Important Dates and Deadlines:

- May 15, 2019: Scientific Session/CE Course Proposal Submission Deadline
- October 9, 2019: SOT Awards Nomination and Application Deadline for Most Awards
- October 18, 2019: 2019 Abstract Submission Deadline
- October 18, 2019: Undergraduate Diversity Award, Perry J. Gehring Diversity Student Travel Award, and Pfizer SOT Undergraduate Award Application Deadline

www.toxicology.org/2020
Preface

This issue is devoted to the abstracts of the presentations for the Continuing Education courses and Scientific Sessions of the 58th Annual Meeting of the Society of Toxicology, held at the Baltimore Convention Center, Baltimore, Maryland, March 10–14, 2019.

An alphabetical Author Index, cross-referencing the corresponding abstract number(s), begins on page 522.

The issue also contains a Keyword Index (by subject or chemical) of all the presentations, beginning on page 553.

The abstracts are reproduced as accepted by the Scientific Program Committee of the Society of Toxicology and appear in numerical sequence. If a number is missing in the numerical sequence, the abstract assigned to the missing number was withdrawn by the author(s). Author names that are underlined in the author block indicate the author is a member of the Society of Toxicology. For example, J. Smith, SOT members may sponsor abstracts that do not include an author with SOT membership. New in 2019, authors who are members of designated organizations could serve as the sponsor of the abstract if an SOT member was not a co-author; these types of sponsorships are displayed as follows: Sponsor: J. Doe, Organization Name.

Scientific Session Types:

- CE Continuing Education Courses
- EC Education-Career Development Sessions
- IS Informational Sessions
- PL Platform Sessions
- PS Poster Sessions
- R Roundtable Sessions
- S Symposium Sessions
- W Workshop Sessions

The 2019 SOT Event App and Online Planner

The Event App is available via the SOT Annual Meeting website and app marketplaces. The Event App, alongside the Online Planner available on the SOT Annual Meeting website, enables you, the attendee, to engage with organizers, exhibitors, and each other and to manage your time and maximize your experience during the Annual Meeting. You also can access ePosters electronically via the Event App until May 15, 2019.

To cite a 2019 SOT Annual Meeting Abstract, please format as follows: The Toxicologist, Supplement to Toxicological Sciences, 168 (1), Abstract #__, 2019, Title, First Author.

Society of Toxicology
11190 Sunrise Valley Drive, Suite 300, Reston, VA 20191

This abstract book has been produced electronically by the Society of Toxicology. Every effort has been made to faithfully reproduce the abstracts as submitted. The author(s) of each abstract appearing in this publication is/are solely responsible for the content thereof; the publication of an article shall not constitute or be deemed to constitute any representation by the Society of Toxicology or its boards that the data presented therein are correct or are sufficient to support the conclusions reached or that the experiment design or methodology is adequate. Because of the rapid advances in the medical sciences, SOT recommends that independent verification of diagnoses and drug dosage be made.
1001 SR01: Handling Uncertainties in Evaluating Mixtures: What’s the Difference between a “Similar” and a “Sufficiently Similar” Mixture?

S. C. Fitzpatrick, US FDA, College Park, MD.

Evaluating the safety and potential health risks from exposure to multiple chemicals, such as environmental chemicals, pharmaceuticals, consumer and personal care products, and pesticides and food contaminants, poses one of the major challenges for toxicological research and risk assessment. Significant advances have been made in recent years in better understanding and evaluating chemical mixtures. A key factor in risk assessments of chemical mixtures is the availability of reliable data on the identity, levels of exposure, toxico-kinetics, toxicodynamics, and toxicological interactions for the whole mixture or its individual components. Limited data or lack of data has a direct impact on uncertainty of the risk assessment of mixtures. As a result, risk assessment of chemical mixtures requires a lot of assumptions and uncertainty assessment. The commonly used risk assessment methods for chemical mixtures are whole mixture approaches and component-based approaches. The whole mixture approach is used when toxicological data are available for the mixture itself or toxicity data are available for a similar mixture or a sufficiently similar mixture that can be used as surrogate for the mixture of concern. This CE course will (1) provide an overview of challenges related to whole mixtures risk assessment and highlight approaches for evaluating sufficient similarity among related mixtures, and (2) present recent advances in safety assessment of complex mixtures using an alternative tiered approach, which utilizes in silico and in vitro approaches to identify safety data gaps and inform the need for additional studies. Attendees will be equipped to use similarity and sufficient similarity for whole mixtures, understand the assumptions, and understand how to address the uncertainties. This course would be of interest to scientists who conduct mixture risk assessment in different sectors, such as occupational health and safety, product safety, public health protection, or regulatory decision-making. This sunrise CE course complements the previous CE courses and sessions at SOT on mixtures and focuses specifically on the uncertainty assessment aspect of similar and sufficiently similar mixtures, which has not been discussed before.

1002 SR02: Publicly Available Exposure Tools to Inform the Toxic Substances Control Act

J. Wambaugh, US EPA/NCCT, Research Triangle Park, NC.

Exposure is a key component of chemical risk assessments, as highlighted by the recent amendment to the Toxic Substances Control Act mandating the US EPA to consider conditions of chemical use, as well as human and ecological exposures across the chemical life cycle. The US EPA Office of Research and Development has many ongoing exposure modeling efforts that may be informative for chemical safety decisions. This sunrise CE course covers how 21st-century exposure science tools could be used to inform chemical risk assessments. The first instructor will present a series of databases and models that are both peer reviewed and free to use. The second instructor will cover new, consensus exposure predictions for instances where minimal exposure data are available. Each lecture will provide examples that can be easily modified by course attendees for specific chemical risk assessment applications.

1003 AM03: Assay Development Principles and Good Research Practices for Rigor and Reproducibility in In Vitro Toxicology

M. Xia, NIH/NCATS, Bethesda, MD.

Toxicological research and testing heavily depends on the application of cell and molecular assays to provide mechanistic insight into the effects of chemical exposures as well as model systems to overcome the constraints of in vivo human and animal exposure studies. Despite being powerful tools, these assays are not immune from the "reproducibility crisis" that has cast a considerable shadow over all fields of biomedical research. Improving the rigor, reproducibility, and physiological relevance of both traditional and high-throughput cellular and molecular methods is critical to protect public health, increase the efficiency of drug and consumer product development, and ensure the reliability of data used in chemical regulation. Recent reports in both the scientific and public literature have revealed a need for increased rigor in preclinical research and highlighted experimental design, reagents (including antibodies and cell lines), and data analysis as key challenges to study reproducibility. The goal of this course is to provide participants with "good research practices" for the rigorous development, implementation, and interpretation of robust in vitro toxicological assays for reproducible results using physiologically relevant models. Presentations will follow a broadly applicable workflow, starting with the establishment of a verified cell culture model with increased physiological relevance. Participants will learn how understanding the nature of cells in vitro and treating cells as reagents can ensure the design of more reproducible assays. Strategies will also be shared for the successful implementation of high-throughput assays that enable the rapid and high-throughput assessment of both toxicity and efficacy using in vitro models with increased physiological relevance. This will be followed by global gene expression analysis using RNA sequencing, validation, and exploration of target gene expression with quantitative PCR, assessment of protein abundance, and post-translational modification using immunoassays, and evaluation of cumulative effects of exposures on cell physiology and viability. The final presentation will empower participants with the knowledge and tools to utilize innovative statistical measures that were developed specifically to enable reliable assessments about compound properties based on data from in vitro assays. This course will provide attendees with core principles and practices for widely used methods, which will facilitate the design and execution of a broad range of rigorous and reproducible experiments, increased throughput, and improved in-depth interpretation of data from both study findings and published literature. The content of this course will benefit researchers from industry, government, and academic labs who evaluate the safety of experimental compounds and wish to learn more about the latest models, methodologies, and analysis strategies.

