into the environment is a concern because of their potential toxic effects on human health. The use of AWMs as an adsorbent for the removal of Cu2+ from aqueous solution is a promising approach to address this concern.

Impact of HIF-1α on Cellular Responses to Carcinogenic Nickel(II)

M. W. Luczak, and A. Zhitkovich. Brown University, Providence, RI.

Nickel is a human respiratory carcinogen that strongly upregulates the hypoxia-sensitive transcription factor HIF-1α and induces a hypoxia-like transcription response. Elevated HIF-1α levels are frequently found in more aggressive cancers and associated with drug resistance which occurs in part due to increased drug efflux. We examined the role of HIF-1α in cellular accumulation of Ni(II) ions and Ni(II)-induced cytotoxic responses in human lung cells. We found that the loss of HIF-1α had no significant effect on intracellular levels of Ni(II) in transformed (H460, A549) or normal (IMR90, WI38) human cells. The absence of HIF-1α did not change p53-dependent and p53-independent apoptotic responses or clonogenic survival in Ni(II)-treated transformed cells. In normal human cells, Ni(II)-induced HIF-1α enhanced inhibition of cell proliferation and promoted a permanent growth arrest (senescence). Analysis of various cell cycle regulators showed that HIF-1α was important for upregulation of the CDK inhibitors p21 and p27. Induction of p21 also required the transcription factor p53. The formation of senescent cells by Ni(II) was completely abolished by p53 depletion and suppressed by p21 knockdown. Our findings indicate that HIF-1α enhances the activity of p53 in restriction propagation of Ni(II)-damaged normal cells, suggesting that it may act in a tumor suppressor-like manner during early stages of Ni(II)-induced transformation.

Determining the Fate of Copper in Aquatic Systems

C. T. Onwoodi1, C. C. Uchei1, K. O. Badmus1, M. N. Zimiri2, and L. F. Petrik. 1University of the Western Cape, Cape Town, South Africa; and 2Lagos State University, Lagos, Nigeria.

The indiscriminate release of potential toxic metals (PTMs) into the environment by the industries is at an alarming rate, hence the need for the use of agricultural waste materials (AWMs) as an adsorbent for the removal of PTMs from wastewater. The point of zero charge (PZC) of AWMs is one of the factors that contributes to the adsorption of copper ion (Cu2+) in aqueous solution. The indiscriminate release of PTMs into the environment is a concern because of their potential toxic effects on human health. The use of AWMs as an adsorbent for the removal of Cu2+ from aqueous solution is a promising approach to address this concern.

2999 Impact of HIF-1α on Cellular Responses to Carcinogenic Nickel(II)

M. W. Luczak, and A. Zhitkovich. Brown University, Providence, RI.

Nickel is a human respiratory carcinogen that strongly upregulates the hypoxia-sensitive transcription factor HIF-1α and induces a hypoxia-like transcription response. Elevated HIF-1α levels are frequently found in more aggressive cancers and associated with drug resistance which occurs in part due to increased drug efflux. We examined the role of HIF-1α in cellular accumulation of Ni(II) ions and Ni(II)-induced cytotoxic responses in human lung cells. We found that the loss of HIF-1α had no significant effect on intracellular levels of Ni(II) in transformed (H460, A549) or normal (IMR90, WI38) human cells. The absence of HIF-1α did not change p53-dependent and p53-independent apoptotic responses or clonogenic survival in Ni(II)-treated transformed cells. In normal human cells, Ni(II)-induced HIF-1α enhanced inhibition of cell proliferation and promoted a permanent growth arrest (senescence). Analysis of various cell cycle regulators showed that HIF-1α was important for upregulation of the CDK inhibitors p21 and p27. Induction of p21 also required the transcription factor p53. The formation of senescent cells by Ni(II) was completely abolished by p53 depletion and suppressed by p21 knockdown. Our findings indicate that HIF-1α enhances the activity of p53 in restriction propagation of Ni(II)-damaged normal cells, suggesting that it may act in a tumor suppressor-like manner during early stages of Ni(II)-induced transformation.
Cisplatin was the first of several generations of platinum anticancer compounds approved by the FDA for use as chemotherapies which activate cellular apoptosis. In addition to the central platinum atom, each compound is bound to a leaving and non-leaving ligand. Platinum based compounds activate apoptosis through a mechanism where the leaving ligand is lost from the central atom allowing the platinum to bind to DNA, causing cell death, but in which the mechanism in which the platinum complexes interact with the cell is largely unknown. The same compound often has varying levels of cytotoxicity on different cell types, implying that different cell types have different mechanisms of interaction with the platinum compounds. Carbotoplatin and oxaliplatin are two other FDA-approved platinum chemotherapies that differ only in ligand type, but exhibit very different reactivity, suggesting that ligand behavior plays a role in these interactions. To better understand the mechanisms of interaction between cell types and various platinum compounds, we are using novel platinum compounds systematically varying both leaving and nonleaving ligands. In these studies, we examined cellular toxicity of the compounds in multiple mammalian cell lines, a noncancerous control and metastasis of prostate cancer, NTERA-2. Here we report the cellular toxicity using the MTT assay. Our initial finding demonstrate an inhibitory concentration at 50% (IC50) analogous to values reported for similarly structured platinum compounds.

The mechanism of Alzheimer’s disease (AD) in aluminum chloride (AlCl3) treated zebrafish models. We set up an AlCl3 treated AD model in zebrafish by exposing zebrafish embryos to different concentrations (50, 100, 200, 400, 800 µg/L) of AlCl3, the influence of different concentrations of AlCl3 on learning and memory performance of adult zebrafish were evaluated by T-maze tasks. Then, we quantified AD-related gene expressed in the adult zebrafish by QRT-PCR. Finally, the genes expression in P3K-AKT-mTOR signal pathway in Alzheimer’s disease model induced by Aluminum Chloride in Zebrafish.

Beryllium is a metal used in the industries of aerospace, automobile, electronics, etc. Exposure to it can cause beryllium sensitization (BeS) in some subjects, and the sensitized cases could develop further to chronic lung disease (chronic beryllium disease, CBD). Beryllium lymphocyte proliferation test (BelPT) is an examination to identify the sensitized subjects and CBD patients. The standard protocols were released in 2001 by DOE. However, there are still some controversies over the reliability of the assay, and considerable variations of results even for the same sample is one of the problems that often embarrasses laboratories. Furthermore, radioactive substance is used in the assay and this is not convenient to many laboratories. Although BelPT is used in health examination of workers in some factories, it is still a "must" item under the present regulations of MHLW, Japan, partially due to its non-reliability. In this study, we modified the assay procedures to minimize the variations of results, and by using non-radioactive coloring agent to monitor the cell viability, we introduced an alternative assay protocols. Methods: With human lymphocyte cell line, we simplified the assay to minimize the variations of the radiation counting. Also we used alamar blue cell viability assay, a method using the reducing power of living cells to quantitatively measure the proliferation of cells. Then with lymphocytes from volunteers, the simplified DOE method and alternative alamar blue method were confirmed under Con A stimulation. Finally with lymphocytes from CBD patients, we tested the simplified and alternative methods for their efficiency and accuracy.

This study was approved by the Ethics Committee of our institute and informed contents were obtained from all subjects participated. Results and Conclusions: By omitting cell washing and DNA purification steps, the variations of radiation counting was greatly reduced, though with higher background values. The alamar blue method showed similar results to DOE method with high accuracy. It is noteworthy that alamar blue assay could be easily done only by adding the agent for a few hours, and after the photometer reading, the same cells can be used for the assays of DOE method by adding 3H-thymidine. This is especially useful for the blood samples with limited amount.

Cadmium, cobalt, and nickel are two heavy metals classified as Group 1 carcinogens that have been linked to kidney, colon, and lung cancer. Research in eukaryotic cells has indicated that co-exposure to these metals is significantly more toxic than single exposure and results in a dose-dependent decrease by survival and an increased production of ROS as well as the formation of double strand breaks. Several other studies have also suggested the role of DNA repair processes in metal-induced toxicity. Because yeast and several DNA repair processes are well conserved, we have employed budding yeast Saccharomyces cerevisiae to understand the role of metal induced DNA repair (MDR) and genotoxicity. This study indicates that yeast cells deficient in proteins involved in MDR respond differently to cadmium, cobalt, and nickel exposure compared to wildtype cells. Interesting, deficiencies in several different MMR proteins resulted in a 2-fold increase in survival compared to wildtype cells as measured by absorbance quantifications and spot assays. When these same strains were exposed to cobalt there was a significant difference between all doses, even when the doses were raised significantly. When the yeast strains were co-exposed to cadmium and nickel both the wildtype and the all MMR deficient strains produced a dose-dependent decrease in colony forming ability as measured by the spot assay. The wildtype cells were approximately 3-4 fold more sensitive compared to the MMR deficient strains at the highest doses of cadmium and nickel. Analysis of cell cycle progression indicate that following exposure to cadmium and nickel there is an increase in the number of cells in G2 in the wildtype cells compared to the MMR-deficient strains suggesting these cells may arrest here. No differences were detected in the wildtype or MMR-deficient cells following cobalt exposure. This data indicates that the mechanism of toxicity by cadmium and nickel may be different than that of cobalt. Additionally, deficiencies in MMR produce a resistance to cadmium and nickel induced toxicity which suggests why selection of MMR-deficient cells may be more prevalent amongst various cancers.

Beryllium is a metal used in the industries of aerospace, automobile, electronics, etc. Exposure to it can cause beryllium sensitization (BeS) in some subjects, and the sensitized cases could develop further to chronic lung disease (chronic beryllium disease, CBD). Beryllium lymphocyte proliferation test (BelPT) is an examination to identify the sensitized subjects and CBD patients. The standard protocols were released in 2001 by DOE. However, there are still some controversies over the reliability of this assay, and considerable variations of results even for the same sample is one of the problems that often embarrasses people. Furthermore, radioactive substance is used in the assay and this is not convenient to many laboratories. Although BelPT is used in health examination of workers in some factories, it is still a "must" item under the present regulations of MHLW, Japan, partially due to its non-reliability. In this study, we modified the assay procedures to minimize the variations of results, and by using non-radioactive coloring agent to monitor the cell viability, we introduced an alternative assay protocols. Methods: With human lymphocyte cell line, we simplified the assay to minimize the variations of the radiation counting. Also we used alamar blue cell viability assay, a method using the reducing power of living cells to quantitatively measure the proliferation of cells. Then with lymphocytes from volunteers, the simplified DOE method and alternative alamar blue method were confirmed under Con A stimulation. Finally with lymphocytes from CBD patients, we tested the simplified and alternative methods for their efficiency and accuracy.

This study was approved by the Ethics Committee of our institute and informed contents were obtained from all subjects participated. Results and Conclusions: By omitting cell washing and DNA purification steps, the variations of radiation counting was greatly reduced, though with higher background values. The alamar blue method showed similar results to DOE method with high accuracy. It is noteworthy that alamar blue assay could be easily done only by adding the agent for a few hours, and after the photometer reading, the same cells can be used for the assays of DOE method by adding 3H-thymidine. This is especially useful for the blood samples with limited amount.
studies, iAs3+ exposure significantly decreased insulin secretion by ~50%. Non-cytotoxic concentrations of Mn (12.5, 25, and 50 µM) and Cd (5 µM) also significantly decreased insulin secretion when administered alone, whereas Zn (6.25 and 50 µM) elicited a slight increase in insulin secretion. Interestingly, binary mixtures of iAs3+ and Zn, Mn, or Cd showed no additive or synergistic effect on insulin secretion. Examination of oxygen consumption rate (OCR), a proxy for mitochondrial function, revealed that single exposure to Mn or Cd had no significant impact on mitochondrial function, whereas, iAs3+ drove a significant reduction in maximal OCR. Similar to the effect on GSIS, binary mixtures of these metals did not further decrease or increase OCR from the iAs3+ exposure alone, indicating that Cd and Mn inhibit insulin secretion by impacting other steps of the insulin secretory pathway, which are likely downstream of mitochondrial function. Future work will identify these steps and characterize the mechanisms of Cd and Mn action.

### 3007 Assessment of Thiol-Rich Proteins, Lipid Peroxidation, and Zinc as Biomarkers of Combined Exposure to Lead, Cadmium, and Manganese in Rats

O. O. Oladipo1, C. Uchendu1, J. O. Ayo2, S. F. Ambali1, and B. Mohammed2. 1University of Jos, Jos, Nigeria; 2Ahmadu Bello University, Zaria, Nigeria; and 3University of Ilorin, Ilorin, Nigeria.

Lead (Pb), cadmium (Cd) and manganese (Mn) are known to occur together in the environment, and another method of assessing the potential of clinical symptoms presented in such cases are not specific, and in most cases go unnoticed. Thus, there is need for more systematic research into the chronic influence of the metals at very low concentrations on some biomarkers in vivo. This study aims to evaluate the effect of combined exposure to Pb, Cd and Mn on thiol-rich proteins, lipid peroxidation and trace elements Iron (Fe) and zinc (Zn) in rats. Five orally-treated groups of five rats each received Pb acetate (1.4 mg/kg b.w.), Cd chloride (0.01 mg/kg b.w.), Mn chloride (0.14 mg/kg b.w.) and the combination (Pb+Cd+Mn), as equivalence of NOAELs for each metal, for 15 weeks. Control rats were given deionized water (2 ml/kg). Metallothionein-1 (MT1), glutathione peroxidase-1 (GPx1), malondialdehyde (MDA), Fe and Zn concentrations were analyzed in the serum. The levels of MT1, GPx1 and Zn significantly decreased, while MDA concentration increased in the rats treated with the metal mixtures. The results also implicate possible synergistic effects of Pb, Cd and Mn on MT1, GPx1 and Zn concentrations. Taken together, a definite and important role of oxidative stress is evident in low dose Pb+Cd+Mn- exposed rats, and may be used as sensitive biomarkers in situations of multiple metal exposure scenarios.

### 3008 Establishing a Metal-Interactome in Ovarian Cell Lines

L. Amable, National Institute on Minority Health and Health Disparities, Bethesda, MD.

The cellular metallome serves as an important reservoir to meet the biological needs of the cell. It also becomes altered after exposures to toxic, harmful metals. Recent studies have suggested that cancer cells adapt their metallome to accommodate rapid cellular growth and metabolism pathways. Thus, altering the cancer metallome may yield new avenues to target cancer and chemotherapy responsiveness. Here, we took a systematic approach to characterize the cellular metallome, as well as other cellular responses, under various metal conditions in a panel of ovarian cancer and non-cancer cell lines. In addition, sensitivity to the metal-based chemotherapy drug cisplatin in response to metal treatment was evaluated. The metallome was manipulated by treating cells with either zinc, copper, magnesium, calcium, iron, manganese, or the metal chelator tetrathiomolybdate. Cell proliferation in response to metal treatment or cisplatin was measured by WST-1 assays. Metallomes were quantified by Inductively Coupled Plasma-Mass Spectrometry (ICP-MS) by measuring the following metals: zinc, copper, magnesium, calcium, molybdenum, manganese, iron, phosphorous, and sulfur. Cellular metal concentrations were normalized to sulfur levels. Metal treatment of ovarian cancer cells resulted in differences in cellular proliferation, uptake, and the cellular metallome. The changes in the metallome were not singular in nature as altering one metal resulted in changes in multiple metals, hence evidence of a metal interactome. Differences in how the cells respond to metal treatment were also observed between cancer and non-cancer cell lines. In terms of cisplatin sensitivity, the results suggest that metal alteration is only effective in certain cell lines. The data lend further insight into how an individual’s metallic status, a combination of nutritional and harmful metal exposure, might result in the development and progression of cancer.
risk. Likewise, TCEQ’s more recent URF for arsenic (1.5E-04 per µg/m³) is based on updates of two studies that US EPA used in 1984, as well as an additional cohort. These and other examples emphasize the importance of scientifically-current chemical assessments to best characterize risk/hazard.

3011 Blood Metal Reference Values in a Southern Brazilian Adult Population

M. M. Paoliello. State University of Londrina, Londrina, Brazil.

The assessment of blood concentrations of essential and non-essential metals is important in identifying exposure characteristics and it can be used as a reference for prospective evaluations. The aim of this study was to determine blood levels of As, Cd, Co, Cu, Hg, Mg, Mn, Mo, Pb, Se, U and Zn, and to evaluate differences in blood levels in relationship to demographic and lifestyle characteristics, and to establish reference values (RV) for this population. A cross-sectional study was carried out in a random sample of adults, aged 40 years or older, living in a city in Southern Brazil. Metal blood levels were measured by ICP-MS. The RV were based on the upper limits of the 95th CIs of the percentiles of the measured distributions. A total of 903 adults enrolled in the study. The RV and the geometric mean (GM) (95% CIs) for the total population were respectively: As (12.59 and 5.34 µg/L; 5.15, 3.53), Cd (1.31 and 0.06 µg/L; 0.05, 0.07), Co (0.98 and 0.26 µg/L; 0.24, 0.28), Cu (198.9 and 111.7 µg/L; 108.6, 115.0), Pb (5.88 and 1.93 µg/dL; 1.86, 2.01), Mg (6.14 and 3.91 mg/dL; 3.85, 3.97), Mn (19.56 and 12.11 µg/L; 11.9, 12.3), Hg (8.23 and 1.39 µg/L; 1.29, 1.50), Mo (2.82 and 0.76 µg/L; 0.73, 0.80), Se (132.2 and 83.6 µg/L; 82.5, 85.1), U (5.39 and 0.08 µg/L; 0.07, 0.09) and Zn (121.3 and 50.6 µg/dL; 63.5, 67.7). Cd, Pb and Hg blood concentrations were higher in men compared to women, while Co, Cu and Se concentrations were higher in women. Smokers had significantly higher Cd and Pb concentrations, while Se blood levels were inversely associated with smoking. Participants aged 50-59 years had higher Pb, Mo and Se blood concentrations. These results impart novel information on essential and non-essential metal concentrations in the general population in Brazil.

3012 Correlations between Immunologic Alterations and Metal Exposure within the Navajo Birth Cohort Study

The Navajo Birth Cohort Study (NBCS) was established to address community health concerns about chronic exposure to mine waste. Tribal populations are characterized by health disparities, including infection, kidney function, diabetes and cancer; the immune system plays a role in all of these. Based on past and ongoing work with Navajo Nation and other tribes, we hypothesize that chronic low-level environmental exposure to metal mixtures from mine waste results in immune dysregulation. In this study, we are examining whether changes in lymphocyte phenotypes can be seen in participants who have evidence of exposure to uranium, arsenic, manganese, and cadmium. Samples of whole blood and urine were collected from NBCS participants and analyzed by CDC laboratories for metals via inductively-coupled plasma mass spectrometry (ICP-MS). Biomonitoring revealed an upward shift in blood manganese (BMN) and urine uranium (UUR) in the study population compared with the US population as a whole (NHANES data). Urine total arsenic (UTAS) and urine cadmium (UCD) in NBCS participants is comparable or lower than NHANES data. Whole blood samples were used for immunophenotyping to identify total lymphocytes (CD45), T cells (CD3), T helper (CD4), T cytotoxic (CD8), NK (CD16CD56), and activated (HLA-DR) populations by flow cytometry. Univariate and multivariate analyses (n=80 samples) demonstrate associations between BMN and total lymphocytes. UTAS is associated with changes in the percentage of CD45, CD3, and CD16CD56 subsets. UCD is associated with alterations in CD3, CD16CD56, CD8, and HLA-DR+ subsets. While some metals may increase the percentage of a specific lymphocyte population, other metals may decrease that population, confirming the necessity of modeling the effects of metal mixtures rather than merely single exposure, on immune markers of interest. It is important to understand the relationships between chronic metal exposure and immune alterations to better understand the potential health effects related to this exposure.

3013 Alterations of Micro-Elements in the Body Tissues and Blood of Female Albino Rats Fed with Marijuana Extract

To investigate the effects of different concentrations of marijuana extracts on the levels of microelements in the lungs, brain, kidney, femur and blood, seventy-eight female albino rats (120-150g) were divided into four groups. Control group received olive oil while remaining groups received 12.5, 25 and 50 mg/kg marijuana extract respectively over 2, 4 and 6 weeks. Blood samples and organs were harvested and analyzed for metal (Fe, Cu and Zn) content using flame atomic absorption spectrophotometry. The results showed that the 25 mg/kg extract significantly (p<0.05) increased the copper and zinc concentrations in the femur at 2 weeks and significantly decreased the micro-elements at 4 and 6 weeks. The three doses of the extract significantly (p<0.05) decreased iron concentration in the femur at 4 weeks, however, at 6 weeks, the 25 and 50 mg/kg significantly (p<0.05) increased the iron concentration when compared to their control. Brain copper was significantly (p<0.05) decreased at 2 weeks of 12.5 mg/kg extract whereas at 6 weeks, a significant decrease was observed at 12.5 mg/kg when compared to control. At 4 weeks, a significant increase of copper in the liver was observed at 25 and 50 mg/kg doses at 2 weeks whereas at 4 weeks the copper concentration was highest in the liver of rats administered 25 mg/kg extract with 71% increase when compared to the control. This study shows that marijuana extract administration influences the status of micro-elements in the blood and body tissues of female albino rats.

3014 The Impact of Informal Domestic Work with Jewelry and Fashion Jewelry on Sanitary Sewer System

F. J. Salles1, A. S. Sato1, M. S. Luz2, D. T. Fávaro1, F. J. Ferreira1, W. S. Paganini, and K. P. Olympic1. São Paulo University, São Paulo, Brazil; Technology Research Institute of the State of São Paulo, São Paulo, Brazil; and São Paulo Environmental Company, São Paulo, Brazil.

The outsourcing informal practices adopted by some industrial sectors can causes toxic substances elimination in the effluents and raises a concern for its environmental impact. This study evaluated the levels of micro-elements in the lungs, brain, kidney, femur and blood, seventy-eight female albino rats (120-150g) were collected in 15 markets of three areas during two campaigns of the year of 2016. Furthermore, the sewage sludge (n=2) raw sewage (n=12) and treated sewage (n=12) were collected in two wastewater treatment plants (AS) and TATU operating with different treatment process. The PTEs determination was performed by ICP-OES, direct current plasma analyzer and UV-VIS spectrophotometry. The PTEs found to be above the detection limit of the methods: hexavalent chromium (0.0093 to 0.61 mg L⁻¹), copper (<0.02 to 4.24 mg L⁻¹), nickel (<0.02 to 6.16 mg L⁻¹) and zinc (<0.02 to 1.34 mg L⁻¹). Four sanitary sewage samples exceeded copper or zinc values permitted to be discharged into sewage system; however, the average concentration were lower than that established by Brazilian legislation. High percentages of PTE’s values above the 75th percentile was observed in samples with high Total Organic Carbon values (p<0.05) and in second campaign, therefore in more concentrated sewage. The AS treated sewage presented low concentrations of copper (p<0.05), zinc (p<0.02) and nickel (p=0.01) compared to TATU treated sewage. In the sludge, the copper means exceeded the limits of the Brazilian (1,500 mg kg⁻¹) and International legislations and the zinc results surpass the Canadian limits (1,850 mg kg⁻¹). The heterogeneity of the results can indicate the sporadic nature of the PTE’s sanitary disposal. PTEs used in jewelry and fashion jewelry chain were found in the effluent and may precipitate/concentrate on the sludge, where high concentrations of zinc and copper require its controlled destination. Supported by FAPESP (2015/21253-0) and São Paulo State Environmental Company.
Cement dust deposition on soil has been implicated in changes in trace and heavy metal (HM) contents of soil which may affect the well being of living organisms in the ecosystem. This study assessed the impact of cement dust exposure on the heavy metal contents of soil samples in the vicinity of united cement factory, Calabar, Nigeria. Topsoil samples (5 from each location) were collected at varying distances and directions in the vicinity of the factory and an area remote to the site serving as control. The Pb, Cu, Mn, Fe, Cd, Se, Cr, Zn and As content of the soil samples were determined using atomic absorption spectrophotometry. Data were analysed using ANOVA and LSD post hoc at p<0.05. The HM content of soil samples from all locations studied were below the permissible limits for these metals except for Zn in soil samples collected from location closest to the cement factory which was observed to be above the permissible limit. The HM content of soil samples studied varied significantly with the location and their distances from the factory. The soil Mn, Fe, Zn, Pb, Cu and Cr levels were significantly higher in soil samples collected from location closest to the cement factory compared to samples from other locations. Moderate contamination with Cu and Pb and considerable contamination with Cr were observed in soil samples collected at locations closest to the cement factory. The HM content of soil from all locations studied demonstrated minimal enrichment (EF<2) and average pollution index (IPI<1). Exposure to cement dust is associated with soil contamination with Pb, Cu and Zn but not Mn, Fe, Cd, Se, Cr, Zn and As. Soil contamination with Pb, Cu, and Cr and subsequent transmission to humans via the food chain has been related to specific tissue and organ toxicities. Appropriate remediation strategies for soil contaminants should be implemented to avert undesirable environmental health consequences.

Domoic acid (DA), the cause of Amnesic Shellfish Poisoning, is a naturally occurring excitotoxin that can contaminate shellfish and finfish. Consumption of food contaminated with high-dose DA is associated with gastrointestinal distress, seizures, memory loss, coma and death. It is important to define the health risks associated with chronic, low-dose exposure because the ocean algal blooms producing DA are becoming more frequent and severe. To this scientific end, we have initiated a longitudinal study of the reproductive and neurodevelopmental effects of low-level oral DA exposure in a preclinical nonhuman primate model. Adult female Macaca fascicularis monkeys were exposed to daily doses of DA (either 0, 0.075, or 0.15 mg/kg) during pregnancy and their infants were being evaluated in a specialized nursery to allow for comprehensive behavioral testing. The doses used in this study were selected because they are either at the current TDI for humans or just twice the TDI, well within the margin of safety for human DA exposure. To identify potential effects of DA exposure in the adult females, we regularly conducted evaluations of health and behavior before, during and after DA exposure. Results of our clinical observations indicate that subtle neurological effects (tremors) may be the initial sign of DA neurotoxicity in these animals. The frequency of tremors is 10% (1/10) in control animals, 27% (3/11) in low-dose animals and 63% (7/11) in the higher-dose group. It is noteworthy that some prenatally-exposed infants are also displaying persistent intentional tremors during cognitive testing. Further studies of the females exhibiting tremors compared to those who are not are being conducted using PET and MRI procedures. The results thus far suggest that the current TDI for DA does not provide adequate protection for humans who are chronically exposed.

Biosynthetic organohalogens, including bromopyrroles are emerging pollutants in saline wastewater effluents as disinfection by-products (DBPs). Some DBPs have cytotoxic, genotoxic and developmental toxicity, such as 2,3,5-tribromopyrrole and tetrabromopyrrole. However, there is no information about direct mechanisms by which DBPs induce mammalian neurotoxicity. Herein, several biosynthetic bromopyrrole analogues, including 2,3,5-tribromopyrrole (1), tetrabromopyrrole (2), 4,5-dibromopyrrole-2-carboxylate (3), ethyl 4,5-dibromopyrrole-2-carboxylate (4), 3,4,5-tetrabromopyrrole-2-carboxylate (5), and ethyl 3,4,5-tibromopyrrole-2-carboxylate (6) were tested for their direct engagement of ryanoide receptor type 1 (RYR1) using [3H]ryanodine binding analysis, and influences on patterns of synchronized Ca2+ oscillations (SCOs) of neuronal networks in a concentration-dependent manner with compound 2 (having the highest potency ([Ci]0.41 µM) compared to (1) ([Ci]0.1 µM). These data identify for the first time a new molecular target for bromopyrroles that displays a stringent structure-activity relationship towards modulating RYR1 and neuronal network Ca2+ dynamics. Supported by NIEHS R01 P01 ES011269 and P42 ES04699, and US EPA STAR 829388 and R833292.
Only a small percentage of chemicals in the human chemosphere have been evaluated for their neurotoxic potential. In order to screen the tens of thousands of chemicals for which no toxicity data exists, it is necessary to move from in vivo rodent experiments to in vitro/in silico models and alternative animal models. Zebrafish embryos are a promising model for toxicity screening since they develop fast, are available in large numbers, and their genome is highly homologous to that of humans and there are many transgenic/mutant lines available for mechanistic studies. We used dechorionated Tropical SD wildtype zebrafish embryos to screen a 91-compound library (provided by the National Toxicology Program) for developmental neurotoxicity. Embryos were exposed to 5 concentrations of each chemical up to 100 µM or to an equivalent of vehicle (0.5% DMSO) in embryo media from 6 hours post-fertilization (hpf) to 5 days post-fertilization (dpf). Embryos were examined daily for malformations and mortality until euthanized at 5 dpf. Developmental neurotoxicity was assessed at 4 and 5 dpf using a light-dark locomotor behavioral assay. Malformed and dead fish were excluded from the behavioral analysis. The 87 unique chemicals (4 were provided in duplicates) screened included negative controls, flame retardants (FR), polycyclic aromatic hydrocarbons (PAH), drugs, industrial chemicals and pesticides. All negative controls had no effect on mortality/malformations or locomotor behavior. Many chemicals caused different behavioral outcomes at 4 versus 5 dpf, and different chemical concentrations led to different behavioral patterns. Interestingly, chemicals within the same group caused different behavioral abnormalities, while similar behavioral patterns were caused by chemicals belonging to different groups.

Neuroinflammation is a significant contributor to the initiation and progression of many neurodegenerative diseases including Parkinson’s disease (PD). Inflammatorystimulatory cytokines, including TNF-α, IL-1β, and IL-6, can be released by astrocytes, microglia, or on behavior, and chemicals provided in duplicates produced similar outcomes. Interestingly, most PAHs affected only behavior and no PAH caused only malformations or mortality. Behavioral abnormalities were generally observed at lower concentrations than those that caused mortality/malformations, suggesting that behavioral alterations were not due to toxicity. Many chemicals caused different behavioral outcomes at 4 versus 5 dpf, and different chemical concentrations led to different behavioral patterns. Interestingly, chemicals within the same group caused different behavioral abnormalities, while similar behavioral patterns were caused by chemicals belonging to different groups. Supported by NIH HS (ROI ES01269 to PJL and F32 ES024070 to GMW) and US EPA (R08354320 to PJL).

Characterizing Novel Mechanism-of-Action of Lithium in Caenorhabditis elegans

Lithium is the most commonly prescribed drug for bipolar disorder. Despite its mood stabilizing properties, the specific mechanisms through which lithium exerts its beneficial effects are not clear. Lithium has a narrow therapeutic index and therefore causes serious toxic side effects. Previously our lab showed that lithium increases the serum and glucocorticoid-inducible kinase (SGK) activity in C. elegans. SGK plays a central role in the regulation of Na+ absorption by stimulating the activity and prolonging the half-life of the epithelial Na+ channel (EnaC) and thus regulates extracellular fluid volume, blood pressure, and sodium homeostasis. It is worth noting that hypertension is a recognized side effect of lithium treatment. In the present study, we used lithium for its SGK pathway activating effect. For these experiments, we covered seeded plates with drugs that were dissolved in appropriate solvents, and observed worms periodically to assess development, movement and egg laying. We found that lithium corrected the egg laying and developmental deficits of animals that have a gain-of-function (gf) mutation (unc-58665) in a two-pore domain K+ channel (K2P), which normally causes animals to adopt a rigid posture with constant shaking. We hypothesized that if lithium corrects these deficits through SGK signaling, another drug that activates SGK (clozapine) should also correct these deficits. Clozapine corrected the locomotion and developmental deficits of animals. Lithium and clozapine appeared to correct different deficits in the unc-58 gf strain. When we combined lithium and clozapine, their effects were not additive. This suggested that lithium and clozapine were not acting through SGK signaling to rescue the deficits of unc-58 gf animals. Regardless of the mechanisms, we have identified K2Ps as a possible indirect target of lithium’s actions. By characterizing this novel mechanism of action of lithium, we may learn how to improve its therapeutic activity and diminish the toxic side effects.

3022 Farnesoid X Receptor Agonists Reduce Cytokine-Induced Inflammatory Response of Immortalized and Primary Mouse Astrocytes

Background: Spiral ganglion neurons (SGNs) gradually die after destruction of hair cells, their sole afferent input. During SGN degeneration, the ganglion exhibits both inflammation and upregulation of the major NAD catabolizing enzyme, CD38, an activation marker for inflammatory cells. The novel P7C3 series of neuroprotective compounds helps stabilize neurons in times of energetic stress by activating the rate-limiting enzyme NAMPT in the NAD salvage pathway. Here, we assessed the potential of NAMPT and CD38 as inflammatory activating markers for SGNs and viability in rat models of acute deafening.

Methods: Sprague Dawley rats were deafened by daily intraperitoneal injection of kanamycin for 7 days or postnatal day P16. Rats showing reduced reaction time motor learning task were not included. From P22-P70, rats were injected intraperitoneally with P7C3A20 (20 mg/kg) and/or ibuprofen 40 mg/kg in DMSO/corn oil or vehicle only. Rats were euthanized at P70, cochleae fixed and cryosectioned (6 µm) parallel to the midmodiolar plane. Myosin 6/7 immunofluorescence was used to monitor hair cell loss. NeuN and NF200 immunofluorescence were used to label neurons, which were counted in every fourth near-midmodiolar section. Image analysis was done using the FIJI ImageJ package with custom-written macros. The outline of Rosenthal canal for each turn was manually traced to measure cross-sectional area and to calculate SGN density. Results: Kanamycin injection resulted in loss of inner hair cells throughout most of the cochlea. By P70, SGN density in kanamycin-injected rats was significantly reduced in the basal region. Either P7C3 or Ibuprofen improved the survival of SGNs after deafening in the basal region significantly (P < 0.05), from ~30% to ~50%, whereas a combination of these two agents improved it to ~60%. We conclude that P7C3, Ibuprofen, or a combination of these two is protective against SGN death in basal cochlea after aminoglycoside deafening. This further suggests that dysregulation of NAD+ metabolism in both hair cells and inflammatory cells in the spiral ganglion may play a role in SGN death after deafening, and provide a basis for new therapeutic treatments for patients.
Epidemiological studies indicate that a sedentary lifestyle combined with increased consumption of high-fat diets contributes to increased incidence of obesity and related metabolic disorders. These disorders during pregnancy may make offspring more susceptible to air pollutants. The brain is unique, with varieties of neurons and glial cells each having specialized functions contributing to behavior, learning, and autonomic control. These functions have high energy requirements from mitochondrial bioenergetics, a likely target of chemical-induced neurotoxicity. We have investigated whether maternal high-fat diet and exercise interact with effects of maternal O3 exposure on mitochondrial bioenergetics in brains of offspring. For this study, female Long-Evans rats were fed either a control diet (CD) or a high-fat diet (HF; 60% calories in fat) for 6 weeks starting at 30 days of age and then bred. Gestational day (GD) 1 dams were housed with a running wheel (RW) or without (Sedentary; SED) until parturition. HF diet was terminated at postnatal day 35 and all offspring were fed CD thereafter. Adult offspring (~160 days) were exposed to air or O3 for 2 consecutive days (0.8 ppm, 4 hr/day), then rats were killed, brain regions were dissected on ice, snap-frozen and analyzed for complex I, complex II and complex IV enzymes in the frontal cortex (FC) and cerebellum (CB). Complex I enzyme activity (sucinate dehydrogenase, EC 1.3.5.1) was similar in sex, brain region and O3 exposure group in offspring from CD mothers. O3 exposure increased complex I activity in the CB of male offspring from HF-SED mothers but not HF-RW. Complex II enzyme activity (succinate dehydrogenase, EC 1.3.5.1) was elevated in the FC of male offspring from HF mothers but not CD mothers, which was exposed to O3. CB of air-exposed male offspring from CD-RW mothers, there was an increase in complex II activity. Complex IV enzyme activity (cytochrome c oxidase, EC 1.9.3.1) was increased in the FC of males from O3-exposed HF-SED mothers but decreased in HF-RW mothers. O3 also increased complex IV enzymes from mothers maintained on HF. These results indicate that O3 significantly affects brain mitochondrial bioenergetics and that a maternal diet and exercise regimen play a role in offspring’s susceptibility to O3 effects. This abstract does not necessarily reflect US EPA policy.

3028 Simultaneous Assessment of Heart Rate and Sensory Motor Gating Under Positive and Negative Controls in the Startle Response Test

S. Reed, A. Zmarowski, T. Vinci, B. Visnick, B. Lordo, and M. Hawk.

Potential adverse effects of pharmaceuticals on vital organ systems including the cardiovascular and central nervous systems (CNS) must be assessed. Changes in physiology can impact behavior and alterations in behavior can reciprocally change physiology. However, interactions between these systems are rarely examined at the same time. Drugs may have different effects under resting or stimulated conditions, and therefore the simultaneous investigation of cardiovascular and neurobehavioral endpoints provides a more thorough evaluation of drug safety assessment. This study was conducted to evaluate cardiovascular changes during baseline performance in the startle response test and after treatment with pharmacological agents. Ten animals were implanted with telemetry units monitoring blood pressure (BP) and heart rate (HR). After surgical recovery, animals were treated with vehicle (water for injection), amphetamine (AMPH, 1 and 2 mg/kg), MK-801 (0.1 and 0.15 mg/kg) and Diazepam (DIAZ, 5 and 10 mg/kg) on separate days, and tested in the Startle Monitor II System (Kinder Scientific). After a 5-minute acclimation period, animals were exposed to a 120 dB startle stimulus once every 30 seconds for 50 trials. Maximum force, HR and BP were evaluated. HR and BP increased with the first pulse and decreased over the test duration as animals habituated. With AMPH, HR and BP were elevated throughout the test, but animals still habituated. DIAZ dose dependently reduced HR and BP, and also generated significantly less force than after vehicle treatment. DIAZ also produced a 5-minute acclimation period, animals were exposed to a 120 dB startle stimulus once every 30 seconds for 50 trials. Maximum force, HR and BP were evaluated. HR and BP increased with the first pulse and decreased over the test duration as animals habituated. With AMPH, HR and BP were elevated throughout the test, but animals still habituated. DIAZ dose dependently reduced HR and BP, and also generated significantly less force than after vehicle treatment. DIAZ also produced slightly delayed changes in HR after each startle stimulus. Force generated, HR and BP were significantly higher with MK-801 exposure. HR and BP stayed elevated during the duration of the test and no habituation was evident. The combined assessment of physiological and behavioral endpoints provides a more thorough evaluation of drug-induced effects on sensory-motor gating under baseline and stimulated conditions. This more accurately reflects the heterogeneity of real world conditions and can thereby improve the overall reliability of pharmaceutical safety testing.

3029 Pumpless, Serum-Free, Functional Human Blood-Brain Barrier Model

T. Sasserath1, J. W. Rumsey1, N. S. Narashimhan1, C. J. Long1, M. L. Shuler1,2, and J. J. Hickman1.
1Hesperos, Inc., Orlando, FL; and 2Cornell University, Ithaca, NY.

The blood-brain barrier (BBB) is a complex interplay between astrocyte endfeet and the endothelial cells that comprise the brain’s microvasculature. This network of interconnected cells serves a neuroprotective role by creating a tight physical barrier between the blood and the brain parenchyma that selectively excludes large molecules and other materials that have the potential to upset its delicate neurochemistry. Delivery of therapeutic agents across the BBB is problematic, and solutions to this problem have been a major area of study in recent years. In this study, we developed a pumpless, recirculating, serum free, human in vitro model of the BBB with cocultured human induced pluripotent stem cell (hiPSC) derived brain microvascular cells (BMECs) and primary human astrocytes. Each cell type was cultured on opposite sides of a porous membrane and assembled in a pumpless system that separates each side of the BBB into their own respective compartments, each with their own physiologically relevant flow profile. Efficient tight junction formation was observed in the systems with TEER levels reaching 2500 Ocm^-2 by day 3 and remaining above 1000 Ocm^-2 at day 7. TEER dependent passive transport across the BBB was evaluated by the addition of fluorescently-tagged dextran of differing Stokes radii. Active transport was also evidenced by receptor-mediated transport of the transferrin receptor (TR) antibody and was shown to be independent of TEER. This pumpless, serum-free, humanicased BBB model establishes a refined platform for studying compound pharmacokinetics into the central nervous system and their effects on the integrity of the BBB.

3030 BMP Chemotropic and Inductive Signaling in Response to Acute Ethanol Exposure

N. Habeeb, and J. C. Perron. St. John’s University, Jamaica, NY.
Sponsor: D. Harde

Consumption of excessive quantities of alcohol during pregnancy can lead to the development of Fetal Alcohol Syndrome (FAS), which is a disorder characterized by developmental, cognitive and behavioral disabilities. These disabilities include effects on cellular differentiation and chemotropic activities in a number of different tissues. Bone Morphogenetic Proteins (BMPs), members of the TGF-β superfamily, play important roles in cellular differentiation as well as in chemotropic activities, including axon orientation and monocyte chemotaxis. Stimulation with BMP7 activates distinct intracellular signaling pathways that lead to either gene transcriptional events, through Smad-dependent signaling, or regulation of cytoskeletal organization, through PI3K- dependent mechanisms. This study explores the effects of Ethanol (EtOH) exposure on BMP-7-evoked, transcriptional and chemotropic signaling to determine if the developmental effects of EtOH, as observed in FAS, might be due to perturbation of BMP signaling and reveal whether the chemotactic activity of BMPs might be protective against the morphogenetic effects of EtOH. In order to study the influence of EtOH on BMP signaling, the C2C12 mouse myoblast cell line was utilized due to its abundance of BMP-7 and the ability to differentiate into muscle and respond to BMPs. The C2C12 cell line was selected for this study due to the ease of differentiation into muscle cells and the ability to respond to BMPs. In this study, the C2C12 cell line was differentiated into muscle cells and then exposed to varying concentrations of EtOH to determine the effects on BMP signaling. The effects of EtOH exposure on BMP signaling were determined using a variety of techniques, including Western Blotting and RT-qPCR. The results of this study showed that EtOH exposure significantly inhibited BMP signaling, as evidenced by a decrease in the expression of BMP target genes, including Smad2 and Smad3. These findings suggest that EtOH exposure interferes with the subcellular localization of these signaling mediators. The relationship between BMP7 signaling and EtOH-induced morphogenetic changes over an acute time course was explored. EtOH exposure appeared to have no effect on BMP7-stimulated Smad phosphorylation. EtOH treatment alone caused a dose-dependent decrease in Akt phosphorylation (pAkt) at all concentrations except 7.5%. PP2A partially rescued the effect of EtOH exposure on pAkt at low concentrations indicating that BMPs may provide a protective effect against the acute morphological effects of EtOH exposure.

3027 The Interaction of Maternal High-Fat Diet and Exercise on Brain Mitochondrial Bioenergetics in Rat Offspring after Ozone Exposure

This more accurately reflects the heterogeneity of real world conditions and can thereby improve the overall reliability of pharmaceutical safety testing.
New Insights into the Role Microglia Play in the Etiology of Gulf War Illness

K. A. Kelly, J. V. Miller, L. T. Michalovich, D. B. Miller, and J. P. O’Callaghan, NIOSH, Morgantown, WV.

Gulf War Illness (GWI) is a multi-symptom disorder with symptoms: persistent headaches, chronic fatigue, memory loss/confusion, skin and GI problems. These features are characteristic of persistent sickness behavior, known to result from underlying microglial neuroinflammation. Chronic exposure to corticosterone (CORT), at levels associated with high physiological stress, can prime the CNS to mount an exacerbated neuroinflammatory response (increase in proinflammatory cytokines/chemokines) following systemic exposure to neurotoxins/inflammagens. When we administered CORT (200 mg/L 0.6% ETOH in drinking water) for 7 days prior to exposure to sarin surrogate, disopropyl fluoroephosphate (DFP; 4 mg/kg, i.p.), a heightened neuroinflammatory response was observed without astrogliosis or neurodegeneration 6-72 hours after DFP exposure. While the underlying early symptoms of GWI, they did not address the persistent episodic bouts of sickness behavior that characterize the long-term nature of GWI. As the phenotype is punctuated by symptom flares-ups, systemic exposure to lipopolysaccharide (LPS - a bacterial mimic; 0.5 mg/kg, s.c.) was used to challenge the GWI phenotype 24h following DFP treatment. CORT pretreatment primes the neuroinflammatory response to produce augmented LPS-induced inflammation and a single dose of DFP significantly exacerbated this effect. Here pretreatment with CSF1R inhibitor Pexidartinib (PLX) (290 mg/kg chow ad libitum over 28d), a compound that has been demonstrated to "eliminate" or reduce microglia in brain, was used to investigate the role microglia play in the pathogenesis of this neuroinflammatory disorder. The well documented reduction in DFP-induced mortality by CORT pretreatment was further reduced by PLX in CORT DFP (7%-36%) groups and eliminated in the DFP alone group (0%-71%). CORT pretreatment caused significant thymic involution in both control (35%) and PLX (47%) groups with PLX groups showing reduced thymic weights (11% and 27%, respectively). Brain cytokine/chemokine levels measured by qPCR revealed large increases in IL6 & GGM in response to LPS in PLX pretreated groups (LPS: 125% & 122%; CORT: 178% & 181%; CORT DFP 194% & 194%), respectively) revealing a potential proinflammatory effect of PLX. Findings potentially point to not only a non-microglial origin of these cytokines in this model, but also a protective role of microglia in certain neuroinflammatory conditions.

Using Public Data to Develop an Open-Access Computational Knime Workflow to Identify Any Cholinergic Compound

S. J. Wijeyesakere, D. Wilson, A. Parks, T. Auernhammer, and S. Marty, The Dow Chemical Company, Midland, MI.

One goal of high-throughput data mining in the life sciences is to align compounds with potential mechanistic targets for further in-depth study. As proof-of-concept using two-dimensional structural scaffolding, we sought to identify any unknown compound that might specifically interact with the cholinergic nervous system. The sympathetic and parasympathetic cholinergic nervous systems encompass the foundation of signaling at the mammalian neuromuscular junction. Neurotransmission is mediated by acetylcholine (ACh) via nicotinic (nAChR) and muscarinic (mAChR) ACh receptors and acetylcholines- terase (ACHE). Given the extent of public data from prior studies under- taken on these target proteins, we hypothesized that the cholinergic potential of any novel compound could be computationally predicted using big data mining based on the presence of structural motifs (scafolded) across the known universe of cholinergic agents. Herein we show the development of a computerized workflow to capture and cluster virtually all (~19,000) compounds known to target the cholinergic system. From these, we identified 453 scaffolds that explain the structural diversity of known cholinergins. Using the Tanimoto similarity of these scaffolds to a compound as a covariate within a random forest machine-learning algorithm, we can predict the likelihood a novel compound will target any component of the cholinergic system (nAChR, mAChR or ACHE) with exquisite sensitivity (99.3%) and high accuracy (94%). By building similar models for each separate component of the cholinergic system, we can additionally predict the likelihood of a compound interacting with a specific target (nAChR, mAChR or ACHE) with similarly high sensitivity and accuracy (>96%). In conclusion, our findings demonstrate that it is possible to implement computerized workflows to gather public data, identify key structural scaffolds that describe the known cholinergic agents, and develop automated prediction models to calculate the likelihood of a previously uncharacterized compound interacting with the cholinergic nervous system.

Doxorubicin-Induced Neuromotor Impairments in Male Athymic NCr Mice: Partial Protection by Phenylaminoethyl Selenide

M. A. Arnold, R. A. Sauer, and M. C. Newland, Auburn University, Auburn, AL.

There is considerable research characterizing cardiotoxicity of the anti-tumor drug doxorubicin (DOX), while few studies have focused on neuro- motor and cognitive impairment. DOX has been shown to induce fine-motor deficits in humans and motor neuron degeneration, in vitro. The athymic T-cell deficient NCr (nu/nu) mouse is a frequently used model of cancer growth and chemotherapeutic treatment, but there have been few studies assessing neuromotor function in this strain and none investigating DOX-induced motor impairments and neuroprotection afforded by the antioxidant phenylaminoethyl selenide (PAESe). Male NCr mice were initially tested on rotarod and voluntary wheel running. After initial testing, they were assigned to exposure groups to see if there did not differ prior to treatment. Mice were then administered four weekly i.v. doses of 5mg/kg DOX, 10mg/kg PAESe, a CSFR1 inhibitor Pexidartinib (PLX) (290 mg/kg chow ad libitum over 28d), a compound that has been demonstrated to “eliminate” or reduce microglia in brain, was used to investigate the role microglia play in the pathogenesis of this neuroinflammatory disorder. The well documented reduction in DFP-induced mortality by CORT pretreatment was further reduced by PLX in CORT DFP (7%-36%) groups and eliminated in the DFP alone group (0%-71%). CORT pretreatment caused significant thymic involution in both control (35%) and PLX (47%) groups with PLX groups showing reduced thymic weights (11% and 27%, respectively). Brain cytokine/chemokine levels measured by qPCR revealed large increases in IL6 & GGM in response to LPS in PLX pretreated groups (LPS: 125% & 122%; CORT: 178% & 181%; CORT DFP 194% & 194%), respectively) revealing a potential proinflammatory effect of PLX. Findings potentially point to not only a non-microglial origin of these cytokines in this model, but also a protective role of microglia in certain neuroinflammatory conditions.

Neurotoxic Mechanisms of the Novel Psychoactive Substance Methoxetamine in Rat and Human In Vitro Models

E. Kasteel1, L. Hondebrink1, and R. H. Westerink1, 1Utrecht University, Utrecht, Netherlands; and 2University Medical Center Utrecht, Utrecht, Netherlands.

The use of new psychoactive substances (NPS) is steadily increasing. One of the commonly used NPS is the ketamine analogue methoxetamine (MXE). Although adverse effects have been reported for MXE, there is limited data available on its neurotoxicological mechanism(s) of action. To increase insight in the neurotoxicological profile of MXE, the aim of this study was to investigate the effect(s) of ketamine and its analogue MXE on calcium homeostasis, neuronal activity and monoamine transporters in different rat and human in vitro models. We therefore investigated the effects of ketamine and MXE on several neurotransmitter receptors and voltage-gated calcium channels (VGCCs) using single cell intracellular calcium [Ca2+]i imaging in rat primary cortical cells, human SH-SY5Y cells and human induced pluripotent stem cell (hiPSC)-derived neurons. We also investigated effects on neuronal activity in rat primary cortical cells and hiPSC-derived neurons grown on micro-electrode arrays (MEA). Finally, effects on monoamine transporters were assessed in human embryonic kidney (HEK293) cells transfected with human monoamine transporters. In human SH-SY5Y cells, MXE (10 μM) slightly inhibited the K+ and acetylcholine-evoked increase in [Ca2+]i. In rat primary cortical cells, MXE (10 μM) increased the glutamate-evoked increase in [Ca2+]i whereas ketamine (10 μM) was without effect. MXE and ketamine did not affect VGCCs, but inhibited spontaneous neuronal activity with IC50 values between 10 - 100 μM. Finally, MXE potently inhibited uptake via monoamine transporters (DAT, NET and SERT) with IC50 values in the low micromolar range. Our combined in vitro data indicate that the neurotoxicological profile of MXE that can aid the risk assessment of MXE and provides a rapid screening approach that is also useful to assess the hazard of other emerging NPS. This work was funded by the Dutch Poisons Information Center and the Faculty of Veterinary Medicine (Utrecht University).
Gulf War Illness (GWI) is a multi-symptom disorder with similarities to the features of sickle cell behavior. Previously, we have demonstrated that, like sickle cell behavior, GWI is associated with underlying neuroinflammation. In particular, toxic exposures experienced by soldiers during the Gulf War such as pesticides and nerve agents, as well as physiological stress, have led to a chronic, primed neuroinflammatory state that results in an exacerbated response to subsequent inflammatory challenges. The significant elaboration offlammatory cytokines related to the neuroinflammatory priming observed in our GWI mouse model indicates that this illness may be the result of long-term alterations in the brain’s resident immune cells, namely microglia. Here, we have investigated the potential role of microglia in GWI using the CX3CR1−/− mouse strain and minocycline, an anti-inflammatory drug with effects on microglia. Adult male C57BL/6J or CX3CR1−/− mice were exposed to our GWI model consisting of corticosterone (CORT) in the drinking water at levels associated with high physiological stress for 7 days followed by exposure to the nerve agent surrogate, diisopropyl fluorophosphate (DFP), on day 8 and a subsequent immune challenge with lipopolysaccharide (LPS) on day 10. C57BL/6J mice that were given minocycline received a single dose 30 minutes prior to LPS. To test whether minocy- cline or CX3CR1−/− disrupted LPS-induced inflammation, an additional cohort of animals was exposed to LPS exposure with or without DFP on day 8 in place of DFP. Interestingly, neither CX3CR1−/− nor minocycline-treated mice exhibited major differences in cytokine mRNA expression following CORT+LPS exposure compared to controls. However, both CX3CR1−/− and minocycline treatment removed the contribution of DFP to the GWI phenotype, reducing cytokine mRNA expression to levels comparable to CORT+LPS treatment. The recovery of the GWI phenotype to CORT+LPS levels is clinically significant, because this condition mimics a “healthy sick” state in which stress may potentiate inflammatory conditions. These results suggest that microglia play a crucial role in the development/maintenance of GWI particularly in response to DFP and that drugs with modulatory effects on microglia show promise for the treatment of veterans suffering with GWI.

Mitochondrial bioenergetics play a key role in the mechanisms of neurodegenerative disorders and chemical induced neurotoxicity. However, mitochondrial bioenergetic parameters have not been systematically evaluated within the multiple brain regions in sedentary versus active lifestyle following environmental pollutant exposures. In the present study, we measured complex I, complex II and complex IV enzymes in Brain Mitochondrial Bioenergetics following Ozone Exposure in Sedentary Versus Active Lifestyle of Female Long-Evans Rats

Mitochondrial bioenergetics play a key role in the mechanisms of neurodegenerative disorders and chemical induced neurotoxicity. However, mitochondrial bioenergetic parameters have not been systematically evaluated within the multiple brain regions in sedentary versus active lifestyle following environmental pollutant exposures. In the present study, we measured complex I, complex II and complex IV enzymes in sedentary and active with continuous access to running wheels starting at age of postnatal day (PND) 22 until the age of PND 100 and subjected to Ozone (O3) exposure. A similar effect was observed in HIP, but however, there was an increase of activity in active animals following 4 weeks of exposure in mice. Based on these premises we tested the hypotheses, chronic tobacco smoke exposure to mice for 4 weeks can impact Slc40a1 mediated iron exporter function at the neurovascular unit. Both male and female mice were divided into two groups, chronically exposed via direct inhalation of side-stream smoke) to either tobacco smoke mixed with oxygenated air or oxygenated air alone following 4 weeks of exposure. Two cigarettes/hr, 6 times/day -7 days/week mice were sacrificed and brain tissue collected. Western blot analysis of total brain homogenate was conducted. Interestingly, results revealed the unaltered levels of Slc40a1 in male mice while significant downregulation in female mice. Although needs further validation by downstream relevant assays, this gender difference in Slc40a1 expression and possibly iron shuttling is indeed a novel finding suggesting that tobacco smoke could differentially impact the cerebrovascular system (and possibly CNS functionality) based on gender.

Relevance of Gender in Tobacco Smoking-Dependent Dysregulation of the Iron Exporter Slc40a1

Cerebral iron homeostasis is crucial to maintain optimal CNS functionality. Iron is a vital cofactor involved in the processes of energy production, thus alteration of its transmembrane efflux can impact cell and mitochondrial viability. Specifically, the excess of iron resulting from unwaranted intracellular accumulation can react with oxygen to form cytotoxic free radicals leading to cellular damage. Previously, the functional carrier family Slc40a1 (1 or ferroportin 1) of a transmembrane iron exporter, has been well characterized in enterocytes, hepatocytes and reticuloendothelial system. Activity of this transporter is linked to Nh2-2e pathway to regulate cellular iron metabolism and redox balance. Our previous findings demonstrated that pharmacological inhibition of Nh2 by Snithiophosphate produces a significant upregulation of the mitochondrial Slc40a1 (both gene and protein) in various in vitro models of mouse and human blood-brain barrier endothelium. We have also shown that, tobacco smoking progressively downregulated Nh2 in total brain homogenates following 4 weeks of exposure in mice. Based on these premises we tested the hypothesis, chronic tobacco smoke exposure to mice for 4 weeks can impact Slc40a1 mediated iron exporter function at the neurovascular unit.

Is BMAA an Agent of ALS? A Preliminary Study in Zebrafish

Amyotrophic lateral sclerosis (ALS) is a progressive and fatal neurodegenerative disease with a prevalence of about 3.9 out of 100,000 people. Individuals with ALS are usually diagnosed between the ages of 40 and 70, and have an average life expectancy of three years post-diagnosis. The disease is characterized by motor neuron degeneration, leading to muscle atrophy, paralysis, organ systems failure, and eventual death. Ten percent of ALS cases are familial, with the remaining 90% classified as sporadic. While many gene mutations have been associated with ALS, it is likely that a combination of genetic and environmental factors contribute to the disease. β-methylamino-L-alanine (BMAA) is a non-protein amino acid produced by cyanobacteria, which has been implicated in several neurodegenerative diseases, including ALS. It has been postulated that exposure to BMAA could lead to formation of protein aggregates, oxidative stress, or sequestration of glutamate receptors, mechanisms that have been implicated in the etiology of ALS. However, no causal relationship between BMAA exposure and the onset of ALS has been proven. We are leveraging a transgenic zebrafish line carrying the sod1 G93R mutation to explore the possible connection between chronic and acute exposure to BMAA and ALS-like phenotypes. Wild type (WT) and sod1 mutant embryos were exposed to BMAA from six hours post-fertilization to seven days post fertilization (dpf). BMAA exposure in WT fish was associated with reduced density of neuromuscular junctions (NMJ), as determined by immunohistochemistry, and hyperactive-like behavior. By contrast BMAA did not elicit a significant behavioral change in the sod1 mutants, leading us to speculate that increases in superoxide radicals in sod1 mutants might ameliorate BMAA neurotoxic properties. Overall, our preliminary results suggest that, although some effects of neurotoxin exposure were seen, these short-term developmental exposures are not sufficient to make definitive conclusions about any possible role of BMAA in the etiology of ALS. Long-term exposures are underway to more closely assess the onset and severity of ALS-like symptoms in zebrafish exposed to BMAA and to examine motoneuron viability and function over time, and how such potential compromises might reveal mechanisms involved in neuro-muscular degeneration in ALS when analyzed by behavioral, histological and proteomic assays.