1004 AM04: Complex Mixtures and UVCBs: Analysis, Testing, and Risk Assessment

C. V. Rider, NIEHS/NTP, Research Triangle Park, NC.

A complex mixture, as defined in a 2018 update to the Agency for Toxic Substances and Disease Registry Framework for Assessing Health Impacts of Multiple Chemicals and Other Stressors, has many chemicals (often of different chemical classes), has a composition which may not be fully characterized, and can arise from a single source or multiple sources. The related, but more specifically defined, term, UVCB substances (Chemical Substances of Unknown or Variable Composition, Complex Reaction Products and Biological Materials), has been applied by both the US EPA in the Toxic Substances Control Act (TSCA) Chemical Substance Inventory and the European Chemicals Agency (ECHA) under the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) regulations. Complex mixtures and UVCBs can include foods and beverages, personal care or consumer products, reaction by-products, emissions, and leachates. They can exhibit a wide array of physicochemical properties and fall under different regulatory jurisdictions. However, there are common principles that can be applied to these substances to gain an understanding of their complex chemistry and evaluate their toxicity and/or safety. Historically, the prevailing dichotomy was to either treat these substances as single entities, thereby ignoring their complex and often dynamic nature, or apply a reductionist approach that only considered a small subset of known constituents (i.e., identified chemical constituents with available toxicity data). Progress in analytical chemistry techniques, untargeted analyses, and in vitro screening tools has allowed for a more comprehensive and holistic approach to complex mixtures. In this course, state-of-the-science approaches for evaluating complex mixtures and UVCBs will be presented. It will begin with a presentation of the regulatory challenges and views of complex mixtures from the perspective of the US FDA Center for Food Safety and Applied Nutrition (CFSAN). Next, recommended methods for chemically analyzing complex mixtures and identifying biological constituents will be presented. Untargeted approaches for assessing complex mixtures, such as metabolomics and chemometrics, will be addressed. The use of in vitro assays and alternative animal models in screening complex mixtures will be discussed, with attention on successful applications and pitfalls to avoid. Additionally, available methods and software for combining chemical and biological assay data will be presented. Finally, existing methods for comparing across complex mixtures and determining sufficient similarity of related mixtures will be presented. Presentations will address chemistry, biological activity, and the intersection of the two, with an intentional focus on how these data can be used in safety evaluations of complex mixtures. Throughout the course, speakers will provide terminology and definitions and highlight tools using a diverse array of examples, representing distinct categories of complex mixtures and UVCBs. This course will be useful to those interested in understanding complex mixtures from a product development, research, or regulatory perspective. Course participants will be provided with both big picture context on complex mixtures and specific, data-driven recommendations learned from application of the presented methods.
1005 AM05: Developmental Toxicity of the Skeletal System: Interpretation of Findings in DART Studies and Implications for Risk Assessment

M. R. Garry. Exponent, Seattle, WA.

Skeletal development represents a period of rapid patterning and specification of tissues that form the basis for subsequent growth in the developing organism. As a result, formation of the skeletal elements (e.g., bone and cartilage) is included as a standard endpoint in prenatal developmental toxicity studies. Abnormal findings are classified as variations or malformations; however, the interpretation of these findings and whether they result in functional deficits in postnatal life can significantly impact regulatory decisions. This presentation will highlight the diversity of use cases within each industry. The course will provide participants with an introduction to skeletal anatomy and physiology, that can facilitate the interpretation of abnormal findings from a toxicological perspective. Speakers from academia, industry, and government with expertise in the fields of skeletal biology and developmental toxicology will provide (1) a fundamental review of skeletal development in animal models currently used in developmental toxicity studies, with an emphasis on differences in developmental course and extrapolation between species; (2) a discussion of current and emerging methods to identify skeletal anomalies in prenatal and postnatal/juvenile developmental toxicity studies, and their relation to overall developmental toxicity, both in the animal models and their potential human relevance; (3) case studies to illustrate the concepts introduced by the first two speakers and specific challenges faced in the interpretation of study results; and (4) context from a regulatory perspective on the interpretation of abnormal skeletal findings and the evolving requirements needed to address skeletal toxicity concerns.

1006 Industrial Applications of Computational Toxicology in the 21st Century

Computational toxicology encompasses the development of computational models and computational tools applied to datasets of toxicological concern and the use of such methods for various applications. This is a wide field spanning hazard identification, prioritization for experimental testing, optimization of chemical space, and chemical risk assessment. These methods are used in many different industry sectors, such as consumer products, pharmaceuticals, and agrochemicals, as well as being widely used in the environmental sector and in governmental or regulatory organizations. The methods employed vary from simple to complex depending on availability and quality of data, and range from the application of structural alerts to machine-learning models of large-scale biological data and complex systems toxicology modeling. With increased pressure to reduce the number of animal experiments, accelerate the product development cycles, and lower costs, computational toxicology is a continuously developing area with yet-untapped potential. This course will provide participants with an introduction to the field, followed by a method section where different scenarios will be presented that guide the participants in how data are analyzed and models and tools are built, depending on the use case at hand, as well as data limitations. This will be followed by two presentations on practical applications of computational toxicology, the first one focused on consumer products (e.g., food, cosmetics) and the second on examples from the pharmaceutical industry. Both of these presentations will highlight the diversity of use cases within each industry. The course will end with a presentation discussing the regulatory landscape and examples of how such tools are used to support regulatory safety assessment of various products. The aim of this course is to introduce the discipline of computational toxicology to the nonexpert and provide the participants with a broad understanding of the many benefits of computational toxicology methods, as well as an understanding of the limitations and appropriate use of such methods for successful outcomes in an industrial setting. The learnings from this course are relevant for attendees from all industry sectors as well as from other research-directed organizations.

1008 AM08: Mechanistic Understanding and Quantitative Risk Assessment in Immunotoxicology

E. Corsini. Università degli Studi di Milano, Milan, Italy.

Considering the important health consequences associated with exposure to immunotoxic compounds, quantitative risk assessment in immunotoxicology is an area of growing interest. The discipline of immunotoxicology has refined several powerful tools to assess the safety of new drugs and other products. Novel approaches for assessment of hypersensitivity and cytokine-based assays to examine chemical-specific effects are moving the field away from the use of animals and providing a path forward for hazard identification and risk assessment. Although the majority of immunotoxicity studies are designed for hazard identification, there is a considerable amount of data demonstrating a threshold for both immunosuppression and contact sensitization exists, making quantitative risk assessment possible. The purpose of this advanced course is to provide guidance on how to perform risk assessment using immunotoxicology data. Following a brief introduction (first presentation), examples will be given for both immunosuppression (second presentation) and contact hypersensitivity (third presentation). In addition, to support animal-to-human extrapolation, mechanistic understanding is crucial and will be provided in this course (last two presentations). In 21st-century Toxicology, it is also crucial to integrate all information from in silico and in vitro methods into animal studies. Therefore, in a modern vision of immunotoxicology, integrated strategies will be described and examples provided in each presentation. This course will provide participants with the means and knowledge to conduct quantitative risk assessment using the effect on the immune system as the adverse outcome to protect humans from chemical-induced immunotoxicity and its consequences.

1007 AM07: Role of Toxicokinetics in Human Health Safety Assessments

S. Papineni. Dow AgroSciences, Indianapolis, IN.

Regulatory toxicity testing and risk assessment paradigms historically have been based on external doses, despite acknowledged scientific advantages in using systemic exposures. Integrating toxicokinetics (TK) into regulatory toxicity testing provides an opportunity to develop more relevant data by utilizing systemic dose in animals and predicted (modeled) or measured blood levels of chemicals in humans. This provides a foundation for improved evaluation of human relevance, life-stage susceptibility, mode-of-action or adverse outcome pathway, route-to-route extrapolation, and dose selection. In addition, there is increased emphasis on improving toxicity testing and safety assessment in alignment with the 3Rs principles of animal welfare (replace, reduce, refine), and expanded use and collection of TK information reduces the overall use of animals by eliminating unnecessary or redundant tests and provides more humane dose selections, which are less physiologically stressful on the animals. As with any scientific change in practice, the change in optimization of these approaches across the globe. Increased awareness and communication of the benefits of these approaches is key for global harmonization. This course aims to increase knowledge on the principles of TK and will enable students to explore the opportunities that TK offers to risk assessment (all stages: hazard identification, dose-response assessment, exposure assessment, risk characterization) and provide a forum for students to hear from scientists of varying backgrounds and sectors—regulatory, academic, and industry. There have been many advancements in technology and increased emphasis by regulatory agencies to collect TK data. However, the implementation and applicability of these data in regulatory toxicity testing have lagged considerably. The first talk will introduce the topic and present the basic principles of TK, and also will provide an understanding of why and when TK is useful for investigating issues in toxicology. The second presentation will review the experience of integrating and utilizing knowledge of TK in preclinical safety testing of pharmaceuticals. The third presentation will describe the standard testing protocols, technical details, and considerations to integrate TK in standardized guideline studies without use of additional animals and making the guidelines relevant to assessing risks to human health. The fourth presentation will provide a regulatory overview of integration of TK into various steps in the risk assessment process, using case studies to demonstrate how TK data have been used in pesticide risk assessment to improve the science underlying regulatory decision-making. Overall, this course will provide the needed background and approaches to implement TK, using practical examples that will enable the attendees to have a better appreciation of its utility in risk assessment and decision-making regarding chemicals for human health. This course also will highlight the shift toward utilization of high-throughput toxicity screening and nonanimal methods that both are in alignment with 3Rs principle and offer cost- and resource-effective means to prioritize chemicals. Thus, this course will be of a broad interest to testing laboratories, general toxicologists, and risk assessors across different sectors, including academia, regulatory agencies, and industry.