2,4,6-Tribromophenol (TBP, CAS No. 118-79-6) is a brominated chemical used in the production of flame retardant and wood preservative. TBP is found in marine environments, where it is incorporated in shellfish that may be consumed by predatory fish. It is also created as a byproduct during food processing and water treatment. TBP is a bio-active and bio-concentrated endocrine disruptor that interferes with estrogen and thyroid hormone signaling. Estrogen and thyroid hormones regulate important barrier functions, including the blood-brain barrier. The blood-brain barrier is a selectively permeable barrier composed of microvessels made of endothelial cells that are anchored by tight-junctions and express ATP Binding Cassette (ABC) transporters that actively remove toxic endobiotics and xenobiotics from the brain. In this study, we examined the effect of TBP exposure on the transport activity of three well-characterized ABC efflux transporters: P-glycoprotein (P-gp, ABCB1), Breast Cancer Resistance Protein (BCRP, ABCG2), and Multidrug Resistance-associated Protein 2 (MRP2, ABCG2), in freshly isolated rat brain microvessels from Sprague Dawley rats (Taconic, retired male breeders). To establish a dose response and time course, we treated the ex-vivo microvessels with 1-100 nM TBP for 1-3 hours and then measured transport activity. Transport activity was quantified using a confocal microscopy based assay to measure the steady-state luminal accumulation of a transporter-specific fluorescent substrate. We found TBP exposure resulted in a time and dose dependent decrease in P-gp and BCRP transport activity. We saw no change in MRP2 transport activity under identical conditions, indicating selectivity and capillary integrity. Preliminary studies inhibiting transcription and translation suggest that the TBP-dependent decrease in transport activity is through a non-genomic pathway (signaling). Our future studies will involve immunohistochemistry to determine protein localization, and western blots to quantify protein expression after exposure to TBP. Furthermore, we will measure the activity of P-gp and BCRP after in-vivo dosing with TBP. Our work is meaningful because decreases in transporter activity at the blood-brain barrier can reduce neuroprotection and increase CNS exposure to potentially toxic endobiotics and xenobiotics. Supported by the Intramural Research Program at NCI/NIEHS.

S. Rellick. West Virginia University, Morgantown, WV. Sponsor: T. Nurkiewicz

There is concern among residents living near well sites as to whether or not hydraulic fracturing can impact drinking water by releasing chemical additives into the surrounding ground, potentially contaminating both ground water and drinking water. We evaluated the effects of both acute and chronic exposure BTEX on neuronal cells. The chemical we are currently investigating consists of components of raw petroleum products, collectively referred to as BTEX (benzene, toluene, ethylbenzene and xylene), to determine its effects on neuronal cell viability and mitochondrial function in a neuronal cell culture model using the XFe96 Extracellular Flux Analyzer and Calcein AM assays. We will also expand our studies to a murine model of ischemic stroke. We observed that low concentrations of BTEX that are not toxic to neurons leads to an increase in mitochondrial activity. In a pilot animal experiment, we observed that animals will drink water containing BTEX, and can drink the water for 7 days with no visible health effects. Preliminary data suggest that mice receiving an IP injection of BTEX have increased infarction in the cortex and striatum. The increase in mitochondrial activity with low concentrations of BTEX may increase mitochondrial activity initially, but a sec- ondary insult or injury may prevent cells from being rescued and to this damage, resulting in enhanced cell death. We intend to chronically expose mice to low concentrations of BTEX in drinking water, and then induce a transient middle cerebral artery occlusion to see if exposure to BTEX leads to a worse outcome.
494 2018 SOT Annual Meeting

**3043 Brain Lesions Detected by TSPO Positron Emission Tomography (PET) Are Highly Correlated with Neuroinflammation and Neuronal Necrosis in a Rat Model of Acute Organophosphate (OP) Intoxication**

Current medical countermeasures for acute OP poisoning do not protect against persistent neurodegeneration and cognitive impairment, underscoring the need for preclinical models that enable longitudinal monitoring of novel therapies. Previous studies demonstrated neuroinflammation co-occurred with high progesterone levels in acute intoxication with the OP diisopropylfluorophosphate (DFP), suggesting potential mechanistic relevance. The goal of the current study was to map the spatiotemporal progression of neuroinflammation following acute DFP intoxication, and evaluate PET imaging with the TSPO radioligand [18F]-PBR111 as a non-invasive tool for the longitudinal assessment of acute DFP intoxication-induced neuroinflammation. Adult male Sprague Dawley rats were treated with pyridostigmine (0.1 mg/kg, i.m.) prior to administration of DFP (4 mg/kg s.c.), atropine sulfate (2 mg/kg, i.p.) and Z-PAM (25 mg/kg, i.m.). This paradigm elicited moderate-to-severe seizure behavior in study animals. PET expression in the brain was imaged using a Siemens F120 or Inveon DPET microPET scanner; anatomic registration was obtained using a Bruker 7T MRI. Animals were imaged prior to DFP administration (baseline), and at 3, 7, 14, 21, or 28 days post-DFP intoxication. DFP significantly increased TSPO labeling within the hippocampus, thalamus, amygdala and piriform cortex (100-200% increase of protein tyrosine phosphatase 110) uptake was highly correlated with histopathological assessment of neuroinflammation by glial fibrillary acidic protein (GFAP) and ionized calcium-binding adapter molecule 1 (IBA1) immunostaining and with neuronal necrosis as determined by hematoxylin and eosin staining. The results demonstrate that TSPO PET imaging with [18F]-PBR111 can provide quantitative assessments of neuroinflammation following acute DFP intoxication, which may prove useful for longitudinal evaluation of novel therapies. Supported by NIH CounterACT program (NS079202).

**3044 Nicotine and E-Cigarette Exposure Alters Brain Glucose Utilization in Ischemic Stroke**

A. E. Sifat, B. Vaidya, M. A. Kaisar, I. Cucullo, and T. J. Abbasscato. Texas Tech University Health Sciences Center, Amarillo, TX.

Use of electronic cigarettes (eCig) is a growing health concern in both smoking and nonsmoking populations and rigorous studies are needed to investigate the effects of the nicotine exposure via eCig on the neurovascular unit (NVU) and stroke outcome. Previous studies by our lab have shown that nicotine exposure significantly decreases glucose transport across the blood-brain barrier (BBB) in ischemia-reperfusion conditions. In the present study, we investigated the effects of acute & chronic nicotine and eCig vaping exposure on neuronal & brain glucose utilization. Methods: In vitro primary cortical neurons were exposed to nicotine (10 µM) & cotinine (5 µM) for 1 or 5 days and then subjected to 2 h oxygen-glucose deprivation (OGD) followed by 24 h reperfusion to mimic ischemic conditions. Neuronal glucose utilization was measured by radiolabeled 2-deoxy-D-glucose (DG) uptake. Immunohistochemistry for glutamatergic (GLUT1, GLUT3) and nicotinic acetylcholine receptors (nAChRs) expression was determined using the Western blot assay. Results: In vivo and in vitro, nicotine and cotinine exposure significantly decreases neuronal glucose utilization in OGD-reperfusion conditions which were reversed by a non-specific nicotinic acetylcholine receptor (nAChR) antagonist, mecamylamine (20 µM). Nicotine & cotinine also decreases neuronal GLUT1 & GLUT3 expression which were correlated with a7 nAChR upregulation in OGD-reperfusion. Nicotine decreases neuronal viability (in a dose-dependent manner) in normoxic and OGD-reperfusion conditions. E-cig exposure for 7 and 14 days also decreases deoxy-D-glucose uptake under normoxic and OGD-reperfusion conditions in ABS experiments. Conclusions: These data support, from a cerebrovascular perspective, that nicotine & eCig vaping exposure creates an enhanced glucose deprived state at the NVU which could lead to enhanced ischemic brain injury.

**3045 Computational Proteome-Wide Screening Predicts Neurotoxic Drug-Protein Interactome for the Investigational Analytical BIA 10-2474**

V. M. Shahanai1, S. V. Molinski1, S. S. MacKinnon1, L. D. Moraynis1, M. Laforet1, G. Woollard1, N. Kurji2, C. G. Sanchez2, S. J. Wodak1, and A. Windemuth1. 1Cyclica Inc., Toronto, ON, Canada; and 2 Tulane University, New Orleans, LA. Sponsor: R. Brennan

The investigational compound BIA 10-2474 (PubChem CID: 46831476), designed as a long-acting and reversible inhibitor of fatty acid amide hydrolase (a lipase and member of the serine hydrolase superfamily) for the treatment of neuropathic pain, led to the death of one participant and catheter-related deaths due to intracranial hemorrhage in a Phase I clinical trial in 2016. Although, off-target activities of BIA 10-2474 within the ~200-member serine hydrolase superfamily have been characterized as contributing factors to the observed neurotoxicity in humans (van Esbroeck et al., Science 2017), these activity-based proteomics data do not fully explain the clinical phenotype. Therefore, we performed a proteome-wide screening of BIA 10-2474 within a subset of human disease-relevant serine hydrolases currently in development. The proteome-wide screening identified novel drug-protein interactions for BIA 10-2474, providing actionable insights towards elucidation of toxicological, intracranial, inflammatory, hemorrhagic or clotting processes and/or diseases. Eleven proteins were identified as potential targets of BIA 10-2474, and the two highest-scoring proteins, Factor VII and thrombin, both essential blood-clotting factors, were predicted to be inhibited by BIA 10-2474. In vitro validation of top-scoring targets is currently in progress. In silico proteome-wide screening identified novel drug-protein interactions for BIA 10-2474, providing actionable insights towards elucidation of toxicology. Further, this methodology can facilitate off-target profiling for other small molecules currently in development.

**3046 Prenatal Exposure to DEHP Induces Premature Hippocampal Neurodegeneration**

R. Barakat1,2, P. Lin1, J. A. Flaws1, and C. J. Ko1. 1University of Illinois at Urbana-Champaign, Urbana, IL; and 2Benha University, Benha, Egypt.

Phthalates are a family of synthetic chemicals that are widely used in medical, automotive and consumer products. Di-(2-ethylhexyl) phthalate (DEHP) is an endocrine disruptor that has anti-androgenic activity. This study tested an ongoing hypothesis that prenatal exposure to DEHP results in premature reproductive senescence and impaired memory in adulthood. Male CA1 mice were prenatally exposed to DEHP by dosing their mother daily with 200 µg, 500 mg or 750 mg/kg or vehicle from gestation day 11 to birth. The impact of the exposure on their reproductive and memory were examined when they reached the ages of 8 to 22 months. As early as at the ages of 8 months, the 750 mg/kg/day DEHP group of mice exhibited significantly reduced fertility (p=0.028). The same dose-dependent reduction of fertility continued until the age of 18 months. Six out of seven mice of the 750 mg/kg/day group (86%) were infertile, while only a minor drop of fertility was observed in the control mice (25%). At this age, however, all DEHP-exposed group had lower serum testosterone and higher serum estradiol levels than the control mice, indicating that DEHP-exposed mice exhibit a compromised gonadal steroidogenesis. Impacts on their memory was measured at the ages of 16-17 months. Novel object recognition test and Y-maze test found a significantly reduced memory (p<0.05) and spatial memory (p=0.04) in DEHP-exposed mice, respectively. Because hippocampal navigation and short-term memory, whether hippocampal neurons were impacted by the prenatal DEHP exposure was examined. Nissl staining showed that majority of pyramidal neurons in hippocampus were shrunken, indicating that they were undergoing a neuronal degeneration. Indeed, quantitative Spatial Light Interference Microscopy (SLIM) revealed a significantly less hippocampus pyramidal neurons in CA1 and CA2 regions of DEHP-exposed mice than controls (p<0.01). The hippocampal neurodegeneration was in part caused by inflammation and oxidative stress as COX-2 (inflammatory marker) expression and 8-OHDG (DNA oxidation marker) staining were elevated in the DEHP-exposed group. In summary, this study finds that the prenatal exposure to DEHP induces premature reproductive senescence and hippocampal neurodegeneration.
Mamelonitobin (MMB) is a small-molecule inhibitor of Janus kinase 1 and 2 (JAK1/JAK2). The oral toxicity of MMB was evaluated in a repeat dose toxicity study in rats for 26 weeks before initiating Phase 3 clinical trials in myelofibrosis. Rats were administered MMB at dose levels of 0 (vehicle), 5, 15, and 50 mg/kg/day. Following 26 weeks of administration, cohorts of animals/group were maintained for a 10 week recovery period. Assessments of neurobehavioral effects and general toxicity included, but were not limited to, functional observational battery (FOB) evaluations and neuro- and electrophysiological evaluations at Weeks 1, 4, 13, 26, and anatomic and clinical pathology. Toxicokinetic assessment was conducted for the MMB and its metabolite. Image acquisition of neuroconduction velocity (NCV) and amplitude were measured in the caudal nerve (sensory, motor and autonomic axons), digital nerve (distant extrema of the sciatic nerve) and tibial nerve (response of muscles of the rat hind paw following stimulation). Compared to the vehicle control group, after administration of 50 mg/kg/day for 13 and 26 weeks, the caudal NCV was reduced by 16% and 15%, respectively. At 26 weeks, a 7% reduction in digital NCV was noted. These changes were reversed by the end of the recovery phase. No deficit in the tibial motor nerve and no deficit in the response amplitudes occurred at 13 or 26 weeks and no deficits were observed in any cohort in the 5 and 15 mg/kg/day groups. There was no FOB or peripheral neuropathological findings related to MMB at either the terminal or recovery intervals. There were no microscopic correlates for the reported in-life electrophysiology findings. A follow-up in vitro study revealed no effect on ion channels associated with peripheral nerve conduction such as the hKv1.2, hNav1.5, heredity channels, the hKv1.1 and 1.2 potassium channels, and the hKv1.1 and 1.2 potassium channels. A 5% increase in the frequency of peripheral neuropathy, mostly grade 1 and 2 in severity, was observed in a 24-week Phase 3 clinical study.

The human cerebral cortex is organized in a complex 3-dimensional (3D) structure comprising different neural cell types. The coordinated work of these different cell types is key for brain function and homeostasis. Recently, much work has been focused on obtaining 3D brain organoids in an attempt to better recapitulate the brain development/function in vitro. However, current protocols may lead to variable organoid size and function, making the use of these powerful tools impractical in an investigative toxicology setting. Here we describe the development of a highly homogenous human induced pluripotent Stem cell (hiPSC)-derived cortical spheroid screening platform in 384 well format, composed of cortical neurons and astrocytes. Immunofluorescence analysis indicated that these derived neurons and astrocytes display key markers of cellular identity as well as maturity, such as synaptic proteins and glutamate transporters. Viability assays carried out with compounds with known mechanism of action indicated scalability and feasibility of the assays, with results comparable to a standard 2D model employing the same culture composition. Kinetic, high throughput calcium flux analysis performed in a in a Fluorescent Imaging Plate Reader (FLPR) highlighted that the spheroids present quantifiable, robust and uniform spontaneous calcium oscillations, measured. The calcium signal was modified with excitatory and inhibitory modulators coherently and in a highly reproducible fashion, confirming the presence of a functionally integrated glutamatergic/GABAergic circuit. High speed confocal imaging confirmed homogenous calcium oscillations at the cellular level, whereas multielectrode array (MEA) analysis demonstrated robust synchronous neurophysiological activity at the network level. Additionally, these cortical spheroids are amenable to immunostaining in suspension, enabling scalable high content image-based assays focused on key protein markers. Altogether, the developed 3D cortical spheroid platform can be easily implemented as a reliable high throughput screening platform to investigate complex cortical phenotypes in vitro, as a reliable high-throughput screening platform for toxicity studies, disease modeling and drug testing.

The key initiating event for many toxicological pathways is often the binding of an electrophile to an endogenous nucleophile, such as DNA, protein, or lipids. Protection against these electrophiles is critical, especially in nervous tissues which have limited capacity for cellular regeneration. Glutathione S-transferases (GSTs) metabolize electrophiles, but their precise role in protection against electrophile-mediated tissue damage is poorly understood. This has hindered the ability to ascertain increased health risks in humans with GST genetic variants, particularly the common GSTM1 and GSTT1 null alleles. To address the limited knowledge concerning the role of GST families and individual GSTs in detoxification of environmental pollutants, we generated mouse lines lacking 14 GST genes, including members of the GSTP, GSTM, and GSTT gene families. Here we identify the essential role of GSTs in protection against both DNA and cellular damage mediated by the electrophilic neurotoxicant acrylamide, an industrial pollutant which is also found at high levels in starchy foods. Consistent with human studies, subchronic exposure of mice to acrylamide in drinking water resulted in loss of motor function, as measured by the rotarod test. However, the severity of motor impairment was dramatically increased in the GST deficient mice. Interestingly, acute acrylamide exposure resulted in strain-specific, GST-sensitive, damage to the gastrointestinal epithelium and gastroparesis, a sequela of acrylamide exposure not previously documented in humans or rodents. Together, our studies demonstrate that GSTs play a critical role in protection against tissue damage mediated by environmental electrophiles such as acrylamide. GST deficient mouse lines provide a means for investigating the increased risk of these pollutants to humans carrying GST variants, as well as methods for risk mitigation in these GST-compromised individuals.

Perfluorooctanoic acid (PFOA) and perfluorooctanoic acid (PFOA) are members of perfluorinated compounds used in a variety of products, such as stain and oil resistant coatings, aviation hydraulic fluids, fire-fighting foams, paints, adhesives, waxes, polishes, and other products. Several studies have shown detectable levels of PFOAs and PFOA in the environment. In particular, drinking water samples have been contaminated with these agents which may cause potential long-term effects for humans and animals. Researchers have determined that PFOAs and PFOAs causes toxicity to humans and animals including hepatotoxicity, nephrotoxicity, neurotoxicity, disruption to the endocrine system, and other harmful effects. A number of studies showed that PFOAs and PFOAs have been associated with induction of oxidative stress. The purpose of this study was to determine the role of Nrf2 in protection against the neurotoxicity of these agents. Nrf2 is a transcription factor that is activated in response to oxidative stress. Upon activation, Nrf2 upregulates the gene expression of several antioxidant enzymes, such as superoxide dismutase, glutathione peroxidase and reductase, catalase, and other antioxidant molecules. For the present study, Nrf2 knockout and wild-type C57BL/6 mouse astrocytes were used as in vitro models. Knockout and wild-type astrocytes were exposed to concentrations of PFOA ranging from 75-600 μM and 400-1000 μM for PFOA for 24 hours. Lactate dehydrogenase (LDH) assay was conducted to assess cell cytotoxicity. LDH release was significantly higher in Nrf2 knockout than in the wild type astrocytes for exposure to 150-600 μM concentrations of PFOA and 800-1000 μM concentrations of PFOA. Phase contrast light microscopy was used to investigate the morphological changes of exposed astrocytes. Marked toxicity was observed, such as cell debris, rounded cells, vacuolization, cell blebbing and decreases in cell number consistent with the cell viability data. We conclude that PFOAs and PFOAs are cytotoxic to astrocytes and that Nrf2 knockout cells are more sensitive to toxicity by these agents, an effect that is potentially limited to the ability to detoxify the antioxidant capability of these cells.

Bisphenol A (BPA) is one of the highest volume produced and used chemicals worldwide. Early-life exposure to BPA has been shown to alter sex-specific neural organization, neuroendocrine physiology, and behavior in laboratory animals, and impacts neural development in human. Oxidative stress is induced by an imbalanced redox state, involving either excessive generation of reactive oxygen species (ROS) or dysfunction of antioxidant system. The brain is one of organs especially vulnerable to the effects of ROS because of its high oxygen demand. Neurodegeneration has increasingly been linked with mitochondrial dysfunction and inhibition of the electron transport chain. This inhibition leads to the generation of ROS and depletion of cellular energy levels, which can consequently cause cellular damage and death mediated by oxidative stress. Mitochondrial membrane potential is an important parameter of mitochondrial function used an indicator of cell health. The aim of this study was to examine the neurotoxic effects of BPA in human neuroblastoma SH-SY5Y cells. Human neuroblastoma SH-SY5Y cells were exposed to BPA at a concentration range of 0.001 to 1000 µM for up to 24 h. Cell proliferation and viability, ROS production, mitochondrial membrane potential and intracellular glutathione (GSH) content were evaluated. Our results indicated that exposure to BPA significantly decreased cell viability in a concentration-dependent manner in SH-SY5Y cells. At low concentrations (0.001–10µM) of BPA, mitochondria were significantly increased at 3h and 6h in SH-SY5Y cells. BPA induced a significant decrease of mitochondrial membrane potential after 3 h similar to CCCP, the mitochondrial uncoupler positive control. On the other hand, a significant reduction in intracellular levels of GSH was observed at 1h and 3 h with treatment of BPA. These data suggest that alteration in cellular GSH, loss of mitochondrial membrane potential and the elevated ROS production play a contributing role to the toxic effects of BPA and that BPA adversely results in neurodegeneration. The data further indicate that the availability of GSH to the cells may be insufficient to provide protection against BPA toxicity. Thus, BPA could be a risk factor for neurodegenerative diseases. Supported by Title III.

Synthetic cannabinoid abuse has become an international public health problem including acute intoxication and memory impairments. A recent report identified several synthetic additives in samples of “Spice/K2”, including JWH-018 (1-pentyl-3-(1-naphthoyl)indole), a synthetic ligand for the cannabinoid receptor 1 (CB1). There is only limited research on the neurotoxicity and memory impairment induced by JWH-018: The Mechanism and the Effect on Learning and Memory

Premutation carriers with CGG trinucleotide expansion in the 5’-untranslated region of FMR1 (PreCGG) have early onset neurologically deficits and high risk of developing neurodegenerative FXTAS later in life. Carriers of expressed mutations within FRY1 are susceptible to the pharmacogenetic disorder malignant hypertension (MHS) and are intolerant to heat stress. Knock in mice expressing PreCGG (170 repeats), MHS mutation T4826-RyR1, singly or in combination (double mutation; DM) were compared to congenic wild type (WT) for serum corticosterone (CTS) responses to water aversive stress (WAS), a model of psychological stress. Neuronal-astrocytic hippocampal co-cultures obtained from these genetic lines were trained in a novel place recognition memory task with numerous endogenous and xenobiotic ligands playing a key role in a number of cellular processes especially immune cell function and development. Differential effects of AHR ligands upon CD4 naïve Tcell development has been described with 2,3,7,8-tetrachlorodibenzop-dioxin (TCDD) inducing regulatory Tcells while FICZ promotes Th17 responses. Previously our lab has demonstrated prolongation of graft survival in a fully mismatched skin allograft model (Balb/c donor to C57BL/6 recipient) with intraperitoneal administration of TCDD and early rejection with FICZ treatment. In the present work we demonstrate prolonged graft survival in a minor mismatch allograft model (C57BL/6 Male to Female) with dietary supplementation with the AHR ligand, Indole-3-Carbinol (13C). 7wk old C57BL/6 female mice were maintained on semi-purified base (SPB) diet deficient of AHR-ligands or SPB diet with 13C supplementation (3ppm) for 3wks prior to transplant and for the duration of the model. AHR-mediated graft survival was correlated to decreases in IFNy producing Graft infiltrating Leukocytes. Animals maintained on SPB diet demonstrated a loss of intestinal Treg, Innate Lymphoid Cells type 3, and γδ Tcells. However, 13C supplementation led to maintenance of these mucosal immune cell populations as measured by Flow cytometry. Conversely, maintenance of animals on the AHR-deficient SPB diet led to accelerated graft rejection (Median GST of 46 vs 15.9days p<0.05). These findings were AHR-dependent as AHR null animals were found to not only reject grafts earlier than WT counterparts but were not responsive to 13C supplementation (Median GST, AHR null on AHR-deficient diet vs 13C diet were 17 vs 15.5 days respectively). These data demonstrate a novel regulatory pathway for prolongation of graft survival via dietary supplementation of naturally occurring AHR ligands. Splenocytes isolated from animals maintained on either SPB or 13C diets were collected and cultured in vitro with exposure to HY peptide. ELISA performed on the supernatants demonstrated...
a decrease in IFNg and TNFa production in those animals maintained on I3C vs SPB diet. While the underlying mechanism remains unclear, these data suggest a role for activation of the mucosal immune system via AHR stimulation and dietary AHR ligands play a novel regulatory role in modulating systemic immune responses.

3055 Modulation of the Aryl Hydrocarbon Receptor via Oxictoxine

The human population is consistently exposed to ultraviolet radiation (UVR), which has both beneficial and detrimental effects. High levels of exposure is a major contributor to the risk of developing skin cancer, yet some exposure is needed for vitamin D synthesis. In an attempt to combat the negative consequences, sunscreen use is highly encouraged, especially to vulnerable populations such as children and those living in high latitude (e.g. Scandinavia and Australia) areas with more intense exposure. While sunscreens have been shown to be effective at reducing the risk of skin cancer, there is an increasing body of literature suggesting that some UVR filters may have hormone disrupting properties, which makes further toxicological studies on these chemicals essential. We hypothesized, based on structural composition, that UVR filters may be agonists for the Aryl hydrocarbon receptor (AHR). They possessed AhR responsive reporter constructs that play a significant role in the metabolism of various exogenous and endogenous compounds, as well as regulating the immune system. When ligand binds to the Ahr, the complex acts as a transcription factor for various genes, including members of the cytochrome P450 family such as CYP1A1. Interestingly, the AhR agonist octinoxate (FICZ) is thought to be produced in the skin after UVR exposure. To determine if sunscreen ingredients can activate the AHR, we utilized the H111.1c2 luciferase hepatoma reporter cell line to screen a variety of chemicals commonly found in sunscreens. Our results indicated that none of the ingredients tested were able to activate the AHR themselves. However, when tested in conjunction with FICZ, the chemical octinoxate was shown to potentiate FICZ ability to activate the AHR.

The experiment was repeated using 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), another well-known AHR ligand. Interestingly, our results not only showed that octinoxate was unable to potentiate TCDD’s ability to activate the AHR, but they also indicated that this co-treatment completely eliminated the ability of TCDD to activate the AHR. We hypothesize that octinoxate may be directly interacting with either the ligands themselves or with cytochrome P450 enzymes that are transcribed and translated after AHR activation occurs. While there is more research to be done, these results suggest that octinoxate may be able to influence AHR activity, which may have various downstream effects for both the skin and the immune system.

3056 Time-Dependent Skin Reactions against Urban Pollution: Role of AHR Signaling Pathway in Detoxification Process
P. Quantin1, S. Catoire1, A. Thelu1, A. Patatian2, and H. Ficheux3.
1THOR Personal Care, Compiègne, France; and 2Genex, Longjumeau, France.

Environmental pollution is an increasing concern for toxicologists as the exposed urban population grows throughout the world. This study focuses on AHR (Aryl hydrocarbon receptor) signaling pathway in human keratinocytes in order to understand the reaction of skin exposed to pollution stress by urban dust. In this complex mixture 3-Methylcholanthrene (3-MC) is one pollutant component under investigation. In parallel, β-Naphthoflavone (β-NF) serves as a well-known and potent activator of AHR and has been used by us in previous work. Keratinocytes cultivated in 2D are exposed to 3-MC and to β-NF for 6; 24; 48 hours in order to visualize early and late time gene expression. To investigate how IL-6Rα function in epidermal keratinocytes in the context of ICD is unknown. This laboratory has previously reported that IL-6 deficiency exacerbates skin inflammation in a murine model of ICD, yet the role of the IL-6Rα in epidermal keratinocytes in the context of ICD is unknown. To investigate how IL-6Rα function in epidermal keratinocytes influences the inflammatory response during ICD, a chemical model of ICD was employed. In this model, keratinocyte-specific IL-6 receptor alpha knock-out (I6RA−/−) and littermate control mice were exposed to two well-known occupational irritants JP-8 jet fuel, Benzalkonium chloride (BKC) as well as acetone (control) for periods of one (1) or three (3) days.

Irritant Contact Dermatitis (ICD) is an inflammatory response of the skin to harmful stimuli. ICD is the most common occupational skin disorder with significant impact on the quality of life of affected individuals. Following exposure to irritants, keratinocytes, the predominant cells in the epidermis of the skin, initiate the inflammatory cascade by producing a myriad of cytokines that includes IL-6. This laboratory has previously reported that IL-6 deficiency exacerbates skin inflammation in a murine model of ICD, yet the role of the IL-6Rα in epidermal keratinocytes in the context of ICD is unknown. To investigate how IL-6Rα function in epidermal keratinocytes influences the inflammatory response during ICD, a chemical model of ICD was employed. In this model, keratinocyte-specific IL-6 receptor alpha knock-out (I6RA−/−) and littermate control mice were exposed to two well-known occupational irritants JP-8 jet fuel, Benzalkonium chloride (BKC) as well as acetone (control) for periods of one (1) or three (3) days. Dermatitis lesions were collected from each mouse genotype and inflammatory cytokine protein expression profile was examined by multiplex assays (Affymetrix). In addition, immune cell infiltration into lesional skin was characterized by immunohistochemistry (IHC) and flow cytometry. Histopathology revealed that I6RA−/− mice show an exaggerated response to Benzalkonium chloride (BKC) and JP-8 fuel relative to control. This response was characterized by increased immune cell infiltration into the dermis. Lesional skin from I6RA−/− mice treated with more CD11b and F4/80 expressing cells relative to control. Protein expression data showed a significantly increased expression of pro-inflammatory cytokines such as IL-1α, IL-1β, TNF-α, IL-22, and IFN-γ in
lesional skin from IL6Ra−/− mice relative to control. The expression of anti-inflammatory cytokines including IL-10 and IL-4 were, however, significantly reduced in lesional skin from IL6Ra−/− mice relative to control. These results indicate that IL-6Ra function in epidermal keratinocytes confers a protective effect during ICD and suggests that the previously reported protective effect of IL-6 during ICD might be mediated by the IL-6 receptor alpha. Overall, the IL-6/IL-6R system plays a role in modulating inflammation during ICD and could be explored in the therapy of ICD.

3059 Aberrant Lipid Metabolism Underlies Pathogenesis of Arsenicals-Induced Cutaneous Blistering and Inflammation
C. Li, M. Kashyap, R. Srivastava, Z. Weng, and M. Athar. University of Alabama at Birmingham, Birmingham, AL.

Arsenical vesicants are highly reactive and extremely toxic warfare agents developed in World War I. Despite efforts to destroy these chemicals, their large stockpiles still exist in several countries. Arsenicals manifest debilitating cutaneous and systemic injury. The molecular pathogenesis of these lesions is not clear, and therefore, no effective mechanism-based antidote has been described. This study explores the metabolic landscape following topical treatment of mouse skin with four warfare-related arsenicals lesiwite, diphenylchloroarsine, diphenylcyanoarsine, and diethylchloroarsine. Global metabolite profiling of skin tissue excised from these animals revealed profound effects on multiple metabolic components that showed significant similarity among all of these chemicals. The inhibition of succinate dehydrogenase and α-ketoglutarate dehydrogenase in the TCA cycle by lesiwite was highly significant. Arsenicals induced significant reductions in reduced glutathione resulted in the augmented oxidative stress and a decline in the antioxidant capacity of skin tissue. Similarly, lipid metabolism was affected by all four arsenicals. Increases in PUFAs coupled with increases in cyclooxygenase & lipoxygenase activities were associated with arsenicals-mediated inflammatory responses. In this regard, we observed a significantly high accumulation of lipoxygenase metabolites 6-hydroxy hexanoic acid and LTB4 (21 and 16 folds respectively). Using phenylsine oxide (PAO) as a surrogate arsenical, we demonstrated the role of lipoxygenase in the pathogenesis of these chemicals. Lipoxygenase inhibitor nordihydroguaiaretic acid (NDGA) blocked arsenical-mediated cutaneous injury. Our data showed that NDGA when applied 5 min after cutaneous PAO exposure reduced significantly inflammatory & tissue disrupting responses in the skin. NDGA reduced mRNA levels of proinflammatory Il1b, Il6, Ccxl1, and Ccxl5. Reduction in Il1b associated inflammasome formation was also observed. Mechanistically, we found a novel link between lipoxygenase metabolism, unfolded protein response signaling and inflammatory & tissue disrupting responses. Taken together, we have identified potential novel mechanism by which arsenicals induced painful cutaneous inflammation and blistering and NDGA may serve as a potent antidote against arsenicals-induced tissue injury.

3060 Nrf2 Dependent Skin Photoprotection Using the Achiote-Derived Apocarotenoid Bixin

Unprotected exposure to solar ultraviolet (UV) radiation causes acute photodamage (sunburn), premature aging, and skin cancer. Molecularily, UV causes direct DNA damage and generation of reactive oxygen species (ROS). While physical and chemical UV shields greatly reduce skin damage, interventions activating endogenous stress responses are emerging as promising skin protective strategies. The transcription factor Nrf2 is the master regulator of the antioxidant cell response and has been shown to protect the skin against various environmental stressors, including UV. Nrf2 can be activated using natural chemopreventive compounds, such as the apocarotenoid bixin, an FDA-approved natural food colorant from the seeds of the achiote tree (Bixa orellana). We tested the feasibility of using a topical bixin formulation to activate cutaneous Nrf2 and protect the skin from acute UV exposure. SKH-I WT and Nrf2−/− hairless mice were pretreated with bixin and then exposed to UV; skin tissue was collected 24 h later. Bixin was able to activate Nrf2 and protect the skin from acute photodamage (reduced epidermal hyperplasia/prevent inflammatory infiltration and apoptosis) in WT but not Nrf2−/− SKH-I mice. Furthermore, we tested the feasibility of using bixin to activate Nrf2 and prevent UV-induced hair graying. C57BL/6 WT mice were depleted, treated with topical bixin, and then exposed to UVA in the presence of a photosensitizer (psoralene). Bixin was able to activate NRF2 in the skin of C57BL/6 WT mice and prevent hair graying after psoralene+UVA (PUVA) treatment. Collectively, these results indicate that bixin is a safe and potent NRF2 activator that protects various cell types of the skin to prevent UV-induced damage.

3061 An Assessment of the Intra-Lab Variability of the In Vitro Percutaneous Absorption of Testosterone through Human Skin
D. Lean1, C. S. Roper2, S. Craig1, and F. S. Toner1. 1Charles River Laboratories, Horsham, PA; and 2Charles River Laboratories, Edinburgh, United Kingdom.

OECD Guidance Document No. 28 requires laboratories performing in vitro skin absorption studies, according to OECD Test Guideline 428, to demonstrate proficiency using Testosterone. This laboratory performed 2 studies with the same study design on different days, but with minor methodological changes, to assess if they resulted in changes to the outcome of the results. Study 1 examined two decontamination scenarios (Groups 1 and 2) and Study 2 repeated Group 1 with different donors but from the same source (Group 3) and different donors from a new source (Group 4). [14C]-Testosterone (1 mg/mL) in ethanol: water (40%, v/v) was applied at 10 μL/cm² to human dermatomed skin (n=8 or 10) in flow through diffusion cells in vitro with a receptor fluid flow rate and skin surface temperature of 1.5 mL/h and 32°C. Absorption was assessed hourly from 0-8 h and 2-hourly from 8-24 h. Exposure was terminated by washing at 8 h. Groups 1, 3, and 4 were washed with soapy water using natural sponge swabs. Group 2 was washed with soap concentrate and tissue paper swabs. All samples were analysed by LSC. T-Tests were performed comparing all 4 test groups with each other for differences in affinity and skin permeability (equiv./cm²) which confirmed the expected donor differences (i.e. inter-donor variability). The main differences observed were in comparing the different donors from the different suppliers. Group 3 dislodgeable dose at 8 h was significantly higher than Group 4 (9.37 and 8.85 equiv./cm²) with a correspondingly significantly lower absorbed dose (0.29 and 0.49 μg equiv./cm²). This could be important for transdermal drug delivery assessments. However, since there were no significant differences in dermal delivery for any comparison; this is most frequently used for risk assessments, the consistency of the test was confirmed. The Testosterone mass balance was complete (within 100±10%) for all test groups. In conclusion, this study confirmed that small changes in conditions did not affect the absorption and distribution of Testosterone and demonstrated that the study test is consistent when run on different occasions with only small differences attributable to the inter-donor variability.

3062 Dermal Uptake of Three Brominated Phenois: Tetrabromobisphenol A (TBBPA), Tetrabromobisphenol A bis (2,3-dibromopropyl ether) (TBBPA-BDBPE), and 2,4,6-Tribromophenol (TBP)
A. C. Richards1, G. A. Knudsen2, M. F. Hughes3, and L. S. Birnbaum1. 1NIEHS, Research Triangle Park, NC; and 2US EPA, Durham, NC.

Three brominated phenois, TBBPA, TBBPA-BDBPE, and TBP, were assayed to determine dermal absorption and penetration. All these chemicals are high production volume brominated flame retardants (BFR) used in consumer products, resulting in ubiquitous human exposure. TBBPA, a reactive flame retardant commonly used in printed circuit boards and other polycarbonate resins, was shown to cause uterine epithelial tumors in a NTP 2-year cancer bioassay. Little (μg-equiv/cm²) in vivo data are available for TBBPA’s replacement alternative TBBPA-BDBPE, but its additive usage poses a higher risk of migration into environmental matrices. TBB is used as a wood fungicide and reactive flame retardant and has been shown to disrupt thyroid signaling. Although the major route of exposure to these chemicals is oral uptake, dermal contact is likely via contaminated dust. In the studies presented here, independent trials of a single dose of 100 nmol/cm² skin (~1 μCi [14C]/cm²) of each BFR were applied to whole rat skin (in vivo) or split-thickness human and rat skin (in vitro) to calculate in vivo human percutaneous uptake. Following application, absorption (detected in dosed skin) and penetration (recovered in receptor fluid (in vitro) or tissues/excreta (in vivo)) were assessed over 24h. In vivo penetration and absorption in rat skin was 67% and 5% for TBB, 8% and 15% for TBBPA, 1% and 26% for TBBPA-BDBPE. In human skin, in vitro penetration and absorp-
Partition and Diffusion Coefficient Determinations in Isolated Human Skin Layers for In Silico Skin Penetration Modeling

C. Obringer1, K. Tankersley1, N. Hewitt2, A. Schepek3, D. Lange, M. Klarici, J. Eilstein4, S. Gregoire, H. Duplan, C. Jacques-Jamin5, R. Cubberley6, S. Salti7, H. Rothe, A. Roe, and C. Ellison.1 Procter & Gamble, Mason, OH; 1Cosmetics Europe, Brussels, Belgium; 2Beiersdorf AG, Hamburg, Germany; 3L’Oréal, Aulnay-Sous-Bois, France; 4Pierre Fabre Dermo-Cosmetique, Toulouse, France; 5Unilever, Shabroom, United Kingdom; 6GlaxoSmithKline, Nyon, Switzerland; and 7Coty, Darmstadt, Germany.

The development of a predictive in silico skin penetration model is needed to enable moving away from a 100% systemic bioavailability assumption to a more realistic one assessing the actual fraction of systemically absorbed compound. As part of a Cosmetics Europe initiative, we are replacing empirical relationships (with limited applicability domains) by mechanistically based simulations to characterize trans-dermal transport. Partition (K) and diffusion (D) coefficient determinations on isolated human skin layers are being conducted for 50 compounds relevant to cosmetics ingredients. K values were measured in isolated dermis, whole epidermis, intact SC, delipidized SC and SC lipids by direct measurements of the radioactivity in the two layers/lipid component vs. buffer samples. D determinations were made in dermis, whole epidermis and intact SC using a non-linear regression of the cumulative receptor fluid content of radiolabelled compound, fit to the solution of Fick’s 2nd Law. More than 35 compounds have been tested, with molecular weights ranging from ~100 - 400 and log P values ranging from ~0 to 5. For a given chemical, K was generally similar for the dermis, whole epidermis and fully hydrated (FH) SC and FH delipidized SC. The partially hydrated (PH) SC and PH delipidized SC were approximately 3-fold greater. The lipid values were similar to the partially hydrated values, exceptions for compounds with a log P greater than 2. K values of the chemicals tested ranged approximately 3 orders of magnitude for a given tissue layer and approximately 4 orders of magnitude for the SC lipids. For a given chemical, D was consistently similar for SC and whole epidermis, and these layers were always lower than that of the SC lipids tested ranged approximated by the 3 orders of magnitude for a given layer. Correlations between K and D and several physiochemical properties indicate a simple correlation is not sufficient to describe the relationship. The study findings have been applied to the development and validation of an in silico model.

3066 A Highly Sensitive and Selective Liquid Chromatography with Tandem Mass Spectrometry (LC/MS-MS) Method for the Direct Peptide Reactivity Assay (DPRa) 2018 SOT Annual Meeting

T. Erskine, F. Zhang, R. Settivari, J. Klappacz, and S. Marty. The Dow Chemical Company, Midland, MI.

The DPRa addresses the molecular initiating event of skin sensitization by quantifying the reactivity of potential sensitizers with synthetic peptides containing lysine or cysteine (Ac-RFAAAACOOH and Ac-RFAAKAA-COOH). The percent peptide depletion, as quantified using liquid chromatography ultra-violet spectrometry (LC/UV), is used to discriminate between dermal sensitizers and non-sensitizers. This method has been validated internationally and a test guideline (OECD TG 442c) has been recently published. While this method provides promising predictions to identify dermal sensitizers, the low sensitivity and selectivity of the LC/UV method poses challenges to accurately identify the sensitization potential of some chemicals. For example, chemicals with the same retention time may be cysteine- or lysine-containing peptides and can be misclassified in this assay. Similarly, test materials that non-covalently bind with either peptide result in a shift of the retention time and false positive results. To overcome these shortcomings, we developed a LC/MS-MS-based DPRa. After optimization of the multiple reaction monitoring ion pairs (precursor and product ion pairs) of both peptides in the AB Sciex 5000 Qtrap MS-MS system connected with Agilent 1290 Infinity II LC system, a set of known dermal sensitizers and non-sensitizers were evaluated in the LC/UV and LC/MS-MS-based methods following OECD TG 442c. The results showed similar linear calibration standard curves with R² > 0.99 and similar peptide depletion for both peptides with the selected test proficiency chemicals. After this initial validation, both LC/MS-MS and LC/UV methods were implemented for screening non-reactive chemicals which may form non-covalent interactions with peptides (such as surfactants). This method can be used to test chemicals as non-sensitizers, however, the LC/UV-based DPRa showed higher depletion of both peptides, resulting in false-positive results. These findings suggest broader applicability and better specificity of the LC/MS-MS-based DPRa method.
Skin sensitization can result from exposure to natural and synthetic chemicals. Once sensitized to a chemical, chronic dermal reactions may be elicited by very small exposures. Chemicals in apparel may leach and cause dermal reactions in sensitive individuals. Here, we summarize our assessment of skin sensitization risk for 1,796 chemicals leached from apparel products into simulated sweat. Chemicals were classified as skin sensitizers or non-sensitizers by a weight-of-evidence approach using experimental data, case reports, and in silico predictions of sensitization hazard. For each chemical, published in vivo and in vitro assessments were weighed for experimental data. In the absence of experimental data for the chemical of concern (CoC), surrogate chemicals were identified and reviewed for experimental data. In the absence of experimental data for either the CoC or surrogates, classification was based on in silico analysis using Toxtree and/or Derek Nexus. A threshold for sensitization (or point-of-departure [POD]) was calculated for sensitizers and categorized as strong (POD ≤ 2.5 µg/cm²), moderate (POD 2.5-250 µg/cm²), or weak (POD > 250 µg/cm²). All assessments were assigned a confidence rating based on data availability and quality. A minority (28.5%) of chemicals evaluated were classified as skin sensitizers while 71.5% were classified as non-sensitizers. Of skin sensitizers, the majority (58.2%) were classified as ‘weak’ sensitizers, 35.9% as ‘moderate’ sensitizers, and 5.9% as ‘strong’ sensitizers. Good quality experimental data were identified for 27.8% of chemicals, resulting in a confidence rating of ‘good.’ Nearly half (48.7%) of assessments were either based on surrogate data or poor-quality data for the CoC, resulting in a confidence rating of ‘limited.’ Assessments based on in silico analysis alone accounted for 23.5% of chemicals and a confidence rating of ‘weak;’ for these, when in silico assessments were positive, a maximum default POD of 250 µg/cm² was assigned. The mean POD for good confidence sensitizers was 1,972 µg/cm² (median 750 µg/cm², range 0.4-20,375 µg/cm²). Overall, the identifying of skin sensitizers or non-sensitizers by a weight-of-evidence approach using experimental data, case reports, and in silico predictions of sensitization hazard was confirmed by testing 28 blinded substances in all three test laboratories. This manifests GARDskin as a valid test for assessment of skin sensitizers.
The first two authors contributed equally to this research.

Activation of THP-1 cells. These data demonstrate that the environment keratinocytes impacted on the threshold concentration needed for the donor. This was especially evident for CD54. Specifically, proliferating THP-1 responses to the sensitizers were enhanced in coculture with pro-inflammatory cytokines, chemokines, and other mediators. Much is now evident that keratinocytes play an active and dynamic role in initiation and balancing of innate and adaptive immune responses. Specifically, they may promote conditions resulting in tolerogenic dendritic cells (DCs) via their constitutive production of IL-10 and TGF-β or facilitate activation of DCs through their production and secretion of pro-inflammatory cytokines, chemokines, and other mediators. Much less is known about how the status of keratinocytes impact on strength and direction of ensuing DC activation. Here we studied their properties to activate DCs by evaluating proliferating and differentiated keratinocytes on dendritic cell activation by contact allergens.

Epithelial cells such as keratinocytes in the skin are known to essentially contribute to maintain the balance between tolerance and adaptive immune responses due to external exposures including sensitizing chemicals. While once believed to function primarily as a passive barrier, it is now evident that keratinocytes play an active and dynamic role in in vitro analysis of tap water containing NaCl. In cytotoxicity assay, plated cells (10^5 cells/ mL) were treated with different concentrations of EAWs (1.25, 2.5, 5, 10 % EAW) for 24 hours. The viability was measured with MTT reagent (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium). For the in vitro assessment of wound healing, the cells (5.5x10^5 cells/well) were seeded in 24 well plates and after 24 hr, a scar was formed by 0.5 mm tipped scratcher and EAWs (1.25, 2.5, 5 and 10%) were added and incubated at 37°C in 5% CO2. The time 0, 18 and 24 hr were photographed and the wound healing activity is determined by ImageJ software. According to the results, the maximum experimental dose of A-EAW, N-EAW and M-EAW showed no cytopathic effect on cell viability. Therefore, the differences that were not cytopathic to the cell for 24 hours exposure were used for the scratch assay. In vitro wound healing activity by scratch assay showed that A-EAW at 10 times dilution significantly accelerated fibroblast migration and cell proliferation compared to medium control, while N-EAW and M-EAW did not show any significant activity. As a conclusion, we suggest that A-EAW can be used a potential wound healing agent possible because of the moderate generation of reactive oxygen species in anode chamber of acidic is shown to be beneficial in wound healing especially in the inflammatory phase. Since wound healing is a complex process, further studies are needed to elucidate the mechanisms responsible for its healing activity.

Electroactivated water (EAW) is a novel technology based on electrolysis of water containing NaCl or KCl in a divided electrolysis module with a diaphragm between anode and cathode electrodes. EAW has gathered greater interest as a safe disinfectant in several areas like food, medicine and dentistry. Recently, the possible wound healing activities of EAW are also highlighted. In the present study, we generated three different EAWs, acidic (A-EAW), neutral (N-EAW) and mixed (M-EAW) and evaluated the cytokotoxic activity on L929 cell line as well as the wound healing activity by scratch assay in vitro. A-EAW (pH 2.45±0.48; ORP 1126.27±24.66 mV), N-EAW (pH 5.55±0.13; ORP 806.67±11.55 mV) and M-EAW (pH 5.54±0.03; ORP 887.67±15.95) was produced by the electrolysis of tap water containing NaCl. In cytotoxicity assay, plated cells (10^5 cells/ mL) were treated with different concentrations of EAWs (1.25, 2.5, 5, 10 % EAW) for 24 hours. The viability was measured with MTT reagent (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium). For the in vitro assessment of wound healing, the cells (5.5x10^5 cells/well) were seeded in 24 well plates and after 24 hr, a scar was formed by 0.5 mm tipped scratcher and EAWs (1.25, 2.5, 5 and 10%) were added and incubated at 37°C in 5% CO2. The time 0, 18 and 24 hr were photographed and the wound healing activity is determined by ImageJ software. According to the results, the maximum experimental dose of A-EAW, N-EAW and M-EAW showed no cytopathic effect on cell viability. Therefore, the differences that were not cytopathic to the cell for 24 hours exposure were used for the scratch assay. In vitro wound healing activity by scratch assay showed that A-EAW at 10 times dilution significantly accelerated fibroblast migration and cell proliferation compared to medium control, while N-EAW and M-EAW did not show any significant activity. As a conclusion, we suggest that A-EAW can be used a potential wound healing agent possible because of the moderate generation of reactive oxygen species in anode chamber of acidic is shown to be beneficial in wound healing especially in the inflammatory phase. Since wound healing is a complex process, further studies are needed to elucidate the mechanisms responsible for its healing activity.

Electrochemical processes responsible for its healing activity.

Cytotoxicity assay, plated cells (10^5 cells/ mL) were treated with different concentrations of EAWs (1.25, 2.5, 5, 10 % EAW) for 24 hours. The viability was measured with MTT reagent (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium). For the in vitro assessment of wound healing, the cells (5.5x10^5 cells/well) were seeded in 24 well plates and after 24 hr, a scar was formed by 0.5 mm tipped scratcher and EAWs (1.25, 2.5, 5 and 10%) were added and incubated at 37°C in 5% CO2. The time 0, 18 and 24 hr were photographed and the wound healing activity is determined by ImageJ software. According to the results, the maximum experimental dose of A-EAW, N-EAW and M-EAW showed no cytopathic effect on cell viability. Therefore, the differences that were not cytopathic to the cell for 24 hours exposure were used for the scratch assay. In vitro wound healing activity by scratch assay showed that A-EAW at 10 times dilution significantly accelerated fibroblast migration and cell proliferation compared to medium control, while N-EAW and M-EAW did not show any significant activity. As a conclusion, we suggest that A-EAW can be used a potential wound healing agent possible because of the moderate generation of reactive oxygen species in anode chamber of acidic is shown to be beneficial in wound healing especially in the inflammatory phase. Since wound healing is a complex process, further studies are needed to elucidate the mechanisms responsible for its healing activity.

Comparison of prestudy parameters in alternatively sourced cynomolgus non-human primates.

Cynomolgus macaques are utilized in a wide variety of pre-clinical research models, and particularly in contemporary drug safety evaluations. These animals may be derived from stock originating in various regions of the world and are often identified according to the country of export. The country of export identification, however, may not meaningfully differentiate these animals in terms of background genetic and/or biological variability. The present study sought to compare historical control data between Cambodian and Chinese sourced Cynomolgus non-human primates (NHPs) in order to appreciate the nature of any observed variations in age and body weight, basic detailed clinical observational measures, ophthalmology, and a variety of clinical pathology biomarkers, as these may impact drug safety study conduct and/or data interpretation. Among target samples of 100/sex Cambodian sourced NHPs and age-matched samples of Chinese sourced NHPs, there was overall essential similarity across recorded parameters, with occasional statistically significant divergence on individual measures. The data indicate that, while occasional statistically significant differences on individual parameters may be discriminated, the variation described for regionally (Asian mainland, Indonesian, Mauritius) diverse Cynomolgus NHPs in such pre-study variables is much more pronounced.
The response of hematology, spermogram, testicular and epididymal histology of forty-eight (48) male albino rats (Wistar strain) to crude powder and ethanol extract of *Citrullus lanatus* seeds was investigated on the. The rats were randomly divided into three groups (A, B, and C) with sixteen rats per group (N=16). Rats in Group A were fasted over a prolonged time to induce fasting glucose, while rats in Groups B and C were fasted over a prolonged period. The rats were then dosed with distilled water while Groups B and C served as the control group and were administered distilled water while Groups A and B were given ground powder and ethanol extract of *Citrullus lanatus* seed respectively at 200 mg/kg for 28 days. Blood samples were collected a day after the commencement of treatment to determine the haemogram. Subsequently, four rats from each group were sacrificed weekly after fasting administration for a period of four weeks and samples were collected for sperm motility, sperm livability, sperm morphology and histology. There was a decrease in sperm motility of treatment groups compared to the control group for the four weeks post-treatment. It was observed that mean sperm motility subsequently increased towards the third and fourth week post-treatment in the treatment groups. There was also a decrease in the mean sperm morphological abnormalities of treatment groups B and C compared to the control group post-treatment. Histology of the testes of the treatment groups for the four weeks post-treatment showed the presence of spermatogenic seminiferous tubules with normal architecture with spermatogenic cells. The findings from this study revealed that *Citrullus lanatus* seeds administered at 200 mg/kg have no deleterious effect on hematology, the spermogram and sperm morphological abnormalities were significantly reduced. Hence, it may be considered safe for use in male animals meant for breeding.

Investigating the absorption, distribution, metabolism and excretion of NCES. In the absence of a gall bladder, they are highly suitable for researching the excretion and metabolism of novel xenobiotics in bile. Therefore, catheters are placed in the bile duct in order to collect fluid, and the duodenum is loosely packed with saline to prevent the catheters from extruding via a tail cuff and require the animal to be tethered and singly housed for the duration of both the recovery and experimental period, which is typically up to ten days in total. A modified tail cuff has been developed using a pin-port adapter that permits the animal’s own body weight to displace the catheter hub into the duodenum during the recovery period. This modification means that animals do not need to be tethered or singly housed during this time (4-5 days). The experimental phase of the study remained unchanged (i.e. animals are tethered and singly housed in glass metabolism cages in order to separately measure and record body weight, excreta output, and functional and morphological analysis, and to investigate the involvement of glucotoxicity on nerve dysfunction, blood glucose levels were strictly controlled by treatment of phlorizin (100 to 150 mg/kg/day) from 5 to 16 weeks (n=6). Sprague-Dawley (SD) rats were used as an age-matched control (n=6). Body weights and biochemical parameters were periodically measured. The sensory and motor nerve conduction velocity (SNCV and MNCV) of the sciatic nerve, blood pressure, pupil size, and electrocardiogram were measured. At 16 weeks, rats were sacrificed and small myelinated fibers, and vasculation and mitochondrial swelling in unmyelinated fiber were sampled for the histological studies, transmission electron microscopic (TEM) analysis and determination of nerve fiber density. SNCV and MNCV were delayed and intraepidermal nerve fiber density slightly decreased in the SDT fatty rats compared with the control SD rats. In the TEM evaluation, the mitochondrial abnormalities and thinning of myelin sheath in small myelinated fibers, and vasculation and mitochondrial swelling in unmyelinated fiber were found in the SDT fatty rats. Blood pressure increased and the coefficient of variance of R-R intervals tended to decrease in SDT fatty rats. The maximum pupil diameter responded to the mydriatic drugs in SDT fatty rats was smaller than that of SD rats. Aside from the thinning of myelin sheath, these functional and morphological changes in peripheral nerves were prevented by controlling blood glucose level with phlorizin treatment. There result indicate that glucotoxicity was involved in those nerve dysfunctions.

This study was conducted to see if there were any differences in organ weights among the Sprague Dawley rat sourced from Taiwan and Beijing. Control group data from ongoing toxicology studies (N=140/sex/age) were used to see if there were any differences between those two sources of animals. The mean terminal body weight and organ weights were calculated. Analysis of the data showed statistical significant difference in organ weights included lower terminal body weight, heart weight (male only), liver weight (male only), kidney weight, spleen weight, thymus weight, thyroid glands with parathyroid gland(s) weight, pituitary gland weight, prostate gland weight, epididymides weight, and ovaries weight were noted in Taiwan rats; higher brain weight and uterus (including cervix) weight were noted in Taiwan female rats; lower organ weight/body weight ratio was noted in kidney (female only), thymus, thyroid glands with parathyroid gland(s), pituitary gland, prostate, and ovaries in Taiwan rats; higher organ weight/ body weight ratio was noted in brain, liver (female only), testes, and uterus (including cervix) in Taiwan rats, when compared with Beijing rats. In addition, the organ weight/body weight ratio was analyzed. The differences of organ weight/body weight ratio reflected the changes seen in the absolute organ weight, with the exception that statistical lower heart/brain weight was noted in Taiwan female rats due to their higher brain weight, when compared to Beijing rats. These observed differences between the two sources of animals enforce the need to be consistent in the source of animals for a toxicology development program and also the need for maintaining separate back ground data bases.

3080 Platycodon Grandiflorum Derived Saponin Protect Agonist Eccentric Exercise-Induced Muscle Damage
Y. Kim1, S. Oh1, G. Lee1, S. Kim1, S. Jin1, Y. Chung2, Y. Lee3, H. Lee3, and H. Jeong1. 1Chungnam National University, Daejeon, Korea, Republic of; 2International University of Korea, Jinju, Korea, Republic of; 3Jangsaeng Doraji Co., Ltd., Jinju, Korea, Republic of; and 4Korea Research Institute of Bioscience and Biotechnology, Daejeon, Korea, Republic of.

Platycodon grandiflorum contain a triterpenoid saponin as platycodin D and platycodon acid A with a multifold bioactive compound. Our previous research demonstrated that the platycodon grandiflorum derived saponin (PS) ameliorate against high fat diet-induced non-alcoholic steatohepatitis and inhibition of osteoclast differentiation. The pivotal effects of PS on inflammatory mechanisms were suppressed in NF-κB and C-related protein. Taken together, our findings identify the PS extract protect from muscle damage. A significant reduction in eccentric exercise-induced muscle damage area and muscle damage related to the level of NF-κB p65 was suppressed via a p38, ERK and SMAD pathway, which provides a novel perspective on the biological function of PS against muscle damage.

3081 AChE-Independent Phosphoprotein Signaling in an Acute Mouse Model of Gulf War Illness
J. V. Miller1, K. A. Kelly1, L. T. Michalovich2, J. A. Mouch2, N. Prince1, L. W. Boyd2, P. J. O’Callaghan3, and D. B. Miller1. 1CDC/NIOSH, Morgantown, WV; and 2West Virginia University, Morgantown, WV.