2019 SOT Annual Meeting
Physiologically based pharmacokinetic (PBPK) modeling is widely recognized as a scientifically sound approach to characterize uncertainty in the quantitative relationship between internal and external exposures. The number of regulatory reviews of PBPK models has risen significantly in recent years to support decision-making regarding safety of environmental chemicals and pharmaceutical compounds. For environmental chemicals, PBPK modeling allows for extrapolations across species, life stages, and exposure routes/sequences of human biomonitoring measurements. For pharmaceutical compounds, PBPK modeling can be used to identify the need for dose adjustments in subpopulations, the potential for drug-drug interaction, and undesired pharmacokinetics properties such as low bioavailability or rapid clearance. The application of PBPK models to support regulatory risk assessment requires thorough vetting in the context of whether the model's performance is appropriate for its intended purpose. However, the growing list of applications and different acceptance criteria among agencies and across countries have increased the need for a more standardized approach to both model submission and review processes. To achieve such a goal, this course is designed to provide an overview of how PBPK models might be applied to investigate health outcomes resulting from exposures to environmental or pharmaceutical compounds, as well as to discuss the key elements being reviewed by different regulatory agencies. This overview will help to promote dialogue among developers, users, and evaluators of PBPK models across government, industry, and academia who seek to establish consistent model submission and review practices. In addition, this course provides training to both modelers and non-modelers, with the purpose of increasing the pool of potential peer reviewers for regulatory agencies so that they can conduct proper review of models in a timely fashion. To accomplish these training objectives, topics to be covered in this course include the principles of pharmacokinetics, fundamental concepts underlying PBPK modeling, data needs, and quality assurance during model development and implementation. The overarching objectives of this course are to highlight opportunities for harmonizing model submission and review processes and to increase the likelihood of model adoption at regulatory agencies. Disclaimer: The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

### 1009 PM09: Applications and Review of Physiologically Based Pharmacokinetic Modeling for Regulatory Risk Assessment

### 1011 PM11: Conducting Systematic Review in Toxicology—Why, When, How?

M. Wilks, University of Basel, Basel, Switzerland.

Systematic review is gaining interest in the field of toxicology, highlighted by regulatory requirements being globally instituted to conduct systematic review in support of safety assessments of chemicals and foods (e.g., via US EPA Toxic Substance Control Act [TSCA], US EPA Integrated Risk Information System [IRIS], and European Food Safety Authority [EFSA]). Systematic review refers to the objective and transparent process of collecting and synthesizing scientific evidence for reaching conclusions on specific research questions. While systematic review has been successfully used for decision-making in areas such as clinical medicine for many years, the implementation of systematic review within a toxicological context using established frameworks presents unique challenges. As such, several groups that conduct toxicological research have developed systematic review frameworks that take into consideration the breadth of data relevant to the environmental health and food safety sciences by extending and adapting the approaches developed for clinical medicine. This course will survey available approaches and tools for conducting systematic reviews in toxicology, provide information on the components and conduct of systematic review, and provide instructions on reporting and appraising systematic reviews. Particular emphasis will be placed on determining when a systematic review would be useful and how to determine the specific research question(s), critical appraisal of study quality for human and animal evidence, and structured integration of the evidence across evidence streams. Presenters will highlight and demonstrate tools and other software that can be used for study selection and screening, study quality appraisal, documentation, visualization, and decision-making. The course will provide the opportunity for participants to gain an understanding of why to choose to conduct a systematic review, when it is appropriate to do so, and how to conduct the critical elements of a systematic review, as well as gain an appreciation for the rigor and transparency that a systematic review requires (thus setting it apart from traditional narrative reviews). This course has strong relevance to toxicologists from diverse sectors, including researchers, regulators, risk assessors, consultants, and industry, who may need to use systematic review processes or even consider the results of systematic reviews in their practice.

### 1010 PM10: Beauty of the Skin Is in the Eye of the Beholder: A Basic Course on Dermal and Ocular Toxicology

M. F. Hughes, US EPA, Research Triangle Park, NC.

Every day we use our eyes to see what is going on in the world, while our skin provides key information to our brains by sensing the world around us through touch. Skin also protects our body by regulating our temperature. While the eyes and skin are two distinct organs, they have some commonalities. First, they both provide our bodies with a barrier to the external environment. Although the barrier properties of the skin and cornea are not impermeable or equivalent in their ability to protect, they provide a degree of impedance to physical assaults such as sunlight and xenobiotic penetration. Secondly, the outer anatomy of the skin and the eye are epithelial in nature, derived from the ectoderm. These two organs have differences in their physiology, functional purpose, toxicological response, and pathological outcome. Both organs are important to toxicology because they are exposed to the external environment but react differently to toxic insults than internal organs. The purpose of this course is to provide the audience with the fundamentals of dermal and ocular toxicology and methods to assess absorption and toxicity. The first presentation will focus on dermal anatomy and methods to assess dermal absorption. Factors that can affect dermal absorption will be discussed, as well as those learned from in vitro studies (e.g., static, flow-through methods) and in vivo methods to quantitate absorption. The strengths and weaknesses of these methods will be presented. The second presentation will emphasize dermal toxicity. An overview of the manifestations of dermal toxicity, its assessment biomarkers, and useful animal models of chemical-threat agents exposure will be presented. The third presentation will discuss ocular toxicity. The anatomy of the eye and manifestations of ocular injury and toxicity from a variety of drug and chemical classes will be presented. The fourth presentation will highlight toxicology of the cornea. The anatomy of the cornea, absorption of chemicals and drugs through this tissue, and implications of toxicity on the function of the cornea will be presented. The fifth presentation will cover advances in the field of nonanimal alternatives to toxicity testing for skin sensitization and ocular dermal irritation. Work to develop and validate integrated testing strategies and progress toward regulatory implementation will be discussed. Overall, by attending this session, the audience will gain basic information to understand the potential toxicological outcome of xenobiotic exposure to the dermal and ocular systems.