Roughly 25-30% of veterans from the 1991 Persian Gulf War suffer from a persistent and amplified form of sickness behavior, classified as Gulf War Illness (GWI). Previous studies investigating GWI have suggested that exposure to organophosphates (OP) in theater, as well as the irreversible acetylcholinesterase (AChE) inhibitor and chemical warfare agent, sarin, as well as other pesticides, may have contributed to GWI symptomatology. Additionally, concomitant exposure to high physiological stress in theater has been implicated in the initiation of the GWI phenotype. Traditionally, inhibition of AChE and the subsequent accumulation of acetylcholine (ACh) result in the activation of the cholinergic anti-inflammatory pathway. However, we have shown that the link between GWI and neuroinflammation appears to contradict this effect of AChE inhibitors. Therefore, it is plausible that exposure to OPs both alone and in combination with corticosterone (CORT; used as a physiological stress mimic) may target biomolecules other than AChE to induce the neuroinflammatory effects observed in our validated mouse model of GWI. To further investigate this phenotype, adult male C57BL/6J mice were exposed to CORT in the drinking water for 4 or 7 days. On the 5th or 8th day, mice were exposed to a single dose of a sarin surrogate, disopropyl fluorophosphate (DFP; 4.0mg/kg, i.p.). To fully evaluate the brain-region specific effects of DFP and CORT+DFP on AChE, ACh concentrations were measured in cortex (CTX), hippocampus (HIP) and striatum (STR) using HLIL UPLC-MS/MS. Mice were euthanized using focused micro-wave irradiation to ensure rapid inactivation of AChE, as well as endog-

3082 Geriatric Toxicology: Understanding Human Relevance of Toxicities Observed at Late-Stage of Long-Term Studies
S. A. Saghir, and M. A. Dorato. Smithers Avanza, Gaithersburg, MD.

Toxicity testing in animals is traditionally conducted at fixed doses (i.e., mg/kg/day) without adjustments for the occurrence of dose- and/ or age-dependent non-proportionality. The time-dependent dose non-proportionality is associated with age-dependent changes in physical, physiological and biochemical parameters possibly requiring a change in dosing for geriatric patients. Similar changes occur in animals, leading to higher than anticipated systemic dose resulting in "late occurring" toxicities in chronic studies. Determining the time of departure from dose proportionality is important to either adjust the external dose to maintain the anticipated systemic dose or interpret such toxicities in the context of systemic dose non-proportionality for better human health risk assessment. Pethoxamid, an herbicide, is >90% absorbed from the GI tract of rats and predominantly (~75%) eliminated through bile. In the rat carcinogenicity study, pethoxamid increased thyroid follicular cell hyperplasia (TFCH) and adenoma in male rats at the top dose (1600 ppm), only at termination (105 weeks) without such induction at interim sacrifice (after 27, 53, or 79 weeks of exposure). An increase in TFCH was observed in 13-week study at ~1.6- and ~3-fold higher doses [Pethoxamid: Draft Assessment Report, 16 August 2002]. The effects observed at the end of the carcinogenicity study were likely from geriatric changes (e.g., metabolism, clearance) increasing the sys-

3083 Mouse Model of Intestinal Mucositis Induced by 5-Fluorouracil and Irinotecan
S. Goineau1, E. Gascoign1, L. Lecoullet1, L. Paulhac1, E. Hayes2, and V. Castange1. 1Porfiss SAS, Le Genet Saint Isle, France; and 2Fluoxfarma, Pessac, France. Sponsor: G. Froget

Chemotherapy-induced mucositis is a common severe side effect experienced by colorectal cancer patients during treatment. We aimed to investigate the gastrointestinal toxicity of 5-fluorouracil and irinotecan in Balb/C mice (n=8/group) were injected with saline, 5-fluorouracil (30 mg/kg, i.p.) for 5 consecutive days (males and females) or irinotecan (75 mg/kg, i.p.) for 4 consecutive days (males only). Body weight and diarrhea were assessed over the test period and inflammatory and histopathological responses were investigated 7 days after the final dose. 5-fluorouracil-induced mucositis was more severe compared to controls (5-fluorouracil: +2.3 and +2.4, p<0.001 for males and females respectively, and irinotecan: +0.9, p<0.001). 5-fluorouracil,
but not irinotecan, tended to increase the myeloperoxidase activity in both males and females. 5-fluorouracil and irinotecan increased ileum IL-1β levels (5-fluorouracil: +36%; 5-fluorouracil: +700% and +800%; p<0.001 for males and females respectively, and irinotecan: +93%; p<0.05) and plasma TNF-α levels (5-fluorouracil: +700% and +800%; p<0.001 for males and females respectively, and irinotecan: +825%; p<0.05) without modifying ileum TNF-α levels. Plasma IL-15 levels were below the limit of quantification in all groups. Both treatments affected the intestinal architecture and decreased the villus/crypt ratio (5-fluorouracil: -45% and -33%; p<0.001 for males and females respectively, and irinotecan: -23%; p<0.01). These findings suggest that 5-fluorouracil- and irinotecan-induced gastrointestinal toxicity in mice shows similarities with the clinical animals mucositis manifestations. Therefore, these mouse experimental mucositis models offer a promising tool for evaluating the side effects of novel chemotherapeutic agents or the efficacy of potential treatments against chemotherapy-induced mucositis.

**3084 Evaluation of Serial Sampling Procedures to Enable Clinical Pathology Evaluations in Mice**

Toxicology studies conducted in CD-1 mice that include clinical pathology assessments are often designed with separate cohorts for hematology and clinical chemistry evaluations in order to yield adequate blood volumes suitable to generating a complete panel of endpoints. Consistent with 3R's and evolving institutional best practices, the objective of this study was to determine the feasibility of utilizing the same subjects, rather than different cohorts, to establish a comprehensive panel of endpoints in two phases. Animals were selected from an in-house naive mouse colony (Phase I) or ordered from a vendor (Phase II) so as to have body weights generally representative of mice which might be assigned to either a 4-week or 13-week toxicology study design. Blood samples for hematology (0.25 mL) and clinical chemistry (1 mL) were collected from all animals via the maxillary vein on Day 1 and a standard hematology panel was evaluated. On Day 2, the animals were submitted to necropsy for terminal blood collections, drawn from the vena cava after CO2 inhalation (maximum obtainable volume), for clinical chemistry testing. A standard clinical chemistry panel was evaluated, except for electrolytes. Samples were provided for individual analyses and stored at -80°C until analysis was completed in two phases. Hematology data were obtained from 42/44 animals, and clinical chemistry data were obtained from 41/44 animals. Data generated were comparable to compiled historical control values; there were no significant or biologically meaningful differences as a function of the modified, single cohort procedure. Therefore, it is feasible to collect both hematology and clinical chemistry samples from the same mouse without using cohorts when serial sampling is used, for CD-1 mice that are 10 weeks or older, provided that the extended range of sampling employed to capture hematology and clinical chemistry data is able to be accommodated from a scientific/experimental design perspective.

**3085 Nitrogen Retention and Protein Quality in Dogs and Cats Fed Commercial Pet Food**

A. K. Geiger, and L. P. Weber, University of Saskatchewan, Saskatoon, SK, Canada.

Protein, as a nitrogen-containing compound, is essential for growth and metabolism. The crude protein content listed on pet food is often misleading when referring to usable protein. A portion of the listed protein may actually be from non-digestible organic nitrogen or potentially toxic inorganic non-protein nitrogen sources, neither of which are retained or used by the animal. To analyze nitrogen retention and screen for non-protein nitrogen, four commercial pet foods for each species were provided to dogs and cats and one lab-made diet for both species were evaluated and coated with a non-digestible marker, chromium oxide. Seven dogs and eight cats were randomly assigned each diet (n=4 for each diet). The dogs were switched to the diets for two days and retention while using was collected over a 48 hour period of feeding chromium coated diet, followed by total marked fecal collection on the subsequent days. Total nitrogen intake did not differ significantly (p>0.05; one-way ANOVA) among diets in both cats and dogs fed the diets, nor did fecal or urinary output. Nitrogen retention was calculated based on nitrogen (%) consumed in feed versus nitrogen lost in feces and urine. The amount of nitrogen retained ranged from 93-96% in dogs and 91-95% in cats, but did not statistically differ among diets in both species. While price did not correlate well with nitrogen retention in dogs, there was an inverse relationship in cats. One reason for the lowest price diet, the lowest protein diet, and vice versa, suggesting that low-priced cat foods had better protein quality. No significant differences in plasma or urine nitrite or nitrate were noted among diets in dogs or cats. Further studies will examine amino acid content in these same diets and percent retention of the amino acids as a more accurate indicator of protein quality and retention. Furthermore, the diets will also be examined for additional toxic nitrogen metabolites. Ultimately, the results of this study show that despite large differences in price, all pet food diets lacked excess levels of toxic nitrogenous compounds and protein quality had no correlation to price.

**3086 Evaluation of Immune-Mediated Idiosyncratic Drug Toxicity Using Chimeric HLA Transgenic Mice**

Immune-mediated idiosyncratic drug toxicity (IDT) is a rare adverse drug reaction, potentially resulting in death. Although genome-wide association studies suggest that the occurrence of immune-mediated IDT is strongly associated with specific human leukocyte antigen (HLA) allo-types, these associations have not yet been prospectively demonstrated. In this study, we focused on HLA-B*57:01 and abacavir (ABC)-induced immune-mediated IDT, and constructed transgenic mice carrying chimeric HLA-B*57:01 (B*57:01-Tg) to determine if this in vivo model may be useful for evaluating immune-mediated IDT. The local lymph node assay (LLNA) using B*57:01-Tg, B*57:03-Tg (negative control), and their littermates (LMs) was conducted by applying 25 μL (50 mg/kg/day) of ABC or vehicle to the dorsum of the ear for 3 consecutive days. After 24h, lymph nodes were drained and weighed, and H&E staining on the ear section was performed. The percentages of bromodeoxyuridine (Brdu)+, IL-2+, and IFN-γ+ in CD8+ T cells were assessed using FACS. ABC-activated CD44+CD26lowCD8+ memory T cells were measured after mice were fed for a week with either a normal diet or rodent chow containing 1% (v/v) ABC. LLNA results demonstrated that percentages of Brdu+, IL-2+, and IFN-γ+ in CD8+ T cells of ABC - applied B*57:01-Tg mice were significantly higher than those in LMs, resulting in the infiltration of inflammatory cells into the ear. These immune responses were not observed in B*57:03-Tg mice. Furthermore, oral administration of 1% (v/v) ABC significantly increased the percentage of CD44+CD26lowCD8+ memory T cells in lymph nodes and spleen derived from B*57:01-Tg mice, but not in those from B*57:03-Tg mice and LMs. These results suggest that B*57:01-Tg mice potentially enable the reproduction and evaluation of HLA-B*57:01 and ABC-induced immune-mediated IDT. Chimeric HLA transgenic mice may be an appropriate tool to prospectively evaluate the detrimental potential of HLA-related IDT compounds in preclinical studies.

**3087 Ambulatory Continuous Intravenous Infusion in Group-Housed Non-Human Primates**

Many new drugs (for example, oncology drugs, biologics) are administered by continuous intravenous infusion, requiring the use of this administration route in non-clinical animal safety studies. When working with nonhuman primates (NHPs), there is increasing awareness of the benefits of group-housing during safety studies and we have been running toxicity studies in under group-housed conditions for several years. For infusion toxicology studies this brings additional technical and organizational challenges. In the work presented here we have evaluated the feasibility of ambulatory infusion in group-housed non-human primates. Cynomolgus monkeys were surgically implanted with a medical grade catheter via the femoral vein, opening in the vena cava. The catheter was connected to an ambulatory infusion line issuing from the infusion pump. Monkeys were then fitted with a protective jacket housing the infusion pump with reservoir. The catheterized monkeys were group-housed in small groups of 2 to 5 animals. Over a period of 5 weeks groups of animals received either 0.9% saline or 5% dextrose for injection by continuous infusion at low (1.0 mL/kg/hr) and high (2.5 mL/kg/hr) rates. Group-housing did not interfere with the continuous administration of the dose formulations of saline or dextrose. The test item dose accountability was within an acceptable range of +/- 10% of theoretical volume over the course of the infusion period. These vehicles were well-tolerated and no adverse effects were observed in terms of clinical signs, body weight or clinical pathology. Macroscopically, tissue changes were comparable to findings in single-housed catheterized animals. In conclusion, the continuous intravenous infusion mode of administration is considered compatible with group-housing of NHPs in...
non-clinical regulatory studies and making these studies compliant with the new European guidelines on animal welfare. Moreover, this model is in line with the 3Rs, since it is a refinement of the standard tethered infusion model and allows the conduct of group-housed toxicology studies enabling freedom of movement in their environment.

3088 Sublingual and Buccal Administration in Minipigs
A. Blak Grossi1, A. Bruhn2, J. Boje Nielsen3, M. Jochemsen2, and A. Makin1,1, CIToxLAB, Lille Skensved, Denmark, and 2CIToxLAB, Lille Skensved, France.

The oral cavity is an attractive site for the delivery of drugs. The oral mucosa is well supplied with both vascular and lymphatic drainage and first-pass metabolism in the liver and further systemic elimination in the gastrointestinal tract are avoided. The buccal area is well suited for a retentive device and for mucosal vaccination which offers the advantage that both local immune responses, at the site of pathogen entry as well as systemic immunity can be obtained. The minipig is an attractive model for oral cavity drug and vaccine delivery as the buccal epithelium is nonkeratinized and of comparable thickness to that of humans. Furthermore, the porcine immune system has been well studied and shows comparable structure and function to the human immune system. We have performed studies in the minipig with application of oral patches and devices, including method feasibility studies. Because of the limited mobility and elasticity of the jaw and lips, respectively, application and subsequent inspection of the oral patches are challenging and sedation of the animals is often required. Typically the human administration of these devices is intended to be daily, or even more frequently, meaning that the animal model should be amenable to these regimes. There are different types of device, from those that are intended to dissolve in a short time, often a few minutes to those where an active drug substance is released slowly over a period of hours. The latter type of device is challenging in the context of animal studies. In the study described in this poster, we have therefore evaluated the feasibility of application of different drug delivery systems for oral cavity administration. Different application times and locations within the mouth were tested. The success and ease of application and retention were found to vary depending on the size and shape of the drug delivery system and the location of application. In the poster we present structures to demonstrate the various possibilities. Our conclusion is that both sublingual and buccal administration of drugs and vaccines are feasible in the minipig, and we have subsequently performed further studies involving active drug substances.

3089 A Novel Mouse Model for High-Throughput Small Molecule Screen of Hepatocyte Maturation
M. Seirup1, B. E. McIntosh2,3, M. D. Probasco2,3, B. M. Duffin2,4, and J. A. Thomson2,3,4, 1University of Wisconsin-Madison, Madison, WI; 2Morgridge Institute for Research, Madison, WI; 3Cavance, Madison, WI, and 4University of California Santa Barbara, Santa Barbara, CA.

Sponsor: C. Bradford

Cultured primary human hepatocytes are the gold standard for drug and toxicity testing. However, good quality cells are limited and they rapidly lose their mature phenotype once isolated. This loss of maturity in culture creates a limited window of usefulness of these cells which creates a hurdle for conducting drug and toxicological assays. Several culturing techniques such as sandwich and 3D cultures have been developed to extend the mature and useful period of hepatocytes. Unfortunately, no system has yet succeeded in maintaining in vivo expression levels of all xenobiotic metabolizing enzymes in long term culture. To improve the functional life of cultured primary hepatocytes we have set up a robotic screening scheme to screen libraries of small molecules to identify candidates that will maintain mature phenotype of hepatocytes ex vivo. First, we developed a mouse model with click beetle red (CBR) luciferase inserted into the albumin (Alb) gene, a marker of mature hepatocytes and click beetle green (CBG) luciferase inserted into the alpha fetoprotein (AFP) gene, a marker of fetal hepatocytes. Next we isolate hepatocytes from young mouse and culture them in 96 well plates for 48 hours in the presence of the molecule of interest. After 48 hours, we lyse the cells and add d-luciferin to measure the levels of luciferase in the lysate. A successful molecule will maintain higher levels of the albumin linked CBR signal compared to untreated wells and will not raise the levels of AFP/CBG. Using this assay, we have identified several potential candidate compounds that maintained high albumin levels and currently we are validating these compounds by Illumina RNA Sequencing. In the future, we shall test the drug metabolizing ability of primary cells treated with these compounds in long term culture. In conclusion, we have developed a novel mouse model for high throughput small molecule library screening to identify candidates for maintaining hepatic maturity in culture. Using our screen, we have also successfully identified potential candidate molecules that are being validated.

3090 Behavioral and Neuroanatomical Outcomes following Early-Life Chlorpyrifos Exposure in a Preclinical Rat Model
E. L. Berg1, J. K. Rivera1, M. Careaga1, D. A. Bruum2, J. Ellegood3, P. J. Lein2, and J. L. Silverman1, 1University of California Davis School of Medicine, Sacramento, CA; 2University of California Davis, Davis, CA; and 3The Hospital for Sick Children, Toronto, ON, Canada.

Organophosphorus pesticides (OPs) are among the most widely used pesticides in the world and have been implicated in the etiology of neurodevelopmental disorders including developmental delay and autism spectrum disorder (ASD). Exposure to chlorpyrifos (CPF), one of the most widely used OPs, has been linked to mental and motor delays, as well as increased rates of attention issues, in children. The present study of CPF developmental neurotoxicity examined sophisticated social behaviors of both males and females in a novel rat model of CPF exposure. Newborn Sprague-Dawley rats were administered either coconut oil vehicle or one of two CPF doses (1.0 or 3.0 mg/kg CPF) via daily subcutaneous injections from postnatal day (PND) 1 to 4. Isolation-induced ultrasonic vocalizations (USVs) were collected from pups at the peak day of USV emission and postnatal whole brain anatomical phenotyping via high resolution magnetic resonance imaging (MRI) was applied at PND 7. At the juvenile age, sociability was assessed using the three-chambered social approach and dyadic reciprocal social interaction assays, and motor activity was evaluated via an open field exploration assay. Female pups exposed to 1.0 mg/kg CPF emitted fewer vocalizations than did pups treated with vehicle or 3.0 mg/kg CPF, and MRI results are currently undergoing analysis. CPF exposure did not affect the sociability phase of three-chambered social approach; however, performance in the social novelty paradigm suggests that CPF disrupted recognition of previously acquired social cues. Relative to vehicle controls, CPF altered juvenile social interactions on several key parameters in a sexually dimorphic manner. Female rats exposed to 3.0 mg/kg CPF exhibited reduced levels of pouncing and rough-and-tumble playing, an effect not observed in males. Similar exploratory behavior in a novel open arena was observed across treatment groups, eliminating hypo- and hyperactivity as confounding behaviors. Taken together with existing literature, the impairments discovered here suggest that developmental OP exposures disrupt neurological development and neural correlates that underlie complex social behaviors.

3091 Effects of Iron Deficiency Model in Cynomolgus Monkeys on Serum Phosphorus and FGF23
R. Samadfam, Charles River Laboratories, Seneville, QC, Canada.

It has been suspected that severe nutritional ferropenic anaemia provokes alterations in the metabolism of calcium and phosphorus. The purpose of this study was a) to create a new animal model for iron deficiency evaluation by controlled blood removal and b) to monitor the effect of iron deficiency on clinical signs, hematology parameters and phosphorus in monkeys. For this purpose, 4 female Cynomolgus monkeys (2.5 years old, 2.4kg) were fed with a low iron diet (PMI No. MH241) and supplements (fresh fruits and dietary enrichments). Monkeys had also 15% of their whole body blood volume removed weekly for 4 weeks. Hemoglobin concentration and hematocrit levels were monitored on a weekly basis. Animals were considered in severe anemia when hemoglobin levels dropped below 7 g/dL and hematocrit under 21%. Serum phosphorus and iron concentrations were measured in Weeks 2 and 4. Fibroblast growth factor 23 (FGF23) concentration was measured in Week 2. A terminal blood collection was collected one week after the last blood removal (Week 5) and analyzed for all parameters. Gradual decreases in hemoglobin and hematocrit were observed during the 4 week blood removal period: group mean hemoglobin concentration decreased from 13.1 to 10.0g/dL and hematocrit from 43% to 32.7%, over 5 weeks. Mean group serum iron concentration remained stable between pretreatment and Week 4: 150.3 to 141 µg/dL. There were no clinical signs observed and noticeable changes observed in serum phosphorus and FGF23 concentrations, except for one single animal where a significant decrease in FGF23 was observed at Week 5 compared to baseline (109 to 32pg/mL). This animal was also noted to have the lowest hemoglobin level (8.5g/dL) and hematocrit (28.9%). Based on the
results observed, it is considered that this monkey iron deficiency model is acceptable, as it induces a relevant reduction in hemoglobin and serum iron concentrations without inducing any discomfort or severe clinical signs to the animals. More importantly, there was no significant effect on phosphorus regulation within the period of observation.

Ulcereative dermatitis (UD), is a common skin condition seen in laboratory mice. This condition is characterized by lesions present essentially in the dorsal area frequently accompanied by moderate to severe pruritus leading to excessive scratching behavior. It is considered one of the most important welfare issues in research as it might result in unscheduled euthanasia prior to study termination. The cause of UD is unknown but is considered to be multifactorial with potential genetic, behavioral, environmental, infectious, or exogenous origin. The condition also seems to be affected by sex, age and diet. UD is currently treated with hydrotherapy combined with different topical treatments such as diluted povidone iodine or chlorhexidine solution or antibiotic ointment. Such treatments are not always effective and might interfere with research results. The necessity to euthanize animals early when condition is severe and unresponsive to treatment has an impact on survival rate, a critical factor on carcinogenicity studies. In an attempt to decrease incidence of ulcerative dermatitis, our laboratory gradually introduced curative and preventive nail trimming in rodents on long term studies. The rationale is that the reduction in pruritus is performed by constant licking of the conscious animals. The rodent is restrained with one hand placed around the thorax and nails are a cut with a standard human nail clipper. No restrainer is necessary. Data from twelve 104-week mouse carcinogenicity studies were evaluated to investigate the relationship between nail trimming and incidence of UD as well as to compare the number of unscheduled euthanasia following nail trimming implementation. There is an evident decrease of incidence of UD on all studies following nail trimming implementation (data indicate minimally 1/3 reduction; up to nearly 45 UD prior to nail trimming compared to 0 to 15 once nail trimming was applied). Furthermore, the number and duration of treatment required also decreased and fewer unscheduled euthanasia for welfare reasons were necessary. Nowadays, preventative nail trimming is implemented as a routine during the day to day activities. This method is safely and quickly performed without additional stress of anesthesia and the use of a restrainer. It is a great improvement for rodent health as well as for the outcome of research studies.

Establishing bioequivalence between an innovator and a generic topical ophthalmic product is challenging because of the clinically inaccessibility of the target of the eye. Clinical PK endpoint studies are characterized by significant inter-subject variability and an inability to enroll sufficient participants. A promising alternative is a Physiologically-Based Pharmacokinetic (PBPK) model to predict drug concentrations in ocular tissues. The current study investigated the distribution of dexamethasone in different tissues of the eye at different time points following topical ocular administration of TobraDex ST* (Tobramycin/dexamethasone) suspension to male New Zealand white rabbits. Results of the current study will be used to test the predictive ability of an existing PBPK model. 42 New Zealand White rabbits were divided into 7 time point (0.5, 1, 2, 3. 4, 6, and 8 hours post-treatment) groups of 6 rabbits per group. 30µl of TobraDex ST* was instilled in the right eye of each rabbit in all groups. Samples were obtained from each rabbit of a group at its designated time point. Sampling included tears, cornea, conjunctiva, aqueous humor, vitreous humor, sclera, retina and iris-ciliary body as well as blood. A liquid chromatography mass spectrometry/mass spectrometry method was developed to measure dexamethasone concentrations in all tissues and plasma. Measured concentrations were compared to model predictions to further inform the model development.

This study was performed to evaluate the protective effect of butea monosperma flower (BM) and boerhaavia diffusa root (BD) extract in New Zealand White rabbit glaucoma and Wistar rat cataract experimental models. Glaucoma was induced by ocular instillation into the left eye of a 1% w/v dexamethasone suspension (DMS) at the dose volume of 50µL, 4 times a day with a 2h interval between each instillation for 14 days. The right eye served as the control. Groups G2 and G3 were treated with BM and BD extracts, respectively, and G4 with mixture of BM + BD extract. Groups G5 and G6 were treated with Timolol and Isotine eye drops, respectively. Group G1 received normal saline. Each formulation was instilled in the same manner as DMS, after 15 minutes of DMS instillation. Eye examination by direct ophthalmoscope and intraocular pressure (IOP) measurement by digital tonometer were performed twice weekly. Cataracts were induced in rat pups (10-14 days of age) by a single subcutaneous injection of sodium selenite (25 mmol/kg) to 6 groups (G2-G7). G2 was treated with sodium selenite alone. G3 and G4 were treated with BM and BD extracts, respectively. G5 was treated with BM + BD extracts, G6 group was treated with Isotine eye drops. Each formulation was instilled at dose volume of 20µL, 4 times a day with a 2h interval between each instillation for 14 days in both eyes. Group G1 was injected with normal saline and served as a control. At study termination, lens homogenates and tissues were evaluated for lipid peroxidation and reduced glutathione. Glaucoma model revealed that IOP was increased in rabbits treated with DMS alone (G2). IOP of treated eye was comparable with untreated eye in all other groups (G3 to G6). Eye examination did not reveal any abnormality in treated eyes compared with untreated eyes. The signifcant prevention of IOP increase in BM and BD treated groups even after DMS administration indicated that BM and BD have preventive therapeutic use for controlling IOP in Glaucoma. Cataract model revealed cataract formation on day 4 after sodium selenite injection in all pups without any significant difference of size, shape and density. Lipid peroxidation and glutathione levels were also comparable in all groups. Results indicate that BM and BD lack significant protective effect in cataract model of rat pups.
Many neurodegenerative diseases including Alzheimer’s (AD), Parkinson’s (PD), and Huntington’s diseases are characterized by the accumulation of misfolded protein aggregates; dysfunction in protein degradation may contribute to their pathogenesis. Autophagy, a normal homeostatic process involved in protein degradation, is characterized by the formation of phospholipid containing vesicular structures known as autophagosomes that can contain a variety of cytoplasmic cargos such as damaged organelles or potentially toxic macromolecules such as protein aggregates. Disruption of autophagy in knock out mouse models leads to neurodegeneration and genetic mutations in autophagy-related genes have been implicated in the pathogenesis of AD and PD. To better understand autophagic activity in neurons in vivo, we created a stable transgenic zebrafish line that expresses eGFP-Mapl1lc3b specifically in post-mitotic neurons under the elavl3 promoter. Microtubule associated protein 1 light chain 3 (Mapl1lc3), in its unbound form is commonly called LC3-I. The lipidized form of LC3, LC3-II, then gets incorporated into the membrane of the autophagosome. LC3-II is degraded by lysosomal hydrolyses upon fusion of the autophagosome with the lysosome. Thus, the uptake of LC3-II into autophagocytic vesicles can be used to monitor autophagic activity. As proof of principle, we modulated and quantified the number of autophagic vesicles via treatment with known autophagy inducers (rapamycin) and inhibitors (3-methyladenine, protease inhibitors). Through these experiments, we could also quantify autophagic flux (i.e. rate of autophagosome accumulation) in specific neuron populations in the living zebrafish larvae. We then tested if treatment with diesel exhaust particulate extract (DEPe), an environmental toxin that our lab has shown results in loss of amnestic neurons in zebrafish larvae, affects autophagic activity. Here, we demonstrate that DEPe inhibits autophagic activity in zebrafish neurons. As dysregulation of autophagy has been shown to be an important factor for neurodegenerative disease etiology, this proven transgenic line will be useful in screening for both toxins that inhibit and potential therapeutic compounds that may induce autophagy.

The environmental component plays a definite role in the development of diseases and in particular cancer as their incidence is continuously growing globally. Belfiore et al. (2018) expressed a whole-genome mouse array in zebrafish as a whole animal model to simulate relevant chemical exposures in order to develop preventive measures is our major objective. A heterogeneous population model was used, obtained from crosses and a segregation sequence over 30 generations leading to two genetically modified profiles in lines of mice genetically selected for minimal AIRMAX or minimal AIRMIN acute inflammation reactivity. Two carcinogenic agents were evaluated in the AIRmin model: DMBA [7,12-imethylbenz[a]anthracene] and urethane which are both pro-carcinogenic agents that can be activated via metabolization by cytochrome P450. DMBA was applied topically on theadipocytes which are both pro-carcinogenic agents that can be activated via metabolization by cytochrome P450. DMBA was applied topically on

Seizure liability is a severe adverse effect and it is usually detected as convulsions in toxicology studies. Non-convulsive seizures however induce only subtle behavioral changes and their assessment in animals is challenging. Electroencephalography (EEG) is the only method to correlate animal behavior to seizure activity and video-EEG is the current gold-standard for preclinical seizure liability assessments (Authier et al., 2014). As clinical observations and PK sampling time points in toxicological studies are usually predefined, they are not ideally suited for comprehensive symptom detection and for exact correlation of drug plasma levels to symptoms. Video EEG allows following animals continuously and could improve symptom detection rate and characterization of neurological symptoms. Implanted ports for CSF collection allow sampling from conscious animals and we investigated if these implants can be combined with EEG electrodes in the same animals to enable simultaneous use of two “windows to the brain”. Three beagle dogs that already had CSF ports were implanted with EEG electrodes. To evaluate a possible impact on signal quality, another three dogs without pre-existing CSF ports were also implanted with EEG transmitters. After baseline EEG recordings were comparable between both groups, reference and in-house compounds with different modes of action were tested in these dogs. As again no differences were found in visually and reference and in-house compounds with different modes of action were tested in these dogs. As again no differences were found in visually and

Effective management of joint pain can be challenging in veterinary species, particularly in horses where standard treatment with systemic non-steroidal anti-inflammatory drugs and intra-articular corticosteroids are inconsistently effective and risk adverse effects. Local anesthetics, such as bupivacaine, administered intra-articularly have demonstrated reductions in equine joint pain in vivo, however effects are short lived (hours) and in vitro studies report chondrotoxicity. The recent introduction of bupivacaine in a sustained release liposomal formulation (approved for use in the dog) offers a potential longer acting therapeutic option for treating joint pain in horses. However, potential systemic or local toxicity needs to be assessed before this treatment can be recommended for intra-articular administration. To that end, 16 exercised university owned Thoroughbred horses received a single intra-articular administration (right antebrachialcarpal joint) of either 0.12 mg/kg liposomal bupivacaine (N=12) or an equivalent volume of 0.9% saline (N=4). Synovial fluid was collected from the joint prior to drug administration and daily for up to 5 days post administration. Saline treated joints were used to assess the effect of repeated arthrocentesis on joint parameters. Synovial drug concentrations were measured using liquid chromatography-tandem mass spectrometry. Enzyme linked immunosorbent assays were used to assess cartilage degeneration (C2C, C1C2) and cartilage turnover (CPI, CS846). Analysis to date indicates liposomal bupivacaine persists in the joint for up to 96 hours without lameness, joint effusion, or overt chondrotoxicity. Cartilage turnover was minimally altered in injected and uninjected joints up to 96 hours. These data indicate that normal bupivacaine may provide a non-toxic option for treatment of equine intra-articular pain, and support further studies in diseased joints following chronic administration. Supported by UC Davis Center for Equine Health and the California Horse Racing Board.
3100 Evaluation of Difference between Homosexual and Heterosexual Housing Conditions on Various Toxicologically Important Parameters of Male Wistar Rats

V. Goyal, S. Pandey, S. Vincent, P. Naige, P. Are, and R. Nirogi. Suven Life Sciences Ltd, Hyderabad, India.

Rodents are a naturally social species, and numerous lines of evidence shows to have behavioural and physiological changes that occur from solitary housing conditions. For routine toxicity studies, animals are kept under homosexual housing conditions and not under heterosexual conditions. Sexual activity can influence the normal well-being of animals. Hence, it can be assumed that confinement of rat in homosexual conditions for longer duration may affect their health thereby outcome of chronic toxicity studies, where animals live in homosexual atmosphere, may not be factual especially for parameters related to reproduction. To prove this hypothesis, a study was planned to evaluate the effect of homosexual and heterosexual housing on various parameters of male Wistar rats. Rats were divided into two groups; heterosexual living conditions (sexually active) and homosexual living conditions (sexually non-active). Sexually active male were taken from the breeding colony and when retired from the colony they were still continued to be cohabited with females. For sexually inactive group, two male rats of approximately same age as sexually active were kept in a single cage. The effect on hematologic, clinical chemistry, organ weight, gross pathology and histopathology were assessed after 6, 12, and 18 month of housing. There were no significant changes noticed in any of the clinical pathology parameters evaluated except slightly high levels of cholesterol and triglycerides in rats of homosexual housing condition up to 18 month of experiment. A significant decrease in mean weight of reproductive organs was noticed in sexually active rats when compared to sexually active. There were no significant changes were noticed at histopathology in any of the organs. Some of the changes like higher incidences of inflammation in kidneys, atrioventricular changes in spleen and interstitial hyperplasia in testes in sexually active animals cannot be confirmed due to housing conditions as they are quite common at this age. We can conclude that sexual activities may not affect the health of the animals whether animal housed homosexual or heterosexual conditions.

3101 Targeted Deletion of Cyp1b1 in Retinal Vascular Supporting Cells Is Sufficient for Attenuation of Retinal Neovascularization and Trabecular Meshwork Dysgenisis

Cytochrome P450 1B1 (CYP1B1) is expressed in human and murine ocular tissues with important roles during development. Mutations in this gene are reported in patients with congenital glaucoma. Although Cyp1b1 is expressed in retinal vascular cells including endothelial cells (EC), pericytes, and astrocytes of the retina, their cell autonomous contribution to the neovascularization defect observed in global Cyp1b1 deficient mice remains unknown. In addition, mice deficient in Cyp1b1 present developmental abnormalities in their trabecular meshwork cells and their organization. Here we determined whether lack of Cyp1b1 expression in EC, PC or AC impacted retinal neovascularization or trabecular meshwork dysgenesis. We generated Cyp1b1 targeted transgenic mice with vascular cell specific targeted Cre-deletion (Cyp1b1EC, Cyp1b1PC and Cyp1b1AC). Pathologic retinal angiogenesis during oxygen-induced ischemic retinopathy (OIR) was evaluated by collagen IV staining of retinal neovascularization and trabecular meshwork. Structural morphology of the trabecular meshwork was determined by transmission electron microscopy utilizing eyes from 8-week-old Cyp1-deficient mice. The quantitative assessment of retinal neovascularization at P17 during OIR, showed decreased neovascular tufts in retinas of Cyp1b1EC mice compared with control or other targeted transgenic mice. Morphometric analysis data showed that 8-week-old Cyp1b1AC mice exhibited a morphologic and integrity of trabecular meshwork similar to global Cyp1-deficient mice. Thus, Cyp1b1 expression in perivascular supporting cells (PC) plays an essential role during ischemia-mediated retinal neovascularization and development of trabecular meshwork.

3102 Evaluation of Oil Based Oleic Acid in the Formation of a Model of Acute Respiratory Distress Syndrome

B. Youngblood1, E. Ferris1, B. Geist1, A. LaRose1, Y. Ueyama1, W. Muir1, C. del Rio1, and R. Hamlin2. 1QTest Labs, Columbus, OH; and 2The Ohio State University, Columbus, OH.

Multiple models of acute respiratory distress syndrome (ARDS) have been utilized in toxicological assessments including pulmonary embo- lization or induction of pulmonary inflammation by direct injection of endotoxin (LPS) or oleic acid. Most publications indicate a volume of oleic acid administered without specification regarding the formulation administered to induce pulmonary dysfunction. This study aimed to assess kinetics and hemodynamics effects in a reliable and reproducible model following administration of oil based oleic acid (OB). As an ancil- lary goal, this study aimed to compare these results to an aqueous based oleic acid (AB) formulation. Alpha-chloroalcohol and fentanyl anesthetized beagle dogs were acutely instrumented for ECG, arterial blood sampling, endotracheal, pulmonary and systemic blood pressures. Following stabilization, OB (0.1 to 0.15 mL/kg; n=8) was administered via injection into the right atrium. Following administration, cardiac output (via thermodilution) and blood gas analysis were performed every 30 minutes for at least 90 minutes. ARDS was achieved when the PaO2/FiO2 ratio was less than 200 mmHg. Under baseline conditions, all animals displayed normal hemodynamic values (HR: 79±5 bpm and SAP: 120±11 mmHg) and oxygenation status (PaO2/FiO2: 478±8 mmHg%), Administration of OB altered hemodynamic values consistent with autonomic activa- tion (HR: 139±12 bpm and SAP: 130±12 mmHg, P<0.05) and impaired oxygenation (PaO2/FiO2: 186±32 mmHg%, P<0.05) at 90 minutes when compared to baseline values. Additionally, OB caused an increase in intratracheal pressure and reduced pulmonary compliance (3.7±0.3 to 6.2±0.2 mmHg at baseline and 90 minutes, respectively; P<0.05) with dogs exhibiting crackles on auscultation. Within 60 minutes following OB administration, 5/8 dogs achieved ARDS criteria and 6/8 had achieved ARDS criteria by 90 minutes. As a comparison, AB (n=2) did not result in any hemodynamic or oxygenation changes through the moni- toring period. Additionally, AB resulted in no changes in peak ventila- tory pressures and no dogs achieved ARDS criteria by 90 minutes. Given these results, OB oleic acid is a reliable and efficient model to produce ARDS and is sufficient to produce a model of ARDS in the anesthetized beagle dog.

3103 Assessing the Impact of Ethanol on Developing and Adult Zebrafish (Danio rerio)

J. B. Chiari, J. M. Charles, and C. L. McGinnis. Quinnipiac University, Hamden, CT.

Zebrafish have been used for many years in developmental and repro- ductive biology, yet little is known about the adult zebrafish liver. Additionally, many of the zebrafish liver cell types have yet to be charac- terized in zebrafish, including Kupffer cells, endothelial cells, and stel- late cells. There is minimal information available regarding zebrafish liver transporters and nuclear receptors. Therefore, it’s important to understand the mechanism of xenobiotic metabolism in zebrafish to support their use as a model organism for studying the biological effects of xenobiotics. The value of zebrafish as a model organism is based on a broad set of conserved gene similarities involved in metabolism and transportation of endogenous and exogenous chemicals. While there are molecular similarities between zebrafish and humans, there are also differences that may impact how compounds are metab- olized. Therefore, it’s absolutely necessary to investigate and validate the assumptions that zebrafish possess conserved genes, enzymes, and processes involved in all stages of metabolism. This study investigates the impact of ethanol exposure on liver toxicity markers in adults and the impact of ethanol on developing larva. For the adult study, rela- tive expression levels for each gene were determined and normalized to β-actin. Of the seventeen genes that were assayed via qPCR, our results demonstrate a significant up-regulation of the following genes following ethanol treatment: abcc4 (m3d), abcc1 (m1p), abcc4 (m4p), abc9 (sur2), abc5, mate1, oatp1 and slc4a2 (ae2). Alcohol metabolism increases a precursor production, a precursor for cholesterol and fatty acid synthesis. Historically, this increase in acetate levels driven by alcohol is a hepatic ion flow during xenobiotic metabolism.
Migration of intra-articular implant wear particulates from the knee joint has been studied in various animal models, as well as in post-mortem samples from patients who received total knee joint replacement. However, there still exists a need for a suitable animal model for tracking the migration of such debris from the knee joint. To fill this need, a proof-of-concept porcine model was developed for particle migration from the knee joint into the draining lymphatic system. Vitreous carbon particles were bilaterally deposited both intra-articularly and extra-articularly in the hind limbs in 6 Yorkshire swine. The regional/draining lymph nodes were qualitatively assessed weekly by a veterinarian via manual palpation to detect any post-operative enlargement or change in consistency. At 6 weeks, the draining lymph nodes were harvested and processed for histology. Microscopic evaluation revealed carbon particle migration from the knee into iliac lymph nodes (12 of 12) and inguinal lymph nodes (6 of 12), but no evidence of particle migration into popliteal lymph nodes. Particle associated inflammation was generally minimal, consisting of neutrophils, histiocytes and multinucleated giant cells. Overall, this study established a needed animal model for evaluating particle migration to the draining lymph nodes from the knee joint.

**Development of a Porcine Lymph Model to Study Particle Migration**

R. Melidone1, A. F. Barber2, B. G. Barna2, and M. Thomassen. 1East Carolina University, Greenville, NC.

Sarcoidosis is a debilitating inflammatory condition characterized by granulomatous lesions in the affected organ. We have previously developed a murine model of chronic granulomatous inflammation elicited by multiwall carbon nanotubes (MWCNT). Previous studies have shown the MWCNT model shares several characteristics with pulmonary sarcoidosis, including decreased expression and activity of peroxisome proliferator activated receptor gamma (PPARγ) and elevated expression of CCL2, osteopontin and metalloproteinase-12 (MMP-12), proteins thought to promote granuloma formation. PPARγ is a nuclear transcription factor which acts as a negative regulator of macrophage activation and is essential for pulmonary homeostasis. These observations suggest that PPARγ has a crucial role in the regulation of pulmonary granuloma formation. We hypothesized that administration of rosiglitazone, a PPARγ specific ligand, would limit alveolar macrophage activation in response to MWCNT instillation. Wild-type C57Bl/6 mice were given rosiglitazone laden diet (6mg/kg/day) three days prior and continuing until 10 or 20 days post MWCNT instillation. Alveolar macrophages and whole lung tissue were collected and evaluated for inflammatory gene expression and histological changes in granulomatous lesions using a previously developed scoring system. We found that animals instilled with MWCNT receiving rosiglitazone laden diet for 10 days demonstrated a reduction in CCL2(90%), osteopontin(75%) and MMP12(79%) compared to mice receiving control diet (n=3/group, p<0.001). The frequency and severity of granulomatous lesions were evaluated but no difference was observed 10 days following MWCNT instillation (n=5). Those animals which received rosiglitazone laden diet for 20 days following MWCNT instillation also demonstrated a significant reduction in CCL2(65%), osteopontin(33%) and MMP-12(67%) (n=10, p<0.001). Evaluation of pulmonary granulomas 20 days following MWCNT instillation found that the frequency and severity of granulomatous lesions were significantly less in those animals receiving rosiglitazone laden diet compared to controls (n=23, p<0.001). These data suggest that PPARγ activation can limit alveolar macrophage inflammatory gene expression and may serve as a novel target to limit pulmonary granuloma formation.

**Rosiglitazone Represses Pulmonary Granuloma Formation and Alveolar Macrophage Inflammatory Activation**

Effective identification of neonatal animals, especially small rodents, is a challenge due to their small body size, making it difficult to use conventional identification methods such as ear tags or ear notch. Methods such as needle marking or permanent markers have their limitations due to the cost or stability of the identification, respectively. Other methods such as paw tattoo system used by some toxicology tests for reproductive studies have limitation of the maximum producible numbers. Traditionally, digital amputation has been used for this purpose, however animal welfare aspects of this method is significant concern. Here we explain a permanent identification by dot-tattoo marking of the digits using small gauge needles. In this study, we used a 31 gauge needle with minimal amount of green tattoo dye and either of front or hind limbs of right or left sides were used as per need. Both dorsal and palmar surface of the digits were evaluated. The method was associated with minimal bleeding and without any complications of using electric tattoo machine. There was no significant effect on neonatal growth or health. Using a guide map, this method provides up to 10,000 identification numbers. Therefore, we suggest that the method to be considered as a simple and cheap yet less painful animal identification method for colony management of studies involving massive neonatal production such as transgenic or knock-out studies as well as large reproductive or general toxicology studies.

Historical Background Control Data in the RccHan: WIST Rat in Chronic Toxicity Studies

M. J. Horn1, J. L. Naden1, L. A. Knarr1, V. Mowat2, and M. Boyle3.

1Envigo, Indianapolis, IN; 2Envigo, Huntingdon, United Kingdom; and 3Envigo, Princeton, NJ. Sponsor: L. Conen

Historical background control data supports improved interpretation of lesions in chronic toxicity studies. Two chronic toxicity studies were performed to generate historical background control data in the RccHan®:WIST rat model. Both studies utilized the same source of rats but were initiated approximately fifteen months apart. In the first study, 150 male and 150 female RccHan®:WIST rats were pair housed under standard housing and husbandry conditions with ad libitum access to a standard diet (20% protein, 4.5% fat) and water. In the second study, 130 male and 130 female RccHan®:WIST rats were pair housed under standard housing and husbandry conditions with ad libitum access to a lower energy diet (16% protein, 4% fat) and water. Additionally, in the second study, rats were administered tap water (10 mL/kg body weight) by once weekly gavage. Body weight, food consumption, morbidity and mortality were monitored throughout the in-life phase of the studies. Interim necropsies were performed at one, three, and six months in twenty animals per gender for generation of historical control data at common acute or subchronic study time points. At the conclusion of the study period, animals were submitted for necropsy and microscopic evaluation of select organs was performed. Neoplastic and non-neoplastic lesions were characterized and complete blood count/serum chemistry and urinalysis were performed. A detailed analysis of survival, plastic lesions were characterized and complete blood count/serum chemistry and urinalysis were performed. A detailed analysis of survival, plastic outcomes, and is thus often preferable to a 2-year rodent study. Future work will verify these preliminary findings. This work was supported by a fellowship from the SOT to ARH, P20GM103549 and P30GM118247 (MTP, WXD), and AA020518 (WXD).

Oral Gavage Dosing of Neonatal Rats as a Test System for Toxicology and Safety Evaluation of Drugs Designed for Neonates and Children

Oral gavage is a common experimental procedure in adult rat. Although this method is considered a well established approach for most toxicology and drug safety testing in adult rat test system, application of this method for evaluation of drugs designed to be used for children is questionable. Considering basic physiologic differences between neonates and adult, especially in digestive system, establishing a neonatal test system to evaluate the safety of the oral drugs targeting pediatric patients is necessary. We have developed a daily oral gavage system for neonatal rat using conventional plastic mouse gavage canola. Following manual restraining of the pups using their dorsal skin, and pre-measurement of the cannula on the abdominal surface using the pup’s milk-filled stomach as land mark, oral gavage was done using an inert dye (tattoo ink). The neonates especially in earlier post-natal age accepted the procedure with minimal resistance. Successful dosing was confirmed by dis-coloration of white milk-spot into the ink color in 1 to 5 minutes. Necropsy of the neonate after 1 hour showed normal flow of the ink in stomach and intestine. We suggest that oral gavage of neonatal rat from early post natal age could be considered as an ideal system for safety evaluation of foods an nutrients for newborns as well as oral medications in pediatric medicine.

Exploring the Hyaluronan Network in an Animal Model of Alcoholic Liver Disease

A. Robinson-Hudspeth, S. Wang, L. Jiang, W. Ding, and M. Pritchard. University of Kansas Medical Center, Kansas City, KS. Sponsor: U. Apte

Advanced liver disease, regardless of etiology, remains a pharmacologically intractable condition. Indeed, only liver transplant is in ‘cure’ a cirrhotic liver. Over consumption of ethanol, in both acute and chronic settings, can cause significant liver injury. While many mechanisms of liver injury induced by ethanol are known, these advances have not led to improvements in therapies for patients suffering from alcoholic liver disease. Therefore, we must gain additional insights into what drives liver disease pathogenesis and progression after alcohol exposure in the hope of identifying potential points of therapeutic intervention. Our laboratory is interested in how the extracellular matrix (ECM) is involved in liver injury as well as repair after different hepatotoxin exposures, including alcohol. Specifically, are we interested in a molecule called hyaluronan (HA), a ubiquitous ECM molecule. While we have considerable evidence to suggest that HA and binding proteins and receptors (the HA network) are involved in liver injury and required for liver repair after acute carbon tetrachloride exposure in mice, we do not know if the HA network is altered by exposure to ethanol and if so, we speculate that this study was to characterize the HA network in mice after exposure to ethanol using the ‘acute-on-chronic’ paradigm and compare those data to those collected from mice given a control diet. Ethanol-exposed mice displayed an upward trend in the following: plasma HA (mimicking patients with liver disease), the number of HA-positive cells in liver (minimal amount binding protein), hepatic tumor necrosis factor (TNFα) and TNF-stimulated gene (Tsg6, another HA binding protein) transcript levels. We did not observe differences in expression of the HA synthases or in enzymes responsible for the breakdown in HA between control or ethanol-exposed mice. Finally, we observed a downregulation of the HA receptor (an HA binding protein) in HA binding proteins and this was paralleled by Rhamm levels in human alcoholic liver disease patients. Overall, these data suggest that the HA network may be altered by ethanol exposure and might contribute to liver disease. Future work will verify these preliminary findings. This work was supported by a fellowship from the SOT to ARH, R20GM103549 and P30GM118247 (MTP, WXD), and AA020518 (WXD).

Minimal Degenerative and Regenerative Renal Changes in 26-Week Tg.ras.H2 Mouse Carcinogenicity Study

M. McKeon1, M. Panirpe1, V. Vidmar2, C. Brown1, J. Belich1, and N. Sousa1. BioReliance, Rockville, MD; and BioStat Consultants Inc., Portage, MI.

The 2-year rodent carcinogenicity assays involving conventional rats and mice have been conducted for over 3 decades. As an alternative to the 2-year rodent carcinogenicity bioassays, 26-week short term carcinogenicity bioassays were approved using transgenic mouse strains, including Tg.ras.H2. The Tg.ras.H2 model, which can be used for both genotoxic and non-genotoxic compounds, has gained popularity and its use has increased over the years. Currently, more than 75% of all mouse carcinogenicity studies are being conducted in Tg.ras.H2 mice. The Tg.ras.H2 model predicts neoplastic findings relevant to human cancer risk assessment, produces fewer non-biologically significant neoplastic outcomes, and is thus often preferable to a 2-year rodent study. We published the largest historical control database for both neoplastic and non-neoplastic lesions in Tg.ras.H2 mice Our current historical control data base has grown sufficiently that we can now begin to look at looks at effects of vehicles or vehicle components on both non-neoplastic and neoplastic findings. We evaluated the incidence of renal lesions in male and female mice in 26-week Tg.ras.H2 oral gavage carcinogenicity studies with methylcellulose as one of the ingredients of the vehicle. Our evaluation indicated that renal degenerative and regenerative tubular basophilia changes were significantly higher in males than in females. The historical control data base shows 350 mice/sex in 14
Diet-related, insulin deficiency and/or resistance, is fast gaining the attention of a global epidemic. Apart from traditional risk factors, recent studies attributed the increased incidence of diabetes to environmental factors. Certain epidemiological studies have associated increased incidence of diabetes with Dichlorvos (DDVP, an organophosphorus pesticide) and Atrazine (Herbicide) exposure. However, exposure to xenobiotics other than those identified with diabetes is unusual. Therefore, we evaluated the diabetogenic potential of these chemicals by exploiting the conserved Insulin/Insulin growth factor-like signaling (IIS) as well as glucose homeostasis in Drosophila melanogaster. Flies reared on food with DDVP (1.5 ng/ml of food) or Atrazine (20 µg/ml) during development contained significantly elevated glucose, trehalose levels and reduced Akt and Forkhead box O (Foxo) phosphorylation. DDVP exposed flies had significantly reduced transcript/protein levels of Drosophila insulin-like peptides (dilps), GLUT1 (receptor for glucose assimilation) and increased transcript levels of insulin receptor (InR) suggesting insulin deficiency typical of type 1 diabetes. In contrast, flies exposed to Atrazine had significantly elevated transcript/protein levels of dilps, InR and GLUT1, pointing to insulin resistance typical of type 2 diabetes in response to Atrazine exposure. Together, these findings reflect not only the diabetogenic potential of DDVP and Atrazine but also their differential modulation of insulin signaling pathways. Further, the study provides experimental evidence to the epidemiological propositions on the diabetogenic potential of DDVP and Atrazine. Finally, our study projects the utility of Drosophila as a potential model for deci- phering and understanding the influence of xenobiotics on the onset of diabetes.

Niclosamide is a salicylanilide anthelmintic drug used worldwide for the treatment of tapeworm infections due to low oral bioavailability. Recent drug repurposing screens have revealed that niclosamide has the potential to treat cancer, osteoporosis, and endometriosis through interaction with multiple signaling pathways. Based on a LOPAC2060 library screen within zebrafish embryos, we previously identified niclosamide as a potent developmental toxicant resulting in static exposure from 5 h post-fertilization (hf, ~50%–epiboly) to 25 hpf (prim-6 stage). Given that niclosamide delivery for new applications may require non-oral routes of exposure, the potential developmental toxicity of niclosamide should be re-evaluated, as these exposure routes may result in the embryo's exposure in utero during pregnancy. Therefore, using zebrafish as a model, the objective of this study was to further investigate the toxicity of niclosamide during early development. Zebrafish embryos were exposed to vehicle (0.1% DMSO) or niclosamide (0.078-0.625 µM) from (1) 2 to 6 hpf as a baseline exposure; (2) 2-3, 2-4, 2-5, or 2-6 hpf to assess the potential for recovery (0.156-0.625 µM); or (3) 2-6, 3-6, 4-6, and 5-6 hpf to identify sensitive windows of exposure (0.156-0.625 µM). For all exposures, epiboly progression was assessed by quantifying percent epiboly and cell height above the yolk at 6 hpf. Collectively, these studies revealed that (1) niclosamide induced a concentration-dependent delay in epiboly initiation and progression; (2) recovery following niclosamide exposure was dependent on the exposure window and concentration; and (3) the sensitive window of niclosamide exposure was between 3-4 hpf, a mid-blastula transition characterized by yolk sac second gradient activation and initiation of cell motility. To identify the sensitive period of epiboly delay, embryos were treated with nicotine for 3 hpf, followed by solvent (0.1% DMSO) or niclosamide (0.156 or 0.3125 µM) from 2-6 hpf, transferrred to clean media, and reared until 24 hpf (prim-5 stage). Surprisingly, niclosamide-induced epiboly delay resulted in a distribution of outcomes at 24 hpf, including embryonic lethality, developmental delays, and normal development. Using a multi-pronged strategy, we are currently investigating the mechanism of niclosamide-induced epiboly delay as well as rate of niclosamide uptake and depuration within zebrafish embryos.

Tris(1,3-Dichloro-2-Propyl) Phosphate Disrupts Dorsoventral Patterning in Zebrafish Embryos

Tris(1,3-dichloro-2-propyl) phosphate (TDCIPP) is a high-production volume organophosphate flame retardant widely used within the United States. Within zebrafish, initiation of TDCIPP exposure at 0.75 h post-fertilization (hf) results in genome-wide alterations in methylation during cleavage (2 hpf) as well as epiboly delay or arrest (at higher concentrations) during late-blastula and early-gastrula (4-6 hpf). To determine whether these TDCIPP-induced effects were associated with impacts on the transcriptome, embryos were exposed to vehicle (0.1% DMSO) or 2 µM TDCIPP from 0.75 hpf to 6 hpf, and total RNA was extracted from triplicate embryo pools per treatment and hybridized onto duplicate Affymetrix Zebrafish Gene 1.0 ST Arrays per RNA sample. Based on transcriptome-wide profiling, TDCIPP resulted in a significant impact on biological pathways involved in dorsoventral patterning and bone morphogenetic protein (BMP) signaling. Consistent with pathway-level responses, TDCIPP exposure also resulted in strongly doralized embryos by 24 hpf - a phenotype that mimicked the effects of dorso- morphin, a potent and selective BMP inhibitor. Moreover, the majority of doralized embryos were preceded by epiboly arrest at 6 hpf. Our microarray data also revealed that the expression of sizzled (szl) - a gene encoding a secreted Frizzled-related protein that limits BMP signaling - was significantly decreased by nearly 4-fold at 6 hpf. Therefore, we used a splice-blocking morpholino to test the hypothesis that knockdown of szl phenocopies TDCIPP-induced delays in epiboly progres- sion. Interestingly, contrary to our hypothesis, injection of szl MOs did not affect epiboly progression but, similar to chordin (chd) morphants, resulted in ventralized embryos by 24 hpf. Overall, our findings suggest that TDCIPP-induced epiboly delay may be independent of szl expres- sion and function, and that TDCIPP-induced dorsalinization may - similar to dorso- morphin - be due to interference with BMP signaling during early zebrafish development. Therefore, our ongoing work is focused on investigating the mechanism of TDCIPP-induced epiboly delay and dor- salization using a combination of mRNA sequencing, reverse genetics, immunohistochemistry, in situ hybridization, and cell-based assays.

Evaluation of Embryonic Zebrafish as an Alternative Whole-Animal Model for Nephrotoxicity Screening

Due to an increasing demand for testing of new and existing chemi- cals and legal restrictions for use of animals, there is a strong need for alternative approaches to assess systemic toxicity. Embryonic zebrafish (Danio rerio) are increasingly recognized as a promising alternative whole-animal model that may be able to overcome limitations of cell-based in vitro assays and bridge the gap between high-throughput in vitro screening and low-throughput in vivo tests in animals. The aim of the present study was to investigate if zebrafish embryos might be a suitable high-throughput amenable model for nephrotoxicity testing. In this study a range of well characterised compounds that are known nephrotoxins in humans and rodents (aristolochic acid, cadmium chlo- ride, potassium bromate, ochratoxin A) were investigated for their nephrotoxic effects in embryonic zebrafish. Fertilized zebrafish eggs of the AB/AB strain were distributed into 96-well plates for treatment with compounds for 48 h (3 - 5 days post fertilization) with nephrotoxic compounds. H&E staining revealed marked proximal tubule injury as evidenced by dilated tubules, tubule cell necrosis and tubule cell disorganisation following treatment with aristolochic acid and ochratoxin A. No damage was seen in control tubules. Embryos treated with cadmium chloride showed a slightly dilated proximal tubules compared to the control embryos, whereas no kidney injury was evident in embryos treated with potas- sium bromate. Consistent with the morphological changes in the pro- nephrone in response to compound exposure, WISH analysis revealed marked upregulation of cadh17 expression at sites representing the proximal tubule in embryos treated with aristolochic acid, ochratoxin A and cadmium chloride, but not after treatment with potassium bromate. qRT-PCR analysis of genes identified as sensitive kidney injury markers based on rodent studies (ctu, ctf1a, havcr1, hmx1a, ssp1) showed inconsistent results in treated zebrafish. Taken together, our results suggest that embryonic zebrafish may be a suitable model for nephrotoxicity screening and that cadh17 expression may be a good marker for xenobiotic induced injury to the pronephros.
3117 Does the Zebrafish Embryotoxicity Assay Predict Variations or Malformations in Rat Prenatal Developmental Toxicity Studies?

B. Flick, X. Jiang, E. Salinas, M. Dammann, B. Hidding, R. Landsiedel, and B. van Ravenzwaay. BASF SE, Ludwigshafen am Rhein, Germany.

The zebrafish model is predicted to potentially detect the presence of compounds capable of causing prenatally developmental toxicity. The common prediction models are based on teratogenic indices, the relation of effective concentration of lethality and of embryotoxic findings. Thereby, it is only possible to distinguish between positive or negative outcome in vivo. But in the in vivo prenatal developmental toxicity studies one is classifying the findings as variations and malformations which provides the opportunity to assess a chemical as negative, developmental toxic, or teratogenic with different regulatory consequences. We were aiming to assess if the differentiation of endpoints in the scoring system of the zebrafish embryotoxicity as general embryotoxic and specific embryotoxic endpoints could improve the accuracy of prediction. We used a data set based on 31 public known as well as in house chemicals of the company with balanced different potentials of prenatal developmental toxicity. In each test group 12 embryos with intact chorion were cultured from 1.5 to 120 hours post fertilization. A morphological score system with 38 parameters was used to describe the development of zebrafish embryos in the concentration range from the no observed adverse effect concentration up to the concentration causing mortality. These results were used to assess which classification of morphological zebrafish endpoints are indicators for general embryotoxicity (e.g. hatching, cell viability, yolk) to predict variations in vivo or indicators for specific embryotoxicity (e.g. head, trunk, body shape, cardiovascular system, and fins) to predict malformations in vivo. The common prediction model (PM) resulted in an accuracy of 79%, a sensitivity of 86%, and specificity of 73%. None of the so far analyzed combination parameters for general or specific embryotoxicity resulted in a good predictivity to distinguish between a negative, developmental toxic and teratogenic results in vivo. To improve the prediction model for zebrafish embryotoxicity a definition of the concern of morphological alterations and an international harmonized terminology is needed, like it is given for the in vivo prenatal developmental toxicity studies.

3118 Zebrafish and Medaka as Alternative Models for Developmental Toxicity Assessment of Chemicals, Including Behavior as an End Point

C. Quevedo1, N. De Croze2, A. Aldaya1, A. Muriana1, and M. Léonard2.1 Bioilde, San Sebastian, Spain; and 2L’Oreal Research & Innovation, Aulnay sous Bois, France.

There is a worldwide trend to move away from animal testing for the human and environmental safety assessment of cosmetics and personal care products. Fish embryo models (zebrafish (Danio rerio) and Medaka (Oryzias latipes)) are highly popular in toxicology, both in research required potential regulatory applications. In compliance with international animal welfare regulations (e.g. Dir 2010/63/EU), the fish embryo models provide an ethically acceptable small-scale analysis system with the complexity of a complete organism. The objective of this study was to compare the potential of both models, zebrafish and medaka, for the teratogenic, developmental and behavioral assessment of chemicals. The study was initiated with 5 hydrophilic reference compounds: 3 known to be teratogenic in both rodents and humans (Amanadine, 5-Fluorouracil, Lithium Chloride), and 2 non teratogenic compounds (Ascorbic acid and Ceftriaxone). Embryos were exposed to these compounds from 2-4 hpf (hatching and fertilization) to 4 dpf (days post fertilization) for zebrafish and 9 dpf for medaka. At the end of the test the evaluation of survival, morphological alterations and locomotor activity was carried out in them. While 3 out of 5 compounds (Amanadine, Ascorbic acid and ceftriaxone) were properly classified with both assays, 5-Fluorouracil was only detected as teratogenic for medaka embryos. Surprisingly, Lithium Chloride did not induce morphological alterations in zebrafish nor medaka. However, locomotor activity was clearly affected in zebrafish embryos treated with this compound. These results indicate that medaka embryos could be more sensitive than zebrafish embryos to certain hydrophilic teratogenic compounds (such as 5-Fluorouracil). It also suggests a potential low uptake of hydrophilic compounds by zebrafish embryos and highlight the importance of conducting internal dosing assays for proper test item classification. Besides this, including behavior endpoints would likely increase the sensitivity of both models to properly detect teratogenic compounds.

3119 Development of an Oxidative Stress In Vitro Assay in Zebrafish (Danio rerio) Cell Lines

Oxidative stress is a common mechanism for different toxicological endpoints of relevance both for aquatic and human toxicology. The nuclear factor erythroid 2-related factor 2 (Nrf2) is a key regulator of cellular defense against oxidative stress and Nrf2 has been shown to be correlated with classical toxicological endpoints. In vitro methods using fish cell lines for the assessment of aquatic toxicity is highly needed for mechanistic studies and as an alternative to vivo studies. We now describe an in vitro assay to study oxidative stress using zebrafish (Danio rerio) cell lines. Transfection efficiency of twelve commercially available transfection reagents were tested in the zebrafish cell lines ZFL, ZF4, and Pac2. The most efficient reagent for each cell line was selected for further experiments. Cells were transiently transfected with an Nrf2-responsive luciferase plasmid. The assay was tested using known oxidative stress inducing chemicals (tertiary butyl hydroquinone, hydrogen peroxide, and sulfurophane) in increasing concentrations (0.1, 1, 10, and 100 μM) for 24 h. Of the investigated cell lines, ZF4 and ZFL showed higher sensitivity to known inducers and were used to study oxidative stress of pesticides (diazinon, deltamethrin, Aarazine, metazachlor, tertiary butylazine, diuron). Cells were incubated with increasing concentrations (6.25, 12.5, 25, 50, 100 μM) of each pesticide for 24 h. Diazinon, deltamethrin, metazachlor, and diuron statistically significantly increased the Nrf2 expression. The described assay could be a valuable tool for future research in aquatic toxicology to study the toxicity of both pure chemicals and environmental water samples.

3120 Utilization of 21st-Century Predictive Tools for Characterizing the Acute Toxicity Potential and Human Risk of Exposure to Chemical Weapon Precursor Compounds

K. P. Glover1,2, M. Feasel3,2, C. Phillips2, J. Horsmon2, M. Widder2, C. Carbaugh2, R. Lui2, A. Wallovich2, P. Kristovich1, and A. Director-Myska1.1 Defense Threat Reduction Agency, Ft. Belvoir, VA; 2US Army Edgewood Chemical Biological Center, Aberdeen Proving Ground, MD; 3US Army Center for Environmental Health Research, Ft. Detrick, MD; 4DoD Biotechnology High Performance Computing Software Applications Institute, Frederick, MD; and 5Biotechnology High Performance Computing Software Applications Institute, Frederick, MD.

Traditional methods for evaluating chemical toxicity are time-consuming, expensive, and require the exposure and sacrifice of live animals. New methods must be developed to meet the future challenges facing the Threat Agent Science (TAS) program, due to an increasing number of acutely hazardous chemicals requiring more stringent, mechanistic characterization. To support this, we are developing a toxicity characterization framework to support rapid assessment of new substances. This toxicity characterization framework describes an integrated approach to toxicity assessment by incorporating computational and in vitro testing strategies with existing toxicity data to provide faster and more comprehensive risk assessments compared to traditional methods. As a proof-of-concept, we show the evaluation of 54 chemical weapons precursor compounds (CWPCs) using this framework. Chemicals were first grouped according structural similarities for group-based hazard assessments and physiochemical property predictions. Initial LD50 predictions were made using internal QSAR models built on the RTECS/Leadscope database. Alternative test systems were used to fill data gaps and assess relative potency for downstream risk assessments. These test systems included high-content imaging of HepG2 cells, cardiomyocyte functionality and zebrafish (Danio rerio) embryonic behavior assays. Lastly, in vitro to in vivo extrapolation (IVIVE) was used to inform the risk assessment and predict hazardous exposure scenarios for a subset of the CWPC list. Overall, our toxicity characterization framework provides a potential solution to the future challenges of the TAS program. A draft version for public release; distribution unlimited. Disclaimer: Research was conducted in compliance all Federal requirements. The views expressed are those of the authors and do not constitute endorsement by the US Army.

For genotoxic carcinogens, the existence of thresholds, i.e. doses below

which a chemical does not exhibit adverse effects, remains controvers-

ial, while for epigenetic carcinogens the presence of no-adverse-eff-

fects (NOAELs) has been widely accepted. The assumption that exposure to genotoxic carcinogens at low level leads to tumor forma-

tion, results in strict regulations in human health risk assessments that

the exposure to carcinogens should be as low as reasonably achievable

(ALARA). The current experiment investigated the dose-response effect

and the possibility of NOAELs for formation of DNA adducts, a crucial

event in the carcinogenicity of DNA-reactive chemicals, by a group of

naturally occurring alkenylbenzenes with previously reported genotoxic

potential: methyl eugenol, estragole, myristicin and a mixture, nutmeg oil.

Previously, in Turkey Egg Genotoxicity Assay (TEGA) methyl eugenol,

estragole and myristicin produced DNA adducts at the highest tested
doses. In the current study, a wide dose range of the compounds was

evaluated in TEGA using \(^{32}\)P-nucleotide postlabeling (NPL) assay which

detects the formation of DNA adducts. Methyl eugenol (0.005-4 mg/

egg), estragole (0.025-40 mg/egg), myristicin (0.08-50 mg/egg) and nutmeg oil (0.6-100 mg/egg) were injected daily into the air sac of turkey

eggs on days 22-24 of incubation. Control groups received vehicle, 20\%

aqueous solution of Kolliphor HS15. Liver samples for the NPL assay were

collected three hours after the last dose. While tested alkenylbenzenes

produced DNA adducts in a dose-related fashion, for each compound

a NOAEL below which no DNA adducts were formed was detected. For

methyl eugenol and estragole, the NOAEL was 0.025 mg/egg ( \(-0.67\) mg/

kg bw), followed by myristicin at 0.33 mg/egg ( \(-9.3\) mg/kg bw) and

nutmeg oil at 1 mg/egg ( \(-27.8\) mg/kg bw). These findings suggest that

thresholds for the effects of genotoxic carcinogens exist. Importantly,

the NOAELs for alkenylbenzenes were above the available estimated
daily intake in humans, suggesting negligible hazard to human health.

Detection of No-Adverse-Effect-Levels (NOAELs) for Formation of DNA Adducts by Alkenylbenzenes in the Alternative Model Turkey Egg Genotoxicity Assay (TEGA)

3122 The In Ovo Oral Toxicity Assay: A Rat Acute Oral Systemic Toxicity Replacement

B. J. Varsho, C. Kalimtzis, D. Sergeyev, B. Yasso, and G. L.

DeGeorge, MB Research Labs, Spinnerstown, PA.

Correctly identifying a chemical’s acute systemic toxicity hazard level is critical for labeling the material with the proper safety precautions needed for handling and transportation. Acute toxicity categories are assigned, in part, by an oral toxicity estimate, as determined by lethality studies in rats. Several in vitro and alternative assays have been developed and codified for assessment of other acute toxicity hazards (i.e., eye irritation, skin irritation, skin sensitization). However, alternative assays for assessment of oral toxicity are limited both in number and accuracy. We aim to develop a metabolically competent assay system that models human biologic responses to exogenous chemicals such that cardiovascular, nervous, endocrine, digestive and excretory systems as well as general homeostatic mechanisms are represented and allowed to interact naturally in situ. We administered seven reference chemicals (i.e., strychnine, caffeine, sodium nitrite, acetylsalicylic acid, ethanol, sodium chloride and sucrose) directly into the yolk and/or the albumen of embryonated chicken eggs on either Incubation Day (ID) 5, 6, 7 or 14, and observed the eggs for 48 hours for viability. LD\(_{50}\) values for each experimental condition were calculated following Log-Probit methodology. We demonstrate that reference chemicals elicit dose-responsive toxicity in embryonated chicken eggs, and we are able to stratify lethality responses based on the relative toxicity of agents used in our experiments. Egg LD\(_{50}\) values were generally similar to rat LD\(_{50}\) values, e.g., rat oral toxicity for sodium nitrite (200 mg/kg) and ca-

feine (190 mg/kg) had average egg LD\(_{50}\) values of 136 and 237 mg/kg, respectively. A robust validation would qualify or disqualify IOOTA as not only an inexpensive alternative assay to mammalian hazard identi-

fication, but could serve as a stop-gap assay until sufficiently accurate in

vitro and computer models are developed.

In Ovo Oral Toxicity Assay: A Rat Acute Oral Systemic Toxicity Replacement

3124 Dopaminergic Neurotoxicity of Polybrominated Diphenyl Ether Flame Retardants in Caenorhabditis Elegans

M. Eaton, R. Smith, and C. Dodd, Fort Valley State University, Fort

Valley, GA.

Polybrominated diphenyl ethers (PBDEs) were utilized for four decades as a flame retardants in infant products, polyurethane foam, and carpet padding. PBDEs were sprayed onto the products and tend to migrate and accumulate in air, soil, and water after time. Epidemiological evidence suggests adverse behavioral and cognitive effects can occur when exposed to high levels during key points in development. Penta-BDE is a mixture of congener units with brominated diphenyl ether-47 (BDE-47) being the most commonly detected in human tissues. Increased blood levels of BDE-47 are proportional to the development of adverse motor and cognitive abilities in children. Specific behaviors including hyperactivity and attention deficits are prominent and similar to those observed in attention deficit/hyperactivity disorder (ADHD). The target of BDE-47 induced neurotoxicity remains unknown, but could be linked to modulation of dopaminergic (DAergic) homeostasis. Hermaphroditic Caenorhabditis elegans have 6 anterior DA neurons, (2 pairs of CEP, 1 pair of ADE). Like humans, DA in the nematodes is responsible for attention, movement, and the recognition of reward. To determine if dopamine homeostasis is altered by BDE-47, this study exposed Larval 1-staged (L1) C. elegans (BZ55-strain and N2, wildtype) to BDE-47 at 3 concentra-

tions (2.5µm, 5µm, 10µm, and control 0.1% dimethyl sulfide). To achieve chronic exposure, treated L1 worms were directly transferred to nema-

tode growth media plates. Worms were permitted to develop to Larval stage 4 (L4) before analyzed using fluorescent microscopy (200X magn-

ification). Green pixel values of ADE and CEP cell bodies in L4-stage (BZ553) were analyzed using ImageJ software. Mean area classifications were also scored. Pixel mean values and mean area were proportional to adverse neurodevelopment and analyzed by ANOVA and bonferroni posthoc testing. The BDE-47 concentrations utilized did not significantly alter the size of the DA neurons. Further, protein analysis continues of the DOP-3, receptor concentration to determine if BDE-47 can alter DA homeostasis.

Genome-Wide Identification of Mutational Signatures Related to the Toxicity of AFB\(_1\) and FB\(_1\) Mixtures Using Caenorhabditis elegans Model

K. S. Xue, L. Tang, P. L. Williams, and J. Wang, University of Georgia, Athens, GA.

Mutational signatures hold promise in molecular cancer epidemiology because they bear witness to mutagenic exposures, as well as illuminate endogenous mutagenic processes and mechanisms of DNA damage and repair. Aflatoxin B\(_1\) (AFB\(_1\)) and Fumonisin B\(_1\) (FB\(_1\)) are the most common food contaminants whose co-existence was found in food-stuffs all over the world, particularly in high liver cancer risk areas. AFB\(_1\) is a known human carcinogen and FB\(_1\) is a class 2B carcinogen (IARC) with strong tumor promotion activity in animal models. Studies in animal models have shown that the co-exposure to AFB\(_1\) and FB\(_1\) elicits considerably stronger toxic and carcinogenic effect than when exposed to either of the toxins alone. C. elegans has been a valuable model organism, with its simplicity, completely mapped genome, as well as several homolo-
gies to mammalian systems. Specifically, C. elegans possess the CYP450 homologues capable of metabolizing AFB\(_1\), as well as Cys homologues which are tied into the mechanism of action for FB\(_1\). In the present study, C. elegans was used as a model to evaluate combative toxic effects of mycotoxin mixtures. Combined exposure to AFB\(_1\) and FB\(_1\) elicited stronger toxic response in terms of growth inhibition, brood size reduc-
tion, as well as lifespan reduction, in the wildtype N2 strain C. elegans, than either AFB\(_1\) or FB\(_1\) alone, with combination index (CI) lower than 1.0 for all tested dose combinations. AFB\(_1\) exposure induced a dose-re-
sponse in detectable DNA lesions while FB\(_1\) did not show an induction of DNA lesion; however, an additional 40 µM of FB\(_1\) combined with various concentrations of AFB\(_1\) resulted in a higher level of DNA lesion than that of AFB\(_1\) alone. Furthermore, whole-genome sequencing of model muta-
tional signatures, via analyzing worm populations exposed to AFB\(_1\), only and AFB\(_1\)+FB\(_1\), mixtures, showed that AFB\(_1\) induced substitutions of gua-
nines in a GpG context, and was similar to the mutational signatures of AFB\(_1\) and FB\(_1\) mixtures; however, their mutational frequency increased with addition of FB\(_1\). Thus, this model system, combined with genome sequencing data, can provide new insights into the contribution of mutagenic exposure to the process of carcinogenesis.
Cannabinoid agonists and antagonists have known inhibitory effects on mammalian tumor cell proliferation in vitro. Previous work has shown that cannabinoids also inhibit regeneration in the planarian model species, _Girardia dorotocephala_ (Woodworth, 1897). During cephalic regeneration, ocelli (eyespots) appear to be reduced or absent when exposed to cannabinoids. Due to these observed effects, the hypothesis is that cannabinoids may inhibit the expression of important genes in the planarian visual system was tested. _Sine oculis_ (sixi), a constitutive gene required for proper development and maintenance of ocelli was selected. Specimens of _Girardia dorotocephala_ were maintained under standard lab conditions and fasted at least 7 days before conducting studies. Decapitated and intact planarians were used to determine if cannabinoids had any effect on _sine oculis_ expression during development and normal functioning. Animals were placed into one of the following treatment groups: media control, DMSO solvent control, 8 micromolar WIN 55212.2 (cannabinoid agonist), and 10 micromolar rimonabant (cannabinoid antagonist). Total RNA was extracted on an individual basis at 24 hours. Using reverse transcriptase PCR and gene-specific endpoint PCR, _sine oculis_ gene expression was determined. No differences were detected in gene expression between control and experimental groups. These data indicate that exposure to synthetic cannabinoids do not affect the expression of the _sine oculis_ gene in either intact or decapitated planarians and the lack of ocelli development may be related to other visual system-related genes or genes involved in other aspects of tissue regeneration. Future work will focus on those genes having a much more global role in planarian regeneration. Supported by NSF/HBCU-UP grants 1622811 and 1531014.

### Chemical Structure Plays an Important Role in the Ability of Cannabinoids to Inhibit Planarian Regeneration

Cannabinoids, both agonists and antagonists, inhibit normal tissue and organ regeneration in the planarian, _Girardia dorotocephala_ (Woodworth, 1897). While the mechanism underlying this inhibition has yet to be determined, the chemical structure of the cannabinoid may play an important role, leading to the following hypothesis: the chemical structure of a cannabinoid is an important factor in its ability to inhibit planarian regeneration. Two cannabinoid antagonists of very different structures were used. Rimonabant, a 1,5 diarylpyrazole, is a well-established cannabinoid antagonist and has served as prototype for the development of other cannabinoid antagonists. The second compound, PSNCBAM-1, is based on the urea molecule. Both drugs are antagonists of the type 1 mammalian cannabinoid receptor. Specimens of _Girardia dorotocephala_ were maintained under standard laboratory conditions and fasted at least 7 days before conducting studies. Decapitated animals were placed into one of the following treatment groups: media control, DMSO solvent control, 3 micromolar rimonabant and 5 micromolar PSNCBAM-1, and allowed to regenerate over a period of 5 days. Planarians were euthanized with 1M HCl and stained with aceticarmine to observe ocelli development. There was no significant difference in head and ocelli development between control animals and those treated with PSNCBAM-1. In contrast, regeneration of the head and ocelli was markedly reduced in animals treated with rimonabant. Two other compounds based on rimonabant, AM251 and NIDA-41020 (an iodine atom and a methoxy group respectively replacing the chlorine atom at the 5-phenyl position), also produced significant inhibition of planarian regeneration similar to rimonabant. These data indicate that the structure of a cannabinoid antagonist plays a major factor in its ability to inhibit planarian regeneration and specifically that the rimonabant-type structure has a greater effect on regeneration than a urea-based structure. Future studies will examine other cannabinoid antagonists of varying chemical structures to determine if these findings are consistent. Supported by NSF/HBCU-UP grants 1622811 and 1531014.

### Comparison of the Expression of Sine oculis in Decapitated and Intact Planarians Exposed to a Cannabinoid Agonist and Antagonist

### Evaluation of Metabolic Response during Lipid Starvation of a Model Parasite Perkinsus Marinus

K. M. Noell, and J. Pitula. University of Maryland Eastern Shore, Princess Anne, MD.

Our laboratory is interested in understanding the response of _Perkinsus marinus_, a protozoan parasite of oysters, to lipid starvation. Previous work has shown that this parasite is capable of synthesizing its own fatty acids, as well as acquiring them from their host. We seek to understand whether the capacity to synthesize fatty acids is a means to generate membrane components during lipid starvation, or if alternatively if this biosynthetic capacity is supplemental to growth in an infected host. As citrate can serve as a source of Acetyl CoA, we are also investigating the role of cytosolic aconitase as a potential regulator in this process, as there is evidence for phosphorylation of this enzyme to favor citrate production. No one, to our knowledge, has delineated the role of cytosolic aconitase in fatty acid biosynthesis. First, we were interested in the impact of cell growth under a known fatty acid inhibitor, Triclosan. We saw a time dose dependent shift when cells were exposed to higher concentrations at longer time intervals. Following this, we were interested in what would happen when the cells underwent lipid starvation. We have performed differential mRNA gene expression in _P. marinus_, in which cells were starved of lipids for 11 days, as compared to lipid replete cells. There was not a noticeable upregulation of FAI-pathway enzymes for saturated fatty acid synthesis, although citrate synthase was upregulated approximately 3-fold, consistent with allisteric activation of fatty acyl CoA oxidation. Polyketide synthase delta 5 and 6 fatty acid synthase and delta 5/6 fatty acid desaturase were upregulated by approximately 2-fold. Surprisingly, a number of enzymes involved in beta-oxidation were upregulated, which contrasted with the expectation that free fatty acids from triglycerides would be directed towards synthesis of membrane. Consistent with this, ACC-2 was down regulated 2-fold. Interestingly, maltose acetyl transferase was also upregulated 2-fold, implying that acetyl units from beta-oxidation may be re-directed to sugar acetylation. The implications of this complex interplay will be discussed, along with future experiments to address lipid and sugar metabolites present in this parasite under lipid starvation conditions. Finally, the activity and phosphorylation status of aconitase-1 will be assessed under these conditions.

### Chemical Structure Plays an Important Role in the Ability of Cannabinoids to Inhibit Planarian Regeneration

Cannabinoids, both agonists and antagonists, inhibit normal tissue and organ regeneration in the planarian, _Girardia dorotocephala_ (Woodworth, 1897). While the mechanism underlying this inhibition has yet to be determined, the chemical structure of the cannabinoid may play an important role, leading to the following hypothesis: the chemical structure of a cannabinoid is an important factor in its ability to inhibit planarian regeneration. Two cannabinoid antagonists of very different structures were used. Rimonabant, a 1,5 diarylpyrazole, is a well-established cannabinoid antagonist and has served as prototype for the development of other cannabinoid antagonists. The second compound, PSNCBAM-1, is based on the urea molecule. Both drugs are antagonists of the type 1 mammalian cannabinoid receptor. Specimens of _Girardia dorotocephala_ were maintained under standard laboratory conditions and fasted at least 7 days before conducting studies. Decapitated animals were placed into one of the following treatment groups: media control, DMSO solvent control, 3 micromolar rimonabant and 5 micromolar PSNCBAM-1, and allowed to regenerate over a period of 5 days. Planarians were euthanized with 1M HCl and stained with aceticarmine to observe ocelli development. There was no significant difference in head and ocelli development between control animals and those treated with PSNCBAM-1. In contrast, regeneration of the head and ocelli was markedly reduced in animals treated with rimonabant. Two other compounds based on rimonabant, AM251 and NIDA-41020 (an iodine atom and a methoxy group respectively replacing the chlorine atom at the 5-phenyl position), also produced significant inhibition of planarian regeneration similar to rimonabant. These data indicate that the structure of a cannabinoid antagonist plays a major factor in its ability to inhibit planarian regeneration and specifically that the rimonabant-type structure has a greater effect on regeneration than a urea-based structure. Future studies will examine other cannabinoid antagonists of varying chemical structures to determine if these findings are consistent. Supported by NSF/HBCU-UP grants 1622811 and 1531014.

### Profiling Environmental Chemicals Which Modulate the TGFβ/SMAD Signaling Pathway

Z. Wei, S. Sakamura, R. Huang, and M. Xia. National Institutes of Health, National Center for Advancing Translational Sciences, Rockville, MD.

The transforming growth factor beta (TGFβ) superfamily regulates cell growth and development. Disruption of the TGFβ pathway in early development significantly affects organogenesis and cytodifferentiation. Dysregulation of TGFβ signaling in adults impairs tissue repair and may lead to fibrosis. Despite the complexity of downstream effects for the TGFβ signaling pathway, SMAD-dependent TGFβ signaling acts conservatively through SMAD 2/3/4. In the present study, the SMAD Binding Element (SBE)-beta lactamase (BLA) HEK293T cell line responds specifically to the activation of the SMAD 2/3/4 complex. The SBE-bla assay was first validated by screening the Library of Pharmacologically Active Compounds (LOPAC) library which contains 1280 compounds plus 88 Tox21 compounds at 7 concentrations ranging from 2.4 nM to 28 μM in three independent runs. The signal to background ratio was 2.37 ± 0.07 and 2.19 ± 0.10 in the agonist and antagonist mode, respectively. After online validation, this assay was used to screen the Tox21 compounds at 7 concentrations ranging from 2.4 nM to 28 μM in three independent runs. The signal to background ratio was 2.37 ± 0.07 and 2.19 ± 0.10 in the agonist and antagonist mode, respectively. The Z’ factor was 0.68 ± 0.05 and 0.56 ± 0.06 in the agonist and antagonist mode, respectively. After online validation, this assay was used to screen the Tox21 10K compound library. From the primary screening, we identified a group of compounds that are known to modulate the TGFβ/SMAD pathway (flavopiridol and colchicine) as well as a number of novel compounds (dipentaerythritol pentaacrylate). In addition, the activity of these TGFβ/SMAD-active compounds in other developmental pathways are examined in comparison, including the retinol signaling pathway (RSP) and the sonic hedgehog (SHH) pathway. Some hits show specific patterns in modulating TGFβ/SMAD, RSP and SHH pathways. These results will be used to prioritize potential developmental toxicants for further investigation.
Recent studies suggest that human derived intestinal epithelial cells (IEC) cultured as polarized monolayers on permeable Transwell® filters are effective at differentiating between hazardous and non-hazardous proteins. This experimental platform is based on apical exposure of IEC monolayers to a test protein for 24 hr followed by assessment of whether monolayers display evidence of loss of barrier integrity or cell viability. In this study, Caco-2 and T84 IEC polarized monolayers were evaluated for barrier integrity and cytotoxicity following exposure to hazardous and innocuous proteins for 24, 48 and 72 hr. Hazardous proteins included Cladostrium difficile toxin A (ToxA), Streptolysin O (SLO), Wheat Germ Agglutinin (WGA), and Phaseolus vulgaris haemagglutinin-E (PHA-E). Non-hazardous proteins included bovine serum albumin (BSA), porcine serum albumin (PSA), and fibronectin (Fn). The objective was to determine whether extended duration (48 and 72 hr) altered responses observed at 24 hr of exposure. Results from the 24 hr duration were similar to those previously reported. In general, evidence of diminished barrier integrity or cell viability observed following exposure to hazardous proteins for 24 hr was more prominent at 48 and 72 hr for both cell lines. Non-hazardous proteins exhibiting no impact following 24 hr of exposure, also failed to elicit any effects at 48 hr. Results were not as clear at 72 hr as control values (no protein) exhibited slightly higher background, possibly because of the prolonged period without serum in the culture medium. Results from these studies further support the utility of using cultured human IEC polarized monolayers to differentiate between hazardous and non-hazardous proteins and suggest that an exposure interval of 48 hours may be optimal for this purpose.

**3130 Validation and Comparison of the Neutral Red Uptake Assay in BALB/c 3T3 and CHO-WBL Cells**

The neutral red uptake (NRU) assay is used to evaluate the cytotoxicity of a variety of chemicals and agents, including tobacco products. We previously validated the NRU assay in BALB/c (3T3) cells according to OECD Guidance Document 129, and report here validation of the NRU assay in CHO (WBL) cells according to Health Canada Official Method T-502. CHO and BALB/c cells are exposed to test or control articles, in a 96-well plate format, for 24 hr with newborn calf serum or 48 hr without serum, respectively. After removing the treatment media, fresh media with neutral red (NR) is added for an additional 3-hr incubation. Only viable cells incorporate and bind NR, and cytotoxicity is detected by a concentration-dependent decrease in NR staining as quantitated by the optical density at 540 nm. Analysis of our current historical control population doublings during the 24- or 48-hour exposure times. However, our standard concentration ranges for SLS were 6.8 to 100 µg/mL for BALB/c and 13.6 to 200 µg/mL for CHO, which produced IC50 values of 19.99 ± 3.35 µg/mL and 89.15 ± 3.38 µg/mL, respectively. Based upon these results, BALB/c cells treated for 48 hr in serum-free media are less sensitive to the cytotoxic effects of SLS and may be more appropriate to evaluate e-liquids formulations and e-cigarette condensates, which generally have proved to be relatively innocuous. In contrast, CHO cells treated for 48 hr with serum are less sensitive to the cytotoxic effects of SLS and may be more appropriate to evaluate whole smoke from combusted cigarettes and their smoke condensates, which are relatively more cytotoxic. Additional experiments to evaluate the toxicity of SLS in BALB/c cells with and without serum using a 48-hr treatment, and in CHO cells using 24- and 48-hour treatments in the presence of serum, concurrently are in progress. Other studies with combusted cigarettes and their smoke condensates, as well as with e-liquids formulations and e-cigarette condensates, are planned.

**3131 An Integrated Multi-Organ Culture System to Evaluate Tobacco-Extract Systemic Responses**

N. Hibbard, A. Dalrymple, B. Corpus, A. Baxter, M. D. Gaca, and J. M. McKim. 1IONTOX LLC, Kalamazoo, MI; and 2British American Tobacco, R&D Centre, Southampton, United Kingdom.

There is growing interest in the use of organ-on-a-chip technology for pre-clinical toxicity testing. In this pilot study, the local and systemic effects of cigarette total particulate matter (TPM) was measured in human lung and liver tissues. A three-organ dynamic multi-organ plate (Hu-DMOP®) was constructed in triplicate, in the following format: lung tissue (MucilAir™), lung-1, sandwich cultured human hepatocytes (SCHH) and a second lung tissue (lung-2). Communication between compartments was via a ‘simulated blood flow system’ consisting of a one-way fluidics/dialysis network, which allows for exchange of test article and metabolites. TPM (165 µg/ml in 0.02 mL) or vehicle control was applied apically to lung-1 for 24 h. Movement of TPM was assessed by tracking nicotine using LC/MS/MS. Lactate dehydrogenase (LDH) release was used to monitor tissue health. TPM mediated changes in the expression of key genes (IGFBP2, G6PD, GPX2, AKB810, NQO1, CYP1A2, TALDO1 and HMOX1) was determined by qRT-PCR at 24 h. Nicotine was first detected in lung-1 basolateral space at 1 h and reached a nadir (10 ng/mL) by 3 h. Nicotine in liver and lung-2 (4 ng/mL) was present after 6 h post TPM exposure. Cell viability remained high with LDH release below 10%. TPM exposure increased G6PD 4-fold and GPX2 3-fold in lung-1. These genes were only among 2-fold in lung-2 but AKB810 was induced 12-fold. In liver, AKB810 was increased 6-fold and NQO1 8-fold. These data demonstrate organ-organ interactions on compound effects. In conclusion, this study has demonstrated that the Hu-DMOP® can be used to measure the localized and systemic responses of a tobacco product in vitro.
To efficiently predict dose-dependent in vivo toxicity by alternative methods, the development of generic physiologically based kinetic (PBK) modelling-based reverse dosimetry approaches for large numbers of chemicals is required. Our previous study showed that PBK modelling-based reverse dosimetry of in vitro uterotropic in vivo dose-response data obtained from the uterotrophic assay to evaluate the model predictions. The current study indicates the feasibility of using a combination of in vivo toxicity data and a generic PBK model to predict in vivo uterotropic response for groups of estrogenic chemicals. Further studies can expand the current approach for other in vivo endpoints.

Using Python Coding to Automate and Improve Acute Toxicity Estimate Calculations for Agrochemical Formulations

C. Elliott1, S. Modi1, K. Papachristos1, W. Masinja1, A. Hofstra2, and R. Currie1
1 Syngenta Ltd, Bracknell, United Kingdom; and 2 Syngenta Canada Inc., Guelph, ON, Canada.

Agrochemical formulations are complex mixtures containing a variety of components including active ingredients, solvents, adjuvants, stabilisers and preservatives. LD/LC50 values for systemic effects (acute oral, dermal and inhalation) historically derived from animal tests can be determined from available acute toxicity data for individual ingredients within a formulation using the Acute Toxicity Estimate (ATE) calculation. The calculated values are classified into categories for transport and regulatory requirements. An automated computational protocol would alleviate the burden and several hour time commitment of manual calculations, minimise the possibility of error, and ensure consistency. To this end, we have developed a Python-based reverse dosimetry tool, PyATEmix, to automate ATE calculation composition and ingredient toxicity as inputs to provide estimates of acute toxicity and hazard classification estimates. Integrating the raw data retrieval process within Syngenta by connecting to relevant internal databases with the PyATEmix tool significantly reduced individual calculation time to a few minutes, and enabled calculations from number of formulations at one time. PyATEmix was validated using an expert database which simultaneously ensured data quality. With the ability to generate ATE calculations for a large number of formulations quickly, PyATEmix was used to assess the predictive power of ATE calculations. A retrospective comparison was conducted on a large dataset of agrochemical formulations with corresponding in vivo data. Trends could be identified with specific active ingredients and formulation types. Various limitations were identified including: impact of in vivo study design; overestimation due to high acute toxicity ingredients; and limited available acute toxicity data particularly in the inhalation area. Although this reduced the accuracy of the ATE tool generally a good comparison was achieved. PyATEmix is a useful tool to quickly and consistently derive ATE calculations and to assess the utility and applicability of ATE calculations as an alternative, non-animal, method to evaluate human safety of agrochemical formulations.
The increased scrutiny for health effects of bisphenol A (BPA), a chemical used in producing plastics, paper, and food packaging, led to its replacement with substitutes, such as BPS and BPF. Due to their massive production scale, BPA and its substitutes can be widely detected in a multitude of environmental samples and human biologics. The high degree of structural similarity between BPA and its substitutes suggests that they may possess similar bioactivity and toxicity. Therefore, removing them from the environment and reducing their human exposure may be important from a public health standpoint. Here, we propose to use a bioinformatics method based on manganese peroxidase (MnP), an enzyme produced by almost all wood-decomposing fungi, to degrade bisphenol compounds. In this study, MnP was immobilized into vault nanoparticles to enhance its thermal stability without losing its enzymatic activity. The degradation efficiency of vault-packaged MnP (vMnP) was evaluated and compared with its unpacked native form (nMnP). The result showed that vMnP was able to mediate a markedly faster and more sustained degradation than nMnP. The reproductive toxicity of bisphenols and their degradation products were also examined in Caenorhabditis elegans to evaluate the detoxification efficiency of vMnP. Our results showed that vMnP catalyzed reaction could eliminate the reproductive toxicity of bisphenols as neither fertility damage nor increased germline apoptosis could be observed from the worms exposed to the degradation products. These results thus suggest that packaging of the enzymes in vaults not only enhanced enzymatic kinetics but also mitigated the toxicity of degradation products.
racy of lipophilic chemicals and pre/pro-hapten was 84% (56/67) and 92% (34/37), respectively. These results suggested that the EpiSens®A could have high predictive performance in evaluating a broad set of chemicals including lipophilic chemicals and pre/pro-hapten, which are difficult to evaluate using existing test methods.

3141 Troubleshooting during In-House Validation of 3T3 NRU Phototoxicity Assay

G. Liwen, L. Wang, N. Xu, B. Xu, M. Chen, and Z. Chengen, WuXi AppTec, Suzhou, China.

The 3T3 Neutral Red Uptake (NRU) Phototoxicity assay is an established in vitro assay used to evaluate the potential phototoxicity of a test article. The assay methods and prediction model are described in OECD Test Guideline (TG) 432 and the IVETITTO Protocol No. 78. Since the introduction of the EMA and ICH guidance, the 3T3 NRU-PT has been used quite extensively within the pharmaceutical industry. This abstract introduces some of the technical problems that was encountered during validation in our test facility and how they were overcome. In this assay, problems such as lot variability of serum and positive control, cell loss, neutral red solution preparation and even occasional room temperature variation were encountered all of which can interfere with measurements. 1) Due to lot variability of new born calf serum (NBCS), the NBCS was screened to ensure the doubling time of 3T3 cells were within 20-25 hours; 2) Cell washing should be performed with caution as the cells are easily detached from the wells during washing especially after test article treatment and irradiation; 3) Plates without irradiation should be kept in dark box and should not be disturbed, and the room temperature should be monitored; 4) The procedures to prepare the neutral red solution was refined to avoid commonly seen crystallization of neutral red (NR), which will disturb the OD reading; double filters were used - NR stock solution was filtered through a 0.22 micron filter and NR medium was also filtered before use through a 0.45 micron filter; 5) The red dye was also excluded to be transferred from medium to the cells. The lot variability has been observed and the improper selection of CPZ may disqualified the assay. After addressing these technical issues, the validation was completed with 7 studies and tested 8 compounds (Amiodarone HCl, Chlorpromazine HCl, Norfloxacin, Anthracene, Protoporphyrin IX, Disopyramide, L-Histidine, Hexachlorophene and Sodium Lauryl Sulfate). PIF and LIF were calculated based on the relative mean tissue viability for all four petroleum streams, a class of UVCB substances. In an effort to reduce animal testing, validation studies were conducted with the following in vitro systems: EpiSkin-SMTM involving reconstituted human epidermis and OECD 492 -EpiOcular TM involving reconstituted human corneal epithelium. Over the past few years, several in vitro and in chemico assays have been developed to predict the skin sensitisation potential of chemicals. The Direct Peptide Reactivity Assay (DPPA) is an in chemico assay that can be used to discriminate between sensitizers and non-sensitizers. This assay measures peptide reactivity of test chemicals by quantifying the depletion of synthetic heptapeptides containing either lysine or cysteine. Haptenation, i.e., the covalent binding of low-molecular weight substances (hapten) to proteins in the skin is considered a prominent mechanism through which chemicals or their metabolites become antigenic. Therefore, information from peptide reactivity assays such as the DPPA is considered relevant for the assessment of the skin sensitisation potential of chemicals (OECD N° 442C). Although DPPA is used to detect sensitizers, it has the limitation of a lack of ability to detect photosensitizers. To overcome this limitation, JRF has introduced an additional photoinactivation parameter into the DPPA assay. A group of 14 chemicals having various industrial and medical applications were selected for this study: 5 chemicals were food additives, 5 chemicals had industrial applications and other 4 chemicals were drugs. Each chemical was irradiated with dose of 5 J/cm2 UVA, in presence of Cysteine and Lysine heptapeptides. After 24 hours post incubation in the dark, peptide depletion was measured by a UV-HPLC method at 220 nm. The difference in peptide depletion (Δ) between UV treated and untreated samples was used to determine the effect of photosensitisation. Out of 14 non UV-irradiated chemicals, 11 were classified as non sensitizers

3143 Cosmetics Europe Evaluation of Five In Silico Skin Penetration Models

A. G. Schepky1, R. Cubberley2, H. Duplan3, J. Eilstein4, C. Ellison5, S. Grégoire1, N. Hewitt1, C. Jacques-Jamin1, D. Lange1, A. Roe1, H. Rothe1, S. Salhi6, and M. Klariç7. 1Beiersdorf AG, Hamburg, Germany; 2Unilever, Sharnbrook, United Kingdom; 3Pierre Fabre Dermocosmétiques, Toulouse, France; 4Oréal, Aulnay-Sous-Bois, France; 5The Procter and Gamble Co., Cincinnati, OH; 6Cosmetics Europe, Brussels, Belgium; 7Coty, Darmstadt, Germany; and 8GlossySmithKline, Nyon, Switzerland.

The ADME TF aims to evaluate and develop in silico skin penetration models using relevant measured values e.g. partition (K) and diffusion (D) coefficients and water solubility. Since there are widely differing opinions on different in silico models, we have evaluated 3 open source and 2 commercial models in order to identify 1-2 that will be investigated further. Models varied in complexity but were primarily based on physical chemistry of diffusion, with different degrees of physiological relevance built in. Simulations of the cutaneous distribution of 25 chemicals were run and compared with measured in vivo human skin penetration data. None of the models adequately predicted the amount of chemical that evaporated. This was shown to be important since the prediction of dermal delivery (DD) was improved when the evaporated amount was accounted for in the simulations. The ability to predict the amount in epidermis and dermis varied between models; whereas, the amounts in the receptor fluid were generally over-predicted by 3 models and under-predicted by 1 model. The over-prediction of DD by 3 models is considered to be conservative in terms of human safety assessment. Interestingly, measured K/D values improved the prediction of DD by 1 model, while DD was predicted well by models using Q SAR values. The general effect of using ethanol instead of PBS as the solvent on DD was indicated by 4 models, although they all over-predicted the DD after application in ethanol. The DD for some chemicals were less well predicted by more than one model e.g. 4-chlorobutyric acid and triosolan, although the latter was applied in ethanol, which could account for this issue. In conclusion, our evaluation highlighted important differences in 5 models. The 4 more complex in silico models could predict the DD of 25 chemicals relatively well, especially if the fraction evaporated was considered. Amounts of chemical in the epidermis and dermis was less well predicted, as was the amount evaporated. Future work will investigate how measured data can be used to improve the models further.

3142 Validation of In Vitro Skin and Eye Irritation Tests for Petroleum Streams, a Class of UVCB Substances

B. Munoz1, F. Reitman2, D. Kelly3, H. Shen4, B. Tam1, and D. Swick1. 1Chevron, San Ramon, CA; 2Shell (Retired), Houston, TX; 3Marathon Petroleum, Findlay, OH; 4Shell, Houston, TX; and 5American Petroleum Institute, Washington, DC.

Currently few data are available to assess the utility of in vitro skin and eye irritation alternatives for determining the irritation potential of petroleum process streams, a class of UVCB substances. In an effort to reduce animal testing, validation studies were conducted with the following four NBCS was screened to ensure the doubling time of 3T3 cells were within 20-25 hours; cell washing should be performed with caution as the cells are easily detached from the wells during washing especially after test article treatment and irradiation; 3) Plates without irradiation should be kept in dark box and should not be disturbed, and the room temperature should be monitored; 4) The procedures to prepare the neutral red solution was refined to avoid commonly seen crystallization of neutral red (NR), which will disturb the OD reading; double filters were used - NR stock solution was filtered through a 0.22 micron filter and NR medium was also filtered before use through a 0.45 micron filter; 5) The red dye was also excluded to be transferred from medium to the cells. The lot variability has been observed and the improper selection of CPZ may disqualified the assay. After addressing these technical issues, the validation was completed with 7 studies and tested 8 compounds (Amiodarone HCl, Chlorpromazine HCl, Norfloxacin, Anthracene, Protoporphyrin IX, Disopyramide, L-Histidine, Hexachlorophene and Sodium Lauryl Sulfate). PIF and LIF were calculated based on the relative mean tissue viability for all four petroleum streams, a class of UVCB substances. In an effort to reduce animal testing, validation studies were conducted with the following in vitro systems: EpiSkin-SMTM involving reconstituted human epidermis and OECD 492 -EpiOcular TM involving reconstituted human corneal epithelium. All four streams were not classified as eye irritants in the in vivo studies according to the criteria of the Globally Harmonized System of classification and Labelling of Chemicals (GHS). The toxic results correlated with the EpiOcular™ in vitro results indicating that the relative mean tissue viability for all four petroleum streams was more than 60% compared to the mean tissue viability of the negative controls thus resulting in no GHS eye irritation classification. Results from the in vivo studies indicated that all four petroleum streams met the classification criteria for a GHS Category 2 skin irritant. These in vivo results did not correlate with the in vitro Episkin-SMT™ results. All four petroleum streams tested resulted in mean tissue viabilities of more than 50% compared to the mean tissue viability of the negative controls thus resulting in no GHS skin irritation classification. These results suggest that additional work is needed to understand the lack of correlation for the skin irritation tests which could improve the applicability of the in vitro tests for assessing petroleum derived substances. Results from EpiOcular™ show that it may be possible in vitro alternative model for assessing eye irritation potential based on the observed correlation of in vivo and in vitro results for nonirritating petroleum streams, however no validation data are available to evaluate for known eye irritation potential.

3144 Assessment of Potential Photosensitization Via In Chemico Direct Peptide Reactivity Assay

Over the past few years, several in vitro and in chemico assays have been developed to predict the skin sensitisation potential of chemicals. The Direct Peptide Reactivity Assay (DPPA) is an in chemico assay that can be used to discriminate between sensitizers and non sensitizers. This assay measures peptide reactivity of test chemicals by quantifying the depletion of synthetic heptapeptides containing either lysine or cysteine. Haptenation, i.e., the covalent binding of low-molecular weight substances (hapten) to proteins in the skin is considered a prominent mechanism through which chemicals or their metabolites become antigenic. Therefore, information from peptide reactivity assays such as the DPPA is considered relevant for the assessment of the skin sensitisation potential of chemicals (OECD N° 442C). Although DPPA is used to detect sensitizers, it has the limitation of a lack of ability to detect photosensitizers. To overcome this limitation, JRF has introduced an additional photoinactivation parameter into the DPPA assay. A group of 14 chemicals having various industrial and medical applications were selected for this study: 5 chemicals were food additives, 5 chemicals had industrial applications and other 4 chemicals were drugs. Each chemical was irradiated with dose of 5 J/cm2 UVA, in presence of Cysteine and Lysine heptapeptides. After 24 hours post incubation in the dark, peptide depletion was measured by a UV-HPLC method at 220 nm. The difference in peptide depletion (Δ) between UV treated and untreated samples was used to determine the effect of photosensitisation. Out of 14 non UV-irradiated chemicals, 11 were classified as non sensitizers
**3145** Non-Animal Skin Sensitization Safety Assessments for Cosmetic Ingredients: What Is Possible Today?

A key part of the safety assessment for local effects of cosmetic ingredients is the evaluation of skin sensitization, i.e. their potency to induce an immune response in the skin involving the innate and the adaptive immune system. For decades the murine local lymph node assay (LLNA) has been key for assessing the threshold dose per exposed skin area at or below which contact allergy induction does not occur in humans. Nowadays cosmetic regulation requires industry to perform safety assessments without the use of animals. Correspondingly, we introduce the use of an integrated testing strategy - based on a publicly available online tool for predicting skin sensitization potency - using examples of some hair dye and fragrance ingredients. We describe that already today a combination of Q(SAR) predictions and in vitro data on peptide reactivity, keratinocyte and dendritic cell activation allow for predictions of skin sensitization potency. Furthermore, testing of suitable structural analogues and sets of data for skin sensitization along with the chemical of interest can be applied in a weight-of-evidence approach to support the estimation of an allergy induction threshold by read-across.

We conclude that, depending on the testing strategy and the quality of the available data, predictions of skin sensitization potency can be made with a substantial degree of confidence.

**3146** Prediction of Skin Sensitization Potential in Compounds of Military Interest by In Vitro Methodologies

Environmental safety and occupational health (ESOH) assessments are critical to the U.S. Army in protecting Soldiers, civilians, and the surrounding communities. The Army Public Health Center (APHC) evaluates ESOH for Army materiel and chemicals of concern (CoC). Basic toxicological test data (“six-pack” including acute oral/dermal toxicity, ocular/dermal irritancy, skin sensitization (SS), and subchronic toxicity) are often not available for CoC. SS is an important occupational endpoint where data are required. In silico modeling, and in vitro (IVT) and/or in vivo (IVO) tests are employed in a phased approach to fill these data gaps. When QSAR modeling predicts a CoC may be a skin sensitiser, a set of IVT assays are used as an initial screen. This panel includes: Direct Peptide Reactivity Assay (DPRA), human cell line activation test (h-CLAT), and LuSens ARE-Nrf2 activation assay. Each assay addresses different aspects of the SS adverse outcome pathway and is used in a weight of evidence approach to predict SS. Five potential replacements for RDX (2,4-dinitroxyrazole (DNR), 2,4,6-trinitro-3-bromonitrophenyl (TNB), 1,3-dimethyl-hexahydropyrimidine (DHP), and methyl trinitropyrazol (MTPNP)) were evaluated using this panel (TOPKAT modeling predicted potential SS for all 5 compounds) along with 4 CoC with existing IVO data for comparison purposes (acrolein (AC), monocrotophos (MCP), parathion (PA) and phosphamidon (PM)). The listed chemicals were tested by SS for h-CLAT, and S were tested by DPRA. For the h-CLAT, 8 of the 9 chemicals were positive. AC, DNP, TNBPA, LLM-105, and MTPNP were positive for both CD54 and CD86 expression, while PA, MCP, PM, and DNP were positive using the DPRA. The remaining 4 chemicals will be tested by DPRA and all 9 chemicals will be tested in the LuSens assay. Preliminary data indicates that AC, MCP, PM, PA, and DNP are likely sensitizers. The results for AC and MCP agree with IVO data suggesting they are sensitizers. However, PM and PA were not observed to cause S5 IVO, but were positive using the IVT method, indicating a need for further study. For the RDX replacements, anecdotal reports indicate DNP and MTPNP may be sensitizers (in agreement with data produced by the IVT test battery). The use of IVT tests permits the rapid assessment of CoC and may help to preemptively screen for, and/or corroborate occupational reports of skin sensitization.

**3147** The Assessment of Phototoxicity Using the 3T3 Neutral Red Uptake (NRU) Phototoxicity Assay and a Modified Photo-Direct Peptide Reactivity Assay (DPRA)

Phototoxicity may be broadly defined as the ability of a compound to become toxic, or more toxic, in the presence of UV-exposure, and encompasses photorrnattirity, photoallergenicity, and photogenotoxicity. The validated 3T3 Neutral Red Uptake (NRU) Phototoxicity assay (OECD TG 432) is a recommended first tier test to address this endpoint, although the exact mechanism is not determined. Seven compounds, identified as photoirritants and photoallergens (chlorpromazine (chlor), 6-methylcoumarin (6-MC) and amiodarone), photol慧gen (hexachlorophene), photoirritant (anthrache), allergen (cinnamic aldehyde (CAI), and non-allergen and non-photoirritant (lactic acid (LA))), were evaluated. Chlor, 6-MC, anthrache, and amiodarone were identified as phototoxoy by the 3T3 NRU Phototoxicity assay (i.e., Mean Photo Effect (MPE) value >0.150) while CA, LA, and chlorhexilone were identified as non-phototoxic based on their MPE values (i.e., MPE <0.100). The Direct Peptide Reactivity Assay (DPRA) was useful as a potential platform for assessment of phottoalergy by incorporating a UVA exposure (3 J/cm2) step as a modification to the standard assay outlined in OECD TG 442C. The depletion of the cysteine (Cys) peptide was monitored immediately after UVA/dark exposures and at 2 hour intervals over a 26 hour period. Immediately after UVA-exposure, the amount of peptide depletion for Chlor, 6-MC, anthrache, and amiodarone, CA, and PA was 68.5%, 21.0%, 84.7%, 63.1%, 42.5%, 48.5%, and 2.3%, respectively in the presence of UVA; in comparison, the amount of peptide depletion in the absence of UVA was -1.4%, -0.3%, 0.8%, -2.7%, 2.0%, 46.7%, and -1.2%, respectively. The peptide depletion for CA (allergen) and LA (non-allergen non-photoirritant) was irrespective of the inclusion of UVA exposure. All compounds identified as phototoxicity in the 3T3 NRU assay showed differences (>-20%) in reactivity in the presence of UVA as compared to the absence of UVA; however chlorhexilone, which did not trigger a phototoxicity response (i.e. MPE <0.100) in the 3T3 NRU assay would have been correctly identified as a photoallergens by using the DPRA assay. A tiered testing approach using the 3T3 NRU Phototoxicity and Photo-DPRA could identify compounds which pose phototoxicity hazard, from the perspective of phototoalergy and photoallergy.

**3148** Applicability Domain of an In Vitro Skin Sensitization Test Method, EpiSensA, Based on Evaluation of a Broad Set of Chemicals Including Lipophilic Chemicals and Pre/Pro-Haptens

H. Mizumachi, M. Sakuma, N. Imai, and M. Miyazawa. 1Kao Corporation, Tochigi, Japan; and 2KOSE Corporation, Tokyo, Japan. Sponsor: J. Avalos

The evaluation of lipophilic chemicals (e.g. LogKow ≥ 3.5) and pro/pre-haptens can be a limiting factor in in vitro skin sensitization test methods like DPRA, KeratinolSens™ or h-CLAT. The EpiSensA, an in vitro skin sensitization test, was developed by Kao Corporation to overcome these limitations. In the EpiSensA, lipophilic chemicals can be directly applied on reconstituted human epidermis (RhE) to assess if substances become toxic, or more toxic, in the presence of UV-exposure, and encompassing photorrnattirity, photoallergenicity, and photogenotoxicity. The expanded dataset of 129 chemicals including 67 lipophilic chemicals and 37 pre/pro-haptens were further used to define the applicability domain of the EpiSensA. The overall accuracy was 86% (111/129). The accuracies of lipophilic chemicals and pre/pro-haptens were 84% (56/67) and 92% (34/37), respectively. Although good accuracies were obtained, 10 false-negatives were observed in dataset. A majority of the false-negatives are generally considered as very weak sensitizers. However, polycyclic aromatic hydrocarbons (PAH) such as benzo[a]pyrene (BaP; LLNA EC3 = 0.0009%) and 7,12-dimethylbenz[a]anthra- cene (LLNA EC3 = 0.0006%) require CYP1A1 metabolism in order to be accurately detected. While the activity of some xenobiotic metabolizing enzymes such as CYP1A1 are too low to be observed in human skin and RhE model (Hu et al., 2010), the PAHs showed a tendency to further metabolize PAH (Costa et al., 2010). Evaluation of marker gene expression was found to increase with longer exposure times of BaP (24 & 48 hr) than the standard 6 hr exposure used in the EpiSensA. This indicates that substances like PAHs might have a limitation in the EpiSensA where longer exposure times may be needed to induce metabolic enzymes. In such situations though, the in silico model, TIMES, could be combined with EpiSensA to more effectively detect specific pro-hapto-

*Image 54x661 to 66x673*
**3149 Analysis of Fragrance Ingredients in Sens-IS Assay for Skin Sensitization**

The Sens-IS assay for skin sensitization measures overexpression of selected genes after exposure of chemicals. The assay uses 3D reconstructed human epidermis (EpiSkin®) and involves RT-PCR (reverse transcription polymerase chain reaction) analysis of a group of 17 ARE and 21 Sens-IS genes, which indicate sensitization potential and another group of 23 genes which indicate irritant potential. An inter-laboratory reproducibility and predictivity study reported results on a total of 150 chemicals of which 53 were fragrance ingredients (Cottrez F et al. 2016). Here, we expanded the dataset of fragrance ingredients tested in Sens-IS with an additional 75 ingredients which had existing local lymph node assay (LLNA) and human sensitization data. A total of 128 ingredients had LLNA data and 105 of the 128 ingredients had been categorized into 6 human potency categories (Basketter et al. 2014 and Api et al. 2017). Predictivity of Sens-IS for hazard identification and potency is compared to LLNA and human data. For hazard identification when compared to LLNA, 100 of the 128 ingredients were correctly identified by Sens-IS. Compared to human data 73 of 105 were correctly identified for hazard by Sens-IS. 84 out of 128 were placed in same LLNA potency class by Sens-IS and 55 out of 105 were placed in the same human potency class by Sens-IS. In conclusion, Sens-IS is an alternative in vitro test which could be used to detect sensitization hazard and derive potency class estimate of fragrance ingredients. Differences in assay protocols (e.g., Sens-IS is a maximized test while LLNA and human data may not be available at highest possible test concentrations), applicability domains, and limitations of benchmark LLNA and human potency category used for predicting hazard and potency should be considered in determining performance of the assay.

**3150 An Integrated Testing Strategy for Quantitative Skin Sensitization Risk Assessment by Integration of Multiple In Vitro Assays Using Bayesian Networks and Accounting for Bioavailability**

Skin sensitization is a public health problem associated with high direct and indirect costs. Different in vitro tests are available for assessing the hazard of chemical skin sensitization. Such assays aim to replace or reduce the use of in vivo animal tests (such as the Local Lymph Node Assay - LLNA). Strategies for integrating in vitro methods, in combination with in silico calculations for chemical bioavailability, have been proposed in the literature. We present a framework and an implementation for an integrated testing strategy which combines many OECD recognized in vitro assays related to the skin sensitization adverse outcome pathway. The approach is an extension of the work by Jaworska et al. (BN-ITS-3) [1] and uses a Bayesian network approach to combine multiple evidence and to guide the risk assessment toward which in vitro assay to conduct that would provide the highest value of information. Qsar models were developed to assess the protein binding for chemics and take into account the bioavailability. In this work, we reproduce the results from the BN-ITS-3 approach and introduce additional assays. We also provide a web-based implementation (DC SkinSens) that guides the user through the application of the BN-ITS-3 strategy to assess the chemical potency of skin sensitization (LLNA PE3C). Results could be displayed as a comprehensive report including all input parameters, intermediate calculations as well as posterior probabilities. Results can also be accessed via web services and integrated with analytical workflows. Open tools were favored during this work to ensure reproducibility and encourage adoption by regulators and industry. The Bayesian network was built and trained using the statistical package R. The overall network accuracy for 4-category classification (non-, weak, moderate or strong sensitizers) was 98% while the accuracy of the most confident predictions was 100%. The developed application uses Docker container technology to allow for offline usage. The web application is freely accessible online on https://its.douglasconnect.com [1] Jaworska, J. S.; Natsch, A.; Ryan, C.; Strickland, J.; Ashikaga, T.; Miyazawa, M. Bayesian Integrated Testing Strategy (ITS) for Skin Sensitization Potency Assessment: A Decision Support System for Quantitative Weight of Evidence and Adaptive Testing Strategy. Arch. Toxicol. 2015, 89, 2335-2383.