### 1012 PM12: Current Dose-Response Modeling Strategies and Applications in Chemical Risk Assessment

K. Shao, Indiana University, Bloomington, IN.

Quantifying dose-response relationships to evaluate the toxicity of environmental chemicals is a key step in human health risk assessment and has substantially evolved in recent years. The purpose of this course, to be delivered by a mix of groups of experts from government, academia, and industry, is to provide participants an overview of the currently prevailing dose-response modeling methodologies and tools with case studies and applications in chemical risk assessment. The first presentation will introduce basic concepts and terminologies of the benchmark dose (BMD) method, including discussions on the use of US EPA benchmark dose software (BMDS), how to model commonly available toxicological data, and how to interpret the results. The second presentation will discuss the categorical regression modeling approach, together with the US EPA Categorical Regression Analysis (CatReg) software and its application to chemical risk assessment. The third speaker will present how to apply the BMD methodology in a Bayesian framework to produce probabilistic estimates of interest (e.g., model parameter estimates, single model BMD estimates, and model averaged BMD estimates) to support probabilistic dose-response assessment. While the first three presentations complement each other regarding modeling methodologies, the last speaker will provide an overview to summarize the utilities of the strategies and tools through three case studies in the agrochemical industry to help participants reinforce the knowledge by using real-world relevance and experience.
The microbiome consists of indigenous microbial communities and the host environment that they inhabit. Current paradigm-shifting research indicates that the interaction between the host and the microbiome is an important regulator of many diseases and is changing the way that scientists think about the role microbes play in human health. The microbiome includes microbes that are both helpful and potentially harmful, and in a healthy individual, these microbial communities coexist without problems. However, when this balance is disturbed, dysbiosis can occur. One such factor that is emerging as a regulator of this balance is exposure to environmental pollutants that may perturb host-microbiome interactions to promote disease. The microbiome is a rapidly emerging field, and toxicologists from industry, academia, and federal agencies understand the importance of studying the impact of toxicants and pharmaceuticals on gut microbiome dysbiosis and host responses. However, approaching this vast area of study can seem daunting. This course is designed to provide practical information from experts in the field with the latest state-of-the-art tools so that toxicologists can incorporate the study of microbiome and host-associated responses into mechanistic research, risk assessment, and/or therapeutics. Following this course, participants will be familiar with current advances in microbiome research as it pertains to toxicology. An overview of experimental models and case study examples of microbiome toxicity and immunotoxicity will be presented. Further discussion on how xenobiotics change the microbial population and immune status of animals during developmental exposures will be provided. Concepts will be reinforced in a multigenerational toxicology case study that will take the participants through steps of experimental design, data collection, and reporting. The course will provide participants with practical knowledge and tools to conduct microbiome analysis using the metagenomics analysis server (MG-RAST). The latest information related to regulatory aspects for microbiome-based therapeutics approaches will be presented to participants. Overall, this course will provide a comprehensive overview of study design, data analysis, and challenges in biotherapeutics using examples of toxicant-induced intestinal microbiome dysbiosis.

Mitochondria are critical subcellular organelles, as they provide more than 95% of the energy for biochemical and physiological functions, in addition to playing a critical role in lipid metabolism, steroidogenesis, and programmed cell death. In the context of this course, both structural and functional features of the mitochondria will be addressed. Involvement of mitochondria in health and in drug-induced cellular and subcellular toxicities will be discussed, and the practical applications will be described. In the first lecture of this course, the prominent role of mitochondrial toxicity in adverse outcome pathways (AOPs) mechanistically describing a wide spectrum of organ-specific toxicities will be demonstrated. In the second lecture, the central role of mitochondria in drug-induced programmed necrosis and the impact of adaptive mechanisms such as autophagy and mitochondrial biogenesis on cell survival and regeneration will be highlighted. The third lecture will focus on evaluation of mitochondrial function by confocal and multiphoton microscopy, and measurement of respiration and glycolysis. In the last lecture, the metabolic capacity of mitochondria in terms of local reactive metabolite generation, as well as toxicological outcomes, will be discussed.

**Advances in In Vitro to In Vivo Extrapolation: Approaches and Applications**

N. Kleinsteuber, NIEHS, Raleigh, NC.

The development of nonanimal-based testing strategies of chemicals is important in current human safety testing. Many efforts focus on the development and standardization of in vitro new approach methodologies (NAMs) that provide concentration-response data. However, concentration-response data obtained from in vitro models are inadequate for human risk and safety assessment. In order to use these data for risk assessment purposes, the in vitro concentration-response data should be translated to in vivo dose-response data. However, concentration-response data obtained from in vitro models are inadequate for human risk and safety assessment. In order to use these data for risk assessment purposes, the in vitro concentration-response data should be translated to in vivo dose-response data. However, concentration-response data obtained from in vitro models are inadequate for human risk and safety assessment. In order to use these data for risk assessment purposes, the in vitro concentration-response data should be translated to in vivo dose-response data. However, concentration-response data obtained from in vitro models are inadequate for human risk and safety assessment. In order to use these data for risk assessment purposes, the in vitro concentration-response data should be translated to in vivo dose-response data. However, concentration-response data obtained from in vitro models are inadequate for human risk and safety assessment. In order to use these data for risk assessment purposes, the in vitro concentration-response data should be translated to in vivo dose-response data.
1018 IVIVE Tools for Risk Assessment
N. Kleinsteuber, NIHES/NICEATM, Research Triangle Park, NC.
For regulators to comfortably use in vitro data and other new approach meth-
odologies in risk assessment requires translation of activity concentrations to estimated doses, which can then be compared to traditional animal toxicology studies or human exposures. The Integrated Chemical Environment (ICE; https://ice.ntp.niehs.nih.gov/) houses high-quality, curated data from the National Toxicology Program Interagency Center on Alternative Toxicological Methods (NICEATM) and its partners. The ICE Integrator currently provides access to in vitro and in vivo data for about 10,000 chemicals; endpoints include acute oral toxicity, skin irritation, eye irritation, skin sensitization, and endocrine activity, and curated high-throughput screening data from the Tox21 program. The ICE interactive workflow section allows users to select in vitro data, apply IVIVE, and compare the estimated doses to in vivo data. IVIVE models are automatically parameterized using experimental values for plasma protein binding and intrinsic clearance, where available, and in all other cases these values are predicted using high-performing quantitative structure activity relationship models. Scientific confidence can be established by quantitatively comparing estimated doses derived from validated in vitro models to regulatory guideline in vivo studies, across sets of reference chemicals. This publicly available, easy-to-use tool facilitates implementation of IVIVE in risk assessment and regulatory decision making.

1019 PBK Modeling-Based IVIVE for the Toxicological Assessment of Potential Endocrine Disruptors
E. Fabian, BASF SE, Ludwigshafen, Germany.
In order to obtain effect- or no-effect levels from non-animal methods, effect concentrations in vitro are translated to external doses, by reverse dosimetry calculations. For this approach, we extrapolated for several compounds assumed to cause a hormonal-imbalance, the lowest effect concentrations (LOEC) from in vitro assays to lowest observed effect levels (LOEL). For modeling, we applied a one compartment model and an eight compartment PBTK model. Substance specific input parameters for were the molecular weight, the plasma protein binding (PPB) and the hepatic clearance and for PBTK modeling logP and apparent permeability through Caco-2 cells (Papp) in addition. Calculations were performed for ten compounds (Bisphenol A (BPA), Fenamimot (FBPA), 17ß-Ethynylestradiol (EE), Aetaziminospongen (APAP), Caffeine (CAF), Ketocoazolone (KET), Fluamide (FLU), Genistein (GEN), Methyltestosterone (MTT) and Trenbolone (TRE)), using the lowest effect concentrations from in vitro assays addressing interaction of the test substances with estrogen- and androgen-receptors as well as steroidogenesis. The oral LOECs which were extrapolated from in vitro data were compared to LOELs obtained from in vivo studies. For the one compartment model seven and for the PBTK model six out of the 10 substances, the extrapolated and measured LOEL were in the same order of magnitude (assessed as correctly predicted). Correct predictions in both models were obtained for BPA, FEN, APAP, CAF and KET. Although less complex, the one compartment model yielded results closer to the measured in vivo LOELs than the PBTK model for 6 out of the 10 modeled substances (FEN, APAP, CAF, FLU, MTT, TRE). In conclusion, reverse dosimetry calculations can provide correct predictions for some substances, whereas it fails for others. There is a need to improve the models or identify substance groups for which the reverse dosimetry models are not sufficient beforehand. Increasing the number of compartments in the model is obviously not a comprehensive solution, optimizing the input parameters appears more promising.

1020 Development of a Generic Physiologically Based Kinetic Model to Predict In Vivo Endocrine Activity in Rats Based on In Vitro Bioassays
M. Zhang, Wageningen University, Wageningen, Netherlands. Sponsor: B. van Ravenzwaay
Given that the elaboration of a PBK model for individual compounds can be resource and time consuming, efforts are directed to the development of efficient and general models for large groups of compounds. The potential of a generic PBK model to predict the in vivo endocrine activities in rats for a larger series of compounds is assessed. Generic “Berkeley-Madonna” PBK models were used for the in vitro concentration-response data for estrogenic and androgenic activity from the MCF-7/BBOS proliferation assay and the yeast estrogen/androgen screening (YES/YAS) assay and translated into in vivo dose-response data. Benchmark dose (BMD) values derived from the predicted dose-response data were compared with the BMD values obtained from the in vivo Uterotrophic assay or in vivo Hershberger assay to evaluate the model predictions. Overall, the feasibility of using a combination of in vitro toxicity data and a generic PBK model to predict in vivo endocrine activities for groups of endocrine disruptors was shown. However, there were also some cases with large differences. The major source of these differences seems to be related to the variability of results in the in vitro assays.