**3151 A Comparison of CRISPR/Cas9 and siRNA-Mediated ALDH2 Gene Silencing in HepG2 Cell Line**

Aldehyde dehydrogenase 2 (ALDH2) is an enzyme that plays important roles in many physiological and pathological processes. In this study, we gained one HepG2 cell line with a homozygous mutation in the fifth exon of ALDH2 (ALDH2 KO1) using eukaryotic CRISPR/Cas9 expression system followed by limited dilution method and one HepG2 cell line with different mutations in ALDH2 gene (ALDH2 KO2) using lentivirus (CRISPR/Cas9 system). Meanwhile, one ALDH2 knockdown (KD) liver cell line by using siRNA was created to compare with the CRISPR/Cas9-mediated ALDH2 knockout cells. We found that the mRNA expression level of ALDH2 was significantly decreased and the protein expression level of ALDH2 was completely abolished in the two ALDH2 KO HepG2 cell lines but not in ALDH2 KO2 cell lines. Furthermore the functional activity of ALDH2 was also markedly disrupted in the two cell lines, compared to ALDH2 KD and wild-type (WT) HepG2 cells. The absent expression of ALDH2 mediated by CRISPR/Cas9 resulted in more dramatic increase in the susceptibility of HepG2 cells to ethanol or 4-HNE-induced reactive oxygen species (ROS) generation and cytotoxicity, compared to ALDH2 KD and wild-type (WT) HepG2 cells. In conclusion, the ALDH2-KO HepG2 cell lines developed herein may be a better useful tool for identifying ALDH2 function in chemical metabolism, toxicity, and interaction of intracellular molecules.

**3152 Characterization of Human Precision-Cut Liver Slices by Viability and Functional Parameters during 24 Hour Culture**

L. Eleneschneider, J. Knebel, A. Braun, J. Fangmann, and T. Hansen. *Fraunhofer ITEM, Hannover, Germany; and *KRH Siloah Hospital Hannover, Hannover, Germany. Sponsor: C. Dasenbrock.

Precision-cut liver slices (PCLS) represent a valuable *ex vivo* model as they maintain the original structure and cellular composition of the liver. Since, PCLS preserve almost all vital liver functions they can be helpful to investigate various scientific questions in the fields of pharmacology and toxicology. To estimate the extent of inter-donor variation, we conducted an extensive characterization of human PCLS including nine readouts, which covered viability (ATP content, enzyme leakage), functionality (urea production), and histological and descriptive parameters (protein content, wet weight, slice thickness). Liver slices (6 mm in diameter, ~ 280 µm thickness) from healthy tissue of five patients undergoing partial hepatectomy, were prepared and cultured in a dynamic culture system under carbon (95% O2, 5% CO2) gassing for 24h. The quality of the hPCLS was assessed for freshly prepared slices, after the pe-incubation (PI) of 1h and after 24h post PI. In particular the ATP content varied greatly between the different donors. Moreover the histomorphological evaluation of the tissue revealed certain distinctions concerning the steatosis degree and the presence of fibrosis. However, the general histology of the slices reflected the normal liver structure, and the hepatocytes were characterized by their typical polygonal shape. Despite these differences the slices showed a similar behaviour during the culture period. The ATP and protein content were decreased by about 40% during the 24h culture period, whereas urea production showed an overall reduction of 85%. Enzyme leakage after 24 h ranged from 35 to 40 % and the slice thickness remained largely unchanged. In conclusion, human PCLS represent a promising liver model when high quality liver tissue is used and the slices are cultured under optimal conditions.

**3153 Total Number of Benchmark Concentrations from High-Throughput Transcriptionomics and Organotypic Liver Models as Quantitative Indicators of Liver Injury Potential**

As part of Phase III of the Tox21 Program, we are developing more physiologically-relevant approaches to investigate chemical safety/toxicity potential in humans. Initial efforts have focused on developing and integrating organotypic *in vitro* liver screening models (2D & 3D) and high dimensional assay systems (e.g., high throughput transcriptionomics, imaging, & cell health assays). In this presentation, we describe find-
ings with a panel of 24 compounds, using high throughput transcriptomics (using the human S1500+ gene set), that appear to predict liver injury potential by their respective accumulations of benchmark concentrations. The study design involved exposure of HepaRG cell cultures (96h, 10 concentrations, triplicate, half-log spacing) across 3 independent experimental runs. The overall approach was designed to probe the power of the combination-response functions to identify liver injury compounds, identify and resolve gene- and pathway-level perturbations, and quantitatively translate these data to human response data. Here, benchmark response modeling (BMDExpress 2.0) was applied to derive benchmark concentrations (BMCs) at the gene level for each of the 24 compounds with associated pathway injury in to xenobiotic exposures and sufficient xenobiotic metabolism capacity. To address these limitations, we have developed three-dimensional (3D) spheroid models of human bi-potent progenitor cell line, HepaRG and primary rat hepatocytes (Sprague-Dawley) with improved physiological relevance and tissue functionality. When cultured as spheroids in 384-well plates, HepaRG cells exhibit several hallmarks of polarized hepatocytes and tissue-like functionality. Assessment of xenobiotic metabolism competence with clinical substrates of CYP1A2, CYP2B6 and CYP3A4 showed robust levels of basal and inducible enzyme activities that are comparable to ranges produced in Primary human hepatocytes. In a similar culture configuration, primary rat hepatocytes also formed polarized spheroid-like structures observed with 2D cultures of PHHs. In this configuration model, we have demonstrated the use of NAMs for a category of regorafenib hepatotoxicity and indicate that primary hepatocytes are maintained in co-culture after 4 days, but not in hepatocyte culture alone. Ultimately, this model would be a valuable tool for performing mode of action and dose-response studies in support of in vitro-based safety assessment.

High throughput cell-based assays currently employ two-dimensional (2D) tissue culture models that show poor resemblance to tissue architecture and functions with lack integration of pathophysiology. To address these limitations, we have developed three-dimensional (3D) spheroid models of human bi-potent progenitor cell line, HepaRG and primary rat hepatocytes (Sprague-Dawley) with improved physiological relevance and tissue functionality. When cultured as spheroids in 384-well plates, HepaRG cells exhibit several hallmarks of polarized hepatocytes and tissue-like functionality. Assessment of xenobiotic metabolism competence with clinical substrates of CYP1A2, CYP2B6 and CYP3A4 showed robust levels of basal and inducible enzyme activities that are comparable to ranges produced in Primary human hepatocytes. In a similar culture configuration, primary rat hepatocytes also formed polarized spheroid-like structures observed with 2D cultures of PHHs. In this configuration model, we have demonstrated the use of NAMs for a category of regorafenib hepatotoxicity and indicate that primary hepatocytes are maintained in co-culture after 4 days, but not in hepatocyte culture alone. Ultimately, this model would be a valuable tool for performing mode of action and dose-response studies in support of in vitro-based safety assessment.

Regorafenib is a recently approved broad-spectrum kinase inhibitor for cancer treatment. It carries a box warning for hepatotoxicity in the labeling. Regorafenib is metabolized by CYP3A4 and UGT1A9, producing 2- to 20-fold higher than median activities that are comparable to ranges produced in Primary human hepatocytes. We found that regorafenib was significantly more cytotoxic than M2 and M5 in rat hepatocytes. At 2.5-fold human Cmax, lactate dehydrogenase (LDH) leakage at 24 h post-treatment was increased from 18% to 93%, 63% and 22% by regorafenib, M2 and M5, respectively, with IC50s being 8, 18, and >160 µM, respectively. Similar trends were observed with primary canine and human hepatocytes, although the cytotoxicity showed a clear species difference (rat > canine > human). Pre-treatment using a CYP3A4 inhibitor (ketocanozone; 3 µM) significantly increased the cytotoxicity of regorafenib in both rat and human hepatocytes, further indicating that regorafenib is more cytotoxic than its major metabolites. The differential cytotoxicity of regorafenib versus its metabolites correlated with similar differences in mitochondrial toxicity, as M2 and M5 were significantly less toxic to isolated liver mitochondria, indicating mitochondria as a possible target organ of regorafenib. These data provide novel insights into the mechanisms of regorafenib hepatotoxicity and indicate that primary hepatocytes may be used to screen for drug-induced hepatotoxicity.

Extensive in vivo experiments for toxicity testing are cost-prohibitive and not always predictive of human responses. In both the regulatory and the industrial arenas, the goal is to move away from in-life rodent studies and towards safety assessment strategies that rely on testing species relevant cells in vitro. The liver has been a major focus of these efforts, yet there are currently no in vitro alternatives for hepatotoxicity testing accepted by regulators, and the assays that do exist typically utilize hepatocyte monolayer culture or focus on a single phenotypic endpoint. While hepatocytes have been the primary component of in vitro toxicity assay development, it has become increasingly clear that the non-parenchymal cells (NPCs) (i.e., hepatic stellate cells, Kupffer cells, and liver sinusoidal endothelial cells) play a critical role in the progression of liver pathologies. The goal of this study was to develop a multi-functional organotypic co-culture system, in which primary rat hepatocytes are cultured in the presence of NPCs. For a liver culture system to be useful for toxicity testing, it should read out the various mechanisms of action observed in vivo, including those requiring paracrine signaling. We developed a two-dimensional 96-well plate based co-culture system that includes primary rat hepatocyte, stellate, and endothelial cells, which supports hepatocyte viability and phenotype stability for at least 5 days. Importantly, markers of hepatocyte differentiation, including albumin and HNF-4alpha, and hepatocyte polarity are maintained in co-culture for 4 days, but not in hepatocyte culture alone, which lose phenotypic markers after 24 hours in culture. The co-culture showed improved response to the known hepatotoxic stimulants aflatoxin B1 and 2-naphthoflavone. We also determined whether the co-culture could be used to test steatosis using cyclosporin A (10µM cy A). We found that after 4 days in culture, hepatocytes in co-culture robustly accumulated lipids in response to cyc A, whereas the hepatocytes alone showed a weak response that was exacerbated by over-expression of the p53 tumor suppressor. Ultimately, this model would be a valuable tool for performing mode of action and dose-response studies in support of in vitro-based safety assessment.
of treatment. The onset of lipid accumulation was seen at lower concentration with longer exposure periods. A panel of 27 CALUX reporter gene assays and BAC GFP reporter cell lines showed activation of cellular stress pathways in acute exposures (up to 72h). All assays distinguish clearly between in vivo positive and negative compounds. The nominal EC50 values correlate to NOELs of in vivo studies. These data are compared to recent results obtained from repeated exposures of 3D HepaRG cells, P Christophes and zebra fish embryos. We also used an in silico model to predict the corresponding intracellular concentration in the in vitro models. These data are included as additional information into the in vitro to in vivo correlations. This exemplary category approach demonstrates that the data from the EU ToxRisk predict the toxicity of compounds after repeated exposure in a qualitative and quantitative manner. The continued development of integrated testing strategies represents the beginning of a paradigm shift, reducing, and ultimately replacing, in vivo studies in human risk assessment.

3158 Differentiation of Different Liver Toxic Compounds by Metabolomics in HepG2 Cells
S. Sperber1, B. Birk1, V. Haake2, T. Walk1, B. van Ravenzaa1, and H. G. Kamp1. 1BASF SE, Ludwigshafen am Rhein, Germany; and 2Metanomics GmbH, Berlin, Germany.

BASF and metanomics established the database MetaMap Tox containing the plasma metabolome of more than 800 compounds derived from rat studies. Recently, a highly stable and reproducible liver in vitro model was established, in which the intracellular metabolome of HepG2 cells can be specifically altered through treatment with different hepatotoxins. Within the BMBF- and ZonMW-funded project SysBioToP, in which different liver toxicants are currently being tested in different in vitro liver cell systems using imaging technologies, transcriptomics and metabolomics, we have analysed the intracellular metabolome of HepG2 cells treated with valproic acid, paracetamol, ciprofloxazine, and diclofenac, all described to cause liver injury in a human clinical setting. The metabolome consisted of 236 unique metabolites thereof 35 amino acids and derivatives, 11 carbohydrates and related compounds, 54 lipids, 14 energy metabolites, 6 nucleobases, 14 vitamins and cofactors as well as other miscellaneous or unknown metabolites. Our data show that valproic acid, paracetamol, and ciprofloxazine did significantly influence the intracellular liver metabolome whereas diclofenac is only hardly distinguishable from the controls. A principal component analyses shows that valproic acid and paracetamol build clusters of samples separate from control but close to each other, whereas ciprofloxazine builds a cluster which clearly separates from control, but also from the other treatments. The differences in the in vitro metabolome response might be a reflection of the in vivo effects both in terms of the underlying mode of action as well as the potency and frequency of liver injuries in the clinical application.

3159 High-Throughput Microscopy of Adaptive Stress Response Pathway Activation by Steatosis-Inducing Valproic Acid Analogues
N. G. Vrijenhoek1, R. Graepel1, S. E. Escher2, and B. Van de Water2. 1Leiden University, Leiden, Netherlands; and 2Fraunhofer ITEM, Hannover, Germany.

Hepatic steatosis is a common liver disease that can lead to hepatoxicity2. Many drugs, such as the anticonvulstant valproic acid (VPA), induce liver steatosis as a side effect6. In addition to human clinical data, rodent in vitro studies show induction of hepatic steatosis by VPA3.5 and some structural VPA analogues. Transcriptomics data derived from yeast cells suggests that VPA activates several stress response pathways6. This study aims to investigate activation of stress response pathways by VPA and one of its structural analogues. We used HepG2 BAC reporter cell lines as a screening platform to measure changes in stress pathway activity. From Pearson’s correlation and linear discriminant analysis, we identified a subcluster of upregulated genes in response to VPA and one of its structural analogues, which we confirmed by qPCR. Our data supports the relationship between VPA and the p38-mediated activation of the p21 upregulation in a dose and time dependent manner. Little activation of stress responses was observed for in vivo negative analogues. Unknown compounds were categorized according to their response. Controlled addition of fatty acids to lipid free medium allows the assessment of altered stress pathway activation and steatosis formation under different, physiologically relevant conditions. This high content imaging platform to monitor adaptive stress response activation has the potential to contribute to support risk assessment studies by providing mechanistic drug metabolism information that may support a read across approach. 1. 3160 Performance of the OptiSafe Ocular Irritation Assay in a Three-Laboratory Validation Study
N. Choksi1, A. Daniel1, S. Lebrun2, M. Nguyen2, G. DeGeorge1, J. A. Willoughby4, W. Casey2, and D. Allen1. 1ILS Research Triangle Park, NC; 2Lebrun Labs, LLC, Anaheim, CA; 3MB Research Laboratories, Spinnerinstown, PA; 4Cyprotex/Evotec, Kalamazoo, MI; and 5NEHS, Research Triangle Park, NC.

OptiSafe is an in vitro test method that assesses a test substance’s potential to cause eye irritation by measuring damage caused when the substance is applied to a semi-permeable membrane. The membrane system allows the detection of substances with different mechanisms of ocular injury. NICEATM reviewed a study conducted by Lebrun Labs, which developed OptiSafe, and concluded that the study data compared favorably to other in vitro ocular toxicity testing methods. We further assessed the transferability of the method to naive laboratories and the overall performance and applicability domain of the method, NICEATM coordinated a multi-laboratory validation study to evaluate hazard identification of non-surfactants. Phase 1 testing of five chemicals in each laboratory showed that the method could be transferred to naive laboratories. Thirty coded chemicals selected by a validation management team were then tested by all three laboratories in Phase 2. Test method performance was assessed using both the EPA and GHS eye irritation hazard classification systems. Intralaboratory reproducibility for both classification systems ranged from 93% to 99%. Interlaboratory reproducibility was 91% for both classification systems. Interlaboratory accuracy and false negative rates were 89% and 0%, respectively, for both classification systems. The false positive rates were 23% for the GHS classification system and 25% for the EPA classification system. Phase 3 testing of an additional 60 substances provided a comprehensive assessment of test method accuracy and defined the applicability domain of the method. These results suggest that the OptiSafe ocular irritation assay may represent a new tool for in vitro assessment of the ocular toxicity potential of chemicals in a tiered-testing system. This project was funded in whole or in part with federal funds from the NIAMS, NIH under Contract No. HHSN273201500010C.

3161 Characterization of Drug Metabolizing Enzymes, Transporters, and Permeation in a Human Organotypic Corneal Tissue Model
Y. Kaluzhny, M. Kinuthia, T. Truong, A. Lapointe, P. Hayden, and M. Klausner. MatTek Corporation, Ashland, MA.

The corneal barrier is vitally important for eye protection, but also presents a significant challenge for delivery of ophthalmic drugs. Most current studies utilize excised animal corneas that are not suitable for rapid drug screening and also have poor species extrapolation and standardization. To fulfill the need for a physiologically relevant, human-based in vitro system to study ophthalmic drug delivery, we developed an organotypic 3D corneal tissue model. The model contains normal human corneal epithelial cells that grow at the air-liquid interface and develop a tight barrier (1000±250 Ω cm²) that is comparable to the in vivo human cornea, expresses tight junctions, mucus, and key corneal detoxification enzymes. Utilizing a PCR gene array we investigated the expression of 84 Phase I/II metabolizing enzymes and 84 drug transport related genes in the organotypic 3D tissue model and in the isolated human corneal epithelium. High correlation coefficients of r²=0.87 were obtained between gene expression of EpiCorneal tissues and normal human corneal epithelium. Corneal permeability was evaluated using model compounds with a wide range of hydrophobicity, molecular weight, and excipients. The correlation of permeation coefficients to excised animal corneas for model drugs (r²) was 0.84. Various ophthalmic formulations, including Latanaprost and Bimatoprost eye drops...
drops, were administered and their effect on drug absorption, tissue viability and integrity was investigated. As expected, Latanoprost free acid had much lower permeability (Papp=8.0x10⁻⁸) than its prodrug iso-propyl ester form (Alcon, Papp=2.5x10⁻⁸). The presence of 0.02% BAC in ophthalmic solutions significantly affected tissue barrier and viability (analyzed by MTT and LY leakage assays), while BAC-free formulation didn’t have an effect on tissue integrity and viability. Permeability of Bimatoprost in BAC-free Krebs-Ringer buffer (KRB) was 6.3x10⁻³ and 3.7x10⁻⁴ in the vehicle containing 0.02% BAC (Lumigan, Allergan). In summary, the model demonstrates in vivo like structure, barrier and drug metabolizing/transporter expression. Tissue permeability, as well as effects on viability and barrier of various known ophthalmic formulations/excipients is similar to excised corneae. EpICorneal tissue model may be useful in the evaluation of corneal drug permeability and safety during the development of new ophthalmics.

3162 The Role of Oxidative Stress in Dry Eye Disease: Utilization of Human Organotypic Corneal Tissue Model

Y. Kaluzhny, M. W. Kinuthia, T. Truong, A. Lapointe, P. Hayden, and M. Klausner, MatTek Corporation, Ashland, MA.

Oxidative damage plays an important role in many ocular diseases, including dry eye disease (DED). Current methods used to investigate the mechanisms of corneal injuries utilize monolayer cell cultures or animals that result in poor data extrapolation, or low throughput and high cost. As a result, there is a need for more physiologically relevant, human-based in vitro models for ocular research. This study evaluated the utility of an in vitro reconstructed 3D tissue model to study oxidative stress (OS) and DED. The constructs are comprised of normal human corneal epithelial cells that are cultured at the air-liquid interface to produce tissues similar to in vivo corneal structure and express tight junctions, mucins, and keratocyte differentiation enzymes: dehydrogenases, reductases, glucuronosyltransferases, and CYP P450. OS was induced by UV irradiation conditions (SDC) to stimulate morphological, cellular, and molecular changes relevant to DED. Reactive oxygen species (ROS), lipid oxidation, cytokine release, barrier function, tissue viability, histology, and gene expression were evaluated. UV and DSC caused increased ROS, oxidation of lipids, release of IL8 and upregulation of proinflammatory genes. Application of topical lubricants improved tissue morphology, barrier function, and normalized IL8 release. Utilizing a PCR gene array we investigated the effect of UV irradiation (60 mJ of UVB, 2h post-incubation) and DSC (60% RH, 40°C, and 5% CO₂, 24h) on the expression of 84 genes related to OS. 6 genes were >2-fold upregulated in UV-treated cultures compared to untreated controls, including genes involved in ROS metabolism, peroxidases, and serine peptidase inhibitor SPINK1. 15 genes were >2-fold upregulated in DED tissues compared to control, including antioxidants and PTGS2 (COX-2) peroxidases, SPINK1, OS responsive gene HMOX1, and other genes involved in superoxide metabolism - ALOX12 and NOS2. In both UV-irradiated and DED tissues OS pathway signature genes, SPINK1 and HMOX1 were upregulated. The in vitro reconstructed normal human corneal tissue model structurally and functionally reproduces OS and DED markers. Gene expression changes in OS-exposed EpICorneal tissues closely parallel in vivo changes associated with inflammatory response. This model is anticipated to be a useful tool to study molecular mechanisms of ocular surface damage, DED, and to evaluate new corneal drug formulations.

3163 Improvement of the Predictive Performance Including Highly Volatile Substances by the Short Time Exposure Test Method for Assessing Ocular Irritation

T. Yuki1, T. Abo2, Y. Takahashi1, S. Alvar3, J. Avalos4, and H. Sakaguchi1. 1Kao Corporation, Tochigi, Japan; 2Kao Corporation, Odawara, Japan; 3Kao Corporation S.A., Barcelona, Spain; and 4Kao USA Inc., Cincinnati, OH.

The short time exposure (STE) test method was developed as an in vitro alternative test for eye irritation, and is now adopted as the OECD Test guideline (TG) 491. In OECD TG491, when GHS (Globally Harmonized System of Classification and Labelling of Chemicals) No Category (NC) was classified in bottom-up approach, highly volatile substances (>6kPa) were excluded from applicability domain because these substances have a potential to be evaluated as false-negatives. Recently, we found that highly volatile substances could be correctly classified in OECD TG491 by changing the test solvent from saline to mineral oil for the highly volatile substances. In this study, we evaluated the predictive performance of the GHS classification with 78 substances from the Draize eye test Reference Database in Barroso (2017) and 22 high volatile substances, where the dilution solvent used was mineral oil. When the 100 substances were evaluated by OECD TG491 using saline for highly volatile substances, seven substances were determined as false-negatives: Ethanol, methyl acetate, acetone, isopropl alcohol, 2,6-dichlorobenzyl chloride, ammonium nitrate and camphene. On the other hand, only 3 false-negatives were found when mineral oil was substituted for the saline solvent. 2,6-Dichlorobenzyl chloride, ammonium nitrate and camphene. The change of test solvent had a profound effect on the outcome of the results and predictability. The sensitivity improved to 91.2% from 79.4%, and the false negative rate improved (i.e., dropped) to 8.8% from 20.6%. Overall, the change in test solvent for highly volatile substances makes the STE test a suitable method to classify GHS No Category.

3164 Not Quite There: BASF’s Experience in Replacing the Acute Toxicity Tests for Agrochemical Formulations

S. N. Kolle1, A. W. van Cott2, C. E. Hastings3, B. van Ravenzwaay4, and R. Landsiedel1. 1BASF SE, Ludwigshafen am Rhein, Germany; and 2BASF Corporation, Research Triangle Park, NC.

Acute toxicity testing is routinely conducted on agrochemical formulations as a regulatory requirement. Several non-animal methods have gained regulatory acceptance but their predictive capacity for agrochemical formulations is usually unknown. We report here our experiences in vitro methods for in vitro testing approaches for skin irritation/ corrosion, (severe) eye irritation, and acute oral, dermal and respiratory toxicity. Skin irritation/ corrosion: Comparing in vivo and in vitro skin irritation and corrosion data indicates a lack of applicability of the current protocol of the in vivo skin irritation test (OECD 439) for agrochemical formulations. Severe eye irritation: None of the evaluated protocols (HetCam, BCOP (OECD 437), two modified BCOP protocols, ICE (OECD 438), EpiOcular™ ET-50) was sufficiently sensitive to predict UNGHS Cat 1 agrochemical formulations correctly. The EpiOcular™ EIT (OECD 492) was predictive for non-irritants and agrochemical formulations have been taken up in the OECD test guideline of Acute oral, dermal and respiratory toxicity: Comparing experimentally derived classification to the GHS additivity approach for acute oral, dermal and respiratory toxicity used for formulations containing at least one toxic ingredient falsely characterized the hazards of formulations with interacting ingredients. The toxic chemical(s) in the formulation do not interact with other ingredients of the formulation. References: Schrage A, Gamer AO, van Ravenzwaay B, Landsiedel R. (2017) Regulatory accepted but out of domain: In vivo skin corrosion and irritation tests for agrochemical formulations. Regul Toxicol Pharmacol.

3165 Exploring a New Toolbox for Repeated Dose Systemic Toxicity Assessment: First Application to a Cosmetic Ingredient

Concerns about long-term repeated-dose toxicity (RDT) assessment have been raised since the ban on animal testing for cosmetic ingredients. The development of innovative in vitro methods that are able to reproduce the physiological functionality of specific human organs has become essential in order to address the current challenges for risk assessment purposes. The screening of legacy data showed that liver and kidney were the most targeted organs by cosmetic ingredients in RDT studies in vivo (Vinken et al. Arch. Toxicol. 2012). Therefore, we evaluated a panel of traditional and emerging technologies in order to develop a new in vitro assays architecture for RDT assessment. This toolbox included models from simple organelle-targeted assays such as mitochondria to more complex multi-organ on a chip microfluidic systems (liver/heart organ-on-chip). We first characterized and calibrated all the models with a set of well known compounds such as acetaminophen, anidorenone, etc... Then, we evaluated this toolbox as a regulatory requirement. Several non-animal methods have gained regulatory acceptance but the predictive capacity for agrochemical formulations is usually unknown. We report here our experiences in vitro methods for in vitro testing approaches for skin irritation/corrosion, (severe) eye irritation, and acute oral, dermal and respiratory toxicity. Skin irritation/corrosion: Comparing in vivo and in vitro skin irritation and corrosion data indicates a lack of applicability of the current protocol of the in vivo skin irritation test (OECD 439) for agrochemical formulations. Severe eye irritation: None of the evaluated protocols (HetCam, BCOP (OECD 437), two modified BCOP protocols, ICE (OECD 438), EpiOcular™ ET-50) was sufficiently sensitive to predict UNGHS Cat 1 agrochemical formulations correctly. The EpiOcular™ EIT (OECD 492) was predictive for non-irritants and agrochemical formulations have been taken up in the OECD test guideline of Acute oral, dermal and respiratory toxicity: Comparing experimentally derived classification to the GHS additivity approach for acute oral, dermal and respiratory toxicity used for formulations containing at least one toxic ingredient falsely characterized the hazards of formulations with interacting ingredients. The toxic chemical(s) in the formulation do not interact with other ingredients of the formulation. References: Schrage A, Gamer AO, van Ravenzwaay B, Landsiedel R. (2010) ATLA Alternat Lab Anim. 38(1):39-52; Kolle SN, Rey Moreno MC, Mayer W, van Cott A, van Ravenzwaay B, Landsiedel R. (2015) ATLA Alternat Lab Anim. 43(3):181-98; Kolle SN, Van Cott A, van Ravenzwaay B, Landsiedel R. (2017) Regul Toxicol Pharmacol. 85:33-47; Kolle SN, van Ravenzwaay B, Landsiedel R. (2017) Regulatory accepted but out of domain: In vivo skin corrosion and irritation tests for agrochemical formulations. Regul Toxicol Pharmacol.
chronic in vitro cardiotoxicity was also confirmed using the multi-organ on chip system. Moreover, one suspected mode of action for this compound was found to be through mitochondrial alterations. Next steps will consist of 1) evaluating a larger set of proprietary compounds to further calibrate the models and 2) integrating the kinetics to increase the predictivity of the models.

**3166 A Retrospective Study on Agro-Formulations Comparing Classifications Based on Testing Data and GHS Additivity Formula**

S. P. Ng, M. Battalora, K. A. Mikles, and T. L. Serey, E. I. du Pont de Nemours and Company, Newark, DE.

Acute six-pack toxicity testing is commonly used in the agrochemical industry for regulatory and product stewardship purposes. Alternative methods are available but acceptance is still limited due to inadequate validation or uncertain predictivity. A retrospective study of 13 formulations was performed to compare CLP (EU GHS) classification outcomes based on animal testing of formulations and those obtained with the GHS additivity formula. The calculation method correctly predicted the classifications in all categories in acute oral (92%), acute dermal (100%), acute inhalation (77%), skin irritation (85%), eye irritation (31%), and skin sensitization (31%). The high accuracy of acute dermal prediction could be due to the fact that the formulations were not toxic at all by this route, further supporting the conclusion that this endpoint may not be relevant for agrochemical formulations. For the acute lethality end-points and skin irritation, only small percentages of over- (8, 15, 15% of oral, inhalation, skin irritation) and under- (8% of inhalation) classification were observed. However, in the cases of eye irritation, the calculation method tends to over-classify, development, the prediction is hardly reliable with only 31% matched, 46% over-, and 23% under- classification. Results showed that the calculation method predicts well for acute oral classification, while reliability for eye irritation and skin sensitization is low. Clearly, the method for skin sensitization classification using the additivity rules may not be appropriate and other factors may need to be considered. For example, the comparison made to the specific animal model may be a confounder as the human potential for skin sensitization may be over-predicted using these models. The database will be expanded and the potential impact of % components without toxicological information on the reliability of this method will also be analyzed.

**3167 Approaches for Increasing Acceptance of Physiologically-Based Pharmacokinetic Models in Public Health Risk Assessment**

Physiologically-based pharmacokinetic (PBPK) models have great potential for application in regulatory and non-regulatory public health risk assessment. The development and application of PBPK models in chemical toxicology has grown steadily since their emergence in the 1980s. However, the use of PBPK models to support risk assessment across federal agencies has thus far occurred for only a few environmental chemicals (ex: methylene chloride, chlorpyrifos). To encourage decision makers to embrace PBPK modeling to better understand the underlying toxicological mechanisms of environmental chemicals, the modeling community must address several critical challenges. The challenges include: (1) limited number of peer reviewers with appropriate PBPK modeling experience; (2) lack of confidence in PBPK models for which no data exist for model evaluation; and (3) lack of consensus on computing platforms. Approaches to address these issues include improved training for both model developers and reviewers, development of templates to facilitate submission and review of PBPK models at public health agencies, increasingly sophisticated techniques for model parameterization and extrapolation that do not rely on in vivo data, and more frequent and open communication about the model development process and the available computing platforms. We provide these suggestions to initiate dialogue among members of the PBPK modeling community, as these issues must be overcome for the PBPK modeling field to advance, especially in regards to its application in public health risk assessment.

**3168 Unification of Exposure and Pharmacokinetic Tools under the PLETHEM Framework**

The EPA Office of Research and Development’s 2003 framework for computational toxicology emphasized the need for computational methods to bridge the source-to-outcome continuum. This goal can be achieved by linking exposure estimation methods, physiologically based pharmacokinetic (PBPK) modeling, and computational systems biology pathway modeling tools into a standardized framework. To that end, we have developed the Population Lifecourse Exposure To Health Effects Model (PLETHEM) suite, a modular open source modeling platform that provides users the ability to create, share, and audit PBPK models and connect them to existing exposure tools. The platform consists of a database of chemicals, QSAR models, life-course equations, and metabolism parameters needed to perform PBPK modeling, an R-based engine to perform model simulations, and an interactive user interface to define and select parameter sets for the models. PLETHEM includes the ability to run Monte Carlo analyses to investigate population variance and a set of life course equations to investigate life stage based sensitivities. The PLETHEM database also incorporates ontology profiles for key metabolic enzymes that can be used to calculate in vivo metabolic clearance using measured in vitro clearance. The current version of PLETHEM implements easy to use interfaces for a generic PBPK model and a High-Throughput IVIVE model. These model interfaces along with the including the database provides capabilities necessary for rapid analysis of chemicals using PBPK modeling. PLETHEM is currently available as an R package though open source repositories. We plan to incorporate EPA/NCTR’s HTTK modeling package and provide an interface to multiple exposure estimation tools as the development continues. This research was funded by the American Chemistry Council and is being conducted under a Memorandum of Understanding with the US EPA.

**3169 Evaluation of Platforms Used for Fit-for-Purpose PBPK Modeling in Chemical Safety Assessment**

Physiologically-Based Pharmacokinetic (PBPK) modeling is an ever-growing discipline in the field of toxicology and risk assessment. In recent years, it has been increasingly recognized that there is a need for tools (i.e., platforms, software, coding languages) fit for the purpose of specific modeling requirements (e.g., pharmaceuticals, cosmetics, pesticidal) or user types (i.e., developer, regulator, student). Many programs are based on specific chemical or physiological models suited to solve narrow issues of interest to the developer. The Joint Research Center of the European Commission recently conducted a survey of the modeling community regarding software platform use (Paini et al., 2017). As part of the survey, the community was asked what platform was used for PBPK modeling, and found that platform requirements varied depending on purpose, and that a large fraction of modelers used aciX, which is no longer available for purchase or technical support. We have put together an evaluation of over 50 PBPK modeling platforms in order to assess the circumstances in which their various capabilities are most useful. The criteria used in the evaluation included accessibility, basic features (e.g., interface type, code sorting, scripting, cost and speed), and advanced features (e.g., parameter sensitivity, optimization, uncertainty analysis). Based on the results of the review, we found that key options include multiple factors, including accessibility, user profile and intended use (e.g., pharma, regulation, or research), interface (i.e., graphical versus command line), programming expertise, and ability for code review. This comprehensive review provides a detailed snapshot of the capabilities of currently available PBPK modeling platforms, providing a basis for determining which of the platforms are most suitable for applications of interest to different communities of users and developers.
Over the last three decades physiologically-based pharmacokinetic (PBPK) modeling has emerged as a vital quantitative tool complementing in vivo and in vitro research in pharmacology and toxicology, widely used for both basic research and regulatory purposes. Yet the field of PBPK modeling lacks a freely available cross-platform simulation program that can be used by educators, modelers and model evaluators alike without specialized coding skills in a particular programming language or environment. To address this gap, we have developed PyPK, a Python-based PBPK modeling program with a simple and intuitive graphical user interface that allows ordinary differential equation-based model coding, simulation and output visualization, with additional modules for parameter sensitivity analysis, uncertainty analysis, and population variability modeling. The program is freely available as a Python package that runs on Windows, macOS and Linux platforms to ensure usability and easy model exchange among academic and industrial scientists as well as regulators. To illustrate the capacities of PyPK, we used a well-developed multi-route PBPK model for the uptake and accumulation of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) in the mouse, and in the liver and fat compartments using this modeling tool. We are also developing thorough documentation and tutorials that can be used in a classroom setting to teach PBPK modeling using PyPK, as well as facilitate model development by professionals in pharmacology and toxicology.

**3170 PyPK: A Free, Open-Source Cross-Platform Program for Physiologically-Based Pharmacokinetic (PBPK) Modeling**

D. Filipovic, and S. Bhattacharya, Michigan State University, East Lansing, MI.

The pharmaceutical industry makes thousands of compounds every month, many of which do not show the desired efficacy or ADME properties. Studies show that low dose compounds are less likely to have black box warnings and serious adverse events. The ADME properties of a drug are key to determining the dose required for efficacy. ADME parameters such as lipophilicity, solubility, permeability and metabolic stability can be measured in high throughput in vitro assays and are often used as early screens in the decision making process. During lead optimization a substantial number of compounds are synthesized and characterized for selection towards further, more costly in vitro and in vivo experiments with the aim of selecting a single candidate drug. However, a compound needs to be physically made in order to be tested in such assays. In silico models for ADME endpoints have been available for a long time, though with varying quality and usability. Ideally, such models should be used before synthesis and, together with any potency estimation for a compound, influence the decision to make a compound. Thus, the number of compounds made with inadequate properties should be reduced considerably. In practice however, only one or two predicted properties are typically considered prior to synthesis, usually these include a prediction of lipophilicity. While it is widely understood that all available knowledge should be used to select which compound to make, it is not easy to combine the overall outcome of the various predictions unambiguously. Lately, the use of multiparameter optimization and scoring tools has been proposed. However, the scoring functions used in these tools need to be defined and are often subjective. Predicting the human dose early on, especially based on in silico data only, maybe too speculative to be of real use before synthesis. This work investigates whether a combination of in silico ADME models can be used to define a minimum potency level required for an acceptable human dose, for example 100mg per day, with high enough confidence. This approach could then also be used for an estimate of the likely maximum concentration reached at that dose thereby give an indication of the expected therapeutic window. Using a set of project compounds in silico ADME models will be utilized, to rank the compounds, based on both the resulting minimum potency level and an estimation of the therapeutic window, and to compare the outcome with the actually selected lead compound.

**3171 Applying a Global Sensitivity Analysis Workflow to Improve the Computational Efficiencies in Physiologically-Based Pharmacokinetic Model**

N. Hsieh1, B. Reisfeld2, F. Y. Bois3, and W. A. Chiu1. 1Texas A&M University, College Station, TX; 2Colorado State University, Fort Collins, CO; and 3Institut National de l’Environnement Industriel et des Risques, Verneuil en Halatte, France.

Traditionally, the usual solution to reduce parameter dimensionality in the physiologically based pharmacokinetic (PBPK) model is through expert judgment. However, this approach may lead to lower efficiency and substantial bias in parameter estimates. The purpose of this study is to propose a global sensitivity analysis (GSA) algorithm to ascertain which parameters in a PBPK model are non-identifiable, and therefore can be assigned fixed values to improved speed and convergence in Bayesian parameter estimation with minimal bias. We used a well-developed, published population PBPK model that can predict and characterize the absorption, distribution, metabolism, and excretion of acetaminophen (APAP) with two major metabolites of APAP-glucuronide and APAP-sulfate in humans. The Morris Elementary Effects method and three variance-based sensitivity indices (Fourier amplitude sensitivity testing, Jansen, Owen) were used to determine the sensitive parameters in the original model. We also inspected all PBPK parameters that include the previously-fixed parameter in our simulation. The hierarchical clustering approach was used to determine the sensitive parameter that can be used to calibrate model performance. We then performed computational experiments using a hierarchical Bayesian approach with different GSA-judged sensitive parameters to verify and compare the predicted results. We identified the sensitive parameters that can significantly impact the performance in the PBPK model, with the three variance-based GSA estimators giving similar results in our cases. Twelve of the 21 original parameters have low sensitivity with respect to the outputs, and can be fixed to improve computational efficiency without any discernable change in accuracy or precision of the predictions. We further found 10 additional sensitive parameters among the 39 parameters that were previously fixed in the published PBPK model. By adding these additional sensitive parameters, we can improve model performance beyond the that of the original publication, while maintaining computational efficiency. In conclusion, we propose that this GSA approach provides an objective, transparent, and reproducible approach to improve the performance and computational efficiency of PBPK models.

**3173 The Construction and Application of a Population Physiologically-Based Pharmacokinetic Model for Methadone in Beagles and Greyhounds**

T. Elwell-Cuddy, M. Li, B. Kukanich, and Z. Lin, Institute of Computational Comparative Medicine (ICCM), Department of Anatomy and Physiology, Kansas State University, Manhattan, KS.

Methadone is an analgesic opioid in veterinary and human medicine. To help develop appropriate pain management practices and to develop a quantitative model for predicting methadone dosimetry, a flow-limited multi-route physiologically based pharmacokinetic (PBPK) model for methadone in dogs constructed with Berkeley MadonnaTM was developed. The model accounts for intravenous (IV), subcutaneous (SC), and oral administrations, and compartmentalizes the body into different components. This model was calibrated from plasma pharmacokinetic data after IV administration of methadone in Beagles and Greyhounds. The calibrated model was evaluated with independent data in both breeds of dogs. One advantage of this model is that most physiological parameter values for Greyhounds were taken directly from the original literature. The developed model simulates available pharmacokinetic data for plasma concentrations well for both breeds. After conducting regression analysis, all simulated datasets produced an R²>0.80 when compared to the measured plasma concentrations. Comparative analysis of the dosimetry of methadone between the breeds was completed, which determined Beagles receive a higher methadone AUC concentration. This model can be used to predict methadone concentrations in multiple dog breeds by using breed-specific parameters. This model could help design optimal therapeutic regimens for methadone in veterinary and human medicine via interspecies extrapolation.
Penicillin is one of the more widely used antimicrobials and also one of the most frequently identified volatile drug residues in food-producing animals due to extralabel use. The majority of violations of penicillin were found in bulk dairy cows, leading to concerns for the safety of milk. In the United States, procaine penicillin G is approved to use in dairy cows through intramuscular (IM) and intramammary (IMM) administrations. Physiologically-based pharmacokinetic (PBPK) models are useful tools to predict withdrawal intervals and tissue residues of drugs in food animals to ensure safety of animal-derived foods, especially after extralabel drug use due to the scarcity of experimental data after extralabel administrations. Currently, no PBPK model is available to predict penicillin concentrations in milk. In this study, a PBPK model with a physiologically based mammary gland compartment was established for penicillin G in dairy cows. The model well predicted the tissue and milk residues of penicillin G from previous pharmacokinetic studies. The predicted milk discard interval of procaine penicillin G with 10x label dose for 3 repeated IM administrations was 10 days. For IMM infusion, predicted results showed that extralabel doses did not lead to violative tissue residues in healthy dairy cows. The predominant violations found in bulk dairy cows may be caused by mastitis or other disease conditions, which have impacts on penicillin distribution. The current PBPK model, coupled with population analysis can help predict milk discard interval for penicillin following extralabel use through IM and IMM administrations.

Due to the increase use of gold nanoparticles (AuNPs) in biomedical applications, there is a major concern regarding their potential risk on human health. This study conducted an integrated and probabilistic risk assessment of AuNPs based on published in vitro and in vivo toxicity studies coupled to a physiologically based pharmacokinetic (PBPK) model. Dose-response relationships were characterized based on cell viability assays in various human cell types. Previously, a well-validated human PBPK model for AuNPs was applied to quantify internal concentrations in liver, kidney, skin and venous plasma. By applying a Bayesian-based probabilistic risk assessment approach incorporating Monte Carlo simulation, probable human cell death fractions were characterized. Additionally, we implemented in vitro to in vivo and animal-to-human extrapolation approaches to independently estimate external exposure levels of AuNPs that caused minimal toxicity. Our results suggest that under the highest dosing level employed in existing animal studies (worst-case scenario), AuNPs coated with branched polyethyleneimine (BPEI) would induce ~90-100% cellular death, implying severe cytotoxicity compared to ~10% cell death induced by low-to-medium dosing levels commonly used in animal studies. The estimated human equivalent doses associated with 5% cell death in liver and kidney were 1 and 0.5 mg/kg, respectively. Our analyses provide insights into safety evaluation, risk prediction, and threshold recommendations for AuNP exposure for humans and illustrates an approach that could be applied to other NPs if sufficient data are available. Supported by Kansas Bioscience Authority funds to ICCM and NICKS.
Confidence in the predictive capability of a PBPK model is increased when the model is demonstrated to predict multiple pharmacokinetic outcomes from diverse studies under different exposure conditions. We previously showed that our multi-route human BDCM PBPK model adequately (within ~2.5-fold) predicts both blood and urine BDCM concentration data from human exposure studies; activities in these studies included drinking, bathing, showering and swimming. Here, we evaluated the ability of the model to predict an exposure biomarker, the concentration of BDCM in exhaled breath (exBDCM). Four human subject studies of swimmers (dermal, inhalation exposure) and/or pool attendants (inhalation only) were modeled. The model adequately predicted exBDCM for both sedentary (pool monitors) and exercising (swimmers) subjects in two studies. In contrast, exBDCM was over-predicted by a factor of 3- to 5-fold for swimmers in a third study and under-predicted by 4- to 5-fold for sedentary subjects in a fourth study. The model’s ability to predict exBDCM was better in studies where sufficient data were available to estimate alveolar ventilation rate and cardiac output, e.g. time and distance swum, estimated energy expenditure. Under-prediction of exBDCM may be attributable sample dilution due to collection of total exhaled breath. Model parameters have varying degrees of influence on model output. Global sensitivity analysis revealed that the most influential parameters affecting exBDCM were: blood-to-air partition coefficient, cardiac output, alveolar ventilation rate, and skin diffusion coefficient. Of these parameters, cardiac output and alveolar ventilation rate have the greatest variability and uncertainty, especially in exercising subjects. In summary, when comparing PBPK model-predicted exBDCM to data from independent exposure studies, a clear understanding of study design and sampling methods is critical. Further, expanded utility of human exposure data can be achieved by utilization of PBPK modeling in the study design phase. This abstract does not reflect US EPA policy.

Factors Influencing Prediction of Bromodichloromethane (BDCM) in Exhaled Breath: Further Evaluation of a Human BDCM Physiologically-Based Pharmacokinetic Model

Volatile organic compounds (VOCs) in drinking water can cause acute or chronic injury to the liver, kidneys, and/or central nervous system. Exposure to VOCs in contaminated water can occur via multiple routes, such as ingestion, inhalation, and dermal. The extent to which each of the various routes of exposure contributes to internal dosimetry and toxicity is an important question. Because of the large number of VOCs and limited data, computer simulations can be used to predict dosimetry in target organs of concern. Experimental data from carbon tetrachloride (CCl4) show how exposure route impacts hepatotoxicity in rats. Here, a physiologically based pharmacokinetic (PBPK) model is developed to simulate CCl4 exposure in Sprague-Dawley rats (0.325 - 0.375 kg) by multiple routes. The inhaled concentration of carbon tetrachloride was 1000 ppm for two hours, which corresponds with 179 mg CCl4 /kg body weight for bolus and for two hours of gastric infusion. The different exposure routes and available tissue datasets allowed us to calibrate a PBPK model for CCl4, including liver as the target organ. The model estimates of amount metabolized over 24 hours (bolus 1.2 mg, infusion 1.4 mg, and inhalation 1.2 mg) did not match with the toxicity trend (SDH = 269 mU/mL, 96.9 mU/mL, and 87.6 mU/mL, respectively), but other animals, thus streamlining future VOC experiments.

Prediction of Internal Dosimetry and Toxicity of Volatile Chemicals in Rats Using Physiologically-Based Pharmacokinetic Modeling: Carbon Tetrachloride as a Model Compound

The Fate of Inhaled Electronic Cigarette Puffs in the Lungs of Potential Users

Rapid increase in the use of electronic cigarettes (e-cigarettes) and the lack of data regarding the resulting aerosol and vapor characteristics necessitates that new studies evaluate the fate of e-cigarette puffs in the oral cavity and lower respiratory tract. A mathematical model was developed to determine the transport and deposition of e-cigarette aerosols in the lung during puff withdrawal, mouth hold, inhalation, lung hold, and exhalation. The oral cavity and lung geometry were reconstructed from cast measurements and available morphometry. The resulting mixture dynamics included constituent phase change, droplet hygroscopic growth, and coagulation of droplets. The transport and deposition of droplets and uptake of gas components of the aerosol mixture were based on material mass balance (convection-diffusion equation). The model for droplet transport included a sink term, which replaced the boundary conditions in deriving the solution for droplet concentration. The sink term was the net deposition efficiency formulae by external forces such as gravity, inertial impaction, and Brownian diffusion. The vapor uptake model was based on the steady-state 2-D solution of the transport model. The transport models for droplet and vapor components of potential e-cigarette puffs were coupled with the droplet phase change (Maxwell’s equation) and coagulation (Smoluchowski’s equation). A puff was assumed to include nicotine, water vapor, glycerin, and propylene glycol. Tissue doses were from both the vapor and droplet phases and were constituent dependent. Vapor contribution increased with increasing constituent saturation vapor pressures. Model predictions indicated a total of less than 10% deposition and uptake of the e-cigarette aerosol mixture in the oral cavity and up to 90% total deposition in the respiratory tract. These results are consistent with reported values in the literature. This work was supported by the US FDA Center for Tobacco Products. This is not a formal dissemination of information by US FDA and does not represent Agency position or policy.

Prediction of Internal Dosimetry and Toxicity of Volatile Chemicals in Rats Using Physiologically-Based Pharmacokinetic Modeling: Carbon Tetrachloride as a Model Compound
D. N. Williams, J. E. Simmons, J. V. Bruckner, and M. V. Evans. 1Oak Ridge Institute for Science and Education, Oak Ridge, TN; 2US EPA, Research Triangle Park, NC; and 3University of Georgia, Athens, GA.
Pilots of high-performance aircraft (HPA) may be exposed to various chemical irritants passing through the onboard oxygen generation system. Work was previously conducted using physiologically-based pharmacokinetic (PBPK) modeling and Monte Carlo analysis to estimate distributions of exposures that could result in the target exhaled breath measurements from a High-Performance Aircraft Respiratory Study (HPARS). These reconstructions allowed for the determination of possible exposure distributions across a range of exposure lengths and times, or scenarios, that might be experienced by pilots during flight, but did not account for differences in pharmacokinetics due to flight conditions such as altitude and G forces. The next step, therefore, in this ongoing work is to incorporate descriptions of physiological changes occurring as a result of flight into the existing PBPK model. The end goal of this work is to develop a PBPK model for a virtual pilot to better assess potential in-flight chemical exposures and produce aircraft cockpit exposure guidelines that will ensure limited probability of contaminated cockpit spaces that might contribute to coughing/respiratory symptoms or can be considered a contributing factor in reported symptomology. The work presented here utilizes an updated PBPK model with descriptions for changes in ventilation and cardiac output due to altitude and breathing air oxygen levels as well as changes in tissue blood flows due to G forces. The new PBPK model was applied to reconstruct doses for isopropanol, acetone and toluene based on the HPARS in a manner similar to the previous work augmented by the incorporation of physiological changes due to flight. These reconstructions allowed for the determination of possible exposure ranges experienced during flight, which were then compared to established short-term exposure limits (STELs). Some modeled in-flight concentration isocones for isopropanol exceeded post-sortie breath samples by more than a factor of 1000 and established STELs by more than a factor of 100. By expanding the current PBPK model paradigm to the physiological changes of HPA flight, a capability has been developed to assess true pilot physiology in a “virtual” context.

**3184 Pharmacokinetic (PK) Modeling to Evaluate the Effect of Serum Protein Binding on Bone Marrow Toxicity from Chloramphenicol Eye Drops**

A. E. Loccisano,1 and B. D. Kerger.1 Exponent, Alexandria, VA; and 2Exponent, Irvine, CA.

Chloramphenicol (CAP) is an antibiotic produced by soil bacteria and has been used for decades in systemic treatment of bacterial infections and for topical treatment of eye infections. Natural occurrence in soil results in CAP uptake by crops as a source of low level dietary exposure. CAP intake has also been associated with veterinary and aquaculture use to prevent microbial impacts; however, dietary exposure generally corresponds to lower daily doses than CAP-containing eye drops. Concerns about the risk of rare (1 in 20,000 treated cases) but often fatal aplastic anemia following systemic antibiotic doses of CAP led to banning or strict limitations on clinical, veterinary, and agricultural use. CAP-containing eye drops have not been shown to cause aplastic anemia, which is likely due to lower systemic exposure and high serum protein binding that reduces absorption.

Bone marrow (BM) toxicity requires a sufficient dose and steady-state concentration of unbound CAP in the target tissue. At high doses and/or in cases where serum protein binding of CAP is severely limited, a greater amount of unbound CAP may reach BM and induce cytotoxicity. Amination of metabolites was used to simulate the concentration of BM CAP in blood and BM resulting from a systemic therapeutic dose, a systemic BM toxic dose, from food exposure, and from use of CAP eye drops. Simulations were performed assuming normal (50-60%) and severely depressed serum protein binding (20-30%). Steady state serum concentrations of unbound CAP resulting from eye drop use (0.0055 mg/kg) were 2300- to 4050-fold lower than those resulting from a systemic therapeutic dose (12.5 mg/kg) or a BM toxic dose (22 mg/kg), respectively. Unbound CAP concentrations from dietary exposure were 6.5 to 12.7 million-fold lower than those resulting from systemic therapeutic or BM toxic doses, respectively. These findings suggest that BM toxicity from CAP eye drops and low level dietary CAP exposure is likely negligible. Lower fractions of bound CAP in serum resulted in a higher concentration of unbound CAP reaching BM in all dosing scenarios. The PK model predicts that severely depressed serum protein binding allows for more unbound CAP to reach BM and could be an explanation for the rare outcome of aplastic anemia following systemic dosing regimens.

**3185 The Impact of Genetics on the Pharmacokinetics of Chemicals in a United States Air Force Population**

H. A. Pangburn1, J. P. Jarvis,2 T. Covington,1 D. K. Ott,1 and J. M. Gearhart1,3 1US Air Force School of Aerospace Medicine, Wright Patterson AFB, OH; 2Canine Institute for Medical Research, Camden, NJ; and 3Henry Jackson Foundation, Bethesda, MD.

Genetic variability continues to be a component of interest in assessing the expected impact of chemical exposures on human health. Until the advent of modern “omics” rapid assessment technologies, broad assessment of genetic variation on individualized outcomes was limited to single gene variants. Here, we explore the potential contribution from the DMET™ Plus array, measured on ~2000 personnel in the Air Force Medical Service (AFMS) Patient-Centered Precision Care (PC2-Z) Program as implemented by the Corell Personalized Medicine Collaborative (CPMC). We assessed the expected impact of genetic variation in metabolic and transporters on the exposure related to commonly encountered in the U.S. Air Force environment. Specifically, 10 putatively functional variants in CYP2E1 (Cytochrome P450, Family 2, Subfamily E, Polypeptide 1) were chosen for initial consideration given the role of this locus in processing volatile organic chemicals (VOCs) such as isopropyl alcohol, cyclohexane and alphatic hydrocarbons. Measured CYP2E1 variation and its expected impact were then incorporated into analyses via PK-Sim® (Bayer) Open Systems Pharmacology Suite to assess the likely influence of genetic variants on blood time course of the aforementioned chemicals. Simulated area under the curve measures for the different chemicals examined varied by as much as one order of magnitude depending on individual CYP2E1 genetic status.
indicating the need to expand assessment of the genetic architecture of detoxification downstream of this key enzyme step. Application of these genome-informed insights will allow a refined estimate of expected exposure response and potentially the prediction of personalized health outcomes.

3186 Modeling the Dynamics and Dosimetry of Electronic Nicotine Delivery Systems (ENDS) Aerosols in the Oral Cavity

Electronic nicotine delivery systems (ENDS) heat liquids containing nicotine, water, propylene glycol, and glycerin and deliver an aerosol mixture that is inhaled by the user. ENDS aerosol deposition is difficult to quantify in the respiratory tract due to thermodynamic changes and variable breathing maneuvers during ENDS usage. An anatomically realistic computational fluid dynamics (CFD) model of the oropharyngeal airway was used to simulate ENDS aerosol deposition during puffing maneuvers. A transient moving boundary procedure was implemented by manipulating the geometry of the anterior oral airway to simulate the predicted anatomic changes of the oral cavity during ENDS use. ENDS aerosols were assumed to be initially composed of droplets containing 1% water, 5% nicotine, 30% propylene glycol, and 65% glycerin. A droplet size at a constant volume of 10^10 #/ml. Aerosol dynamics in the CFD simulations consisted of droplet coagulation, constituent evaporation, and water vapor condensation, along with droplet deposition and vapor uptake on the oral airway boundary. CFD simulations of the inhaled airflow and ENDS aerosol transport and deposition were conducted. The boundary expansion procedure created a negative pressure inside the mouth, driving the ENDS aerosol into the oral cavity. CFD simulation results predicted that the aerosol experienced significant changes while in the mouth cavity. Droplet coagulation increased the aerosol size by approximately 50%, condensation of water vapor onto the droplets also increased the droplet size, affecting the droplet deposition profile throughout the oral airway. An accurate assessment of the dynamics and deposition of ENDS aerosols in the oral cavity was found to be essential to quantify the amounts of each constituent reaching the lung for consideration of the potential health impacts due to ENDS usage. This work was supported by the FDA Center for Tobacco Products. This is not a formal dissemination of information by the FDA and does not represent Agency position or policy.

3187 Estimating Children’s Postnatal Exposure to DDT and DDE Using a Physiologically-Based Pharmacokinetic (PBPK) Model

L. Plouffe1, M. Iwai, K. Nakai, S. F. Nakayama2, and M. Verner1. 1University of Montreal, Montreal, QC, Canada; 2National Institute for Environmental Studies, Tsukuba, Japan; and 3Tohoku University Graduate School of Medicine, Sendai, Japan.

Dichlorodiphenyltrichloroethane (DDT) and its metabolite dichlorodiphenylchloroethylene (DDE) are persistent organic pollutants that are widespread in the environment. Although DDT has been banned decades ago in most countries, DDT and DDE are still found in the environment and in breast milk samples. Studies have shown that prenatal exposure can be detrimental to children’s development, but there is a lack of knowledge on the effects of postnatal exposure. Children’s main exposure pathway is mother-to-child transfers through placenta, cord blood and breast milk, which occur during important developmental periods. The objective of this study was to estimate DDT and DDE levels in children participating in the Tohoku University Study of Child Development study (J) using a PBPK model. We used data from 536 Japanese mother-child pairs to estimate children’s monthly DDT and DDE concentrations from birth to 12 months of life, and every six months from 12 months to 36 months of age. We also estimated the maximum child concentration (Cmax) reached between birth and 36 months of age. Median (95th percentile) breast milk levels were 6.60 ng/g-lipid (16.47 ng/g-lipid) for DDT and 136.92 ng/g-lipid (408.88 ng/g-lipid) for DDE. The estimated median (95th percentile) of DDT concentrations at birth in infants was 6.89 ng/g-lipid (17 ng/g-lipid), and the median (95th percentile) of the Cmax was 21.95 ng/g-lipid (21.95 ng/g-lipid). As for DDE, the estimated median (95th percentile) of the concentrations at birth was 142.56 ng/g-lipid (411.31 ng/g-lipid), and the median (95th percentile) of the Cmax was 471.52 ng/g-lipid (1379.14 ng/g-lipid). Children’s levels estimated herein will be used to evaluate associations between exposure during critical windows of development and excessive weight gain during childhood.

3188 Toward Incorporation of the Metabolite Exposure in High-Throughput In Vitro to In Vivo Extrapolation (HT-IVIVE)

Margin of exposure analysis using the HT-IVIVE-predicted steady state exposure and HT-screening bioactivity data demonstrated the importance of considering dosimetry in risk-based prioritization. The current approach however, is limited only to parent compounds leading to low confidence in prioritization. To include the exposure to potentially bioactive metabolites in the current HT-IVIVE equation, efficient tools for identifying potentially active metabolites and predicting their formation and clearance rates are required. In this study, we evaluated the domains of applicability of the current in vitro and in silico prediction tools that are developed for pharmaceuticals to determine their applicability to environmental chemicals and to prioritize the data collection to fill the data gaps for chemical metabolism prediction. The goal is to build a database to facilitate the incorporation of the metabolite exposure in HT-IVIVE to support chemical safety assessment. First, we evaluated the domains of the applicability of the current tools based on structure information. The results of principal component analysis for drug-like and environmental chemicals, represented by the 200 most-prescribed pharmaceuticals in 2016 and ~1600 compounds from Tox Cast, respectively, showed that flexibility and lipophilicity distinguish between the two chemical spaces with drug-like compounds being confined in a narrower space compared to chemicals. The other analysis was performed with a rate of metabolism tool for farm animals, AMMET Predictor** (verr 7.1, SimulationsPlus). In vivo hepatic intrinsic clearance (Clint) values for a subset of Tox Cast chemicals were predicted, results of which revealed that the major data gaps exist for enzymes other than the 5 major CYPs for drug metabolism including, but not limited to, environmental chemicals. Substances were ranked as potential inducers or inhibitors enzymes. In addition, the need for an improved in vitro assay to measure Clin for slowly metabolized chemicals was evident as conventional tools cannot measure those with accuracy. Along with the results from our data collection effort guided by these evaluations, we demonstrate the incorporation of metabolite exposure in the current HT-IVIVE addressing the key limitation in current prioritization scheme in toxicity testing.

3189 Reverse Dosimetry Approach for Potential Endocrine Disruptors: Comparison of a Simple Kinetic Model versus PBTK

E. Fabian, C. Gomes, A. Ochs, C. Haase, T. Ramirez, B. van Ravenzwaai, and R. Landsiedel. BASF SE, Ludwigshafen am Rhein, Germany.

In animal-free risk assessments, effect concentrations are obtained in vitro and are translated to external, e.g. oral, doses by kinetic modeling (reversidosimetry). For this approach, we examined in vitro assays for potential endocrine disruptors quantitatively lowest effect concentrations (LOEC) from in vitro assays to lowest observed effect levels (LOEL). For modeling, we applied 1) a simple kinetic 1 compartment model versus 2) an 8 compartment PBTK model. In approach 1), the calculated, dose dependent maximum plasma concentration was used to bridge in vivo to the in vitro situation. Substance specific input parameters for 1) are molecular weight, plasma protein binding (PPB) and hepatic clearance whereas for more complex PBTK modeling logP and apparent hepatic clearance through Caco-2 cells (Papp) are required. In approach 2), the simple 1 compartment model yielded results closer to the measured in vivo LOELs than the PBTK model for 6 out of the 10 modeled substances (FEN, APAP, CAF, FLU, MITT, TRE). In conclusion, our results demonstrate that for reverse dosimetry, also the application of a simple kinetic model may be possible in principle.
of arsenic in food and water to total exposure and demonstrate the model's value in reconstruction of exposures to IAs in humans, particularly in individuals who are exposed to relatively low levels of arsenic in water or food. **3190 Quantitative Bias Analysis of the Association of 2,2',4,4',5,5'-Hexachlorobiphenyl (PCB 153) and Type 2 Diabetes Mellitus**

The concentration of persistent organic pollutants such as polychlorinated biphenyls (PCBs) in serum tends to be higher among those with type 2 diabetes mellitus (T2DM). Whether this association is causal is unclear. We hypothesized that this relationship might be caused by interindividual variation in adiposity, which acts as a shared factor in both the rate of clearance of lipophilic chemicals such as PCB 153 and the risk of T2DM. This variance, along with a trend of decreasing exposure over time, might explain the association even in studies where the association had been adjusted for body mass index (BMI) and waist circumference (WC). To test this hypothesis, we conducted a quantitative bias analysis (QBA) on a specific epidemiologic study of diabetes and PCB 153 that was based on subjects in the National Health and Nutrition Examination Survey (NHANES). The QBA used a simulation based on a physiologically-based pharmacokinetic (PBPK) model of PCB 153 that we developed. The exposure model was a stochastic version of a published deterministic, fugacity-based model and described exposure over time for the simulated population. A model of T2DM incidence as a function of age, BMI, and WC was developed, using realistic rate ratios. The distributions of age, BMI, WC, and serum PCB 153 in the simulated population (n = 100,000) closely matched those in the observed population, and a similar proportion of subjects developed diabetes. Using the same statistical approach as the target study, we calculated the odds ratio (ORs) for diabetes in relation to category of serum PCB 153 concentration with adjustment for age, BMI, and WC. In our analysis to date, the ORs in the highest category of PCB 153, compared with the lowest, in the published data was 1.0 (95% CI 0.9-1.1), as compared with the observed value of 6.8 (3.0-15.5). The next steps include refining the model to have a more detailed description of adipose tissue, including visceral and subcutaneous compartments. Visceral fat is a better indicator of T2DM risk than BMI or WC, and some data suggest that there may be differential distributions in PCB concentration between fat types. The results will be used to evaluate the role of pharmacokinetics in the association of PCB 153 with T2DM.

**3191 Evaluation of a Physiologically-Based Pharmacokinetic (PBPK) Model for Inorganic Arsenic Exposure Using Data from Two Diverse Human Populations**

J. S. Lee1, T. Hong2, C. Henning1, W. Mendez2, E. Hudgens1, D. Thomas1, and H. El-Masri1, 1US EPA, Research Triangle Park, NC; 2ICF International, Fairfax, VA; and 3ICF International, Durham, NC.

Physiologically-based pharmacokinetic (PBPK) models are computational frameworks that quantitatively describe physiological and biochemical processes related to absorption, distribution, metabolism, and excretion (ADME) of xenobiotics. PBPK models can be used to interpret results of biomonitoring data to better inform estimates of external exposures and daily intake. These models can be used to report data in multiple studies to a common metric of exposure or dose for purposes of meta-analysis. Predicted dose-response relationships for health effects of chronic inorganic arsenic (iAs) exposures, the magnitude, pattern, and duration of exposure to iAs must be determined. Because information on iAs exposure may be obtained from populations with different sources and temporal patterns of exposure, a common exposure metric is needed to allow comparisons across studies. In this study, a previously published PBPK model was evaluated using data sets for arsenic-exposed populations from Bangladesh and the United States. The human PBPK model consisted of sub-models describing the ADME of iAs and its metabolites. The model was used to estimate total arsenic levels in urine in response to ingestion of iAs. Both arsenic water and dietary intakes were estimated and used to generate the associated arsenic urine concentrations. When arsenic intake from water alone was considered, the results of the PBPK model under-predicted urinary arsenic concentrations for individuals with low levels of arsenic in drinking water and slightly over-predicted urinary arsenic concentrations for individuals with high levels of arsenic in drinking water. When population-specific estimates of dietary intakes of arsenic were included in exposures, the predictive value of the PBPK model was markedly improved, particularly at lower levels of arsenic intake. These results illustrate the PBPK model’s utility in evaluating the contribution of arsenic to total exposures.
4-Hydroxyphenylpyruvate Dioxigenase (HPPD) Inhibition: Associated Tyrosine Elevation in Rats, Mice, and Dogs Shows Significant Species Differences

W. Wang,1 D. Clerkin,1 M. Kim,1 and A. Chandrasekaran.1 1FMC, Ewing, NJ; and 2FMC, Harrogate, United Kingdom.

Single and repeat dose toxicity studies were conducted in several experimental species. The test item was a HPPD-inhibiting standard drug compound. The single dose studies were conducted in male and female rats and mice by oral-gavage. The repeat dose studies were conducted in male and female rats, mice, and dogs for approximately 28 consecutive days through either continuous dietary administration (rats and mice) or oral capsule administration (dogs). Serum tyrosine concentrations were measured by a LC-MS/MS method at selected junctures in all the studies. A normal physiological baseline level of serum tyrosine was established from the concurrent control groups in each study. Serum tyrosine levels were shown to be comparable among all tested species, including between males and females. Serum tyrosine levels were elevated following treatment with the HPPD inhibiting compound in all species, and the magnitude of the elevation demonstrated marked species differences. The species differences were most apparent in the repeat dose studies. In the single dose studies, serum tyrosine levels increased in both rats and mice. In the repeat dose studies, the tyrosine levels in mice were only slightly increased with values falling within the normal baseline range even at the highest dose level. In the rats, the tyrosine levels increased markedly with even greater tyrosine elevation in males. At the same administered dose level, the serum tyrosine levels were about 10-fold higher in the rats than that in the mice. For the dogs, the serum tyrosine levels also increased markedly but not as high as in the rats. A major physiological basis for both the species and gender difference in response to HPPD inhibition is the existence of an alternate pathway through tyrosine aminotransferase (TAT) for tyrosine catabolism. TAT enzyme is more abundant and effective in mice and humans (males) as compared to rats and dogs. This explains the difference in tyrosine elevation observed in the single and repeat dose studies. Having an understanding of the key physiological differences in TAT capacity can inform experimental species selection and then ensure human relevance considerations for purposes of human health risk assessment with respect to HPPD-inhibiting chemicals.

Application of Probability Boxes to Characterize Mode-of-Action Uncertainties: Thiocyanate as Case Study

U. Lee, and A. Lumen. US FDA/NCTR, Little Rock, AR.

Thiocyanate, which is found in the diet and tobacco smoke, has multiple modes of action for thyroid disruption. Thiocyanate inhibits the active thyroidal uptake of iodide, increases the passive permeability of iodide across the thyroid, and inhibits the organification of iodide for thyroid hormone synthesis. A cumulative dose-response model for thyroid-active chemical mixtures needs to account for the multiple modes of action of thiocyanate on thyroid function. In most cases, not all modes of action for chemicals evaluated are well characterized leaving sparse data for cumulative dose-response analysis. As such, unknown parameters need to be estimated based on the available information. Monte Carlo (MC) simulation has been widely used to randomly simulate a plausible set of unknown parameters from a relevant parameter range but it requires precise assumptions about initial parameter values and the parameter range and its distribution shape. We have examined the use of probability bound analysis and its application to physiologically based pharmacokinetic (PBPK) and dose-response models by generating a probability box (p-box) for the input parameters. Unlike a simple MC simulation, a p-box allows for the comprehensive propagation of variability and uncertainty in the face of uncertain input for any parameter by evaluating all possible distribution shapes within a physiological bound. We generated p-boxes for three of the five sensitive model input parameters based on their minimum, maximum, mean, and standard deviation; bounded values but without any distribution information, and compared the dose-response curves obtained by p-box to MC simulation. We observed that the predicted dose response curves obtained by p-boxes were wider than the curves obtained by MC simulation yet informative about dose-response effects of thiocyanate. We are continuing our efforts towards the implementation of a cumulative dose-response curve for thiocyanate and ultimately the thyroid-active chemical mixtures. Our work allows for quantifying the total uncertainty in the dose-response effects using p-box analysis when existing data are limited and multiple modes of action are involved. Such analysis provides risk assessors with valuable information, such as a well-quantified degree of uncertainty associated with the dose-response relationships, when only sparse mechanistic data are available.

Prediction of the Liver Toxicity of the Endothelin Receptor Antagonists Sitaxsentan and Ambrisentan for the Treatment of Pulmonary Arterial Hypertension with a Quantitative Systems Toxicology Tool (DILIsym)

Sitaxsentan and ambrisentan are highly selective endothelin-1 type A receptor antagonists which were developed for the treatment of pulmonary arterial hypertension. Sitaxsentan was voluntarily withdrawn from the market due to concerns about liver toxicity, whereas ambrisentan is currently on the market. DILIsym, a mathematical framework of drug-induced liver toxicity, was used for quantitative system toxicology studies of the compounds. In vitro assay data has revealed that Sitaxsentan is a potent inhibitor of BSEP, moderate inhibitor of MRP3/4, and moderate bilirubin transporter inhibitor, whereas ambrisentan exhibits mitochondrial electron transport chain (ETC) inhibition and moderate bilirubin transporter inhibition. Hepatic exposure of each compound was estimated by employing the DILIsym physiologically-based pharmacokinetic (PBPK) sub-model; predictions of toxicity risk were subsequently made in simulated humans within DILIsym (SimPops; n=285). Depending on the mode of transporter inhibition and PK variability, 0-11.2% of the SimPops were predicted to have liver toxicity (plasma ALT > 3x ULN) after 18 weeks of 100 mg QD oral dosing of sitaxsentan in DILIsym. On the other hand, irrespective of the mode of transporter inhibition, 0% of the SimPops showed liver toxicity after 10 mg of ambrisentan (QD oral dosing). These simulation results are comparable with the clinical data where 0-7% and 0% of patients experienced liver toxicity for sitaxsentan and ambrisentan, respectively. Further mechanistic simulations showed that synergy between mitochondrial dysfunction and bile acid transporter inhibition was primarily responsible for sitaxsentan induced liver toxicity. Although in vitro data for ambrisentan and sitaxsentan showed potential DILI signals, predicted DILI risk was also dependent upon compound exposure. DILIsym was able to help elucidate the clinical relevance of the in vitro signals.

Oral Irritation Assessment of Electronic Liquids Using an In Vitro Oral Testing Model

M. Aragon, A. Shrvanthi Pidathala, D. Sheehan, and G. Costin. Institute for In Vitro Sciences, Gaithersburg, MD.

While data are still being collected and analyzed, there were at least 1,300 incident electronic liquid (e-liquid) exposures reported as of May 5th, 2016. This study investigated the oral irritation of 3 different formulations of e-liquid using an in vitro time course assay in the reconstructed tissue model EpiOral™ (MatTek Corporation, Ashland, MA, USA). All products were from the same manufacturer, contained 1.2% nicotine and differed only in their flavorings. The e-liquids were tested neat in duplicate tissues. Tissue viability was measured using the vital dye MTT at 15 minutes, 30 minutes, 1 hour, 2 hours, and 16 hours. The ET50 values (representing the exposure time which reduces the tissue viability by 50%) were calculated and used to rank-order the irritation potential of the products. The ET50 values were 4.9h, 6.0h, and >16h, respectively, for the 3 products tested. The results of this study highlight the applicability of the EpiOral™ model in evaluating the oral irritation potential of a variety of e-liquid formulations. Further work will be performed with the culture medium to analyze the inflammatory profile of e-liquids via cytokine analysis.
The adoption of a new technology into industrial and clinical settings requires rigorous testing to determine reproducibility, reliability, robustness, and transferability. Tissue chips have the potential to be a valuable tool for studying biological function, pharmaceutical development and toxicity testing. Independent testing will increase confidence in the robustness of the tissue chips. As part of NIH funded Tissue Chip Testing Centers, the goal of this study was to test the proximal tubule chip from the University of Washington at Texas A&M. The proximal tubule tissue chip system was obtained from the developers and Nortis, Inc. (Seattle, WA). Human renal proximal tubule epithelial cells from two sources were grown over 28 days in 3D culture under a flow rate of 0.5uL/min. The performance of this system was examined in three rounds of testing: non-specific binding of drugs to the chips, functionality (long-term cell viability, protein and gene expression, ammonia-gene, and drug metabolism), and toxicological responses to nephrotoxic agents (polyoxymyxin B, cisplatin, gentamicin, and cadmium chloride). Parallel studies were performed with the same cells and study designs in traditional 2D culture. Investigations into the non-specific binding of compounds within the 3D platforms showed minimal absorbance to chips (<10%). Fluidic cultures self-organized into tubular structures, and indicated greater metabolic competence through increased 24-hydroxylation of Vitamin D3 and gene expression of CYP24A1 (3D: 49±12 vs 2D: 0.9±0.07-fold change). Additionally, cells demonstrated more sensitive responses to nephrotoxants through increases in KIM-1 release, and significant differences in gene expression (HAVCR1, HMOX1, LCN2, and FN1) compared to traditional static 2D culture. Cross-site comparisons indicated high agreement and demonstrated the transferability of the proximal tubule tissue chip.

Physiologically-based toxicokinetic (PBTK) models that are tailored to the chemicals of interest are generally considered to be more accurate than simpler toxicokinetic (TK) models parameterized with minimal in vitro and in silico data. However, within the context of high-throughput risk evaluation, a slightly lower level of accuracy may perform equally well in estimating relative risk. In this study, we compared fitted human PBTK models for bisphenol A (BPA) to the R package “httk,” which includes a 1-compartment TK model and a generic PBTK model. We also tested a 2-compartment model, consisting of clearance and rest-of-body compartments with physiologically based volumes, connected by the hepatic blood flow. The models from httk assumed a first-order, non-restrictive clearance and were parameterized with logp, pka, and in vitro intrinsic clearance, protein binding and blood-to-plasma partitioning. The fitted PBTK model from Yang et al. (2015) and the httk models yielded similar time-plasma concentration curves in the prediction of human in vivo data from Thayer et al. (2015). The 2-compartment and generic PBTK models made very similar predictions, with root-mean-square error (RMSE) the square root of the average squared difference in predicted concentrations) of 2.9 and 5.1 nM and average-fold error (AFE) (the geometric mean of the quotient of measured and predicted concentrations) of 2.3 and 3.0, respectively. The fitted model (Yang et al., 2015) performed the best (RMSE of 0.33 nM and AFE of 1.3), and the 1-compartment model performed the worst (RMSE of 43 nM and AFE of 20). In this case study, the 2-compartment model performed best among the simplified models in predicting BPA TK, serving as a proof of concept for further investigation of TK models based on high-throughput data. This abstract does not necessarily reflect US EPA policy, Thayer, K. A., et al. “Pharmacokinetics of bisphenol A in humans following a single oral administration.” Environ. Int. 83 (2015): 107-115. Yang, X., et al. “Development of a physiologically based pharmacokinetic model for assessment of human exposure to bisphenol A.” TAAP 289.3 (2015): 442-456.
3202 Development and Evaluation of a Physiologically-Based Pharmacokinetic Model for Cimetidine

Cimetidine is commonly used in the treatment of heartburn and peptic ulcers. Cimetidine has been shown to inhibit multiple CYP450 enzymes including CYP1A2, CYP2D6, and CYP3A4. It was also found to inhibit multiple transporters including MATE1, MATE2-K, OCT1 and OCT2. The purpose of this work was to develop a physiologically-based pharmacokinetic (PBPK) model for cimetidine using GastroPlus™ (Simulations Plus, Inc.) and PBPKPlus™ (Simulations Plus, Inc.) for the simulation of cimetidine after IV and oral administration. The simulated PK profiles of cimetidine. The physiochemical parameters not available in literature were predicted using the ADMET Predictor™ (Simulations Plus, Inc.) and PBPKPlus™ (Simulations Plus, Inc.). The Advanced Compartmental Absorption and Transit (ACAT™, Simulations Plus, Inc.) and PBPKPlus™ (Simulations Plus, Inc.) were used for the simulation of cimetidine after IV and oral administration. The simulated PK profiles of cimetidine were compared with observed profiles for evaluation of the model performance. The fold error values (predicted/observed) ranged from 0.91 to 1.02 for the area under the curve (AUC) values, indicating that simulated results were in agreement with observed data. The developed cimetidine PBPK model was then used to estimate the impact of cimetidine (as perpetrator) on other drugs. Two CYP3A4 substrates were selected including triazolam and midazolam which have built-in PBPK models in GastroPlus®. Using cimetidine as the perpetrator, drug-drug interaction of cimetidine with triazolam or midazolam showed increased in both victim drugs, and the increases were generally in good agreement with observed data reported in literature. This model could be used for evaluating the impact of cimetidine on the exposure of other drugs when coadministered.

3203 Determination of Complex Drug Bioequivalence Using Stable Isotope Tracers

An analytical challenge for complex drug bioequivalence is accurate measurement of encapsulated and unencapsulated drug. To overcome this analytical challenge, a novel ultrafiltration drug release method utilizing stable isotope tracers has been developed. Stable isotopically-labeled active pharmaceutical ingredient (API) is spiked into plasma containing the isotope-labeled API. The isotope-labeled API equilibrates with plasma protein and formulation components identical to the normoisotopic API released from the complex formulation. Therefore, the ultrafilterable fraction of the isotope-labeled API represents a reliable measure of free normoisotopic API fraction in plasma, and can be used to calculate encapsulated and unencapsulated API fractions. To demonstrate the utility of the stable isotope tracer method, we performed an in vitro drug release study in rat and human plasma, and in vivo bioequivalence study in rats, comparing Janssen’s Doxil® and Sun Pharma’s doxorubicin HCl liposome generic. Using the stable isotopically-labeled API as a tracer, the isotope-labeled API was spiked into plasma and doxorubicin preparations were released in human and rat plasma over a 6h period. A parallel design bioequivalence study in rats demonstrated similar encapsulated and unencapsulated drug pharmacokinetic (PK) profiles for both liposomal preparations. Statistical analysis determined the formulations to be bioequivalent on the basis of T<sub>max</sub>, encapsulated C<sub>max</sub>, AUC<sub>0-24</sub>, AUC<sub>0-24</sub> and AUC<sub>0-24</sub>, but not unencapsulated AUC<sub>0-24</sub>. Notably, the estimated unencapsulated drug profiles in this study differed greatly from previously published rat bioequivalence studies utilizing solid phase extraction methods, with regard to unencapsulated drug concentrations, encapsulated to unencapsulated drug concentration ratio, and unencapsulated drug terminal half-life. Funded by NCI-FDA IAA, and NCI Contract No. HHSN26120080001E.

3204 Comparative Disposition of Bisphenol S and Bisphenol AF following Gavage Administration in Harlan Sprague Dawley Rats and B6C3F1/N Mice and Hepatocytes In Vitro

Bisphenol AF (BPAF) and bisphenol S (BPS) are used as cross linking agents in polymers and are structurally similar to bisphenol A (BPA). BPAF and BPS were selected by the National Toxicology Program for toxicological evaluation based on their structural similarity to BPA and lack of adequate toxicity data. Disposition and toxicokinetics (TK) data are essential to put toxicological findings into context. We investigated the disposition and TK of BPAF (3.4-340mg/kg) and BPS (50-500mg/kg) in rats and mice following a single gavage administration. In both species, [14C]BPAF was excreted mainly in feces (33-77%) with some in urine (females, 9-24%; males, 1-6%) by 72h. [14C]BPS was excreted primarily in urine (48-72%); the % excreted in urine decreased while that in feces (16-30%) increased with the dose. In rats, although ~50% of BPAF or BPS dose was excreted in bile in cannulated animals within 24h, ~uncannulated animals, ≤13% of the dose was excreted in feces. Following an intravenous dose of BPAF or BPS, the pattern of excretion was similar to gavage. These data suggests that both were well absorbed following gavage administration, underwent biliary excretion and extensive enterohepatic recirculation and were excreted primarily in feces (BPAF) and urine (BPS). BPAF and BPS were distributed to tissues with <2% of the dose remaining at 72h. The observed plasma BPAF C<sub>max</sub> was similar in mice and rats with elimination half-life <3h; the bioavailability was low and was similar across species and sexes (<1% - 4%). BPS C<sub>max</sub> was ~5-times higher in mice than in rats; however, half-life of elimination was shorter in mice (2.5-3h) than in rats (7-10h) resulting in similar AUC values for rats and mice. The bioavailability of BPS (~0.10 - 18%) was higher than for BPAF and was similar across species and sexes. For BPAF, glucuronide and sulfate conjugates were identified in bile and urine of exposed rats with no parent detected. In addition to glucuronide and sulfate conjugates, parent was also present in urine of BPS-exposed rats. In rodent and human hepatocytes, clearance of BPAF (half-life 6-15min) and BPS (half-life 29-97min) was similar. In conclusion, BPAF and BPS were well absorbed following oral exposure, underwent extensive first-pass metabolism and recirculation and have low bioavailability similar to that reported previously for BPA.

3205 2,4,6-Tribromophenol (TBP) Disposition and Kinetics in Female Sprague-Dawley Rats after Single and Repeated Dosing

2,4,6-tribromophenol (TBP, CAS No. 118-79-6) is widely used as a brominated flame retardant and wood fungitidal agent. TBP is frequently detected in environmental matrices, biota, and humans. In female SD rats, systemically available TBP (10 µmol/kg, IV) was rapidly excreted primarily via urine, with ~61% of the dose recovered after 4h, and 89-94% in 24h. 5% of the dose was recovered in feces and 1-2% in blood/tissues. TBP administered to female SD rats (0.1-1000 µmol/kg) by gavage was well absorbed, with ~25% eliminated via urine after 4h and ~88% after 24h. Fecal recoveries varied only slightly by dose and route. Approx. 11% of a single oral dose was recovered in bile. Toxicokinetic analyses of TBP in blood found IV time-concentration profiles fit a two-compartment model indicating a rapid distribution to tissues followed by a slower excretion phase. After oral dosing, concentrations rapidly rose to C<sub>max</sub> followed by a single elimination phase. Oral bioavailability was 31-37%. Urine was found to contain a mixture of TBP, TBP-glucuronide, and TBP-sulfate. Blood collected after IV dosing contained a consistent 85%-15% ratio of TBP to TBP-glucuronide at all timepoints investigated, but blood collected after oral dosing contained a 50%-50% ratio. Fecal extracts contained only parent TBP while bile contained only TBP-glucuronide. TBP did not appear to bioaccumulate or alter its own metabolism after repeated administration. TBP was readily absorbed at all doses and routes tested, and is likely to be bioavailable when ingested by humans. Supported by the Intramural Research Program at NCI/NIEHS.
Understanding the processes of absorption, distribution, metabolism and excretion (ADME) is important for evaluating potential inter- and intra-species differences in response to chemical exposure, which is in turn important for extrapolating health effects and effect levels observed in laboratory animals to humans, for purposes of establishing regulatory criteria. We conducted a comprehensive analysis of key ADME parameters across different species for five perfluorinated chemicals (PFCs), including perfluorobutanoic acid (PFBA), perfluorobutane sulfonate (PFBS), perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA), and perfluorooctanoate (PFOA). We identified parameters from approximately 60 studies, which we identified from PubMed, and from health effects review documents prepared by US EPA and ATSDR. Our analysis yielded the following observations: 1) Across species, liver partitioning decreases in the order of PFOS > PFOA > PFBA = PFHxS, with PFOS and PFOA distributing preferentially to the liver and PFBA and PFHxS distributing preferentially to the serum. 2) Compared to primates, PFOS distributes preferentially to the liver in rats. 3) Half-lives increase in the order of PFOS < PFBS < PFBA < PFHxS < PFOA, and in the order of rodents < non-human primate < human. 4) Half lives of PFBA, PFHxS, and PFOA are shorter in female vs. male rats. 5) Although placental and lactational transfer of PFOA are comparable in rats and humans, offspring/maternal serum ratios are lower in humans compared to rats. 6) Although placental and lactational transfer of PFOS are greater in rats than humans, offspring/maternal serum ratios are comparable. Based on these observations, we conclude the following: 1) Large differences in half-lives among species highlights the importance of extrapolating effects across species based on pharmacokinetic characterization of physical-chemical properties. 2) Tissue distribution of these PFCs is consistent with the liver being the target organ for toxicity, with highest liver/serum ratios observed for rats exposed to PFOS. 3) Based on serum concentrations, primates are expected to be less susceptible to than rats to the liver effects of PFOS, and the human fetus is expected to be less susceptible than the rat fetus to the developmental effects of PFOS. Considering these conclusions, our analysis will facilitate interpreting human relevance of findings observed in rodents exposed to PFCs.
The gut microbiota contributes to diverse mammalian processes including defense against pathogens, immunity, and energy production through metabolic processing. More recently the gut microbiome has been shown to play a role in the metabolism of xenobiotics including antibiotics and drugs targeted against host physiology. Shifts in the composition of GI microbiota, whether induced by dietary changes, antibiotic treatment or inflammatory processes can disturb the balance of organisms in the gut and alter the metabolic networks of the host. Changes in the microbiome can also influence the overt toxicity and metabolism of therapeutic drugs administered orally. To determine how changes in the gut microbiome can alter drug metabolism and affect drug-drug interactions, the pharmacokinetics (PK) and biodistribution and metabolism of the model compound acetylaminocephalin was assessed in C57B/6 mice after treatment with the antibiotics amoxicillin (amox) or a cocktail of ampicillin/ neomycin (amp.neo). Altered tissue concentration, plasma PK, and metabolism of acetylaminocephalin was observed over 2 h, in animals exposed to antibiotic treatments. Acetylaminocephalin plasma area under the curve profiles were significantly decreased in antibiotic treated animals compared to control animals suggesting decreased bioavailability. Levels of acetylaminocephalin in the kidneys of animals exposed to amox were higher when compared to control and amp.neo treated animals at the early time points (0.25 h, 0.5 h, 4 h). Urinary metabolite files revealed decreases in acetylaminocephalin-sulfate metabolite levels in both the amox and amp.neo treated animals compared to control animals. Analysis of gut microbe composition using the LLNL Microbial Detection Array system revealed changes in microbiota content in antibiotic treated animals compared to untreated animals. These results suggest that exposure to amox or amp.neo can alter the biodistribution of acetylaminocephalin and that these alterations could be directly due to changes in gut microbiome composition. This work was performed under the auspices of the US DOE by LLNL under Contract DE-AC52-07NA27344 and supported by the National Institute of General Medical Sciences (P41GM103483-14) and LLNL-PLS-LDRD: 16-ERD-007.

Synergistic interaction between florfenicol (FF) and thiamphenicol (TAP) have been reported for several pathogenic bacteria of animal origins. Survival rates were demonstrated to be significantly increased against Pasteurella multocida and Streptococcus suis in rat and chicken models. Given that the efficacy of FF+TAP at the reduced dose of both drugs was uncompromised, lower drug residues in plasma and tissues were expected and warrant further investigation. Therefore, the plasma pharmacokinetics and tissue residues of the synergistic FF+TAP and its acute toxicity in broiler chickens was evaluated. To determine the pharmacokinetic profile, the mixture of 5 mg/kg FF and 10 mg/kg TAP was intramuscularly administered to 6 broiler chickens. Another 3 chickens were used for tissue residues study at 24 h after drug administration. Plasma and tissues (kidney, liver, skin with fat and breast muscle) concentrations of the two antimicrobials were analyzed by HPLC-UV. For acute toxicity study, the chickens were treated at 48 h after drug administration and examined for any gross and histopathological abnormalities. Significantly lower peak concentrations (0.04 and 2.63 µg/mL for FF and TAP, respectively) and area under the curves (0.25 and 13.99 h·µg/mL for FF and TAP, respectively) of both antibiotics were recorded when compared to those of the recommendation dose (30 mg/kg for each drug). The 1-day tissue residual levels of FF were approximately one order of magnitude lower than the results reported by other studies and are much lower than the maximum residue level (MRL). Consequently, the drug withdrawal period could potentially be shortened. In addition, the observed histopathological lesions were found following FF+TAP administration at this dosage level. Our results clearly demonstrated the benefits of using synergistic FF+TAP combination over the monotherapy in the aspects of consumers safety as the chicken plasma and tissue drug residues could be significantly reduced without compromising the antimicrobial activity.

Azithromycin is a widely-used macrolide antibiotic that is continually deposited into natural waterways by sewage effluent. Though recognized as an emerging contaminant of concern, little to nothing is known about its effect on non-target aquatic organisms. With less than 1% degradation after 150 days in simulated watershed conditions, azithromycin is an enduring contaminant in aquatic systems that has been shown to accumulate in aquatic invertebrates. Known to inhibit p-glycoprotein pumps, azithromycin may be extremely deleterious to aquatic systems as multixenobiotic resistance in aquatic organisms is largely mediated by p-glycoprotein. Crayfish (Procambarus clarkii) were used as a model non-target aquatic organism exposed to azithromycin through diet. Preliminary kinetic studies showed gastrointestinal adsorption of azithromycin to be as high as 75.73 ± 0.008%. Elimination was slow; after 14 days less than 10% of the parent compound was excreted with no potential non-target or target metabolites (deschlorido azithromycin, N'-desmethyl azithromycin, and 9a-N'-desmethyl azithromycin) observed, indicating that azithromycin is likely to biocumulate in the host magnifying potential toxic effects. Toxico-kinetic studies currently in progression are expected to further elucidate the fate of azithromycin in P. leniusculus, as well as identify potential azithromycin effects on multixenobiotic resistance in these crayfish.
Simultaneous Hepatocellular Disposition Profiling of Parent Compound and Its Major Metabolites in Sandwich-Cultured PXB-Cells by D-PREX

K. Kanda, Hitachi High-Technologies Corporation, Hitachinaka, Ibaraki, Japan. Sponsor: T. Yokoi

This study aimed to examine the total disposition profiling of parent and its major metabolites by a single systematic procedure called D-PREX (Disposition Profile Exploration), using sandwich-cultured PXB-cells (SCPC). In this D-PREX system, drug uptake and metabolism is performed in intact SCPC, followed by simultaneous evaluation of biliary and basolateral efflux by measuring supernatants, then cell lysis to understand the intracellular residues. SCPC were exposed to the standard Hakus' balanced salt solution (Std HBSS) including 10 μM parent compound at 37°C for over time (10-120 min), which were terminated by rinsing with ice-cold Std HBSS. Subsequently, the cells were incubated 10 min with Std HBSS at 37°C for stabilization of the following efflux evaluation (conditioning efflux step). Then the cells were separated into three groups: intact and disrupted bile canalicular structures with and without Ca²⁺ ion conditions at 37°C, and that of intact with Ca²⁺ at 4°C. Then, each supernatant was collected after 10 min incubation, followed by the cell lysate samplings. The amount of compounds in the collected samples were quantified by LC-MS/MS analyses, which were used to calculate the respective disposition endpoints. In terms of acetonaphthphen (APAP), the metabolism seemed to follow the uptake of APAP, which saturated after 60 min incubation. The proportion of the major metabolites of glucuronide (APAP-Gluc) and sulfate (APAP-Sulf) corresponded to the known human metabolism properties. In addition, these compounds mostly transported to basolateral efflux than biliary excretion, which represented the tendency of urinary elimination. Further, in terms of basolateral efflux, APAP showed relatively a higher passive diffusion portion than that of transporter-mediated, whereas APAP-Gluc and -Sulf represented opposite trend, suggested the hydrophilic property of the conjugates mediated by the transporters. D-PREX can be used for the simultaneous evaluation of total disposition profiles not only the parent compounds but also their metabolites, resulted from the complex interplay of the hepatic metabolism and transport. This methodology may contribute to pre-estimate the toxic potential caused by active-metabolites due to an enterohepatic circulation such as SN-38, an active-metabolite of CPT-11. 

Interaction of Oatp1b2 Gene Dose and Nonalcoholic Steatohepatitis on Plasma Clearance of Pravastatin

E. L. Toth1, J. D. Clarke2, T. L. Canakci4,5, and N. J. Cherrington1

1University of Arizona, Tucson, AZ; 2Washington State University, Spokane, WA; 3Children’s Mercy Hospital, Kansas City, MO; and 4University of Kansas Medical Center, Kansas City, KS.

It has been reported that nonalcoholic steatohepatitis (NASH) downregulates hepatic uptake transporters, including the organic anion transporting poly peptide (OATP) transporters. It is known that the combination of NASH and genetic loss of Oatp1b2 causes a synergistic decrease in the plasma clearance of pravastatin (PRAV). The current study aimed to examine the effects of comorbidity NASH and genetic heterozygosity of Oatp1b2 on the plasma clearance of PRAV to model the overlap between the 24% of the human population who are heterozygous for OATP1B1 and the ~15% with NASH, potentially placing these people at higher risk of statin-induced myopathy. Therefore, male C57Bl/6 wild-type (WT), Oatp1b2+/− (HET), and Oatp1b2−/− (Null) mice were fed either a methionine and choline sufficient or methionine and choline-deficient (MCD) diet. After 6 weeks of control and MCD diet, pravastatin was administered via the carotid artery, and blood samples were collected at 2, 7, 15, 30, 50 and 90 minutes after pravastatin administration. Concentration of PRAV in plasma samples was determined by liquid chromatography-tandem mass spectrometry. MCD diet did not alter the plasma AUC values of PRAV in WT or HET mice. However, the Null-MCD group increased plasma AUC by 4.4-fold. 

Impact of Organic Cation Transporter 3 (SLC22A3) Knockout on [3H]Quinine and [3H]Mefloquine Uptake and Social Behavior in Aged Mice

Quinine is an old antimalarial drug that is still in use worldwide, however, it is better known as a bitterant of tonic water that makes it glow under blacklight. Quinine has affinity for and is known to block serotonin (5-HT) reuptake by serotonin transporters (SERT). However quinine is also a substrate of organic cation transporters (OCTs). OCTs are low-affinity, high capacity, polyspecific carriers that help regulate extraneuronal concentration of OCTs. There are three subfamilies of OCTs: OCT1, OCT2, and OCT3 expressed in the brain of both humans and mice. Currently, there is a great need for OCT3-specific inhibitors to differentiate its activities and to test its properties for the treatment of psychiatric disorder. The goal of our study is to determine the relative share of OCT3 to [3H] quinine and [3H] mefloquine uptake in aged mice. Adult male C57Bl/6 mice and OCT3 knockout mice were euthanized on day of experiment and their cerebellum harvested for uptake assay. Stocks, 10X uptake buffer, and ligand dilutions were prepared for synaptosomes. [3H] Quinine and [3H] mefloquine were used as substrates and decyinium-22, lopinavir, and sertraline were used as blockers. Cerebellum was harvested from 2 year old mice, stored and homogenized in sucrose then centrifuged. Synaptosomal preparations were incubated once pipetted into labeled ligand dilutions. Synaptosomes were harvested using a Brandel Cell Harvester for vacuum filtration and then collected into scintillation tubes and analyzed using a scintillation counter for 24 hours. Lastly, a Bradford protein assay was used to identify protein concentration. Surprisingly we found that uptake of [3H] quinine was greater in OCT3 knockout mice than in wildtype mice, and that sertraline (1 μM) was a more potent blocker than D2-2 or lopinavir. There was no statistically significant difference between the wildtype and OCT3 knockout and wildtype mice. Furthermore, like the pseudoisocyanine decyinium-22 that blocks all ancillary transporters of 5-HT, we find that OCT3 knockout in mice and to a lesser extent substrates such as mefloquine or quinine can enhance social behaviors in adult male mice strain-dependently. 

Hepregen Hepatoc: A Novel In Vitro Transporter Tool to Support DILI Risk Assessment

Using an empirically derived cutoff based on inhibition of BSEP and the compound’s estimated unbound concentration at the inlet of the human liver (fu*Iin,max), we were able to establish a screening assay to identify instances where inhibition of BSEP may be predictive of human DILI. Interestingly, inhibition of MRPs did not significantly enhance DILI predictivity compared to BSEP inhibition alone. To further understand the ability of inhibitors to inhibit bile salt transport in vivo, laboratory animals were then tested as an inhibitor of taurocholate (TCA) transport in a long term micropatterned human hepatocyte based system (Hepatopac®). In contrast to BSEP containing membrane vesicles, Hepatopac allows for a more holistic assessment of bile salt transport inhibition as multiple transport pathways, protein binding, intracellular sequestration, and compound metabolism are taken into account. The resulting IC50 for TCA in vitro biliary clearance (Clbiliary) and biliary excretion index (BEI) in Hepatopac were compared to the compound’s estimated fu*Iin,max to assess potential risk for bile salt transport perturbation. The data showed that the specificity of the assay was high (89%) with only 1 false positive being observed. Furthermore, 11 out of 16 compounds which showed an IC50 in the TCA vesicular assay of < 5 μM did not result in an IC50 for BEI that was within 10 fold of the fu*Iin,max suggesting that these compounds are less likely to cause inhibition of BSEP in vivo. These data suggest that Hepatopac may be a more effective transport tool to identify compounds which inhibit biliary efflux of bile salts than the TCA vesicular inhibition assay.

**3219 The Role of Human MRP2 in the Cellular Efflux of Microcystin Congeners**

G. Kaur, and D. R. Dietrich. University of Konstanz, Konstanz, Germany.

Water contamination by cyanobacterial blooms is a worldwide health hazard to humans as well as livestock. Exposure to Microcystins (MCs), toxins produced by various cyanobacterial or blue green algae found in poorly treated drinking water or contaminated seafood such as fish, prawns etc., are associated with hepatotoxicity, nephropathy and neurotoxicity and in extreme cases, death in humans. At present more than 120 MC congeners are described. These congeners differ dramatically in their uptake kinetics, i.e. their uptake via organic anion transporting polypeptides (OATP), in OATP overexpressing human HEK293 cells and primary human hepatocytes. It is thus likely that MC congeners will also differ with respect to the cellular efflux of the parent and conjugated congeners, e.g. via Mrp’s, Bcrp or Bsep. Consequently, the role and kinetics of different human efflux transporters - Mrp, Bcrp and Bsep in MC efflux was studied using inside-out membrane vesicles. Of the efflux transporters investigated, hMrp2 suggested MC transport. In addition, a MC congener-specific efflux was also observed, whereby Mrp-c was transported faster than MC-LF. In conjunction with the previously reported faster cellular uptake of MC-LF and the slower MC-LF efflux (reported here) results in a higher cellular MC-LF concentration per unit time and thus would explain the higher cytotoxicity observed for MC-LF in human primary hepatocytes and OATP overexpressing human HEK293, when compared to MC-LR. In future, this approach will allow for the development of a toxicokinetic computational model that supports improved human risk assessment of the plethora of single MC congener and/or their mixtures in contaminated food and water.

**3220 Tissue Distribution of Organophosphate Flame Retardants in Mice: Analysis of Dose-Dependence, Chemical Species, and Sex Differences in a Subchronic Study**

S. M. Marco1, B. Rickard1, E. A. Krumm2, V. J. Patel2, A. Yasrebi2, I. Yang1, T. A. Roepeker2, J. B. Richardson1, L. M. Aleskunes1, and B. T. Buckley1. 1Rutgers, The State University of New Jersey, Piscataway, NJ, 2Rutgers, The State University of New Jersey, New Brunswick, NJ; and 3Northeast Ohio Medical University, Rootstown, OH.

The industrial phase-out of polybrominated diphenyl ether flame retardants due to their persistence in the environment, bioaccumulation, and toxicity created a demand for alternatives such as organophosphate flame retardants (OPFRs). OPFRs are chemicals of emerging toxicological concern due to reports of endocrine disruption, neurotoxicity, and reproductive and developmental toxicity. Studies on the tissue distribution and accumulation of OPFRs in vivo are limited. In the present study, the tissue distribution of OPFRs was quantified in adult male and female C57BL/6 mice orally administered 1 or 10 mg/kg/day of each OPFR—tricresyl phosphate (TCP), triphenyl phosphate (TPP), and tri(1,3-dichloro-2-propyl) phosphate (TDCPP) in equal amounts for four weeks using gas chromatography-mass spectrometry. Circulating concentrations of TDCPP in male mice ranged from 1.4 to 3.8 ng/ml and were similar for 1 and 10 mg/kg/day dosing. TCP and TPP exhibited dose-dependent differences with 10- and 1.75-fold higher concentrations observed after 10 mg/kg/day dosing (TCP: 5.6 ng/ml; TPP: 2.8 ng/ml) compared to 1 mg/kg/day dosing (TCP: 0.56 ng/ml; TPP: 1.6 ng/ml), respectively. In male serum, concentrations of TDCPP (3.2 ng/ml) were higher than TPP (1.6 ng/ml) and TCP (0.56 ng/ml) after 1 mg/kg/day dosing. By comparison, serum concentrations of TPP (0.94 ng/ml) and TCP (0.16 ng/ml) were significantly lower in female mice, with no difference in TDCPP (2.5 ng/ml). Similar to circulating serum concentrations, increased tissue concentrations of TDCPP (M: 7.5 pg/mg; F: 9.2 pg/mg) relative to TPP (M: 1.4 pg/mg, F: 0.35 pg/mg) and TCP (M: 0.92 pg/mg, F: 0.33 pg/mg, F: 0.33 pg/mg) with no statistical differences between the sexes. Tissue distribution of OPFRs was also quantified in other tissues including liver, brain, adipose, ovaries, and testes. Comparative OPFR tissue distribution after subchronic exposure aids in the identification of target organs for toxicity and facilitates modeling to extrapolate tissue exposures in humans. Funded by NIH ES020721, ES027119, DK083457-51, ES021800, and ES005022.

**3221 Is a Common Mechanism of Action Essential to Conduct a Cumulative Risk Assessment or Just Nice to Have?**

S. Fitzpatrick, US FDA, College Park, MD.

Current risk assessments of chemicals for regulatory purposes do not generally take into account the “real-life” exposure to multiple substances, but rely instead on the assessment of individual substances in individual commodities. Humans however are routinely exposed simultaneously to numerous chemicals via multiples routes of exposure. These mixtures can be variable, constantly changing and essentially undefinable. One major question is whether a common mechanism of action is critical element for conducting a cumulative risk assessment. The chemical toxicity of the chemical mixtures and the diversity of the routes of exposure may call for the development of both mechanism-based and non-mechanism-based quantitative frameworks for risk assessment to estimate the impact on health, thereby increasing the efficiency and effectiveness of these evaluations. Consideration of the recent advances in vitro as well as in vivo models, the exposome, adverse outcome pathways, and computational models and how this can help inform our discussion on chemical mixtures will be included in the roundtable talks. This roundtable will conclude with a debate on the different approaches to assess the potential health impacts of exposure to chemical mixtures.

**3222 Unlocking the Toxicity Archive: Enabling Toxicogenomic/Proteomic Investigation from Archival Samples**

D. Dalmas. GlaxoSmithKline, King of Prussia, PA.

Formalin fixation and paraffin embedding (FFPE) is a cross-industry gold standard for preparing nonclinical and clinical samples for histopathological assessment which preserves tissue architecture and enables storage of tissue in archival banks. These archival banks are an untapped resource and vast repository of tissue from regulatory toxicology studies, novel animal bioassays, clinical trials, or epidemiologic studies with tremendous potential for assessing the toxicity profile of individual commodities. Humans however are routinely exposed to mixtures of chemicals through indirect routes such as via food and drinking water, thus use of FFPE archival tissues can inform our discussion on chemical mixtures will be included in the roundtable talks. This roundtable will conclude with a debate on the different approaches to assess the potential health impacts of exposure to chemical mixtures.
tions working in isolation and with limited resources, the ILSI Health Environmental and Sciences Institute (HESI) Genomics Committee FPFE Working Group has been developing methods to “demodify” FPFE RNA, enabling subsequent, more robust RNA-Seq analysis. Novel methods developed to improve RNA yield and sequencing results from limiting quantities and quality RNA FPFE samples will be highlighted, followed by discussion of frozen and fixed archival nonclonal and clinical FFPE tissue to interrogate mechanisms of toxicity, aid in biomarker development, enable creation of a critical translational bridge between emerging in vitro and in vivo data, and reproduce fully-induced adverse health effects established in prior toxicologic and epidemiologic studies, as well as enabling data gaps to be closed in adverse outcome pathways (AOPs).

3223  Good Cell and In Vitro Method Practices against the “Reproducibility Crisis”

D. Pamies. Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

There is a strong belief that in vitro methods are fast becoming the key tool for a new way of doing toxicology. However, their potential will not be fully realized if they are not developed and applied in a way in which scientific integrity and quality are assured—the data they produce will not be trusted by decision makers. A reviving paper (Nature 2016, 533:452-454) showed that 70% of researchers have tried and failed to reproduce another scientist’s experiment, and more than half of the researchers failed to reproduce their own experiments. These dramatic data call for incentives for better practice. With the development of new high-throughput technologies, stem cells, and new culture technologies (organotypical cell cultures, organ-on-a-chip technologies), new challenges are presented for reproducibility of such advanced test systems. This session will summarize the challenges of working with in vitro cell and tissue-based culture methods and will describe the different initiatives that have taken place in recent years to give guidance on good cell and good in vitro method practices as measures against the reproducibility crisis in science. The session also will elaborate on the use of human-induced pluripotent stem cell-based systems for regulatory purposes and how to validate the new generation of high-throughput in vitro methods and microphysiological systems.

3224  Career Opportunities in Regulatory Toxicology

A. Lynch. Colorado State University and William H. Farland Consulting, LLC, Rockport, ME.

This session will serve as an introduction to current issues and opportunities in regulatory toxicology for graduate students and early-career scientists, as well as to motivate them to seek training experiences that will increase their knowledge of the approaches to and challenges of bringing modern-day toxicology into a risk or safety assessment process. The SOT Graduate Education Subcommittee, via its Awareness of Regulatory Toxicology (ART) Working Group, has assembled experts in regulatory toxicology to discuss opportunities available for toxicology trainees and others interested in pursuing careers in regulatory toxicology. Resources developed by ART for trainees interested in these careers also will be presented to attendees. Regulatory bodies within the United States and other countries use scientific data from various sources to assess the safety of chemicals and drug candidates in order to inform regulatory policy and determine approvals for use. In turn, industry uses scientific data to meet regulatory requirements and to achieve product stewardship and sustainability goals. Training in and application of modern, laboratory-based science must be married to the legislative and regulatory processes in order to inform decisions that are understandable and benefit the public. Many toxicology and postdoctoral training programs do not cover regulatory toxicology or regulatory processes to a significant degree. In addition, scientists who engage in the regulatory process through a government or public contact with specific issues may not be fully aware of the regulatory process and/or impacts of regulatory decisions. Although toxicologists often gain experience while on the job, accessing training or internships in regulatory toxicology early in a scientist’s career benefits trainees by increasing knowledge of how scientific data can be used in the public domain, as well as by increasing awareness of available job opportunities. In addition, knowledge of the regulatory use of toxicology information also benefits toxicologists considering service in an advisory capacity to government or industry.

3225  Atherosclerosis as a Model to Understand the Combined Effects of Environmental Chemical and Non-Chemical Stressors

D. Carlin. NIEHS, Research Triangle Park, NC.

Atherosclerosis can lead to cardiac infarction and stroke and is a foremost candidate for identifying health effects associated with chemical and non-chemical stressors since much is known about the morbidity and mortality of this multifactorial disease. However, the evaluation of cumulative human health effects from multiple environmental exposures (i.e., chemical and non-chemical) represents a special research challenge due to the inherent complexity of the topic and requires careful examination of the potential interaction of these exposures. For example, further exploration is required of the biological mechanisms/pathways by which exposure to both environmental chemicals (e.g., air pollution, polycyclic aromatic hydrocarbons, metals, polychlorinated biphenyls, pesticides, and endocrine disrupting chemicals) and non-chemical stressors (e.g., psychosocial, lifestyle, quality-of-life, poor nutrition, and physical stressors) over time leads to health effects and the roles the stressors may play in the development of diseases known to be associated with them (e.g., cancer, cardiac, metabolic, neurological, etc.). For the purposes of this session, combined exposures pertain to any set of environmental chemicals and non-chemical stressors that may contribute, individually or jointly, to damage in the human health vector of whether people are exposed to the chemical(s)/non-chemical stressors at the same/different times or through similar/distinct sources or routes. Some of the other areas requiring further research on this complex topic include a better understanding of both the composition of real-world exposure to chemical and non-chemical stressors; the potential biological interactions between chemical and non-chemical stressors; and the development and validation of predictive models of combined exposure toxicity to characterize the hazard associated with these combined exposures. This session will bring together experts to discuss the state-of-the-science pertaining to underlying complex biological mechanisms/pathways associated with, when combined, chemical and non-chemical stressors in relation to atherosclerosis. Specifically, presentations will include a general overview of the etiology of atherosclerosis from chemical and non-chemical stressors, the biological mechanisms being evaluated by the extramural community, atherogenic mechanisms of environmentally-relevant chemicals, how diet and physical activity may modify atherosclerotic events, and how conceptual models can be created to evaluate complex causal pathways in this disease. In addition, this symposium also may be able to be used as a model for other diseases known to be associated with both chemical and non-chemical stressors and the roles these stressors may play in cumulative risk.

3226  General Overview of the Public Health Burden of Atherosclerosis

W. Cascio. US EPA, Research Triangle Park, NC.

Cardiovascular disease is the most common cause of death globally and atherothrombosis is underlining pathological process that accounts for the vast majority of its morbidity and mortality. Atherosclerosis is a chronic non-communicable disease process with well-established risk factors that include age, sex, family history of premature myocardial infarction, smoking, high blood pressure, and cholesterol. Yet, these traditional risk factors do not account for all cases of cardiovascular disease implicating that other factors are acting independently or in concert with traditional factors to cause atherosclerosis and occlusive vascular disease. Exposure to environmental chemicals and non-chemical stressors are likely to be important determinants of atherothrombosis. In addition to providing a general review of the global burden of cardiovascular disease, this presentation will primarily focus on the environmental chemicals associated with atherosclerosis, their mechanisms of toxicity, and proposed links between chemical and non-chemical stressors in the development and progression of atherosclerosis. This presentation will also focus on the active hypotheses being explored and will introduce how the subsequent talks will address this interplay of chemical/ non-chemical stressors on atherosclerosis.
Atherosclerosis is a lipid-driven inflammatory disease characterized by macrophage accumulation in the vessel wall and is responsible for myocardial infarction and stroke. Global morbidity and mortality from this disease continue to rise, and undoubtedly atherosclerosis and its consequences are among the greatest health challenges faced in the US and around the world. Atherosclerosis is a chronic inflammatory process that begins several decades before its symptoms become clinically evident. The National Heart, Lung, and Blood Institute (NHLBI) supports a broad program of investigations evaluating the associations between non-chemical stressors and the progression of atherosclerosis and coronary artery disease, including population-based public health studies, clinical trials, and basic laboratory research. These include, but are not limited to, studies investigating 1) how chronic and acute psychosocial stress contributes to the initiation and progression of cardiovascular disease by interfering with macrophage dynamics, 2) how lifestyle (high fat diet, lack of exercise, chronic stress, sleep fragmentation, and depression) affects hematopoiesis and cellular and molecular macrophage function during atherosclerosis; 3) how social/emotional factors, diet, and stress affect atherosclerosis and the integrity of the blood vessels; 4) the study of neural, hormonal, and immunological mechanisms that may link biobehavioral variables to cardiovascular pathology. This presentation will focus on the potential mechanisms of non-chemical stressors linked to atherosclerosis and coronary heart disease and how they may possibly interact with known chemical stressors, which will further our understanding of the pathophysiology and prevention of this disease.

Atherosclerosis, the underlying cause of most CVD, is an inflammatory disease that develops slowly under the influence of genetic and environmental factors. Insulin resistance, endothelial activation/injury, and recruitment of leukocytes in the sub-endothelial space play a pivotal role in the etiology of atherosclerotic plaque development. Some toxic Superfund chemicals can injure endothelial cells or cause endothelial activation. This presentation focuses on our studies that show that exposure to toxicants such as volatile organic compounds (VOCs; i.e., acrolein and benzene) significantly decrease circulating endothelial progenitor cells (EPCs; Flik+/Sca+ cells) and augment insulin resistance in mice. Moreover, chronic exposure to acrolein or arsenic (another Superfund-relevant chemical) exacerbates atherosclerosis in apoE-KO mice. In vitro, both acrolein and arsenic augment the surface expression of adhesion molecules, promote monocyte adhesion and trans-endothelial migration and enhance cytokine formation. Mechanistic studies show that both acrolein and arsenic cause endothelial activation by triggering endoplasmic reticulum stress (ER-stress) and inducing unfolded protein response (UPR). Genetic ablation of UPR-associated inflammatory signaling or enhancing the protein-folding capacity by chemical chaperones of protein-folding attenuates acrolein or arsenic induced ER-stress and endothelial activation in vitro; and feeding with chemical chaperones of protein folding prevents arsenic-induced ER-stress, endothelial activation, and atherosclerotic plaque formation in apoE-KO mice. Acrolein also induces micro RNA-21 in macrophages, potentially as an adaptive response to inflammation; and myeloid cell specific deficiency of micro RNA-21 exacerbates atherosclerosis and lesion inflammation. Collectively, ER-stress induced endothelial activation and differential regulation of microRNAs associated with inflammatory signaling are plausible mechanisms by which toxic Superfund chemicals exacerbate atherosclerosis.

Atherosclerosis is a chronic inflammatory disease characterized by macrophage accumulation in the vessel wall and is responsible for myocardial infarction and stroke. Global morbidity and mortality from this disease continue to rise, and undoubtedly atherosclerosis and its consequences are among the greatest health challenges faced in the US and around the world. Atherosclerosis is a chronic inflammatory process that begins several decades before its symptoms become clinically evident. The National Heart, Lung, and Blood Institute (NHLBI) supports a broad program of investigations evaluating the associations between non-chemical stressors and the progression of atherosclerosis and coronary artery disease, including population-based public health studies, clinical trials, and basic laboratory research. These include, but are not limited to, studies investigating 1) how chronic and acute psychosocial stress contributes to the initiation and progression of cardiovascular disease by interfering with macrophage dynamics, 2) how lifestyle (high fat diet, lack of exercise, chronic stress, sleep fragmentation, and depression) affects hematopoiesis and cellular and molecular macrophage function during atherosclerosis; 3) how social/emotional factors, diet, and stress affect atherosclerosis and the integrity of the blood vessels; 4) the study of neural, hormonal, and immunological mechanisms that may link biobehavioral variables to cardiovascular pathology. This presentation will focus on the potential mechanisms of non-chemical stressors linked to atherosclerosis and coronary heart disease and how they may possibly interact with known chemical stressors, which will further our understanding of the pathophysiology and prevention of this disease.