1021 Alpha-Synuclein: A Good Protein Turned Bad in Chronic Brain Diseases with Toxicological Implications
W. Zheng, Purdue University, West Lafayette, IN.
Alpha-Synuclein (aSyn) is a low molecular weight (14.5 kDa), natively un-
folded protein expressed in a wide range of cell types and is particularly abundant in synaptic terminals. The exact function of aSyn remains un-
certain; however, recent evidence suggests that aSyn functions in the brain to maintain synaptic plasticity, regulate dopamine synthesis, and facilitate vesicular dynamics (e.g., stabilization and exocytotic fusion at presynapses). Dysfunction and aggregation of aSyn has been associated with the pathologi-
cology of Parkinson’s disease (PD), Alzheimer’s disease (AD), and Diffused Lewy Body disease (DLB). The monomeric form of aSyn in the brain mainly or-
mates from neuronal cells, yet aSyn present in the circulatory system can pass across the blood-brain barrier (BBB) to enter the brain parenchyma. Recent studies have explored the possibility of using total plasma levels of aSyn as a surrogate marker for the progression of PD and other neurodegenerative diseases such as AD. Thus, it is imperative to understand the mechanism by which the BBB regulates the fluxes of aSyn in and out of the brain to maintain aSyn homeostasis in the central milieu. Excessive aSyn proteins in brain tend to misfold, leading to massive aggregation in Lewy bodies. This aggregation is believed to be promoted by the binding of the protein to phospholipid membranes and by post-translational modifications resulting from mitochon-
drial dysfunction/oxidative stress. aSyn has divalent metal binding sites that are known to affect the protein stability. Toxicological findings support a role for aSyn in chemically induced Parkinsonian disorders; for example, exposure to beta caroline derivatives in food and manganese in the environment greatly increases aSyn aggregation. Also, certain pesticides are known to up-
regulate aSyn expression. These discoveries have established causal relation-
ships between the environmental exposure to toxic substances and altered aSyn gene expression, increased influx to brain, decreased clearance from brain parenchyma, and ultimately accelerated aSyn aggregation. This session brings together in one place the worldwide experts who are actively inves-
tigating aSyn biology, chemistry, neurotoxicity, its underlying cellular and molecular mechanisms, and clinical consequences, to address an interesting question: How does a “good” aSyn protein change to be a culprit in envi-
ronmentally linked neurodegenerative diseases? After a brief introduction of aSyn in health and human diseases, the first presenter will highlight the current understanding of mechanisms of aSyn self-assembly and how exposure to environmental toxicants promotes the protein’s aggregation. The second presenter will discuss the potential of using total and phosphorylated aSyn in the cerebrospinal fluid (CSF) and plasma to diagnose AD and PD, based on human longitudinal studies, and how this approach may be applied to neu-
rotoxicological investigations. The third presenter will extend the subject to illustrate the processes that regulate aSyn transport by the BBB and how the altered aSyn transport at brain barriers may lead to Parkinsonian disorders. The last presenter will review the latest findings showing that Mn exposure enhances the release of misfolded aSyn via exosomes by impairing endoso-
mal trafficking machinery. A sensitive high-throughput method to quantify aSyn in wielder’s serum will also be introduced. This session will present the latest discoveries on the structural, genetic, cellular, and molecular mecha-
nisms of aSyn neurodegenerative diseases, as well as a broad interest from those engaged in toxicological research of neurodevelopment and neurodegenerative diseases, neuroscience, neurotoxicology, metal toxicology, and nanoscience.

1022 How aSyn Converts from Good to Bad: A Role for Environmental Toxicants
J. Rochet, Purdue University, West Lafayette, IN. Sponsor: W. Zheng
This talk will highlight recent findings on the role of aSyn aggregation and aSyn-toxicant interactions in PD. The first part of the presentation will pro-
vide an overview of the protein’s normal physiological function and how this function is modulated by aSyn-membrane interactions. The next part of the talk will be based on mouse models of aSyn aggregation, with an empha-
sis on recent data highlighting the importance of membrane-induced aSyn aggregation in PD-related neurotoxicity. The presentation will also outline new findings suggesting a link between exposure to environmental toxicants, including pro-oxidants in pesticides or herbicides and heterocyclic amines in
Assessing Acute Health Risk: Potential Roles of Peripheral aSyn in Exposure Assessment and Risk Management

The concentration of peripheral aSyn, e.g., aSyn contained in red blood cells (RBCs), is much higher than that in the central nervous system (CNS); however, physiological and pathological roles of this pool of peripheral aSyn are essentially unknown. Recently, we have demonstrated that RBC aSyn likely contributes to CNS pathology seen in Parkinson’s disease and Alzheimer’s disease in addition to being potential biomarkers of neurodegenerative disorders. Peripheral aSyn is also an excellent candidate for interaction with neurotoxicants, especially manganese that has been shown to facilitate aSyn aggregation. Indeed, a peripheral contribution of aSyn to Parkinson’s disease and related disorders substantially strengthens the argument of environmental factors, metals in particular, involved in Parkinson’s pathogenesis. This talk will summarize recent advances in this area and potential future developments.

1024 Transport of aSyn by Brain Barrier Systems and Relevance to aSyn Toxicity

Understanding of how aSyn is transported in and out of brain is critical to predict environmental causes of aSyn-associated neurologic disorders and to design drugs for treatment. Current knowledge to this respect is surprisingly incomplete. This presentation will discuss the new finding of the cerebrovascular targets at the blood-brain barrier (BBB) that affect aSyn clearance from the brain in PD. By modifying transporters, tight junction and receptor expression using in vitro and ex vivo models of isolated brain capillary endothelial cells and SD-Tg(SNCA*A53T) transgenic rats, we have discovered that both native and mutant aSyn isoforms induce a biphasic regulation of ABC-transporters in BBB and that low aSyn concentrations cause a transient reduction of LRPI expression which turns into an up-regulation of RAGE at higher aSyn concentrations after long-term exposure. This process is accompanied by an initial tightening of the BBB but followed by a gradual opening and can be correlated to increasing levels of secreted inflammatory and oxidative stress markers. Inhibitors of clathrin-mediated endocytosis decrease the aSyn passage from the brain to the blood compartment and vice versa, implicating a receptor-mediated mechanism (e.g., RAGE, LRPI). Pathophysiological alterations in the uptake and removal mechanisms of aSyn monomers, oligomers and fibrils from either the blood or brain compartment appear to determine the extent to which toxic aSyn amasses. The presentation will further discuss the vulnerability of these cerebrovascular target sites that are subjected to insults by pesticides and metals as they disturb the BBB transport of aSyn leading to harmful aSyn accumulation in PD.

1025 Translational Relevance of Misfolded aSyn Release via Exosomes in Manganese-Induced Parkinsonian Disorder

A. Kanthasamy. Iowa State University, Ames, IA.

Emerging evidence indicates that a prion-like, cell-to-cell transfer of misfolded proteins contributes to the spreading of aSyn aggregates and neurotoxicity; but the cellular mechanisms underlying the propagation of the protein aggregates during environmental neurotoxic metal exposure are not well understood. This presentation will demonstrate that misfolded aSyn is secreted through exosomes and transfers cell-to-cell following exposures to environmentally relevant doses of manganese (Mn) in neuronal cells. Functionally, these exosomes stimulate microglial cells to activate a sustained neuroinflammatory response subsequently contributing to neurotoxicity. The data will further show that these exosomes can initiate Parkinsonian-like pathological features, including aSyn aggregation and propagation, in an animal model. The presentation will also highlight the translational relevance of our findings to the detection of aSyn aggregates using an ultra-sensitive high-throughput RT-QuIC diagnostic assay in the serum exosomes of welders occupationally exposed to manganese. Overall, this presentation will offer a comprehensive insight into pathological mechanism mediated by aSyn aggregation in chemical induced Parkinsonism as well as potential biomarker value of the protein aggregates in environmentally linked neurodegenerative diseases.

1026 Assessing Acute Health Risk: Potential Application of Next-Generation Toxicological Tools

M. Stewart. US EPA, Research Triangle Park, NC.

Human health risk assessments estimate the nature and probability of adverse health effects in humans who may be exposed to chemicals in the environment. Estimates of health risks resulting from chemical exposure are typically based on an assumption that either low-level, chronic (=year or more) or higher-level, acute (=day or less) exposures adequately span the range of all potential scenarios. However, there are relatively few health effect toxicity values applicable to the general population for acute exposures as opposed to chronic chemical exposures. A primary reason is that a large number of chemicals have a paucity of short-term human and animal data on which to base acute toxicity values. In vitro, computational modeling, conceptual frameworks, and other higher-throughput measurements may help fill these gaps. These next-generation tools have been slowly integrated into chronic chemical hazard prioritization over the last decade, but the use of these tools to quantitatively derive reference values for acute exposure scenarios has not been widely discussed even though these studies are inherently acute in nature. This session will first explore how acute toxicity values are currently being derived and used to assess the potential for short-term risk. The session will continue to discuss both the challenges and the promises of using next-generation toxicological tools (specifically pharmacokinetic or pharmacodynamic modeling, adverse outcome pathway frameworks, and high-throughput testing strategies) to address data deficiencies associated with the derivation and proper application of acute health toxicity values.

1027 Exposure Assessment and Risk Management Using Acute Toxicity Factors to Evaluate Ambient Air Monitoring Data in Texas

T. Bredfeldt. Texas Commission on Environmental Quality, Austin, TX.

In response to the need for exposure assessment of ambient air pollutants, the Texas Commission on Environmental Quality (TCEQ) has designed the largest ambient air monitoring network in the U.S. The agency lists a total of 256 fixed-site monitors in the state, which are owned by various entities including the TCEQ. The Toxicology Division evaluates data from 129 of those sites, which collect concentrations of metals, volatile organic compounds, carbonyls, and polycyclic aromatic hydrocarbons. Concentrations are reported as 30-minute, 1-hour, 3-hour, 24-hour, or annual average concentrations. In order to evaluate data collected at these monitoring sites, the Toxicology Division staff derive chemical-specific toxicity factors that are used as comparison values when assessing chemical concentrations measured in ambient air throughout the state. Given the extensive nature of the air monitoring network in the state, the TCEQ is able to evaluate whether chemical concentrations observed in various locations would be of concern to human health or welfare. Further, the large amount of short-term air data collected enables the agency to have a unique ability to evaluate patterns and trends in short-term ambient air samples, including 30-minute and 1-hour peaks, the frequency of toxicity factor exceedance, region-specific chemicals of concern, and chemicals measured in specific environments such as the Barnett Shale play or the heavily industrialized Houston and Corpus Christi ship channels. This presentation will describe the methods used by the TCEQ to derive chemical-specific toxicity factors. Then, using a number of monitoring sites as case studies, we will present data describing trends in air monitoring data as a function of time, the frequency of toxicity factor exceedances, potential sources, and how these compare to monitoring in rural or suburban areas populated with fewer sources. These data are useful in characterizing and understanding potential health risks associated with acute exposure to various chemicals measured in the environment. Such data are critical to problem formulation and risk management of acute and chronic chemical exposures and could be used as a model to further inform risk assessors and managers in other states about chemical-specific, risk management strategies.
A Conceptual Model for Predicting How Acutely Toxic Exposure Levels Should Relate to Those Associated with Toxicity from Longer-Term Exposures, Suggesting Approaches to Using In Vitro Data in Exposure-Duration Extrapolation

L. Rhomberg, Gradient, Cambridge, MA.

The relationship between exposure levels causing acute toxicity and those (usually lower) that are associated with repeat-dose toxicity hinges on the impact of dose rate. Dose-rate effects, in turn, can depend mainly on underlying pharmacokinetics (PK) or pharmacodynamics (PD). Earlier work examined how equally toxic combinations of acute inhalation exposure level and exposure duration can be understood in terms of the balance between uptake and clearance (for PK) and of damage and repair (for PD), with the process taking longest to reach steady state driving the overall pattern. This now extends the analysis to oral exposures and to longer-term exposures, providing a conceptual framework to predict how dose-rate effects should intervene to result in different acutely toxic dose levels compared to those having effects after ongoing or repeat exposure. This includes brief consideration of how adverse outcome pathways (AOPs) might be examined to identify events that are likely to be drivers of dose-rate effects, and how in vitro evaluation of damage and repair processes related to such key events might be useful in predicting sensitive endpoints for acute toxicity as well as the relationships between acutely toxic exposures and ones associated with longer-term toxicity.

Application of Modern Toxicology Approaches for Predicting Acute Toxicity

D. Dorman, North Carolina State University, Raleigh, NC.

There is a critical need to develop modern approaches for predicting acute, debilitating chemical toxicity. This presentation will present major conclusions from a recent National Academies report entitled Application of Modern Toxicology Approaches for Predicting Acute Toxicity for Chemical Defense. This presentation will discuss the current state of computational and high-throughput approaches for predicting acute toxicity. The National Academies multi-tiered prioritization strategy that consists of initial character- ization, nontesting approaches (e.g., quantitative structure–activity relationship [QSAR] models), high-throughput and medium-throughput assays, and ultimately traditional animal testing will also be discussed. This strategy rests on the hypothesis that chemical structure, physicochemical properties, biochemical properties, or biological activity in isolated cells and tissues or in nonmammalian organisms can be used to predict acute mammalian toxicity. Strengths and limitations of many in vitro assays for predicting acute toxicity were identified by the National Academies and will also be discussed. For example, quantitative linkage of the endpoints used (e.g., cytotoxicity) to a phenotype is often lacking, assays do not account for important pharmacoki- netic characteristics that can influence in vivo toxicity, and nominal chemical concentration used in the assays may not reflect concentrations found in vivo.

Predicting Chemical Affinity and Extrapolating to Safe Acute Exposure Levels (SAELs)

L. Burgoon, US Army Engineer Research and Development Center, Vicksburg, MS.

Warfighters and first responders are at significant risk of acute exposure to chemicals following terrorist attacks, or as the result of traps being triggered in the course of duty. Several US Federal Agencies and stakeholders had been developing Acute Exposure Guidelines (AEGs) for chemicals in the past; however, that program has recently ceased due to a lapse in funding. Thus, there are still thousands of potentially acutely toxic chemicals that lack an assessment. This talk will discuss our strategy to predict safe acute exposure levels (SAELs) using chemical structures as a starting point. The SAELs approach will be demonstrated using the artificial intelligence chemical affinity models that we have built to extrapolate from chemical structures to protein binding affinity and protein activation for the mu-opioid receptor and acetylcholines- terase. We will see how we use this information to inform us about potential adverse outcomes by looking at Adverse Outcome Pathway Networks available in AOPConnect. We will also discuss our approaches for generating chemical binding information to fill in data gaps using the AEGs or other available information. The US Army Chief of Engineers has approved this information for release. The views presented in this article do not necessarily reflect current or future opinion or policy of the US Army Corps of Engineers.

Session Overview: Bringing Next-Generation Toxicological Tools into Acute Health Risk Assessments

G. Woodall, US EPA, Research Triangle Park, NC.

The purpose of this presentation is to provide a holistic overview of the prior presentations and to predict how the next generation toxicological tools can be applied to improve acute human health risk estimates. Traditionally, human health risk assessment from chemical exposures rests on the ability to either observe toxicity to humans directly, or to predict toxicity based on observations in laboratory animals exposed to the chemical of interest. If data for the chemical are not available, estimates may be based on “read-across” from observations with chemicals anticipated to have sufficiently similar structure and biological activity. Modeling approaches have been used to provide more precise predictions using known biological parameters. A more complete understanding of the key events and mechanisms are being eluci- dated at a more granular level by the next generation of high-throughput and in vitro testing platforms, leading to improved predictions through construct- ing adverse outcome pathways (AOPs). Many of these topics are covered to some extent in prior presentations in this session; this talk will discuss how the more recently developed approaches to predicting toxicity might realistically become incorporated into risk assessments - particularly for acute exposures. Discussion will touch upon the current methods used to establish acceptable acute exposures, examine and challenge some of the assumptions used in traditional acute risk predictions, and discuss how more recently developed data streams and analytical approaches may be used to either improve or fill-in data gaps for establishing risk estimate values for acute exposures. The views in this abstract are those of the author and do not necessarily represent the views or policy of the US EPA.