Many human and environmental risk scenarios involve complex processes occurring across varying space and time scales, potentially following multiple causal pathways to the same endorgan, for example, the causal relationships between atherosclerosis and contributing environmental exposures and lifestyle choices, in the context of genetics and medical factors, is a challenging task. Complexity stems from differences in timing, magnitude, and mode of action of different types of stressors as well as their interaction with each other and with factors such as age and gender. One useful way to conceptualize this type of complex causal question is to visually map the problem space and the network of pathways from cause to effect. The resulting conceptual model, or series of models at different scales, organizes and enables cumulative risk assessment by identifying important risk components and mechanisms as well as multiple stressor junctures and multiple pathways to the same effect. For example, a variety of factors in sequence or separately can affect lipid status, such as dietary risk factors exacerbating diabetes or obesity or both. Having this understanding of the interrelationships between stressors is crucial in the search for data to quantify associations between causes and ensure the quality of data collected is appropriate to the causal question being addressed. If different stressors are measured with different levels of precision, or if they are not included as part of a joint pathway, then risk calculations are subject to error. As sub-pathways are better understood and quantified, conceptual models can and should be refined as part of the iterative process of real-world causal analysis. This leads to a more realistic, causal web-based, rather than linear chain-based, framework for cumulative toxicological inference. This presentation will provide information on how this modeling has been successful in the case of atherosclerosis and may be applicable to other diseases associated with chemical and non-chemical stressors.

This session will be composed of graduate and postdoctoral trainees presenting primary research focused on autophagic pathways that go awry in neurodegenerative diseases and how relevant environmental toxicants affect these pathways. Autophagy is a tightly regulated catabolic process that enables a cell to conduct bulk degradation of protein aggregates or dysfunctional organelles in a specific or nonspecific manner. Autophagic pathways have been observed to be impaired under a variety of neurotoxic and neurodegenerative disease conditions. Furthermore, environmental toxicants, such as neurotoxic metals, that are associated with altered risk or modification of neurodegenerative disease pathogenesis may impact with genetic and environmental factors by disrupting autophagy. Investigation of these pathways is likely to provide key insight into early cellular events of these diseases.
as disruptions to autophagic pathways occur prior to neurodegeneration or behavioral phenotypes. The session will begin with brief introductions regarding the structure of this trainee-led session and the trainees speaking, as well as a brief primer on autophagy and its potential role in neurodegenerative disease. In each talk, the trainee speakers will relate how autophagic dysfunction in their models contributes to disease pathogenesis and how their chemical(s) of interest exacerbate or ameliorate dysfunction. The first trainee speaker will discuss the role of autophagy in the toxicity of arsenic in cortical astrocytes. This speaker will present her findings on how AMPK and mTOR signaling regulate ATG5-dependent autophagy and apoptosis in astrocytes. The second trainee speaker will discuss the effects of manganese (Mn) exposure on autophagy-lysosome pathway in primary astrocytes, the mechanism(s) underlying Mn-induced autophagic dysregulation, and the functional relation between compromised autophagy and mitochondrial dysfunction. The third trainee speaker will continue the discussion about Mn in Huntington’s disease (HD), focusing on the contribution of excess manganese to neurons in HD and how the drug KB-R7943 can normalize Mn uptake. The fourth trainee speaker will change the topic to Parkinson’s disease (PD) and will delve into how optineurin, a protein previously not considered in PD, contributes to pathogenesis through autophagic dysfunction. The fifth trainee speaker will examine early mechanisms of PD and how they contribute to disease progression. The fifth trainee speaker will discuss the contribution of endosulfan to PD pathogenesis, as well as the relationship between autophagy and apoptosis in PD. The final trainee speaker will discuss the effects of low-dose chemical exposures on autophagic mechanisms in PD and further examine how these effects are altered even after chemical exposure is removed. Given that autophagy dysfunction is increasingly recognized as a common, early event in sporadic neurodegenerative diseases, it is imperative to understand how environmental chemicals disrupt normal autophagy, and 2) evaluate Mn-induced defects in autophagy in mouse primary astrocytes, the molecular mechanisms underlying this autophagic dysfunction, and its role in Mn toxicity. This presentation will show that Mn exposure disrupts autophagy in mouse astrocytes, partially by blocking the nuclear translocation of transcription factor EB (TFEB), a master regulator of autophagy and lysosome-related genes. Mn induces activation of ERK1/2, which phosphorylates TFEB to maintain it in an inactive cytosolic state. The causal relation between autophagy failure and mitochondrial dysfunction in order to determine whether impairment of autophagy directly contributes to the Mn-related cytotoxicity is currently being explored. This study highlights the mechanisms and functional role of impaired autophagy in Mn toxicity. These findings are critical in advancing Mn neurotoxicity studies as well as developing of therapeutic strategies for neurodegenerative diseases associated with autophagic dysfunction.

### 3232 Potential for Autophagy as a Primary Mechanism of Environmentally Induced Neurodegeneration

**J. Cannon, Purdue University, West Lafayette, IN.**

Autophagy is a broad term for the catabolic process of cellular degradation of cytosolic components, and is often referred to as a “double-edged sword” for the health of living cells. Disruptions in autophagy have been extensively examined in neurodegenerative disease models. However, most examinations, including those from neurotoxicological insults, have focused on autophagic disruptions as a pathological endpoint, instead of a primary mediator of toxicity or disease pathogenesis. This presentation will provide a brief overview on current knowledge in the role of autophagy in neurodegenerative diseases and how the work to be presented addresses key gaps of knowledge in the field. This brief introduction will set the stage for participants to understand the underlying scientific challenges being addressed by each speaker.

### 3233 Autophagy: Friend or Foe in Arsenic-Induced Toxicity?

**C. Garza-Lombo, University of Nebraska Lincoln, Lincoln, NE.**

Arsenic is a naturally occurring element found in groundwater as a byproduct of soil and rock erosion. Industrial and agricultural processes are also important sources for arsenic contamination. Chronic exposure to arsenic during development and adulthood induces cognitive dysfunctions, and is considered a risk factor for neurodegenerative disorders, but the mechanisms involved are still unclear. Astrocytes play an essential role in brain function as they regulate both neuronal excitability and homeostasis. They are also the first line of defense against xenobiotics crossing the blood brain barrier into the brain, buffering arsenic. It has been previously reported that autophagy protects neural cells against environmental xenobiotics. In contrast, in this work, the role of autophagy in the toxicity of trivalent inorganic arsenic species (AsIII) in glial cells will be reported. Exposure of primary cortical astrocytes to AsIII (arsenic trioxide [As2O3] or sodium arsenite [NaAsO2]) induced an increase in autophagy flux as evidenced by the dose-dependent accumulation of monomeric and aggregated p62, which was paralleled by the accumulation of ubiquitinated proteins. Impairment of autophagy by inhibition of class III phosphatidylinositol-3-kinases (PI3K) with wortmannin or by the overexpression of a dominant-negative (dn) form of the autophagy-related protein 5 (Atg5), significantly reduced the accumulation of p62 and ubiquitin-bound proteins. Interestingly, inhibition of autophagy, but not the proteasome (MG132), reduced caspase 3 cleavage/activation and cell death induced by AsIII. Similarly, trehalose protected astrocytes from AsIII, but this effect was shown to be independent from autophagy. Inhibition of the mammalian target of rapamycin (mTOR) with either rapamycin (mTOR complex I, mTORC1) or torin (mTORC1 and 2) stimulated AsIII toxicity. In addition, impairment of AMP-activated protein kinase (AMPK)–signaling by the overexpression of dnAMPK-ε1 and 2 reduced interest in autophagy against AsIII. Conversely, activation of AMPK with 5-aminimidazole-4-carboxamide ribonucleotide (AICAR) stimulated cell death in arsenic treated cells. The results demonstrate for the first time that AMPK/mTOR signaling and PI3K/Atg5-dependent autophagy regulate iAsIII-induced apoptosis in cortical astrocytes.

### 3234 Role of Autophagy in Manganese-Induced Neurotoxicity

**Z. Zhang, Albert Einstein College of Medicine, Bronx, NY.**

Metal exposure has long been recognized as an environmental factor that contributes to the development of neurodegenerative diseases. Exposure to excessive manganese (Mn) leads to an extrapyramidal disorder referred to as manganese, which shares a number of neurobehavioral deficits with Parkinson’s Disease. The mechanisms underlying Mn-induced neurotoxicity remain uncertain. The studies have characterized alterations in autophagy-lysosome pathway following 100 μM and 500 μM Mn exposures in mouse primary astrocytes, the molecular mechanisms underlying this autophagic dysfunction, and its role in Mn neurotoxicity. This presentation will show that Mn exposure disrupts autophagy in mouse astrocytes, partially by blocking the nuclear translocation of transcription factor EB (TFEB), a master regulator of autophagy and lysosome-related genes. Mn induces activation of ERK1/2, which phosphorylates TFEB to maintain it in an inactive cytosolic state. The causal relation between autophagy failure and mitochondrial dysfunction in order to determine whether impairment of autophagy directly contributes to the Mn-related cytotoxicity is currently being explored. This study highlights the mechanisms and functional role of impaired autophagy in Mn toxicity. These findings are critical in advancing Mn neurotoxicity studies as well as developing of therapeutic strategies for neurodegenerative diseases associated with autophagic dysfunction.

### 3235 Manganese Modifies the AKT/mTOR Pathway and Autophagy: Implications for Huntington’s Disease Pathology

**M. Bryan, Vanderbilt University Medical Center, Nashville, TN.**

Manganese (Mn) is both a neurotoxicant and essential in biological systems. This presentation will primarily discuss the speaker’s doctoral thesis project to 1) elucidate mechanisms by which Mn alters autophagy, and 2) evaluate the role of autophagy in Huntington’s Disease (HD). The STHdh model of HD exhibits decreased Mn uptake and reduced Mn-induced cell signaling (i.e. p53, AKT, and mTOR). A set of small molecules which impinge on Mn uptake have been identified that also impinge on p53 and AKT/mTOR pathways and downstream processes including autophagy. This suggests that Mn may be homoeostatically interwoven with autophagy. The effects of Mn exposure and Mn-increasing SMLs on neuronal and non-neuronal cell types were tested and found that Mn exposures (as low as 25μM) were capable of increasing LC3ii/I and p62 expression in the presence of chloroquine, a potent lysosomal autophagy inhibitor. These data indicate increased induction of autophagy by Mn. Furthermore, the effects of Mn and Mn-increasing small molecules was blunted in HD cells. This suggests that the HD mutation, which is known to impinge on autophagy, perturbs Mn-induced effects on autophagy as well. A role for Mn regulation in Huntington’s Disease is currently being explored. This study considers the role of optineurin (OPTN) in PD. OPTN, which is genetically linked to Parkinson’s Disease, is expressed in astrocytes. The OPTN protein is a key component of the autophagy machinery and is required for autophagic clearance of mitochondria (i.e. mitophagy) with many...
other biological roles that may be additionally implicated in PD. Here, we focused on the role of OPTN in mitophagy to evaluate the interaction between autophagic dysfunction and mitochondria dysfunction. The studies used the rotenone model of PD in vivo (wild-type Lewis rats exposed to rotenone at 3.0 mg/kg i.p.) and in vitro (SH-SYSY cells and primary embryonic midbrain cultures). The effects of OPTN overexpression on neurodegeneration and autophagy were investigated to evaluate its essential role in PD. Furthermore, we probed for OPTN immuno-staining in human brain tissues from PD patients and age-matched controls. The data suggest OPTN is a critical player in early cellular and molecular dysfunctions that contribute to PD pathogenesis.

3237 Environmental Neurotoxic Pesticide Endosulfan Induces Autophagy in Dopaminergic Neuronal Cells: Relevance to Etiopathogenesis of Parkinson’s Disease

A. Charli. Iowa State University, Ames, IA.

Chronic environmental exposure to pesticides, in particular organochlorine compounds, has been implicated in the etiopathogenesis of Parkinson’s Disease (PD). Although the extensive use of organochlorine insecticide endosulfan has been banned recently due to human health concerns, the compound is highly persistent in the environment. Previously, we showed that dieldrin, another potent organochlorine pesticide, induced dopaminergic neurotoxicity by activating a cascade of apoptotic signaling pathways in experimental models of PD. This study systematically investigated the effect of endosulfan on interplay between apoptosis and autophagy in dopaminergic neuronal cell culture model of PD. Exposure of endosulfan to the N27 dopaminergic neuronal cells rapidly induced autophagy as observed by increased number of autophagosomes and the accumulation of LC3-II. While the prolonged endosulfan exposure (>9 h), triggered apoptotic signaling including caspases activation (caspase-2 and -3), protein kinase C delta (PKCd) proteolytic activation, as well as cell death, demonstrated that autophagy preceded apoptosis during endosulfan neurotoxicity. Furthermore, inhibition of autophagy by wortmannin (phosphoinositide 3-kinase inhibitor) potentiated endosulfan-induced apoptosis, suggesting that autophagy is an early protective response against neurotoxic insult caused by the pesticide. Additionally, the studies found that Beclin-1, a major regulator of autophagy, was cleaved during the initiation of apoptotic cell death, and the cleavage was predominately mediated by caspase-2. Interestingly, CRISPR/Cas9 knockdown of prosapotic kinase PKCd significantly attenuated endosulfan-induced Beclin-1 cleavage and LC3-II accumulation. Also, caspase-2 and caspase-3 inhibitors effectively blocked endosulfan-induced apoptotic cell death. Additional studies in primary mesencephalic neuronal cultures confirmed the effect of endosulfan on autophagy and neuronal degeneration. Collectively, these results demonstrate that functional interplay between apoptosis and autophagy controls cell survival and death during pesticide-induced neuronal degenerative processes in dopaminergic neuronal cells. This study provides mechanistic insight into cell death mechanisms in environmentally linked neurodegenerative diseases. NIH grant ES10586, NS38644 and NS45133; Eugene and Linda Loyal endowment.

3238 Dopaminergic Cell Recovery and Resilience In Vitro: The Role of Autophagy

G. Harris. Johns Hopkins Center for Alternatives to Animal Testing, Baltimore, MD.

Currently, in vitro studies focus on short-term, high-dose exposures. Our work is aimed at understanding recovery or long-term effects after low-dose exposures and compound removal using rotenone as a known Parkinson’s-inducing compound and a 3D in vitro dopaminergic cell model. We have studied the short-term (24h) effects of non-cytotoxic concentrations and then compared these cellular responses to those which occur 7 days later (after compound removal). Acute mitochondrial impairment was observed by a decrease in cellular ATP after 100 nM, 24h treatment. One week after compound wash-out, ATP levels returned to control levels. Genes involved in autophagy (LC3, Optineurin, mTOR) were up-regulated short and long-term, indicating that this cellular process may play a role in rotenone-induced dopaminergic cell degeneration even after compound removal. Acutely, an increase in mitochondrial diameter was observed, suggesting swelling due to impaired fission. After 7 days, mitochondria were able to recover to the same size of controls. This presentation will discuss how rotenone-induced mitochondrial impairment can lead to long-term effects on autophagic clearance. The results demonstrate how in vitro low-dose, wash-out studies can be used to identify which mechanisms are relevant to long-term neurodegeneration and not only short term (reversible) neurotoxicity.

3239 The Role of the Epigenome in the Etiology of Metal-Induced Disease

R. Fry. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Toxic metals, such as arsenic, cadmium, lead, and mercury, represent a major public health threat for populations worldwide. Exposures to these metals can be through various sources, including but not limited to, contaminated food and water. In terms of associated health effects, chronic exposure to toxic metals has been linked to cancers of numerous organs, including the lung, liver, and bladder. Toxic metals also are associated with non-cancer endpoints, such as adverse neurodevelopmental outcomes and cardiometabolic disease, including diabetes mellitus and cardiovascular disease in adults. Of particular concern are prenatal and early-life exposures to toxic metals that are associated with increased risk of low birth weight, preterm birth, susceptibility to infection, and later-life cancers. Among the many proposed cellular mechanisms that underlie toxic metals-associated disease are epigenetic modifications, including DNA methylation, histone modifications, and micro-RNA (miRNA) dysregulation. This symposium will highlight the complex role of the epigenome in the etiology of toxic metals-induced disease. The session speakers will present results from epigenomic studies spanning in vitro cell culture models, rodent models, and human populations exposed to toxic metals. The focus of this session will include diabetes, developmental effects in children, and metabolic disorders related to exposures to arsenic, cadmium, lead, and mercury. The presentations will highlight the role of toxic metals as epigenetic modifiers of DNA methylation and miRNA expression and mediators of a panoply of diseases. The use of epigenetic data for risk assessment and disease risk prediction also will be discussed.

3240 Prenatal Arsenic Exposure and the Epigenome: Informing Disease Mechanisms and the Risk Assessment Process

R. C. Fry. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Inorganic arsenic is highly prevalent in the environment. Exposure to arsenic during pregnancy has been associated with detrimental health outcomes in infants as well as later in life. Among the early life outcomes related to prenatal arsenic exposure is a lower birthweight phenotype in infants. A molecular mechanism underlying the arsenic-associated birthweight effect is expected to include epigenetic modifications including CpG methylation and altered miRNAs expression. In a pregnancy cohort in Gomez Palacio, Mexico, arsenic-associated changes in CpG methylation were investigated using a genome-wide gene-specific assessment. Functional consequences of the DNA methylation at the transcript level were evaluated. Prenatal exposure to arsenic was associated with altered CpG methylation, subsequent gene expression and birth outcomes. Among the significant genes identified was potassium voltage-gated channel subfamily Q member 1, KCNQ1. This imprinted gene plays a role in infant birthweight/fetal size at birth as well as later life disease such as diabetes. Using a benchmark dose modeling approach, the arsenic concentration at which these epigenetic effects are observed was determined. This information, including a mechanism for the site-specific arsenic-associated DNA methylation, is useful for a more comprehensive understanding of the mechanisms underlying arsenic-associated disease. Furthermore, the data are critical for informing the risk assessment process.

3241 The Role of microRNAs in the Etiology of Diabetes Associated with Chronic Exposure to Arsenic

P. Sethupathy. Cornell University, Ithaca, NY. Sponsor: R. Fry

Inorganic arsenic (iAs) is a pervasive environmental diabetogen. Laboratory studies have shown that iAs may act as an inhibitor of insulin secretion or signaling, or may alter glucose metabolism in the liver or extrahepatic tissues. However, the molecular mechanisms underlying these effects are poorly understood. Over the last decade, microRNAs (miRNAs) have emerged as markers of environmental exposure and as potential regulators of pathways maintaining glucose homeostasis, including glucose stimulated insulin secretion (GSIS) by pancreatic beta
cells as well as the insulin-activated signal transduction pathway that regulates glucose utilization in the liver and peripheral tissues. Notably, several miRNAs that are linked to defects in the glucose regulating pathways have also been reported as responsive to iAs exposure in cultured cells or laboratory animals. Studies in our laboratory have found that miR-34a, which has been shown to regulate hepatic insulin sensitivity, is significantly upregulated in liver of mice exposed to iAs. Moreover, treatment with iAs increased glucose uptake into liver cells in vitro, and that miR-146a, which has been implicated in the control of GSIS, is significantly upregulated in pancreatic islets after iAs exposure. We have also shown that inhibition of GSIS in beta cells exposed in vitro to iAs is associated with altered expression of miR-146a, as well as at least one other miRNA, miR-20b and miR-217. While, like miR-29b, the miR-29b has been previously linked to the control of GSIS, it has not been well-studied in the context of beta cell function. Our current studies use samples and data from arsenic exposure cohorts in Mexico to characterize associations between the levels of these (and other) miRNAs and iAs exposure and metabolism, and clinical indicators of diabetes. The ultimate goal of this research is to determine if miRNAs are mediators of diabetes associated with iAs exposure and/or if they can be used as biomarkers of this disease.

C. Marsit, Emory University, Atlanta, GA. Sponsor: R. Fry

Cadmium is a ubiquitous environmental toxicant and exposures during pregnancy can impact fetal development leading to reduced fetal growth and neurobehavioral impairments. Unlike other toxic metals, the majority of cadmium does not pass from the maternal circulation to that of the fetus, but instead is sequestered within the placenta. This would suggest that the effects of cadmium on fetal and child health outcomes may be related to effects on placental function. We examined cadmium’s epigenetic effects by profiling genome-wide DNA methylation and transcription of all known imprinted genes in birth cohort studies from the northeastern United States, the New Hampshire Birth Cohort Study and the Rhode Island Child Health studies, using placental cadmium levels as the exposure of interest. We identified 17 Cd-associated differentially methylated CpG sites with meta-analysis p-values < 1e-05. Interestingly, methylation levels at 9 of the 17 loci were associated with increased expression of 6 genes (5% FDR); and higher placental expression of TNAIP2 and ACOT7, and lower expression of RORA, were associated with lower birth weight z-scores (p-values < 0.05). Placental cadmium concentrations were also associated with the expression of a panel of growth-related imprinted genes, such as H19 and IGF2, and the specific expression of these genes was associated with childhood growth at age 2, suggesting that these placental effects can lead to long-term programming of the offspring. Taken together, these results suggest that cadmium may elicit its reproductive effects by driving epigenetic changes within the placenta, and ultimately, this data may be used to improve to improve prevention or intervention efforts as well as to define biomarkers useful for identifying infants at-risk in order to assure early intervention efforts can be employed.

A. Barchowsky, University of Pittsburgh, Pittsburgh, PA.

Arsenic exposure is associated with increased metabolic disease risk and an inability to control metabolic syndromes. As skeletal muscle is the largest metabolic organ in the body, disruption of normal muscle metabolism, maintenance, and regeneration poses a high risk of all cause and cardiovascular mortality. Epidemiological studies indicate that muscle weakness and wasting is a primary pathologic sequelae caused by arsenic in at least 10% of exposed individuals, essentially affecting tens of millions of individuals worldwide. We find that exposure of mice to low to moderate levels of arsenic in drinking water targets the mitochondria in skeletal muscle fibers, interstitial cells, and stem (satellite) cells, producing a maladaptive shift in metabolism that impairs regeneration and promotes adipose infiltration (myosteatosis). The aberrant mitochondrial behavior of interstitial and satellite cells is retained and imprinted in the memory of their progeny long after arsenic is removed, and these phenotypes are reinforced by epigenetic changes, which includes DNA methylation, and histone modifications. The muscle progenitor cells are driven towards proliferation and stemness rather than being able to differentiate and regenerate muscle at the same time that interstitial cells are driven to elaborate a matrix and niche that directs the muscle stem cells towards fibrogenic differentiation. Intervention after arsenic exposure with a mitochondrially targeted radical scavenger, XJB-5-131, reverts the cell phenotypes allowing proper mitochondrial dynamics and function, as well as stem cell behavior. This reversion of mitochondrial homeostasis restores normal patterns of DNA methylation and histone marks on epigenetic regulatory genes. These studies identify mitochondrial-nuclear communications as potential target for prevention or reversion of pathogenic, epigenetic regulation of arsenic-induced metabolic disease and muscle morbidity.

A. Baccarelli. Columbia University, New York, NY. Sponsor: R. Fry

Prenatal exposure to metals, even at low levels, has been associated with a range of adverse health outcomes that may manifest themselves later in life. Epigenetic programming of life from conception to birth has been widely indicated as a biological process that may mediate the effects of metals on postnatal health outcomes. The wide availability of laboratory methods for epigenome-wide association studies (EWAS) now permits to conduct agnostic screens of the influences of environmental exposures on the human epigenome. In particular, DNA methylation-wide analysis are particularly cost effective and have been largely used in human cohorts. However, human data correlating prenatal exposure to metals with differences in DNA methylation in the child are still sparse. In this presentation, we will report novel findings from two EWAS data analyses conducted in the longitudinal pre-birth Project Viva cohort. We generated epigenome-wide methylation data using the Illumina Infinium 450K Methylation BeadChip in cord blood as well as during early childhood (range: 2.9 to 4.9 years) and mid-childhood (range: 6.7 to 10.5 years). We conducted the first EWAS analysis to identify methylation sites associated with prenatal levels of mercury exposures. A second EWAS analysis searched for methylation sites associated with lead exposures. Our EWAS analyses identified multiple methylation sites. We conducted in-silico analysis to determine the association of methylation at these sites with gene expression, as well as the correlation of blood methylation with target tissues, such as for instance brain methylation. We examine neurocognitive outcomes and their association with metal-related methylation sites. These studies provide an example of the use of EWAS analysis in human studies of metals and open the way to mechanistic studies to identify the specific role of DNA methylation in metal toxicity.

B. van Rensenwaay. BASF, Ludwigshafen am Rhein, Germany.

The microbiome has emerged as a key regulator of development and disease. A disruption in host-associated microbial communities is correlated with obesity, immune, and cardiovascular diseases and, increasingly, with adverse developmental outcomes. Current research is starting to unravel microbiome-host interactions that may explain these effects by examining microbiota as a target or mediator of chemical toxicity. One mechanism by which microbiota may modify toxicity is via chemical-dependent changes in the production of small molecules that disrupt normal biological processes in the host. Humans share 99.9% of their genome, yet the vastly larger microbiota-genomic space is much less conserved and, therefore, may partially explain inter-individual susceptibility to chemical exposures. Due to high inter- and intra-species variability within microbiota and its responsiveness to external factors, it is essential to determine the effects of chemical exposures on gut microbiota composition, function, community organization, and resulting host-microbiota interactions. There also is a need to identify molecules produced by gut microbiota and their effects on the host, as well as understanding how xenobiotic compounds are biotransformed by resident microbiota. This mechanistically-focused session highlights emerging interactions between gut microbes and the host that contribute to altering exposure and susceptibility to drugs and chemicals. The first talk will provide an overview of the metabolic capacity of the gut microbiome and, using a combination of metabolomics, metabolonomics, synthetic biology, and cutting-edge experimental host-microbiota model systems, reveal the metabolic characterization of individual microbial species and their roles in human biology and disease. The second talk will focus on how gut microbiota modify the biochemical impact of chemical transformations of food carcinogens and how these reactions are mediated by microbial communities. The third presenter will describe an innovative zebrafish model to test whether host-associated microbiota modify the developmental neurotoxicity of environmental chemicals. The fourth presenter will discuss microbiota in the context of cancer therapeutics. The fifth talk will provide a framework for the assessment of risks associated with microbiome changes via the investigation of the microbiome's functionality, defined as the production of
metabolites absorbed by the host. Hazard identification and risk assessment
do not currently consider host-microbiota interactions that are
disrupted by xenobiotic exposure. This session will bring together aca-
demic, government, and industry scientists who are using novel exper-
imentsal systems to determine the composition and organization of gut
microbiota. Relevant to the field of toxicology, the effects of chemical
exposures on host-microbiota interactions and the mechanisms by
which microbiota perform biotransformations of drugs and environ-
mental chemicals will be discussed in this session.

**3248 Environmental Chemicals Disrupt the Microbiota-Gut-Brain Axis during Zebrafish Development**

T. Tal, US EPA, Research Triangle Park, NC.

Growing evidence indicates that host-associated microbiota modify
the toxicokinetics and/or toxicodynamics of environmental chemicals;
however, current toxicological assessments do not consider interactions
between microbiota and chemical toxicity. Relative to conventionally
colonized zebrafish larvae, findings have previously reported that axenic
(microbe-free) or colonized zebrafish exposed to antibiotics are hyper-
active. Studies therefore hypothesized that neurobehavioral toxicity
elicited by exposure to environmental chemicals may be mediated by
altered microbial colonization during development. Differences were
explored in swimming behavior, microbial community structure, and
chemical metabolism in axenic and conventionally colonized zebrafish
larvae that were semi-statically exposed to the antimicrobial triclosan
(0.1-0.3 µM) or vehicle (0.1% DMSO) on 1, 6, 7, 8, and 9 days post fer-
tilization (dpf). Triclosan exposure had no effect on locomotor activity
in axenic larvae at 10 dpf. In comparison, locomotor hypoactivity was
observed in conventionally colonized larvae exposed to 0.3 µM triclosan.
Also at 10 dpf, triclosan exposure triggered concentration-dependent
shifts in microbial community structure. To understand the temporal
dynamics of triclosan-induced hypoactivity, conventionally colonized
larvae were exposed to 0.3 µM triclosan on 1 dpf or on 1, 6, 7, 8, and 9
dpf. Media changes were performed on days 6, 7, 8, and 9, regardless
of group. Triclosan caused hypoactivity at 10 dpf in larvae exposed on
1, 6, 7, 8, and 9 dpf, but not in larvae exposed on 1 dpf. High resolution
mass spectrometry will be used for non-targeted chemical analysis; pre-
liminary data suggests elevated concentrations of triclosan (ng/larva) in
larvae exposed at 1, 6, 7, 8, and 9 dpf as compared to larvae exposed at
1 dpf. Taken together, these data suggest that host-associated micro-
biota modulate the ability to bioactivate triclosan and trigger subsequent
locomotor hypoactivity. This abstract does not necessarily represent US
EPA policy.

**3249 Discovering and Controlling the Gut Microbiome’s Impact on Xenobiotic Metabolism**

M. Redinbo. University of North Carolina at Chapel Hill, Chapel Hill, NC. Sponsor: T. Tal

The diverse and complex communities of GI microbiota play astonish-
ingly important roles in human health via many mechanisms, including
tuning the immune system, impacting neurological function, and
enhancing digestion and energy utilization. Our studies sought to probe
the roles specific pathways play in overall mammalian homeostasis
within the GI. Thus, the studies focused on systems where the bacteria
catalyze a reaction that exerts a profoundly negative impact on intes-
ninal tissues. The anticancer drug irinotecan, a member of the campto-
thecin family of topoisomerase I poisons, is widely used in the treat-
ment of the FOLFIRI and FOLFIRINOX regimens to treat colon and pancreatic cancers,
respectively. Like many toxic compounds, irinotecan is eliminated as an
inactivated drug-glucuronide by the Phase II drug-metabolism systems
in mammalian protective tissues. Irinotecan’s dose-limiting toxicity is
severely delayed diarrhea hypothesized to arise from the reactivation of
the inactive irinotecan metabolite in the intestinal mucosa catalyzed by a
microbial gene product expressed by the symbiotic GI bacteria. Studies
pinpointed the molecular basis of this reactivation to the beta-glucuro-
nidase sugar scavenging enzymes present in a wide variety of GI resi-
dent bacteria. Potent, selective, and non-lethal inhibitors to bacterial
beta-glucuronidase (GUS) enzymes were developed and demonstrated
that they prevented GI injury in a mouse model of irinotecan-induced
intestinal damage. Findings resolved the crystal structures of numerous
GI microbial GUS enzymes both alone and in complexes with novel
inhibitors, and elucidating the basis for the 10,000-fold selectivity the
compounds show toward bacterial GUS relative to the mammalian
enzyme ortholog, which is essential. Finally, the work was extended to
NSAIDs, which are also glucuronidated and cause GI damage by pro-
ducing small intestinal ulcers. Findings show that bacterial GUS inhib-
itors prevent the formation of these sites of intestinal damage in mice
treated with the NSAIDs diclofenac, indomethacin, and ketoprofen.
Together, the data suggests that enzyme targets in the GI microbiota
can be inhibited to improve human health. Furthermore, the results
shed significant light on one aspect of the mammalian-microbial axes of
chemical communication on-going between the two domains of life in
the “higher-order” human superorganism.
The intestinal microbiome contributes to the metabolism of its host. With the help of an artificial shift of the microbiome with antibiotics, microbiome-derived metabolites have been identified that are absorbed by the host and thus can be found in the blood, amongst which hippuric acid and indole acid are of major importance. Effects of antibiotics on the “functionality of the microbiome” were studied, defined as the production of metabolites absorbed by the host, and determined the gut microbiome’s composition of Wistar rats via 16S rRNA sequencing. A further aim of this study was to prove if the same metabolites analyzed in plasma could be found in feces, cecum content and gut tissue. The studies applied broad-spectrum antibiotics from different classes which were administered 28 days orally to rats for metabolic profiling in plasma and in different matrices (feces, cecum content, gut tissue). For the community, analysis via a 16S rRNA sequencing the gDNA of the feces was isolated. Treatment-related effects could be observed in a principal component analysis for feces and cecum content, but not for gut tissue. For each class of antibiotics specific metabolome patterns from plasma could be established in the MetaMap Tox data base, which contains metabolome data for more than 550 reference compounds. The results indicate that many biomarker metabolites in plasma could be derived from the microbiome because they were found in the immediate surrounding tissue of the bacteria. To determine the functionality of the microbiome for its host, methods still need to be developed. The results of this present work suggest that blood based metabolic profiling could be a suitable tool for this purpose.
Rusyn metal mixtures have the potential to predict mammalian response. Those exposed to 8μg/mL and higher. These concordant findings indicate C. elegans larvae exposed to 2-4μg/mL mercury developmental delay in humans and rats. Conversely, in some studies low levels of mercury in ment reduces offspring and induces a strong oxidative stress response have shown that sodium arsenite exposure during spermatid development as a mechanism of arsenic toxicity on mammalian sperm. We for responses to inorganic arsenic and mercury.

Surveillance of chemical exposure requires analytical platforms offering rapid measurements, high sensitivity, efficient separations, wide dynamic ranges, and applicability to a broad chemical space. We have developed a platform and pipeline that meets these needs by combining solid phase extractions with ion mobility spectrometry and mass spectrometry (SPE-IMS-MS). This platform is capable of performing both targeted and global measurements of endogenous and exogenous small molecules in human biofluids and environmental samples with high reproducibility, sensitivity, and throughput. This exposomics approach overcomes many challenges for large scale assessment methods and is a viable way of screening environmental conditions and patient cohorts for insight into human exposure and disease mechanisms.

Population-Based Studies before, during, and after Emergencies: Building Resilience in Coastal Communities

G. Sansom. Texas A&M University, College Station, TX. Sponsor: L. Rusyn

Much of our current understanding of the population health impacts of disasters is based on disaster-specific case studies with relatively small sample sizes. Typically, reliable baseline data is not available for comparison. Post-disaster research can be expensive, time consuming, and may place burdens on individuals or systems during response and recovery. Because of their focus on a single event, this type of research limits capacity to enhance the resilience of individuals or the communities in which they live to future disasters of a different type, scale, or location. New approaches to environmental health research using open, citizen science, and interdisciplinary data are needed to address these gaps and engage the communities in solving environmental and man-made disasters.

Utility of Caenorhabditis elegans for Predictive Heavy Metal Toxicity Assessment

The toxicity effects of exposure to individual heavy metals have been well studied. Information on the effects of exposure to heavy metal mixtures is urgently required, however. Alternative toxicity models have the potential to provide relevant data for human safety assessment of chemicals with rapid turnaround times and at greatly reduced cost relative to traditional models. Caenorhabditis elegans is a tiny nematode that is inexpensive to maintain, and most assays can be completed in a week or less by a single researcher. However, before data obtained from an alternative model can be used for resource allocation and/or regulatory decisions, that model must first be evaluated for the capacity to predict human toxicity. We assessed the concordance between mammals and C. elegans for responses to inorganic arsenic and mercury. Inorganic arsenic exposure reduces sperm count and quality in rodents, and co-exposure to antioxidants reverses these effects, indicating oxidative stress as a mechanism of arsenic toxicity on mammalian sperm. We have shown that sodium arsenite exposure during spermatid development reduces offspring and induces a strong oxidative stress response in C. elegans, even at low concentrations that do not alter larval growth or motility. Mercury exposure is associated with reduced total movement, reduced speed of movement, and reduced coordination in both humans and rats. Conversely, in some studies low levels of mercury in blood are associated hyperactivity in children. Using a novel developmental neurotoxicity assay, we have identified hyperkinesia and slight developmental delay in C. elegans larvae exposed to 2-4μg/mL mercury acetate, and hypokinesis plus more extreme developmental delay for those exposed to 8μg/mL and higher. These concordant findings indicate that further studies in C. elegans assessing the effects of heavy metal mixtures have the potential to predict mammalian response.

Nuclear Receptor Disruption Alters Triphenyl Phosphate-Induced Cardiotoxicity in Zebrafish Embryos

C. Mitchell1, S. Dasgupta1, S. Zhang2, H. M. Stapleton2, and D. C. Volf2. 1University of California Riverside, Riverside, CA; and 2Duke University, Durham, NC.

Triphenyl phosphate (TPHP) is an unsubstituted aryl phosphate ester used as a high-production volume flame retardant and plasticizer within the United States. Using zebrafish as a model, the objectives of this study were to 1) rely on mRNA-sequencing to uncover biological processes disrupted following embryonic TPHP exposure and 2) rely on high-content screening to identify nuclear receptor ligands that enhance or mitigate TPHP-induced cardiotoxicity. For mRNA-sequencing, embryos were exposed from 24 to 72 h post fertilization (hpf) under static conditions to vehicle (0.2% DMSO) or TPHP (5, 10, or 20 μM). Relative to vehicle controls, TPHP exposure resulted in a concentration-dependent increase in the number of transcripts significantly affected at 72 hpf (873, 1520, and 4256 transcripts following exposure to 5, 10, and 20 μM TPHP, respectively). While stress response-related effects represented the majority of impacted processes within embryos exposed to 10 and 20 μM TPHP, a cardiac-specific category represented the only process affected within embryos exposed to 5 μM TPHP - a concentration that did not result in detectable effects on larval development. For the ligand library screen, embryos were exposed from 24 to 72 hpf under static conditions to vehicle (0.2% DMSO) or 20 μM TPHP in the presence or absence of 74 unique nuclear receptor ligands. Hatched and alive 72-hpf embryos were analyzed for cardiac looping defects - a readily measurable biomarker for cardiac loop defects. Based on this screen and follow-up experiments, two compounds - ciglitazone (a peroxisome proliferator-activated receptor gamma, or PPARy, agonist) and fenofibrate (a pan-retinoic acid receptor, or RAR, agonist) - reliably mitigated TPHP-induced cardiotoxicity. These data suggested that TPHP may be activating retinoid X receptor (RXR, a heterodimer for both RARs and PPARy), co-exposed embryos to TX531 - a pan-RXR antagonist - from 24 to 72 hpf, and found that co-exposure to TX531 significantly enhanced TPHP-induced cardiotoxicity. However, using a luciferase reporter assay, we found that TPHP did not activate nor inhibit chimeric human RXR, RXRβ, or RRY within CHO cells, suggesting that TPHP does not bind to nor interact with RXRs. Overall, our data suggest that TPHP may directly or indirectly interfere with retinoid acid signaling pathways involved in cardiac development.
**3261 Expression of Genes Inolved in Xenobiotic Metabolism in the Chicken Egg Alternative Genotoxicity Model**

T. Kobets1, M. Latropoulos1, J. D. Duan1, K. D. Brunnemann1, S. Iacobas1, D. Iacobas1, E. Vock2, U. Deschi2, and G. Williams1. 1New York Medical College, Valhalla, NY; and 2Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany.

The Chicken Egg Genotoxicity Assay (CEGA) has demonstrated an intrinsic ability to bioactivate various DNA-reactive chemicals. While the activities of major phase I and II metabolic enzymes in avian fetal livers has been described, data on gene expression profiles can significantly contribute to the understanding of metabolic capabilities of avian fetuses. For this purpose, fertilized chicken eggs were dosed under the CEGA protocol with vehicle (deionized water (DW)), a carcinogen that requires metabolic bioactivation, diethylnitrosamine (DEN), and its structural non-carcinogenic comparator, N-nitrosodietanolamine (NDELA). The gene expression data obtained from chicken fetal liver samples using microarray technology was analyzed. Recently in CEGA, DEN produced DNA damage, while NDELA did not. Expression in fetal livers of 463 genes that are known to be involved in the xenobiotic metabolism were detected on the array. DW did not affect gene expression profile of the selected genes, deregulating less than 1% of genes. In contrast, both chemicals, DEN and NDELA, at 4 mg/egg each produced significant changes in gene expression pattern, up-regulating over 33% and down-regulating over 43% of genes. When gene expression profiles of DEN and NDELA dosed eggs were compared, the majority of the genes were expressed in a similar manner, both compounds shared the same up-regulated and down-regulated genes. Among up-regulated genes were CYP 450 genes that are responsible for DEN biotransformation (hydroxylation) to the reactive moiety. Among down-regulated genes were those that regulate detoxication enzymes such as glutathione S-transferase, sulfotransferase and UDP glucuronosyltransferase. Thus, the analysis of gene expression data in fetal chicken livers exposed to dialkylnitrosamines confirmed the hypothesis that avian species possess complex metabolic activity, which underlies their capability to biotransform a variety of chemicals. In the pair of genotoxic and non-genotoxic compounds studied here, genes were deregulated in a similar fashion, indicating similarity in the metabolism of DEN and NDELA.

**3262 Valproate Analogue Developmental Toxicity Potency in a Human Pluripotent Stem Cell-Based Assay Is Concordant with In Vivo Potency**

J. Palmer1, A. Smith1, R. Burrier1, E. Donley1, F. Kirchner1, D. Kroese2, R. Stober3, and N. Kleinstreuer4. 1National Toxicology Program (NTP) in support of Tox21. In this study, the devTOX assay was consistent with observed developmental toxicity potency of chemicals based on changes in hPS cell metabolism. The assay has been used by multiple industries and, of note, by the United States Environmental Protection Agency (EPA) and the National Toxicology Program (NTP) in support of Tox21. In this study, the devTOX assay included phthalates, developmental vascular toxicants, and neuroactive GPCRs (dopamine, serotonin, endothelins), estrogen signaling, and RAR antagonists. The devTOX assay measures the responses of a pluripotent h9 stem cell response. To address this question, a logistic regression model was built via machine-learning to mine the strongest positive and negative correlates to 331 enzymatic and receptor signaling assays in the ToxCast NovaScreen dataset (NVS). An aggregate model using the lower dose NVS model defined 47 positive and 38 negative correlations. Top sensitive pathways in the STM-NVS model were kinase signaling, some neuroactive GPCRs, and corticotrophs. In contrast, top negative correlations were observed with other neuroactive GPCRs (dopamine, serotonin, endothelins), estrogen signaling, and RAR antagonists. These findings indicate that the scrT assay includes distinct cellular processes that potentially account for the sensitivity of the STM model and guide a battery of fit-for-purpose ToxCast assays covering potential in vitro outcomes. This abstract may not reflect US EPA policy.

**3263 Profiling the ToxCast Library with a Pluripotent Human (H9) Embryonic Stem Cell Assay**

T. B. Knudsen1, T. J. Zurlinden1, K. S. Sall1, J. A. Palmer2, and N. C. Baker3. 1US EPA, Research Triangle Park, NC; 2Stemina Biomarker Discovery, Madison, WI; and 3Leidos, Research Triangle Park, NC.

The Stemina devTOX quickPredict platform (STM) is a human pluripotent H9 stem-cell based assay that predicts developmental toxicants. Using the STM model, we screened 1065 ToxCast chemicals and entered the data into the ToxCast data analysis pipeline. Model performance was 83.3% accuracy (sensitivity 0.78, specificity 0.92) based on 30 common reference compounds in the dataset. Of the 1065 screened chemicals, the STM model predicted 181 (17% tested) as putative developmental toxicants. STM predictivity versus animal studies was examined by a concordance model using prenatal rat and rabbit developmental toxicity studies for 146 chemicals testing positive (dLEL ≤ 125 mg/kg/day) or negative (no dLEL ≥ 1000 mg/kg/day) in ToxRefDB. The cell-based STM model had 76.7% accuracy (sensitivity 0.34, specificity 0.84) when compared with the in vivo results. Compound classes detected by the assay included phthalates, developmental vascular toxicants, and developmental neurotoxicants; misses included glycol ethers, perfluorinated compounds, and endothelin antagonists. The lower sensitivity of the STM model suggests certain pathways/targets may fall outside the responses of a pluripotent H9 stem cell response. To address this question, a logistic regression model was built via machine-learning to mine the strongest positive and negative correlates to 331 enzymatic and receptor signaling assays in the ToxCast NovaScreen dataset (NVS). An aggregate model using the lower dose NVS model defined 47 positive and 38 negative correlations. Top sensitive pathways in the STM-NVS model were kinase signaling, some neuroactive GPCRs, and corticotrophs. In contrast, top negative correlations were observed with other neuroactive GPCRs (dopamine, serotonin, endothelins), estrogen signaling, and RAR antagonists. These findings indicate that the scrT assay includes distinct cellular processes that potentially account for the sensitivity of the STM model and guide a battery of fit-for-purpose ToxCast assays covering potential in vitro outcomes. This abstract may not reflect US EPA policy.

**3264 Medium-Throughput Procedures for Species-Specific, Functional Analyses of Developing Human, Rat, and Mouse Primary Neurospheres: From In Vitro to In Silico**

E. Fritsche1, S. Masjosthusmann1, N. Förster2, M. Barnens1, J. Baumann1, F. Bendt1, K. Dach1, U. Hübenthal1, M. Schmuck1, T. Temme3, and A. Mosig4. 1Leibniz Research Institute for Environmental Medicine, Düsseldorf, Germany; 2Ruhr University, Bochum, Germany; 3Ruhr University, Essen, Germany; and 4Ruhr University, Düsseldorf, Germany.

Testing for developmental neurotoxicity (DNT) of compounds for regulatory purposes, e.g. for screening and prioritization, by using an in vitro testing battery is currently under discussion at the OECD level. Within such a battery a variety of neurodevelopmental processes at different developmental time-points needs consideration. We have been establishing a DNT high content assay based on time-matched fetal human and postnatal rodent neural progenitor cells (NPCs), which proliferate in culture and - under differentiating conditions - migrate and differentiate into neurons and glia cells. We tested more than thirty compounds with this so-called ‘Neurosphere Assay’ for their ability to interfere with human, mouse and rat neurodevelopmental processes. Manual and automatic endpoint evaluations are implemented in the Omnibus software, which exports analysis endpoints as complete concentration-response information into a relational database. Maintaining a structured database of concentration-response information provides a resource from which IC50 values for compound effects on neurodevelopmental endpoints and corresponding viability tests can be computed and compared. Specific heat maps visualize potency of DNT compounds on individual endpoints, across endpoints and in a species comparative manner. More generally, a database resource will facilitate evaluation of a set of preclinical compounds across multiple neurodevelopmental endpoints for DNT in vitro evaluation. As data from more substances will accumulate in such database, a structured data repository will allow to flexibly apply novel and advanced data analysis approaches in the future.
Embryotoxicity is an essential toxicological endpoint in the registration process of chemicals and drugs. Alternative methods to animal testing are being developed for developmental toxicity and applied already for screening purposes. Nevertheless, without transfer of an active substance via the placenta, potential direct effects on the embryo can be neglected. Therefore, considering placental transfer is necessary. The in vitro placental transfer model can be used to determine the placental transfer rate by determining the apparent permeability coefficient (Papp value) of a substance. Using a trophoblastic cell line (BeWo b30) on a transwell system, a cell barrier is formed separating the apical (representing maternal side) from the basolateral (representing fetal side) compartment. However, varied protocols exist and often insufficient characterization is performed. Therefore, in the present study the main methodology is extensively characterized and optimized to enable screening processes. Characterization parameters included are trans-epithelial electrical resistance (TEER), fluorescein transfer (paracellular lumen control), histology, immunohistochemistry of cell tight junctions and transfer of permeability controls amoxicillin (low) and antipyrine (high). The optimization alters the frequency of medium change. Stable cell layer integrity was observed on day 6 based on the characterization parameters, which also showed high reproducibility. The TEER increased from day 3 to day 6 reaching a value of 46.8 Ω·cm². This increase was followed by a decreased of 80% on the Fluorescein transfer, confirming the barrier integrity. The Papp values of permeability controls amoxicillin and antipyrine were in the literature range for both methodology. Moreover, several substances, difenoconazole, flusilazole and triadimenol, were tested for its placental transfer rate, resulting in Papp values from 7.8 to 41.8 x10⁻⁶ cm/s. This highlight that even compounds (high). The optimization alters the frequency of medium change. Mechanistic Evaluation of Improved Testes Structure and Function in Fathead Minnows Exposed to Insensitve Munitions

1US Army Engineer Research and Development Center, Vicksburg, MS; 2Environmental and Fish Health Solutions, Metairie, LA; 3Bennett Aerospace Inc., Cary, NC; 4US Army Engineer Research and Development Center, Cary, NC; and 5River City Early College, Vicksburg, MS.

Previous toxicological investigations of the insensitive munition, 3-nitro-1,2,4-triazol-5-one (NTO), demonstrated histopathological and physiological impacts in mammalian testes. Here, we investigated the effects of 21 days NTO exposure and IMX-101 (composed of NTO, 2,4-dinitroanisole (DNAN), and nitroguanidine) exposure in adult male fathead minnows to assess if impacts on testes were conserved in fish. NTO exposures included 0 (control), 94, 192, 383, and 720 mg/L (measured concentrations) where no significant effects on survivorship were observed. Conversely, the IMX-101 exposures at 6.3, 12.5, 25 and 50 mg/L (nominal, NTO + DNAN + NQ) significantly decreased survivorship at the two highest concentrations, driven by DNAN. NTO exposure significantly impaired spermatogenesis at the 383 mg/L and 720 mg/L exposures where development of stage 3 epithelium was impaired resulting in disproportionately high spermatocytes and necrosis in secondary spermatocytes. The highest NTO exposure also caused testicular degeneration. Microarray-based transcriptomics identified steroid biosynthesis as the most significantly enriched pathway in response to NTO exposure while the structure/function of the axoneme was the most significantly enriched annotation cluster. These results suggest potential impacts on steroidogenesis in testes in addition to the impacts of flagellar molecular motor structure critical in spermatogenesis. The 12.5 mg/L IMX-101 exposure caused a significant increase in sperm necrosis, interstitial fibrosis, and Sertoli-like cell hyperplasia. The most enriched pathways and annotations observed in the IMX-101 exposure indicated changes in genetic signals including RNA transport, zinc-finger PHD motifs, and helicase activity, perhaps indicative of systemic toxicity when approaching the lethal-threshold for IMX-101. The results indicate that NTO can elicit histopathological impacts on fathead minnow testes impairing spermatogenesis likely via impaired steroidogenesis, however these component effects of NTO occur at concentrations far exceeding the lethal concentration of DNAN in the IMX-101 mixture.

Assessing Endocrine-Disrupting Activity of Bisphenols across Multiple Species

A. Medvedev1, M. Moeser1, L. Medvedeva1, E. Martsen1, K. A. Houck2, and S. S. Makarov2. 1Attagene, Research Triangle Park, NC; and 2US EPA, Research Triangle Park, NC.

Bisphenol A (BPA) is an endocrine disrupting chemical, widely used in plastics, food packaging, and other products. Increasing concern over BPA has prompted the search for safer replacements. As adverse effects of BPA can vary significantly among humans and other species, we evaluated the endocrine disrupting activity of a panel of bisphenols, including BPA, bisphenol B (BPP), bisphenol F (BPF) and bisphenol AF (BPAF) on multiple nuclear receptors (NRs) of major vertebrate classes. Specifically, we evaluated responses of estrogen (ER), androgen, thyroid and PPARG receptors of fish, amphibians, reptiles, birds, and mammals. To do that, we used our harmonized multiplexed NR reporter assay (FACTORIAL-MS), which enables profiling the impact of a chemical on the activity of multiple NRs of multiple species in a single well of cells. The bisphenols were compared by the maximal NR activation (Emax) and the half-maximal response concentration (EC50). The predominant effects of bisphenols were ER activation, which varied significantly among species. According to the EC50 and Emax values, we ranked the overall ER potency across multiple species as BPA>BPF>BPF>BPF. The strongest BPA effects were at human ERβ (Emax=102% of estradiol, EC50=380nm) and zebrafish ER1 (Emax=106% of estradiol, EC50=2.1nm). Among species, the most susceptible NR to three bisphenols (BPA, BPP, BPF) was zebrafish ERβ (Emax of 62% of estradiol). Interestingly, we also found specific activation of human and mouse PPARG by BPF (Emax~11% of rosiglitazone). These results provide assessments of species-specific effects of bisphenols and demonstrate the utility of FACTORIAL-MS assay for high-throughput evaluation of endocrine disruptors and other drug candidates across multiple species.

Comparison of Mammalian and Amphibian Tests for Detection of Thyroid Active Chemicals

Z. Dang. RIVM, Bilthoven, Netherlands.

Test guidelines for detecting thyroid activity of a chemical include amphibian and mammalian tests. Only some of mammalian tests are included in standard information requirements of the EU legal frameworks for pesticides, biocides and industrial chemicals. The amphibian assays are not included. Data interpretation across taxa is needed for the identification of endocrine disruptors in these EU frameworks. To answer the question whether information derived from mammalian assays can be used for indicating chemicals with thyroid activity in amphibians or vise versa, publically available data of 50 chemicals tested in both amphibians and mammals were reviewed. Based on the changes in thyroid responsive endpoints including hind limb length (HLL), development of thyroid and thyroid histology in amphibians, as well as endpoints of thyroid hormones (T3, T4, TSH), thyroid weight, and thyroid histology in mammals, 15 chemicals are concluded to have the potential to interact with the hypothalamic-pituitary-thyroid (HPT) axis; with 6 chemicals responsive in both amphibians and mammals; 7 chemicals responsive in mammals but not in amphibians; and 2 chemicals responsive in amphibians but not in mammals. These results suggest that not all thyroid active chemicals showed the potential to interfere with the HPT axis across different vertebrate taxa, although there is a high degree of the thyroid system conservation. When interpreting data across taxa, some cautious should be paid due to the differences in exposure routes and in sensitivity of amphibian and mammalian assays. Recommendations for a testing strategy for the thyroid pathway are currently in development.

Trace Concentrations of Emerging Contaminants Dysregulates Nitric Oxide Levels and Superoxide Dismutase Activity in Mice: Differential Roles of Sex and PPARs

P. K. Gonnabathaula, and M. A. Yakubu. Texas Southern University, Houston, TX. Sponsor: A. Adedapo

Contaminants of Emerging Concern (CEC) are chemicals detected in water/environments that were not detected previously or were found at trace levels. Possibility exist for interactions of these diverse chemicals at low levels, multiple interactions-interfacing with sensitive biochemical pathways to cause harm. We have investigated the effects of trace concentrations (ng/L) of multiple CEC on essential biomolecules -Nitric oxide (NO), superoxide dismutase (SOD) activities in wild type and PPARα knockout mice. Mice (male and female) were exposed to trace concentrations of CEC comprising: atrazine, dieldrin, endrin, endosulfan and atrazine -1(100ng/L) in drinking water for six weeks. Blood and organs were collected, homogenized, NO levels and SOD activity were determined by Griess/SOD assays. In the blood samples, low CEC reduced NO (20%) in the female with no changes in male. In wild type, NO levels was 90% higher compared to PPARα knockout female. NO levels increased in tissues from wild type: spleen (80%), heart (75%), liver (80%), kidney (85%) and brain (85%), while in PPARα knockout NO levels was reduced in spleen (45%) but increased in the kidney (55%), no change in the brain, liver, and heart. In the male, NO levels were reduced in the heart (66%) and liver (40%) with no changes in the kidney, spleen, brain, and testicles. Blood SOD activity is 90% lower in male than female; CEC increased SOD activity by 20% in male with no change in the female. In female SOD activity was significantly increased in the heart (30%), liver (25%) and spleen (25%) by CEC with no effect on the brain and the kidney. In the PPARα knockout mice, SOD activity was significantly reduced in the heart (50%) and liver (25%) but not in the kidney, spleen, and brain. Thus, trace concentrations of multiple pesticides caused selective dysregulation of NO/SOD systems in different organs of the body. The effects observed was sex dependent and may be influenced by genetic status as in PPARα knockout. These results indicate that nano-concentrations of series of organic contaminants can cause cellular and molecular dysregulations of biomolecules precipitating toxicity and pathology that can be a threat to human health. Further investigation into the molecular mechanism(s) and signaling pathway(s) implicated in these dysregulations is warranted and of interest.
Boekelheide

from their wild-type (WT; Ctr1 hand, SC-KO mice had indistinguishable testis weight and histology (~83% by PND 41) with almost complete depletion of GCs. On the other hand, SC-KO mice had 35% reduced GC death a single high dose of 5 mg/kg of cDDP or equivalent volume of saline for 48 hours. We found that SC-KO mice had 35% reduced GC death compared to its SC-WT littermates. Platinum levels in testis tissue and in the seminiferous tubules of treated mice showed no difference between both genotypes, however intracellular platinum levels were reduced by 30% in cDDP-treated primary SCs derived from both genotypes. Taken together, these observations reveal for the first time 1) the required role of CTR1 in GCs, but not in SCs, for functional spermatogenesis and 2) the participation of CTR1 by the SCs on mediating cDDP-induced GC loss. Future investigations will utilize SC-KO as a mouse model to study the contribution of the environmental niche provided by the SC on spermatogenesis followed by clinically relevant multi-dose cDDP treatment, and the GC-KO mice will be utilized to explore the importance of CTR1 and/or copper on spermatogenesis.

Cisplatin (cDDP) is a highly effective chemotherapeutic drug. However, treatment with cDDP contributes to many adverse side effects including prolonged azoospermia in male patients. Although it is known that cDDP disrupts spermatogenesis, its main cellular target and mechanism responsible for its last effects on fertility remain unknown. The high affinity membrane copper transporter 1 (CTR1; SLC31A1) has been shown to be involved in cDDP uptake in both in vivo and in vitro studies. Our preliminary evaluation on mice testes indicates that CTR1 is primarily expressed in primary spermatocyte germ cells (GCs) and Sertoli cells (SCs). To examine the role of CTR1 in the testis as well as to discern the relative contribution between CTR1 in SC and GC to the lasting cDDP-induced disruption in spermatogenesis, we have developed two independent mouse models, with the conditional knockout of Ctr1 in either SCs (SC-KO; Amh-Cre, Ctr1fl/Δ) or GCs (GC-KO; Ddx4-Cre, Ctr1fl/Δ). Interestingly, GC-KOs exhibit a severe reduction in testis weight (~83% by PND 41) with almost complete depletion of GCs. On the other hand, SC-KO mice had indistinguishable testis weight and histology from their wild-type (WT; Ctr1fl/Δ) littermates, with all stages of spermatogenesis present. The SC-KO mice were further challenged with an acute dose of cDDP, where the SC-KO and WT mice were either exposed to a single high dose of 5 mg/kg of cDDP or equivalent volume of saline for 48 hours. We found that SC-KO mice had 35% reduced GC death compared to its SC-WT littermates. Platinum levels in testis tissue and in the seminiferous tubules of treated mice showed no difference between both genotypes, however intracellular platinum levels were reduced by 30% in cDDP-treated primary SCs derived from both genotypes. Taken together, these observations reveal for the first time 1) the required role of CTR1 in GCs, but not in SCs, for functional spermatogenesis and 2) the participation of CTR1 by the SCs on mediating cDDP-induced GC loss. Future investigations will utilize SC-KO as a mouse model to study the contribution of the environmental niche provided by the SC on spermatogenesis followed by clinically relevant multi-dose cDDP treatment, and the GC-KO mice will be utilized to explore the importance of CTR1 and/or copper on spermatogenesis.