Novel Genetic-Based Tools for Evaluating Toxicity Potential, Mechanism of Action, and Population Dynamics

B. Cummings, University of Georgia, Athens, GA.

The genetic information encoded in DNA and perturbations in the flow of genetic information from DNA to downstream biomolecules (i.e., RNA then protein) following chemical exposure are critical determinants of toxicologi- cal responses in terms of both functional outcomes and variations in response across a population (i.e., inter-individual susceptibility). In general, toxicolo- gists have been cautious regarding when and how to incorporate information about genetically controlled responses or genetic susceptibility into safety and risk assessment pipelines. However, there are a number of recently de- veloped molecular biology tools that can be used to evaluate the role of ge- netic structure, gene regulation, and gene expression in response to drug and chemical exposures that provide informative data for use in various steps across risk evaluation pipelines. The aim of this session is to discuss emerg- ing systems genetics tools that may help advance toxicological evaluation and to present case studies demonstrating their utility. Tools and approaches that will be discussed in this session include (1) the use of genetically diverse population models for investigating the contribution of genetic sequence variation to toxicant susceptibility and applications toward replacement of default toxicodynamic uncertainty factors, (2) the use of gene-editing technol- ogies in a screening context toward discovery of key genetic drivers under- lying susceptibility and resistance to toxicant exposures, (3) the use of methylome-based next-generation sequencing (NGS) for rapid assessment of toxicant-induced changes in DNA methylation patterns and applications for adverse outcome pathway (AOP) integration, (4) the use of targeted RNA-seq in a high-throughput transcriptomics (HTTR) screening context and methods for in vitro point-of-departure estimation and in vitro to in vivo extrapolation (IVIVE), and (5) the use of weighted gene co-expression networks (WGCNA) for toxicant mode-of-action analysis. Participants in the session will gain a broader understanding of emerging genetic and transcriptomic analysis tools, their strengths and limitations, and their applications in testing priori- tization, mechanistic analysis, and human health risk assessment.

Quantifying Inter-Individual Toxicodynamic Variability Using Genetic Reference Populations to Inform Risk Assessment

A. Harrill, NIEHS/NTP, Research Triangle Park, NC.

Toxicology testing is often performed in very limited genetic context (human cells, rodent strains) that do not represent the genetic diversity of human pop- ulations. The question then becomes, which humans is this cell line or rodent strain representing, and how can these results be translated to genetically diverse humans? To overcome these challenges, novel outbred rodent stocks,
such as Diversity Outbred (DO) mice, have been developed with genomes that have a highly randomized allelic architecture and for which each individual is genetically unique (like humans). DO mice can thus act as a population surrogate for human epidemiological studies, allowing investigators to query toxicodynamic variability in responses and their genetic drivers. Data will be presented in which neural progenitor cells from DO mice in vitro are used to assess the impact of toxicants on gene expression. TempO-Seq is a targeted RNA-Seq approach to perform genome-wide functional toxicogenomic analyses. This approach allows for rapid and cost-effective assessment of DNA methylation of a significant portion of the genome, but are relatively expensive. Additionally, MeDIP-Seq assesses a small amount of DNA per cell, while whole genome bisulfite sequencing (WGBS) is rapid and cost effective, but assesses a small amount of DNA per cell. The population-based in vitro data may thus provide regulators with a rationale to replace default uncertainty factors for toxicodynamic variability in setting human dose thresholds.

1034 Genome-Wide and Targeted CRISPR Functional Approaches in Toxicology

Comprehensive identification of cellular pathways involved in chemical toxicity response has recently become more feasible due to the emergence of the CRISPR clustered regularly interspaced short palindromic repeats (CRISPR) genome editing technique. This allows for genome-wide functional toxicogenomic approaches. We used genome-wide CRISPR knock-out screening to identify genes whose loss-of-function alters sensitivity to acetaldehyde and arsenic trioxide. Our screens identified multiple genes that impact cellular toxicity of each of the studied chemicals. Consistent with the reported role of aldehydes in DNA damage, we demonstrated that disruption of aldehyde dehydrogenase (ALDH) gene encoding the enzyme ALDH1A1 increased the toxic effect of acetaldehyde. In addition, we identified a gene of unknown function, OVC2, which modulates acetaldehyde adduct levels in DNA. Confirmatory studies demonstrated that CRISPR-mediated ablation of this gene increased the levels of acetaldehyde-DNA adducts. We hypothesize a role for OVC2 in adduct removal although we cannot rule out a direct role in acetaldehyde metabolism. Our study on arsenic trioxide identified multiple cellular components involved in mitigating the effects of reactive oxygen species (ROS) as playing important roles in acute ATO toxicity. We also revealed a novel cellular link between arsenic toxicity and selenocysteine metabolism. We found that disruption of any of the multiple genes involved in selenocysteine biosynthesis increased arsenical resistance and we discuss two possible hypotheses to explain these findings. Further, we identified key cellular components involved in arsenical uptake and export. Our work further demonstrates the strength of high throughput screening using the CRISPR-Cas9 system in deciphering mechanisms of toxicity.

1035 Novel Methods for Rapid Assessment of Toxicant-Induced Changes in DNA Methylation

B. Cummings. University of Georgia, Athens, GA.

Technologies are presented for assessment of changes in DNA methylation in response to toxicant exposure. Some of these approaches, such as pyrosequencing, are rapid and cost effective, but assess a small amount of DNA per sample. Others, such as methylated DNA immunoprecipitation sequencing (MeDIP-Seq) and the Infinium MethylationEPIC BeadChip®, assess a significant amount of the genome, but are relatively expensive. Additionally, MeDIP-Seq offers more qualitative regional methylation analysis with less resolution, as opposed to quantitative assessment of single differentially methylated sites. While the Infinium MethylationEPIC BeadChip® assesses changes at single sites, it is not as cost effective as MeDIP-Seq, and both techniques offer less dynamic range than reduced representation bisulfite sequencing (RRBS). Most of these techniques are typically used for whole genome analysis. We present case studies highlighting comparisons of methylation analysis platforms including MeDIP-Seq, Illumina 450K and EPIC Beadchip®. We also discuss key factors in variability in DNA methylation analysis including bisulfite conversion and library preparation. We present data derived from a modification of RRBS called targeted bisulfite next generation sequencing (TB-NGS) that allows for rapid and cost-effective assessment of DNA methylation of single gene targets. TB-NGS was used to determine changes in the methylation of the cyclin-dependent kinase inhibitor p21 in response to bromate (a single gene targets. TB-NGS was used to determine changes in DNA methylation of the promoter region of human p21 whose methylation was mediated by DNA-methyl transferase POL3 and the novel CRISPR-Cas9 system in Vtg whose methylation was decreased 50% after EE2 exposure.

1036 High-Throughput Transcriptomics (HTTr) Screening with Targeted RNA-Seq: Applications for In Vitro Point-of-Departure Estimation and In Vitro to In Vivo Extrapolation

J. Harrill. US EPA, Research Triangle Park, NC.

Current initiatives in the field of environmental toxicology include integration of toxicity testing data from in vitro and alternative methods into risk assessment practices. Approaches have been proposed that use potency estimates of bioactivity from in vitro testing alone, coupled with high-throughput toxicokinetic predictions, to calculate human equivalent doses that can, in turn, be used as the basis for screening-level human health risk assessment. The increasing efficiency and declining cost of generating whole transcriptome profiles has made high-throughput transcriptomics (HTTr) a practical option for determining bioactivity thresholds in in vitro models. Recently, US EPA NCTs have performed concentration-response screening of 2,200 chemicals from the ToxCast chemical inventory in MCF-7 cells using the TempO-Seq human whole transcriptome targeted RNA-Seq assay. The TempO-Seq technology has also been used to investigate the effects of volatile chemicals such as acrolein and 1,3-butadiene on gene expression in BEAS-2B and human primary bronchial epithelial cells grown in an air-liquid interface. This presentation will provide a broad overview of the results of these studies and particularly focus on methods and tools for high-throughput concentration-response modeling and in vitro POD estimation in each model. Margin of exposure (MOE) case studies will be presented where the human equivalent doses calculated from HTTr data compare well to bioactivity thresholds that will be compared to those based on other high-throughput in vitro data streams (i.e. ToxCast assays) as well as those generated via high-throughput exposure prediction. HTTr-derived, biological pathway activating concentrations (BPACs) for promiscuous ToxCast chemicals (i.e. those active in dozens to hundreds of ToxCast assays) were often of an order of magnitude lower than the corresponding ToxCast PODs, potentially providing greater resolution and sensitivity for detecting perturbation of sensitive biological processes. This abstract does not necessarily reflect US EPA policy.