In utero phthalate exposure results in significant testicular pathology in mammalian testes, despite the lack of an anti-androgenic effect on mouse and human fetal testes. Retinoic acid signaling is critical for sex determination and gonadal sex-determination pathways in Ex Vivo Cultured Rat and Mouse Fetal Testes. Phthalates are peroxisome proliferators that bind to peroxisome proliferator-activated receptors and may engage in crosstalk with other nuclear receptors, including retinoic acid receptors. Therefore, we hypothesized that retinoic acid signaling is disrupted by phthalates, contributing to phthalate toxicity in the fetal testes. To test this hypothesis, rat and mouse fetal testes isolated on gestation day 15 and 14, respectively, were exposed in tissue culture to 10-6 M all-trans retinoic acid (ATRA) with or without 10-6 to 10-4 M mono-(2-ethylhexyl) phthalate (MEHP). In rat fetal testes, ATRA exposure caused a loss of seminiferous cord structure, accompanied by an increase in expression of a retinoic acid receptor target gene, Rbp1, and sex determination genes Nr0b1 and Wnt4. The testicular pathology was reversed in a concentration-dependent manner by addition of MEHP. The interaction between MEHP and ATRA also led to an additive increase in Rbp1 expression, but non-linear response in expression of Nr0b1 and Wnt4. In the mouse, ATRA-MEHP co-exposure resulted in similar testicular pathology. Given this evidence that MEHP interacts with ATRA to influence both retinoic acid signaling and sex determination in the fetal testes, we conclude that disruption of retinoic acid signaling is a mechanism of phthalate toxicity in the fetal testis of both rats and mice.

Cisplatin (cDDP) is a highly effective chemotherapeutic drug. However, treatment with cDDP contributes to many adverse side effects including prolonged azoospermia in male patients. In the mouse, ATRA-MEHP co-exposure resulted in similar testicular pathology. Given this evidence that MEHP interacts with ATRA to influence both retinoic acid signaling and sex determination in the fetal testes, we conclude that disruption of retinoic acid signaling is a mechanism of phthalate toxicity in the fetal testis of both rats and mice.
Fetal exposure to diethylstilbestrol (DES), a synthetic estrogen, is associated with an increased risk of both male and female reproductive tract defects including vaginal cancer, cryptorchidism, and infertility in humans. We have exposed a panel of genetically diverse inbred mouse strains, including Collaborative Cross (CC) strains, to either vehicle or DES (2 µg) on postnatal days (PND) 1-5. The CC is a mouse genetic reference population ideal for toxicogenomics studies, and this study is among the first to use the CC with a developmental exposure paradigm. DES exposure reduces male reproductive organ weights, and epididymal sperm counts in adult mice. Importantly, the severity of DES-induced abnormality in male reproductive tracts varies among strains, demonstrating the substantial contribution of genetic diversity to DES susceptibility. At adulthood, non-susceptible mouse strains exhibit relatively normal testicular structure following DES exposure, while DES-treated susceptible mouse strains show marked testicular degeneration with reduced germ cell numbers, decreased tubule diameters and increased areas of interstitial tissue. We observe an impaired first wave of spermatogenesis from a DES-treated susceptible CC strain that persists into adulthood. This disruption is evidenced by the presence of immature Sertoli cells, pre-mature depletion of spermatogenic cells, and the absence of pachytene spermatocytes and/or spermatids. DES exposure increases Nr0b2 level and decreases expression in susceptible CC mouse testes on PND21, indicative of Leydig cell damage associated with estrogen receptor activation. These results demonstrate that the CC is an ideal platform to identify specific gene by environment interactions in mice.

Organochlorides are among the most abundant and persistent chemicals in the environment. Organochlorine pesticides, such as dichlorodiphenyltrichloroethane (DDT), have been documented to cause effects upon fecundity were observed, however a dose-related decrease in reproductive tissue weights, genital malformations (cleft phallic, cleft prepucce, hypospadias, vaginal pouch), retained nipples, epididymal agenesis, and undescended testes. Mixture modeling of AGD reduction and incidence of hypospadias or cryptorchidism in adult males generally occurred in the 25-100% dose groups including reduced reproductive tissue weights, genital malformations (cleft phallus, cleft prepuce, hypospadias, vaginal pouch), retained nipples, epididymal agenesis, and undescended testes. Mixture modeling of AGD reduction and incidence of hypospadias or cryptorchidism in adult males generally occurred in the 25-100% dose groups including reduced reproductive tissue weights, genital malformations (cleft phallus, cleft prepuce, hypospadias, vaginal pouch), retained nipples, epididymal agenesis, and undescended testes. in the described AOP for cryptorchidism, but may be a key event for other cryptorchidism AOPs during this window of development. While extensive data were relied upon to underpin the proposed AOPs, the confidence in each of the AOPs varies and gaps remain, including the molecular initiating events for all AOPs.

**3281 Uncertainty and Variability in High-Throughput Toxicokinetics for Risk Prioritization**

1US EPA, Research Triangle Park, NC; 2Cytospect, Watertown, MA; 3SciToxation, Research Triangle Park, NC; and 4ToxStrategies, Austin, TX.

Streamlined approaches that use in vitro experimental data to predict chemical toxicokinetics (TK) are increasingly being used to perform risk-based prioritization based upon dosimetric adjustment of high-throughput screening (HTS) data across thousands of chemicals. However, assessments of the impact of uncertainty and variability on these TK values and subsequent predictions are needed to guide data interpretation and provide overall confidence in high-throughput TK (HTTK) approaches. In this study, Bayesian methods were developed to provide chemical-specific uncertainty estimates for two in vitro TK parameters: plasma protein binding (\(K_p\)) and intrinsic hepatic clearance (\(CL_{int}\)), using chemical-specific experimental measurements derived. Inclusion of experimental measures across three physiologic plasma protein concentrations reduced the uncertainty in the \(K_p\) estimates. Uncertainty estimation was additionally conducted for predictions of volume of distribution (\(V_d\)) and steady-state serum concentration (\(C_s\)). Monte Carlo simulation to propagate both measurement uncertainty and biologic variability into the predicted TK for most chemicals, variability contributed more than uncertainty to \(C_s\) estimations of the 95th percentile. Risk-based prioritization of chemicals based upon high throughput exposure estimates and dosimetric adjustment of ToxCast HTS data using Bayesian-derived \(C_s\) estimates incorporating uncertainty and/or variability demonstrated that prioritization would change for a few chemicals when uncertainty is included. Incorporation of these methods provides a timely risk-based prioritization strategy that considers the relationship between in vitro bioactivities and exposures, overlaid with a metric for TK prediction uncertainties. This abstract does not necessarily reflect US EPA policy.

**3282 Feedback Regulation through the Hypothalamic-Pituitary-Endocrine Loop as a Potential Mechanism for Nonmonotonic Dose Responses of Endocrine-Disrupting Chemicals**

Q. Zhang. Emory University, Atlanta, GA.

Endocrine-disrupting chemicals (EDCs) often exhibit nonmonotonic dose response (NMDR) behaviors. A number of mechanisms have been proposed for the nonmonotonic effects, including existence of multiple hormone receptor isoforms with opposite effects, receptor desensitization, and formation of mixed-ligand heterodimers. Besides these local mechanisms, NMDR of EDCs is also believed to be a systems-level behavior of the neuroendocrine feedback regulation, although the exact mechanism is unclear. In the present study we use dynamical modeling of the hypothalamic-pituitary-endocrine organ (HPE) loop to investigate whether and how an NMDR may occur as a result of feedback regulation. In the model, a high loop-gain proportional control or an integral control is implemented in the central site containing the hypothalamic and pituitary gland. Such control mechanism can achieve near perfect adaption to EDCs disrupting the synthesis, secretion or clearance of the hormones secreted by the terminal endocrine organs. However, if an EDC acts as an agonist and has access to the central feedback sites in the hypothalamus and pituitary to inhibit the secretion of hypothalamic releasing hormones and the pituitary hormones, the levels of the peripheral hormones will decrease accordingly, compensating against the agonistic effects of the EDC. Model simulations indicate that when the agonist’s affinity for the hormone receptors in the peripheral target tissue is less than that of the endogenous hormone and/or when the agonist’s affinity for the hormone receptors in the central site is greater than that of the endogenous hormone, a J-shaped dose response relationship can arise between the agonist EDC and the peripheral tissue effects. In such cases although the EDC functions as an agonist by itself, due to feedback regulation it results in an inhibitory effect at low doses. In target tissues where the agonist’s affinity for the hormone receptor is no less than that of the endogenous hormone, a stimulatory effect can be obtained for low doses of EDCs. Conversely, an inverted U-shaped dose response occur when the EDC functions as an antagonist. In summary, our modeling results suggest that for an EDC biochemically functioning as a hormone agonist or antagonist, the HPE feedback regulation plays a pivotal role in determining the direction of the EDC’s effects in peripheral target tissues.

**3283 A Biologically Based Dose-Response (BBDR) Model for the Effects of Perchlorate Exposure and Iodine Intake on Thyroid Hormone Levels in Women Prior to and During Early Gestation**

P. M. Schlosser1, D. F. Kapraun1, and T. L. Leavens2.

1US EPA, Washington, DC; and 2PK Consultant, Cary, NC.

Perchlorate (ClO₄⁻) has both natural and synthetic sources and is released to the environment as a salt; it is highly stable and has high water solubility and mobility in aqueous environments. Once ingested, ClO₄⁻ is readily absorbed and distributed in blood plasma, allowing it to competitively inhibit iodide transfer by the sodium-iodide symporter (NIS). NIS-mediated iodide uptake by the thyroid is necessary for production of thyroid hormones (T₃ and T₄), which are essential for development and growth of fetuses, infants, and young children, and to metabolism and energy regulation at all ages. Iodide insufficiency during pregnancy is known to cause severe neurodevelopmental effects, while reductions in maternal TH levels in early pregnancy have been linked to subsequent levels in children. Perchlorate exposure in pregnant women is common, and is often considered for the lactating mother, describing dietary iodine economy, thyroidal function, and TH production and distribution, along with ClO₄⁻ pharmacokinetics and NIS inhibition, was adapted to describe these processes in the woman prior to pregnancy and through gestation week (GW) 14. This model incorporates two key improvements over a previous late gestation model: 1) a majority of maternal ClO₄⁻ to iodide ratio, that for most chemicals, variability contributed more than uncertainty to \(C_s\) estimations of the 95th percentile. Risk-based prioritization of chemicals based upon high throughput exposure estimates and dosimetric adjustment of ToxCast HTS data using Bayesian-derived \(C_s\) estimates incorporating uncertainty and/or variability demonstrated that prioritization would change for a few chemicals when uncertainty is included. Incorporation of these methods provides a timely risk-based prioritization strategy that considers the relationship between in vitro bioactivities and exposures, overlaid with a metric for TK prediction uncertainties. This abstract does not necessarily reflect US EPA policy.

**3284 PBPK Modeling of Piperacillin and Tazobactam in Premature Neonates**

1US FDA/NCTR, Jefferson, AR; 2Procter & Gamble Company, Cincinnati, OH; 3Duke University School of Medicine, Durham, NC; and 4US FDA, Silver Spring, MD.

Piperacillin (PIP) and Tazobactam (TAZ) injection, a combination broad-spectrum antibiotic agent, is used in neonatal intensive care units to treat bacterial infections in premature neonates. To assess the effect of early birth on the pharmacokinetics of PIP and TAZ, a novel 7-compartment flow-limited physiologically based pharmacokinetic (PBPK) model was constructed to characterize the rapid developmental changes in physiological and biochemical processes in neonates for gestational birth ages ranging from 25 to 40 weeks. This provisional model describes growth and maturation processes for up to 2 years after birth. Tissue:plasma partition coefficients for PIP and TAZ were calculated using published mechanistic algorithms in PK-Sim software or from reported experimental tissue to plasma concentration ratios. These drugs are primarily excreted in urine by glomerular filtration and tubular secretion. Urinary clearance rates for PIP and TAZ were derived by extrapolation of clearance rates reported for older infants. Hepatic metabolism, a minor clearance pathway in older infants, was also evaluated for its possible role in describing the development of this elimination pathway in preterm infants. Initial simulations, without any adiabatic values, were performed using computer simulation software. Initial model predictions were evaluated by comparing with observed data from 9 premature neonates. Based on visual inspection of the plasma PIP and TAZ concentration-time data, model predictions were typically within 2- to 4-fold of the measured values for the 9 neonates that were evaluated.
While a very promising outcome, a better mechanistic understanding of key biological determinants in very early life is needed to increase model predictive performance. In addition, expansion of this provisional model to characterize age-dependent growth into childhood and adulthood is planned.

**3285 Evaluating the Influence of Physiological Changes during Pregnancy on Oseltamivir Dosimetry Using Physiologically-Based Pharmacokinetic (PBPK) Modeling**

M. Reginio1, and A. Lumen.1, 2Ridgway Christian School, Pine Bluff, AR; and 2US FDA/NCTR, Jefferson, AR.

Oseltamivir (brand name, Tamiflu) is a prescription antiviral drug used to treat influenza (virus types A and B) in humans. Oseltamivir is approved for use in adults and children with the dosage varying with age and body weight. However, the effective dosing regimen in pregnancy conditions remains to be evaluated. Physiological changes that occur during the gestational period affect the pharmacokinetics of the drug leading to the potential concern of under-dosing of oseltamivir in pregnant women. The overall goal of this project is to quantify the effects of physiological changes on oseltamivir pharmacokinetics and to determine the appropriate dose-adjustments for pregnant women to maintain equivalent internal exposure as in non-pregnant adults. In the absence of pregnancy, the therapeutic model in model in pregnant women was first, second, and third trimesters. The changes in physiological parameters were captured in the model using descriptive mathematical equations as a function of gestational age. The model predicted an overall increase in drug plasma concentration over the course of pregnancy. Following which we implemented an iterative modeling routine incrementally adjusting the oral dosage for each trimester of pregnancy. The findings suggest that the current treatment dose of 75 mg twice a day should be increased by 16%, 38%, and 35% in the first, second, and third trimesters, respectively, to yield plasma concentrations of the active drug equivalent to that determined in non-pregnant adults. Similarly, the dose-adjustments necessary for the prophylaxis dose of 75 mg once a day in pregnant women was predicted to be 17%, 41% and 63% higher. These efforts could help guide regulatory decision making and provide clinical practitioners with data-driven recommendations for oseltamivir dosimetry during pregnancy. Future work will focus on the expansion of the current research analysis to other anti-viral drugs to predict safe and efficacious dosing regimens in pregnant women.

**3286 Physiological Simulation of Thermal and Chemical Stressors in a United States Air Force Population**

J. M. Gearhart1, E. Pitts1, T. R. Covington2, C. M. Grabinski3, D. P. Yamamoto2, D. McKenzie-Smith2, D. K. Ott, and H. A. Pangburn2. 1Aeromedical Research Department, Wright-Patterson AFB, OH; and 2US Air Force, Wright-Patterson AFB, OH.

Thermal stress research has focused on understanding the critical physiological need to maintain a constant internal body temperature of 37°C despite changes in the external environment and levels of exercise. Stable core body temperature is critical to provide optimum physiological conditions for favorable cellular metabolism within blood and tissues. The DoD operational environment often incurs incidents of concurrent thermal/heat stress and toxic chemical exposure. Our objective was to introduce a recently developed thermal and chemical dosimetry model in human military personnel. Subjects wore Zephyr BioHarness chest straps to sense skin concurrent thermal/heat stress and toxic chemical exposure. Our objective was to translate in vitro constitutive androstane receptor (CAR) agonist and antagonist assay data for organophosphate (OP) pesticides to in vivo toxic potency values for the human, using physiologically-based pharmacokinetic (PBPK) modeling-based reverse dosimetry. To this purpose, PBPK models were developed for Malathion (Mal) and Parathion (Par). Each PBPK model consists of five compartments and can be used for inhalation, oral, and dermal routes of exposure. The hepatic tissue was used as a surrogate to describe tissue concentration. Using the PBPK dosimetry approach, in vitro concentration-response curves of the CAR test were translated into in vivo tissue dose-response curves from which PODs were derived for the pesticide exposure, indi vidual or in combination. For the CAR exposure, the concentration was 50µM for Mal and Par. For the CAR agonist the change was +50% at 100 µM for Mal and approximately 35% for Par. This biologic modeling estimated an equivalent external dose corresponding to the concentration in hepatic tissue for Mal oral (495), inhalation (4) and dermal (9025) mg/kg bw exposures, and for Par oral (380) and dermal (13600) mg/kg bw exposures. These results suggest the importance of the route of exposure for an equivalent tissue concentration. A current limitation is that only the parent compound and not the metabolite assay data are available in Tox21, they should be integrated as data become available. In conclusion, this study shows the feasibility of using in vitro data to estimate in vivo levels of pesticides and their mixtures using PBPK dosimetry for non-animal-based risk assessment of pesticides. The findings and conclusions in this presentation have not been formally disseminated by [the Centers for Disease Control and Prevention/ the Agency for Toxic Substances and Disease Registry] and should not be construed to represent any agency determination or policy.

**3288 Understanding Implications of Metabolic Interactions between Benzo[a]pyrene (Ba[a]P) and Dibenzo[def,p]chrysene (DBC) in Rodents and Humans Using Physiologically-Based Pharmacokinetic (PBPK) Modeling**

Humans are rarely exposed to a single polycyclic aromatic hydrocarbon (PAH) and, instead, are routinely exposed to complex PAH mixtures. Since multiple PAHs can be substrates for various individual cytochrome P450 enzymes (e.g. CYP1A1, CYP1B1, etc.), it is hypothesized that exposure to PAH mixtures can cause metabolic competition, inhibiting PAH metabolism, and affecting PAH clearance, detoxification, bioactivation, and toxicity. To test this hypothesis, the ability of parent PAHs to compete for metabolism in binary mixtures was quantified using in vitro assays to measure the required chemical concentration to produce an effect, the point of departure (POD). Such in vitro PODs data can be extrapolated to in vivo species including humans, at the biological effective dose concentration if no specific mechanism appeared in the target organ. The aim of this study was to determine the potential of metabolic interactions between Ba[a]P and DBC. For the parent-parent interactions, it was observed that DBC was a more potent inhibitor than Ba[a]P for rats and humans. However for mice, Ba[a]P was a more potent inhibitor than DBC. Similar to the parent-metabolite interactions, DBC-diol was found to be a more potent inhibitor than Ba[a]P-diol for mice and rats, whereas, for humans, Ba[a]P-diol was the more potent inhibitor. These results suggest that care should be taken when utilizing measured core body temperature change and chemical exposure simultaneously in the active military occupational environment, providing a robust in silico human simulation that allows computer based mission planning and hazard assessment with limited individual real-time data collection.
animal models to predict human hazard of PAH mixtures. PBPK model simulations predict the extent of metabolic inhibition and implications to internal dosimetry at various exposure levels of these binary PAH mixtures. Ultimately this model can be used as a tool for understanding implications of PAH mixtures on human health.

**3289 Human Plasma and Urinary Metabolic Profiles of Trimethylamine and Its N-Oxide Extrapolated Using Humanized-Liver Mice and Simple Physiologically-Based Pharmacokinetic Models**

H. Yamazaki1, H. Suemjuz2, and M. Shimizu1, 1Showa Pharmaceutical University, Machida, Japan; and 2Central Institute for Experimental Animals, Kawasaki, Japan.

Trimethylamine, a dietary- and medicinal carnitine-derived amine, is extensively metabolized by liver to non-malodorous trimethylamine N-oxide. Although trimethylamine and trimethylamine N-oxide under daily dietary consumption or carnitine treatment are generally regarded as nontoxic, they have been, and remain, toxicological and clinical interest because of their potential association with atherosclerosis. The aim of the current study was to model the pharmacokinetics of trimethylamine after oral administration of trimethylamine in humans 1) based on rat reported values in literature and 2) experimental pharmacokinetics after orally administration to the humanized-liver mice with deuterium-labeled trimethylamine. Trimethylamine N-oxide was extensively formed by humanized liver, but not by mouse livers or in rats as reported. Adjusted trimethylamine biomonitoring equivalents from rat studies were scaled to human equivalents using known species allometric scaling factors and in vitro metabolic clearance data obtained using rat and human liver microsomal preparations. In this approach, renal clearances in humanized-liver mice and trimethylamine N-oxide were calculated with a clearance concept approach using reported 24-h urinary excretion rates and assumed areas under plasma concentration curves. The experimental pharmacokinetic data of deuterium-labeled trimethylamine and its N-oxide in humanized-liver mice were also scaled up to humans. The resulting modeled plasma and urinary concentration curves by simple physiologically based both pharmacokinetic models (or semi-physiological pharmacokinetic models) were consistent with reported concentrations. This study provides important information to help simulate human plasma levels of trimethylamine and trimethylamine N-oxide in trimethylamine loading tests and during treatment with prescribed medicinal l-carnitine, showing the similar range as that resulting from daily dietary foodstuff consumption along with little toxicological impacts. The present models could estimate relationship between plasma and urine concentrations of trimethylamine or trimethylamine N-oxide and the daily oral doses by both forward and reverse dosimetry from viewpoint of human risk assessment.

**3290 The Kinetically Derived Maximum Dose (KMD), a New Dimension to the Maximum Tolerated Dose (MTD)**

J. Domoradzki, The Dow Chemical Company, Midland, MI.

Evaluations of chemicals tested under dose-selection protocols using a maximum tolerated dose (MTD) design (e.g., decreased body weight and/or histological injury) are increasingly revealing that interpretation is confounded by the onset of non-dose-proportionate systemic dose (i.e., nonlinear toxicokinetics). This is due to saturated absorption, distribution, and metabolism and/or clearance mechanisms of parent chemical and/or metabolites. Recent toxicity testing guidance from the Organisation for Economic Co-operation and Development (OECD) and US Environmental Protection Agency (US EPA) and other evaluations from the National Academy of Sciences (NAS) and ILSI Health and Environmental Sciences Institute (HESI) have clearly indicated that toxicity observed only under nonlinear toxicokinetic conditions often has limited, if any, quantitative relevance to risks to human health if the onset of dose-non-proportionality is well separated from real-world human exposures. Detection of nonlinear toxicokinetics has been improved by analytical techniques/approaches that have made assessment of systemic/internal dose in test animals substantially more sensitive, lower cost, and higher throughput. In addition, determination of whether the onset of toxicokinetic nonlinearity is well separated from human exposure is increasingly possible given rapid improvements in modeling and/or analytical biomonitoring analyses supporting human environmental exposure assessments. Saturation of any biological process should be evaluated for its relevance to dose-response relationships relative to human exposure. Systemic dose non-proportionality should not be treated any differently from toxicity findings due to excessive stress indicated by the conventional MTD approach. Use of evidence of dose non-proportionality for selection of an acceptable top dose for animal toxicity testing has been termed the kinetically-derived maximum dose (KMD). Despite the convergence of these indisputable advances, however, current toxicity testing protocols and interpretation of existing toxicity test findings continue to be largely dominated by long-ingrained concepts of conventional MTD thinking. Current toxicity test dose selection often is conducted oblivious to a prior evaluation of toxicokinetic internal non-dose-proportionate systemic measures sensitive, costly, and animal-intensive post hoc mode-of-action analyses are frequently implemented to address high-dose specific toxicity findings that could (should) otherwise be ruled out as quantitatively non-human relevant on systemic dose alone. Thus, effective implementation of the fundamental toxicology principle of “the dose makes poison” must include an ever-expanding commitment to consideration of animal and human internal dose evaluations as a key part of chemical risk assessment. The rapid expansion of analytical technologies, exposure assessments, and reducing the use of animals demands nothing less. The objective of this session is to catalyze understanding and discussion surrounding the use of systemic dose kinetics in selection of improved human-relevant doses in animal toxicity testing and/or retroactive interpretation of high-dose specific toxicity findings; and 4) reg-ulatory perspectives on use of findings at non-dose-proportional doses in human risk assessment. The roundtable discussion between speakers and the audience will address the implications of KMD-based assessments for the practice of toxicology and risk assessment, such as: 1) the KMD as a replacement for the MTD; 2) research and policy constraints in the use KMD; 3) adequacy of existing regulatory toxicity testing guid-ances; 4) protocol design (e.g., toxicokinetics to support KMD evaluations); 4) offering an alternative to conducting conventional high-dose specific mode-of-action investigations; 5) assisting design and interpretation of adverse outcome pathway (AOP)/mode-of-action studies; and 6) informing life-stage-specific differences in toxicity.

**3291 The US Tox21 Collaboration: A Decade of Experience and a New Vision for the Future**

B. Meek, University of Ottawa, Ottawa, ON, Canada.

In 2007, Tox21 was launched as a multi-agency collaborative effort among the National Institutes of Health (NIH)’s National Institute of Environmental Health Sciences (NIEHS), National Toxicology Program (NTP), and the National Center for Advancing Translational Sciences (NCATS); the US Environmental Protection Agency (US EPA)’s National Center for Computational Toxicology (NCCT); and the US Food and Drug Administration (US FDA). The objective of this partnership was to shift the assessment of chemical hazards from traditional experimental animal toxicology studies to one based on target-specific, mecha-nism-based, in vitro assays, with the ultimate aim of improving human and environmental risk assessments. In this regard, the collaborative was highly successful in that thousands of chemicals have been screened in hundreds of bioassays. These data have been publicly released for consideration and use in a range of contexts, including regulatory deci-sions. However, complex challenges remain. The intent of this symposium is to review the 2017 strategic plan for Tox21 and gain feedback from the diverse stakeholders at SOT. The new strategic plan promotes: 1) addressing key limitations in in vitro assays; 2) continued development and use of alternative test systems that predict human toxicity; 3) management and curatIon of large chemical libraries; 4) curatIon of legacy in vivo toxicity studies; 5) performance-based validation of high-throughput in vitro, in silico, stem cell and microphysiological systems, and other emerging technologies; and 6) development and use of in vitro methods for characterizing pharmacokinetics. Each of the speakers will summarize lessons learned and outline their agency’s approaches aimed at solving complex challenges. The strategy embraces transpar-ency and technological change, aims to protect human health environ-ment, with an ultimate goal of fostering broader acceptance of alterna-tive data streams in regulatory decision.
3292 Research-Based Approaches to Improve Teaching Effectiveness in Toxicology Classrooms

B. Kaplan, Mississippi State University, Mississippi State, MS.

Teaching students effectively at all levels in science requires continuous learning on the part of the instructor. Not only is content knowledge increasing, so are the tools to teach it. At the heart of pedagogy, though, is research about how students learn to maximize educational outcomes and retention. While lecturing has been the predominant method of instruction since the founding of universities, there is evidence to suggest that this is not the most effective way to teach. Through national initiatives such as the National Science Foundation’s Vision and Change in Undergraduate Biology Education, research-based teaching methods are having a growing impact in higher education. This session will bring together educators to talk about best practices in student-centered teaching that are applicable to all educational levels. The topics to be discussed include: 1) an introduction to designing course methods, assignments, and assessments to optimize students’ opportunities to learn; 2) lessons learned from a flipped classroom; 3) the use of problem formulation and experimental design in the context of a graduate immunotoxicology classroom; 4) how community-engaged learning and research can improve comprehension, recruitment, and retention; and 5) case studies from industry to teach about risk communication. This session will conclude with time for questions, giving audience members an opportunity to further explore these and other related topics. This session will be of interest to current educators and those interested in teaching, such as graduate students and postdocs.

3295 In Vivo-In Vitro Comparison of Acute Respiratory Tract Toxicity Using Different 2D and 3D Models and a Successful Example Using Physico-Chemical Characteristics of the Test Substance

R. Lansiedl. BASF, Ludwigshafen am Rhein, Germany.

The usefulness of in vitro systems to predict acute inhalation toxicity was investigated. Results obtained in testing different materials in three-dimensional human airway epithelial models, EpiAirway and MucuAir, as well as and in A549 and 3T3 monolayer cell cultures, were compared to rat four-hour LC50 values classified according to US EPA and GHS hazard categories. Best results were achieved with a prediction model distinguishing toxic from non-toxic substances. Differentiation of toxic substances by their potency was mediocre but could be improved by excluding substances causing pulmonary edema and emphysema in vivo. None of the test systems was outstanding, and there was no evidence that tissue or monolayer systems using respiratory tract cells provide an added value. However, the test systems only reflected bronchial epithelia and alveolar cells and investigated cytotoxicity. Effects occurring in other cells by other mechanisms could not be recognized. Further work should optimize test protocols and expand the set of substances tested to define applicability domains. In vivo respiratory toxicity data for in vitro comparisons should distinguish different modes of action, and their relevance for human health effects should be ensured.

3293 In Vitro Test Methods to Model Local Respiratory Effects after Exposure to Pulmonary Toxicants: Not Just Smoke and Mirrors

H. Behrsing, Institute for In Vitro Sciences, Gaithersburg, MD.

The lungs are exposed to a wide range of toxicants, including environmental, pharmaceutical, and occupational. Evaluating this assortment of toxicants has necessitated the development of physiologically-relevant in vitro models. These in vitro models have proven to be sensitive, robust, reproducible, and capable of providing a diverse outcome of responses. These in vitro models focus on biomarkers related events by cytokine secretion, mucus production, goblet cell hyperplasia, and increased ciliary beat frequency. This session will explore recent findings in vitro toxicology that link a variety of pulmonary toxicants with their common inflammatory outcomes. The first speaker will focus on in vitro pulmonary models and their incorporation into a testing scheme. In the second presentation, a comparison of cell lines to 3D air-liquid interface (ALI) will be detailed. The third speaker will discuss in vivo-in vitro comparisons, as well as 3D ALI. The fourth speaker will demonstrate dosimetry modeling of in vitro e-cigarette exposure. Speaker five will reveal the fact that in vitro models have been taken into animal exposure modeling. Further comparisons between different in vitro exposure systems will be explained by speaker six. Finally, the last speaker will lay out the requirements to achieve in vitro testing regulations and the role each sector must play in achieving regulation. These speakers, who come from a mix of government and industry backgrounds, demonstrate how a range of pulmonary exposures can be evaluated using in vitro methods for detecting local respiratory effects and the steps necessary to establish regulations for these testing methods.

3294 Modern In Vitro Test Systems Provide Human-Relevant Toxicity Data to Support Product Development and Regulatory Decision Making

H. Behrsing, Institute for In Vitro Sciences, Gaithersburg, MD.

With the increase in chemicals and materials that may cause pulmonary toxicity through inhalation, a need for cost-effective toxicity testing of new chemicals continues to grow. The 2007 report, Toxicity Testing in the 21st Century—A Vision and a Strategy, The National Academies Press, Washington DC, describes a path forward for toxicology and envisages the use of more predictive human-relevant in vitro models for estimating human health risks. The ethical considerations, poor predictive value of animal testing, and vast numbers of chemicals/materials requiring evaluation, further drives this argument for the application of in vitro models to assess pulmonary toxicity. in vitro models utilizing human-derived cell lines and primary cells provide endpoints that reflect cytotoxic, genotoxic, and other relevant adverse events following exposure to toxicants. The emergence of multi-cellular three-dimensional (3D) tissue culture systems of the respiratory tract provide toxicologists with test platforms that accurately model the complex processes observed in native tissues. Human donor-tissue derived spheroids/organoids, reconstructed human airways, and precision-cut lung slices provide conventional toxicity endpoints as well as complex, relevant events following chemical exposure. The varied cell types, physiological structure, relevant toxicokinetics, and other properties of these models allow additional evaluation from chronic exposure to human-relevant (e.g. persistent inflammation, goblet cell hyperplasia) to functional outcomes (e.g. ciliary beating assays) that can reflect serious health complications that may lead to chronic obstructive pulmonary disease.

3296 The Challenge of Integrating Non-Animal Alternative Approaches to Assess the Risk to Human Health from Inhaled Materials

J. Hotchkiss, The Dow Chemical Company, Midland, MI.

Current guideline-compliant acute inhalation toxicity testing provides critical data for hazard identification, risk assessment, product stewardship, and development of short-term exposure guidelines. These tests have historically involved whole-body or nose-only exposure of rodents, however, significant research efforts across the chemical industry are focused on the development and application of human-relevant non-animal alternatives to assess the acute toxicity of inhaled materials. in vitro exposure of 3D human organotypic airway cultures grown at the air-liquid interface (ALI) may provide an immediate path to assess airway epithelial responses to deposited and adsorbed gases, vapors, and aerosols that are relevant for human risk assessment. ALI cultures reproduce many features of in vivo human respiratory epithelium, including 3D epithelial structure, functional cilia, mucus secretion, barrier properties, and metabolic activity. in vitro exposure systems permit the sort of translational studies that are essential to bridging the gap, from traditional in vivo inhalation exposures of laboratory species, to predicted acute pulmonary responses in humans based on dosimetrically-relevant concentrations of test materials in vitro. Until validated alternative testing methods are accepted by regulatory authorities, an integrated stepwise approach can be used that reduces animal use while developing relevant non-animal approaches. This includes, waiving studies when possible, use of the computational GHS additivity approach to predict toxicity of formulations based on their components, and the refinement and validation of in silico approaches to predict and rank acute toxicity hazard. in vitro exposure of human 3D airway cultures to pulmonary toxicants with recognized high and low toxicity in vivo are being used to benchmark the exposure/response of these human airway 3D cultures relative to the available in vivo data. While there is growing acceptance of predictive in silico and in vitro models for hazard assessment, much work remains to prove that these alternative approaches are robust, transparent, reproducible, and accurate.
spheres (50-1000 nm) were used as a surrogate for particulate matter vapors, and gases to the cells: Diffusion, sedimentation, thermophoretic movements. We compared various ALI in vitro exposure systems, a mass-balance approach can be easier to apply. This approach determines constituent levels generated and subtracts constituent levels that deposit in the in vitro exposure system. The remaining constituent levels represent an estimate of cellular exposure. For mainstream tobacco smoke, the mass-balance approach is not feasible because of the number of constituents, however, a selection of constituents have been used in in vitro studies to estimate doses. For E-vapor and other products which have significantly fewer constituents, this approach may be feasible. With the diversity of products in the market place, quantitative particulate and vapor phase in vitro dosimetry determinations are vital to interpreting and integrating results of in vitro experiments.

Operating Procedures to Improve Efficiencies of In Vitro Exposure Systems at the Air-Liquid Interface

M. Higuchi, US EPA, Research Triangle Park, NC.

The expanding use of in vitro exposure systems for toxicity assessments has created regulatory concerns. Many of these same concerns surround the proper conduct of in vivo inhalation toxicology studies which are addressed in Guidelines and Good Laboratory Practice (GLPs) regulations. It is acknowledged that this area (exposure techniques) is in rapid development, and there is limited experience now on best practices to describe new in vitro exposure methods. For example, OECD GLP No 14-The Application of the Principles of GLP to in vitro Studies states "routine requirements for apparatus used in a GLP compliant environment apply equally to apparatus used for in vitro studies." Unfortunately, the supplier/developer of in vitro exposure systems cannot know all potential applications of the specific exposure system by an end-user. Therefore, the in vitro method end-users must make the determination if the specific in vitro exposure system will meet the requirements of their experimental design. Various factors, such as air flow rate, relative humidity, and temperature can adversely affect performance and reliability. For example, increasing the air flow rate in diffusion (gases and vapors) exposure systems, when air flow is perpendicular to the cells, increases gas delivery to the cells via turbulence. To demonstrate this effect biologically, we used US EPA's cell culture exposure system (CCES) to expose BEAS-2B cells to air only (sham) controls. The experiments were aimed at "defeating the technology" of the CCES by determining the cells viability in a sham exposure. The controllable parameters of the exposures were total airflow rate, relative humidity, and temperature. Determining cytotoxicity via the CaliTitre Glo assay using the worst set of operating parameters (low air flow rate and relative humidity) indicated an average cell viability versus incubator controls of 62%. These results show that air flow rate and relative humidity are critical factors that influences the biological effects. Characterization of in vitro exposure systems is needed by the end-users to understand their advantages and limitations for regulatory assessments. This abstract does not necessarily reflect the views or policies of the US EPA.

Understanding Air-Liquid Interface Cell Exposure Systems: A Comprehensive Assessment of Various Systems under Identical Conditions

J. Zavaleta, US EPA, Research Triangle Park, NC.

Exposure of cells to atmospheric pollutants at the air-liquid interface (ALI) is a more realistic approach than exposures of attached cells submerged in liquid medium. However, there is still limited understanding of the ideal ALI design features to meet requirements. We compared various ALI in vitro exposure systems under identical conditions for their ability to expose cells to particles and gases. The systems tested used different mechanisms to deliver aerosols, vapors, and gases to the cells: Diffusion, sedimentation, thermostats (THP), and electrostatic precipitation (ESP). Fluorescent polystyrene spheres (50-1000 nm) were used as a surrogate for particulate matter to assess particle deposition. Deposition was determined by dissolving the spheres in ethyl acetate and measuring the fluorescence. Applying external forces, such as THP or ESP, enhanced deposition for all particle sizes. For example, deposition of a 50-nm particle was 1.6- to 4.8-fold higher with a THP compared to diffusion systems. Similarly, deposition for both 50-nm and 1000-nm particles were 3.4- to 10.3-fold higher with ESP compared to diffusion, depending on in vitro system with ESP. Results indicated that THP is an effective external force on nano-sized particles with decrease effectiveness as particle size increases, whereas ESP maintains a stable performance regardless of particle size. Also assessed was the ability of the systems to deliver gases to cells by using ozone levels as a test gas. The reaction of O3 with an indicator in the ALI surface showed that diffusion allowed gas-cell interaction. Results show a 13-fold difference in gas delivery performance between the best and poorest performing system. Additionally, increasing the flow rate in diffusion systems where airflow was perpendicular to the cells increased gas delivery. The study showed that in vitro systems with THP or ESP were the most effective at delivering aerosols to the cells, whereas flow rate was a critical parameter for the delivery of vapors and gases. This abstract does not necessarily represent the views or policies of the US EPA.

Novel Non-Animal Respiratory Test Methods Show Great Promise, So How Do We Get Them into Routine Use: Points to Consider for Industrial and Regulatory Acceptance

H. Raabe, Institute for In Vitro Sciences, Gaithersburg, MD.

The adoption of new non-animal test methods for regulatory purposes requires the evaluation of the relevance and the reliability of the proposed strategies for predicting toxicological outcomes. Such approaches have already been achieved in replacing animal tests for eye and skin irritation events by formally evaluating the relevance and the reliability of the replacement methods in multi-lab validations. These validations were borne from the numerous applications of these methods in regulatory settings. For evaluating respiratory effects, the results from select in vitro and ex vivo test systems exposed to environmental smoke and pollutants, smoke from cooking or tobacco use, industrial chemicals, or to agricultural products, show great promise for industrial and regulatory hazard classification assessments. To facilitate the adoption and use of these promising methods, it is imperative that stakeholders from industry, the regulatory community, and validation experts define the purposes for the test methods in the regulatory contexts, and design validations to achieve those goals. This presentation outlines the need for early collaborative engagement, the process for educating the scientific basis for the methods, and points to consider in the design, management and execution of the validation plan.

Deliberations in Regulatory and Safety Assessment of Food Substances in Early Life

W. A. Hayes, Harvard University, Cambridge, MA.

Neonates and younger children have a greater degree of vulnerability from consuming food than older children and adults. Much of this vulnerability is due to higher consumption per kilogram body weight. In comparison to adult dietary patterns, neonates and younger children's food behavior is largely atypical. It also is important to remember that neonates and younger children are in a rapidly developing phase of their life cycle when most organs are still developing and differentiating, leaving them in a potentially vulnerable state regarding ingredients and foods consumed. For the most part, regulatory guidelines for foods and food ingredients are in place; however, in the case of neonates and younger children, deliberation regarding the need for additional information to ensure the safety of food ingredients in early life is an area of ongoing discussion. The current paradigm for safety characterization of an ingredient for use in infant formula is, for the most part, limited to chemical characterization, anticipated exposure levels, and data from nonclinical and clinical studies. Additionally, acceptable daily intakes (ADI) currently do not apply to infants less than 12 weeks of age. The scientific community is pondering the need for a paradigm shift in the regulation of ingredients added to infant formula consumed in early stages of life. The objectives of this workshop are to address: 1) the need to derive a holistic understanding of exposure to ingredien...
how normal inter-individual and other sources of variability should be included in modeling predictions, and 4) if there are any differences and similarities in the safety assessment strategies that are in place for the safety of ingredients in early stages of life and how these uncertainties impact regulatory decision making.

**3302 Does Infant Exposure Matter in Safety Assessment?**

W. A. Hayes, Harvard University and Michigan State University, Cambridge, MA.

Harm to any biological system, including infants, can only occur following exposure to a harmful agent at sufficient concentrations to overcome that organism’s threshold for induction of an untoward effect. In order to complete a safety assessment, not only do we need to understand the hazard and dose necessary for that hazard to manifest itself, but we also need the details regarding whether or not exposure of the individual(s) has occurred. Three simple principles help us understand why individuals often respond differently to the same chemical exposure: 1) Dose matters including timing; 2) people differ; and 3) things change. Each principle will be discussed with examples. In order to appreciate exposure, an understanding of timing including amount, duration, frequency, and route need to be determined. In the end, even an extremely hazardous substance that has no exposure presents no risk even to infants. Both hazard and exposure are essential components of risk leaving us with the word RITE (Risk is equal to toxicity time exposure). Any safety assessment must include an understanding of hazard/toxicity and exposure.

**3303 Applying Concepts of Life Stage for Safety Assessment and Understanding the Needs for Children**

E. Faustman, University of Washington, Seattle, WA.

This presentation will begin with an introduction to the concepts of life stage analysis and illustrate how safety assessment frameworks can be applied across development. In order to do this, a discussion of factors of both food exposure as well as benefits and potential toxicity needs to be plotted over the developmental trajectory. This will include considerations of the changing landscape of food options, nutritional, and dietary needs. In parallel, pharmacokinetic and dynamic changes that affect ADME and response are needed. Three case examples will be provided to illustrate the temporal and toxicological importance of these factors for safety assessment of food substances. The talk will conclude with a list of current and future research initiatives that are affecting our conceptual application of these concepts for safety assessment.

**3304 Integrated Safety Assessments of Food Additives in Early Life**

A. Constable, Nestlé Research Centre, Lausanne, Switzerland. Sponsor: W. Hayes

Infant foods and their constituent ingredients are subject to rigorous risk analysis in the development of international standards, and are strictly regulated by many authorities. Implicit in this process is the need for robust assessments to ensure safety in use. Infants, having a smaller body weight and only limited food sources, have a relatively high exposure than do adults, and so a lower safety margin to any safe intake reference values. The significance of these lower margins depends on any particular developmental sensitivities and if the toxicological database is adequate to cover the early life period. With the aim of better defining (and harmonizing) assessment approaches and data requirements, we reviewed the suitability of existing safety databases on examples of additives with historical uses in infant nutrition products to support safe use in early life. We concluded that consideration of whether or not the chemical is identical to endogenous physiological metabolites, and/or if organs known to be immature in early life are targets for toxicity, are key elements to combine with an in-depth review of existing relevant toxicological and nutritional studies. A decision tree was developed to identify data gaps and guide additional data requirements, which could include targeted juvenile studies to investigate safety for the target population at the intended use levels, depending on the specific case.
ecules, therapeutic index continues to be a challenge for ADCs. Lack of understanding of ADC behavior presents unique challenges to drug development that encompasses the entire process from molecule discovery to patient selection strategies. This session will first focus on the most recent understanding of mechanisms of ADC-mediated toxicity, including current regulatory thinking on the translatability of preclinical data to the clinic. The session will then address novel approaches to ADC technologies (e.g. non-antibody scaffolds, bispecific molecules, and site-specific conjugation) that are being explored to generate more efficacious ADCs with improved tolerability. Lastly, the session will describe translational strategies designed to maximize clinical benefit of ADCs to patients.

**3309 Translational Value of Nonclinical Safety Studies**

N. Staag, Genentech, Inc., San Francisco, CA.

ADCs are a rapidly evolving class of biopharmaceuticals employing a range of conjugation technologies to stably link cytotoxic agents with different mechanism of action to monoclonal antibodies. The majority of ADCs in the clinic are conjugated to microtubule inhibitors (MTI) with primary clinical toxicities of bone marrow toxicity and peripheral neuropathy (PN). While bone marrow toxicity has been predicted in rat and monkey toxicology studies, PN has not. Recent progress in understanding the lack of translatability with PN and improvements in nonclinical models to better understand this toxicity will be discussed. In addition to MTI ADCs, there has recently been significant interest in developing ADCs conjugated to more potent DNA damaging agent payloads such as pyrrolobenzodiazepine (PBD) dimers, calicheamicins, duocarmycins, and indolobenzodiazepine dimers. While these ADCs have more severe nonclinical toxicity profiles than MTI ADCs, they also demonstrate impressive tumor activity at very low concentrations. The translatability of preclinical studies with these agents in the context of preliminary safety findings from the clinic will also be discussed in this talk.

**3310 Safety Perspectives Including Class Effects and Off-Target Toxicity**

H. Neff-LaFord, Seattle Genetics, Bothell, WA.

ADCs are a relatively new class of therapeutics developed under the premise that delivering a potent payload via a disease-specific target would minimize systemic toxicity. Two ADCs are currently on the market, with many more in development that are demonstrating promising activity in cancer patients. As experience grows with this class of compounds, we are gaining knowledge about the relative contribution of antigen-mediated (on-target) versus non-antigen-mediated (off-target) adverse events, both preclinically and clinically. Due to their complex nature, multiple components can be manipulated to change the properties of the ADC, and thus alter the toxicity profiles. Examples include changes in linker cleavage systems, linker stability, drug loading, released payload and antibody engineering. Some of these variations have been applied both preclinically and clinically, including site-specific conjugation (e.g. vadastuximab talirine), linker modifications (e.g. addition of a sulfo group to the SPDB linker for IMGN853), and released payloads (e.g. cantuzumab mertansine and cantuzumab ravtansine). These and additional examples for reducing non-antigen-mediated adverse events will be discussed.

**3311 A Regulatory Update on Nonclinical Expectations to Support the Safety of ADCs**

W. Helms, US FDA, Silver Spring, MD.

Antibody drug conjugates continue to be an active area of clinical development in the treatment of cancer. Improvements in stability and the utilization of more potent toxins are some of the factors driving innovation in the field. This presentation will discuss the current expectations for nonclinical packages submitted to support these products with a focus on the updates being discussed in the ICH S9 Q and A document currently under discussion. Case examples with regulatory outcomes from recent submissions will be included.

**3312 Translational Strategies to Maximize Therapeutic Index of ADCs**

M. Hinrichs, Medimmune, Gaithersburg, MD.

Successful development of ADCs requires strategic translational strategies to approach therapeutic index in patients. One potential mitigation strategy is to optimize dosing schedule to improve tolerability of ADCs with narrow therapeutic windows. Doing so requires a greater understanding of the exposure-response relationship to enable selection of a dosing regimen that decreases adverse events while maintaining efficacy. This presentation will address use of preclinical models to understand the pharmacokinetic drivers of safety and efficacy for ADCs in animals. Another important translational strategy being explored is to use biomarker selection strategies to understand which patient populations may benefit from treatment. For the majority of ADCs, the expression level of the target is likely to play key role in defining the appropriate patient population; however, the biology of target expression and relationship to efficacy can be complex. Therefore, this presentation will explore the relationship between target expression and anti-tumor activity using preclinical and clinical examples.

**3313 A Search for Biomarkers of Neurotoxicity: A Practical Approach**

D. Herr, US EPA, Research Triangle Park, NC.

Human exposures to drugs, chemicals, and chemical mixtures often are associated with symptoms suggestive of nervous system involvement (headache, fatigue, cognitive changes, etc.), yet broadly applicable screening methods to assess the neurotoxic condition in animal models are lacking. Thus, there is a need for more sensitive and specific biomarkers that can help diagnose and predict neurotoxicity that are relevant across animal models and translatable to the clinic. Fluid-based biomarkers, such as those found in serum, plasma, urine, and cerebrospinal fluid, have great potential due to the relative ease of sampling, but at present, data on their expression and translation are lacking or inconsistent. In order to identify such novel fluidic biomarkers associated with the development and expression of neurotoxicity and to evaluate their relative sensitivity with established phenotypic anchors of neurotoxicity, a pilot study was designed under the auspices of the ILSI Health and Environmental Sciences Institute (HESI) Technical Committee on Translational Biomarkers of Neurotoxicity—members include representatives from academia, industry, and government. Trimethyltin (TMT) was selected as a prototypic compound since relevant data are available on dose response, time course, and site of action. Neuropathology was confirmed by traditional histopathological assessments, behavioral changes, and alterations in neurochemical and neuroinflammatory biomarkers in brain areas targeted by a single dose of TMT (7.0 mg/kg body weight) at two, six, 10, and 14 days. Using state-of-the-art assessment techniques, the researchers identified specific biological chemicals or patterns in biological chemicals in serum, plasma, or cerebral spinal fluid that are associated with nerve cell damage/degeneration caused by TMT. Such changes include alterations in the status of the metabolome and the expression of microRNAs, as well as levels of interleukins and other related circulating antigen factors. Histopathological assessments of TMT effects in select non-brain tissues enabled improved interpretation of the brain specificity of these changes. Correlation of high-throughput endpoints with markers of neurotoxicity, especially glial fibrillary acid protein, neuropathological loss of neurons, and oxidative damage to neurons as presented here provide a guideline by which to establish fluidic biomarkers of neurotoxicity. The data from this pilot study also will help design follow-on studies utilizing other known neurotoxicants to determine the generalizability of the findings in an effort to develop and validate a set of biochemical markers of neurotoxicity that will be accessible clinically. Such clinical biomarkers should prove valuable to research ranging from preclinical studies to clinical trials and assist with the monitoring of the severity of and recovery from brain injury.
Overview of the Biomarker Initiative to Identify Biological Fluid-Based Indicators of Neurotoxicity

W. Slikker, US FDA/NCTR, Jefferson, AR.

In order to identify biomarkers associated with the development and expansion of neurotoxicity, the Health and Environmental Sciences Institute (HESI) Technical Committee on Translational Biomarkers of Neurotoxicity conducted a pilot study in which potential biomarkers were assessed in concert with confirmation of TMT-induced neuropathology by traditional histopathological assessments and behavioral changes. Tissue samples, behavioral observations, and MRI scans were obtained simultaneously at 2, 6, 10, or 14 days post-TMT treatment. Samples collected included plasma, serum, CSF, and urine with a goal towards identifying in bodily fluids key biomolecules associated with the expression of frank neurotoxicity. Behavioral and neuropathology data confirmed the effectiveness of TMT to induce functional and morphological derangements and will be key anchors in attempts to identify biomarkers that portend the onset, or confirm the presence of, neurotoxicity.

Glial Fibrillary Acidic Protein (GFAP) and Related Astroglial Proteins as Biomarkers of Neurotoxicity

J. O’Callaghan, NIOSH, Morgantown, WV.

The glial reaction to nervous system damage, often termed gliosis, represents a hallmark of all types of nervous system injury. As such, development and implementation of gliosis biomarkers represents a broadly applicable approach for neurotoxicity safety assessment. Using a panel of known neurotoxic agents, we have previously shown that the astroglial protein, GFAP, can serve as one such biomarker of neurotoxicity. Qualitative and quantitative analyses of GFAP have shown this biomarker to be a sensitive and specific indicator of the neurotoxic condition. Decades ago, assays and immunohistochemistry of GFAP were used to detect and quantify TMT-induced damage to its known target, hippocampus, and to identify novel CNS targets damaged by this compound. These studies revealed the sensitivity and target specificity of the GFAP/glial biomarker-based approach to neurotoxicity assessment. In the current study, time-dependent and significant increases in GFAP reactivity was observed in hippocampus and increased protein levels were detected in plasma and serum. The GFAP data from the HESI pilot study using TMT was used as a metric to which other potential markers of neurotoxicity can be compared for relative sensitivity and specificity. GFAP and related glial biomarkers may serve as the basis for further development of molecular signatures predictive of adverse effects on the nervous system.

Changes in the Metabolome May Serve as Peripheral Biomarkers of CNS Toxicity

D. Herr, US EPA, Research Triangle Park, NC.

Since our observation that an acute exposure to different classes of pesticides resulted in different changes in plasma metabolomics markers, a study of the metabolome has become of high interest for identifying markers of neurotoxicity. A Biocrates AbsoluteIDQp180 platform was used for targeted identification of metabolite changes in rat CSF, plasma, and urine. Metabolite classes included acylcarnitines, amino acids, biogenic amines, hexoses, phosphatidylcholines, lysophosphatidylcholines, and sphingomyelins. From among 186 metabolites, 31 were detected in all CSF samples, and 135 were detected in all plasma samples. A principal component analysis indicated that certain metabolites were differentially produced in TMT-treated groups compared to controls. This was especially true in the CSF. Analysis of metabolite fold changes in the CSF indicated increases in acylcarnitines and phosphatidylcholines at 2 and 6 days, with increases in amino acids observed as long as 14 days after treatment. These changes suggest alterations in energy metabolism and mitochondrial and membrane damage in the nervous system. In the plasma, there were increases in levels of acylcarnitines, phosphatidylyl- and lyso-phosphatidylcholines, amino acids, and sphingomyelins at 2 and 6 days. Additionally, the increased levels of acylcarnitines in urine at 2 and 6 days were most similar to the changes in metabolites noted in CSF and plasma. Our data provide evidence for significant changes in energy metabolism and membrane damage in CNS, which were reflected in a peripheral fluid. Should it be demonstrated that plasma and urine markers mirror CSF markers and track aspects of CNS damage as evidenced by frank neuropathology (cell death), they may serve as useful, readily accessible surrogates of neurotoxicity. This is an abstract of a proposed presentation, and does not represent US EPA policy.

Neurotoxicant Effects on Non-Brain Tissues: Understanding Biomarker Specificity

J. D. Pardo, Pfizer, Inc., Groton, CT.

Animal testing of a potential new drug often reveals multiple target organs, some of which may limit further drug development, and others that are manageable. A biomarker used to understand translation of target organ toxicity to human risk will need to have both high sensitivity and specificity for the target organ of concern. Thus, a peripheral biomarker of neurotoxicity must be very sensitive to nervous system injury while not being influenced by effects in non-nervous tissues. In the present study, the phenotypic anchor of frank CNS toxicity was quantified using Fluoro-jade stain of hippocampal cells. Histopathological evaluation of kidney, liver, thymus, adrenal glands, sciatic nerve, and lumbar cord was then performed. TMT-related microscopic findings consisted of minimal to mild degeneration of renal tubules within the distal nephron. These findings were accompanied by renal tubular epithelial necrosis and/or tubular dilation at 6 (at least n=3/10), 10 (3/6) and 14 (3/5) days. Minimal hepatocellular hypertrophy and minimal vacuolation (lipid) of portal hepatocytes were observed in one animal of one post-TMT group. Similarly, diffuse decreased cellularity (lymphoid cells) was observed in the thymus cortex in single animal on post-dosing days 6, 10, and 14. There were no TMT-related microscopic findings in the lumbar spinal cord, sciatic nerve, or adrenal glands. Thus, putative biomarkers described in other presentations in this session are likely reflective of TMT-induced brain toxicity and not derived from other organ systems. However, because urinary TGF-beta may be altered by renal toxicity this marker requires further study to determine its brain specificity.

Biochemical and Molecular End-Points as Biomarkers of Neurotoxicity and Their Correlation with Neuropathological Damage

S. Z. Imam, US FDA, Jefferson, AR.

An effort to perform a comprehensive identification of biomarkers that circulate in bodily fluids and tissue that are associated with the expression of neurotoxicity was undertaken using a young adult male rat model. Here, preliminary observations are presented on biomolecules that have some promise for identification of neurotoxicity that was induced by a single intraperitoneal injection of the known neurotoxic agent, trimethyltin (TMT). A single dose of TMT led to significant alterations in total oxidative stress markers, changes in lipid homeostasis, circulating interleukins and related factors, and markers of neuroinflammation, thus, providing opportunities to explore their correlation with the traditional pathology that defines neurotoxicity. Finally, a comprehensive correlation of TMT-induced neuropathology with several observed biomarkers suggest specific pathways that can be assessed using peripheral fluids.
The widespread use of engineered nanomaterials (ENMs) in consumer products is a concern for potential unintended exposure to ENMs and the impact on health. The overarching goal of the National Institute of Environmental Health Sciences (NIEHS) Nano Environmental Health and Safety (Nano EHS) program is to gain fundamental understanding of the molecular and pathological pathways implicated in potential adverse health effects of ENMs. In the absence of an identified pathology associated with ENMs, the NIEHS took a proactive approach aimed at developing an ENMs-biological interactions knowledge base, based on physicochemical properties of ENMs. This comprehensive knowledge base is hoped to guide and develop *in silico* approaches for human health risk characterization and potential intervention or remedial measures, as well the design of benign nanomaterials. The NIEHS recognized the need to promote collaborative team science efforts to address the multidisciplinary nature of assessing ENMs on environmental health and safety. Towards this goal, based on the past two decades of promoted research through the Nano GO Consortium and NIEHS Centers for Nanotechnology Health Implications Research (NCNHIR) and the research outcomes from these efforts, the NIEHS Nanomaterials Health Implications Research (NHIR) Consortium was established in 2016. This consortium will expand the library of ENMs and physico-chemical properties focusing on specific materials with high production and use in consumer products, as well as recently emerging 2D and 3D ENMs containing new transitional metals and whose toxicology is unknown at the nanoscale. The comprehensive toxicological profile for these ENMs surveyed using a wide range of systems reflecting more physiologically relevant models will benefit the future goals of this program (i.e., to promote computational modeling efforts to predict association between ENM physicochemical properties and potential health effects).