1037 TXG-Map: Systems Biology Approaches to Understanding Adverse Outcomes

Y. Webster. Eli Lilly and Company, Indianapolis, IN. Sponsor: J. Harrill

Despite investment in toxicogenomics, nonclinical safety studies are still the mainstay to predict clinical liabilities for new drug candidates. Network-based approaches for genomic analysis help overcome challenges with whole-genome transcriptional profiling using limited numbers of treatments for phenotypes of interest. In this talk, a co-expression network analysis platform, TXG-Map, will be described and applied to safety assessment using rat liver gene expression data. To develop the TXG-Map, we utilized data from two large publicly available gene expression repositories, Drug Matrix (DM) and the open TG-GATEs (TG). Using weighted gene co-expression network analysis (WGCNA) and 9071 liver-expressed genes, we defined 415 co-expressed gene modules. Annotation of the TXG-Map is provided based on pathway and Gene Ontology (GO) term enrichment as well as literature curation at a level of granularity sufficient to identify biological processes associated with co-expression networks. Changes in specific networks are interpreted in the context of changes in the entire set of networks to produce a provisional mode of action hypothesis. Some of these unique modules were highly correlated with liver toxicity phenotypes. For example, tunicamycin is a prototypical ER stress inducer. In one case study, we tried to identify other compounds that induce ER stress and caused similar pathology. We searched all module profiles (i.e. describing each as a vector of 415 module scores) using tunicamycin as a query. The most similar compound was ethanomide, a second line therapy for mycobacterial infection, with hepatotoxicity liability. Further analyses showed that among modules most induced by both chemicals, module 70 contains Ddit3 and was top-ranked for single-cell necrosis/apoptosis and module 76 contains canonical ER chaperones Hspa5 and Hsp0901b (Grp94). Notably, module 85 was also induced by both compounds and contains Atf4 and Atf4-target genes. When we treated rat primary hepatocytes with ethaminothiurea, there was a concentration-dependent increase in Atf4, Grp78 and...
Endocrine disruption is a major health concern for many persistent environmental chemicals, with adverse outcomes in metabolism, development, reproduction, and cancer. The endocrine systems are robust nonlinear dynamical systems by nature, which can resist perturbations to maintain hormone homeostasis through feedback regulations between multiple organs. Simple linear extrapolation from high-dose data to environmental low-dose effects is thus not applicable to predicting the health risk of endocrine-disrupting chemicals (EDCs). Moreover, as toxicity testing is increasingly shifting to cellular or organoid-based in vitro assays, the demand for in vivo extrapolation that can predict systems-level hormonal outcomes and apical endpoint consequences in human populations is also rising. Bridging these data gaps calls for a computational systems biology approach to mechanistically model the endocrine systems and their responses to perturbations by endocrine disruptors acting via diverse molecular initiating events (MIEs). This session is organized to present the state-of-the-science in mathematical modeling of endocrine systems in the context of chemical risk assessment through presentation of a series of computational works on thyroid, reproductive, and adrenal systems. The first presenter lays out the general design principles for the homeostatic regulation of the endocrine systems involving feedback interactions between the hypothalamus, pituitary, and endocrine organs. Using the thyroid system as an example, the presentation illustrates how mechanistic computational models constructed according to these principles and incorporating individual variability can aid the interpretation and quantitative prediction of the health outcomes of EDCs. The second talk presents a more detailed model of the thyroid system to understand the effect of iodine nutritional status on thyroid hormone levels during pregnancy and lactation. While the model is unable to explain why repletion of iodine intake cannot ameliorate the effect of iodine deficiency, it provides mechanistic insights into the dynamic functioning of the hypothalamic-pituitary-thyroid (HPT) axis during the reproductive stage of women. The third talk presents the modeling work on in vitro to in vivo extrapolation (IVIVE) for the risk effects of EDCs on both the hypothalamic-pituitary-adrenal axis and male reproductive systems. By using in vitro data from thyroperoxidase and sodium-iodide symporter inhibition assays and a purified rat Leydig cells assay that detects alterations in testosterone production, the speaker illustrates quantitative adverse outcome pathway (qAOP) models that can extrapolate in vitro data to predict mammalian neurodevelopmental deficits. The fourth talk presents the models on the hypothalamic-pituitary-adrenal axis and how its interaction with the circadian rhythm can affect between-sex and within-sex variability. The model provides a computational tool that can be tapped to understand the heterogeneous responses in human populations to stress and to aid risk assessment of EDCs interfering with the physiological stress response. The final presentation includes a comprehensive modeling framework that links exposure, toxicokinetic, and ovarian cycle models. The work illustrates how modeling the exposure-to-outcome continuum through linking these models and incorporating ToxCast assay data can aid in the identification of putative inhibitors on menstrual cycle length and ovulation. In summary, the session will demonstrate that through integrating chemical and biological data from in vitro, in vivo, epitoxinology, and exposure studies, computational systems biology models of endocrine systems can play a key, bridging role in quantitatively understanding and predicting the health risks of EDCs.

**1038 Application of Computational Modeling to Risk Assessment of Endocrine Disruptors**

Q. Zhang, Emory University, Atlanta, GA.

Indicates that the biochemical amplifier, required to achieve a high feedback loop gain, is located in the brain not in the thyroid gland. Multiple signaling events in the hypothalamus and anterior pituitary collectively contribute to a highly ultrasensitive motif that amplifies small changes in TH levels to regulate TSH synthesis and secretion. This design minimizes the chance of thyroid hormone alteration by protecting the sensitive signaling part within the blood-brain barrier. Depending on the molecular initiating event (MIE), EDCs affecting TH synthesis, metabolism, and action can exhibit different shape of dose-response curves for their effects on the hormone levels in the low-dose region. The inverse relationship between TSH and THs observed in the human population suggests that most sources of individual variabilities stem from the peripheral tissues whereas the pituitary system is relatively consolidated. Although this screening can be useful in examining the potential of chemicals to disrupt the hypothalamic-pituitary-thyroid axis, it provides mechanistic insights into the dynamic functioning of the hypothalamic-pituitary-thyroid (HPT) axis during the reproductive stage of women. The third talk presents the modeling work on in vitro to in vivo extrapolation (IVIVE) for the risk effects of EDCs on both the hypothalamic-pituitary-adrenal axis and male reproductive systems. By using in vitro data from thyroperoxidase and sodium-iodide symporter inhibition assays and a purified rat Leydig cells assay that detects alterations in testosterone production, the speaker illustrates quantitative adverse outcome pathway (qAOP) models that can extrapolate in vitro data to predict mammalian neurodevelopmental deficits. The fourth talk presents the models on the hypothalamic-pituitary-adrenal axis and how its interaction with the circadian rhythm can affect between-sex and within-sex variability. The model provides a computational tool that can be tapped to understand the heterogeneous responses in human populations to stress and to aid risk assessment of EDCs interfering with the physiological stress response. The final presentation includes a comprehensive modeling framework that links exposure, toxicokinetic, and ovarian cycle models. The work illustrates how modeling the exposure-to-outcome continuum through linking these models and incorporating ToxCast assay data can aid in the identification of putative inhibitors on menstrual cycle length and ovulation. In summary, the session will demonstrate that through integrating chemical and biological data from in vitro, in vivo, epitoxinology, and exposure studies, computational systems biology models of endocrine systems can play a key, bridging role in quantitatively understanding and predicting the health risks of EDCs.

**1039 Design Principles of Endocrine Systems and Their Applications to Understanding Endocrine Disruptions: A Case Study with the Hypothalamic-Pituitary-Thyroid Axis**

Q. Zhang, and Z. Shi. Emory University, Atlanta, GA.

The endocrine systems are one of the most robust physiological structures in animals and humans. Understanding nature’s design principles for biological robustness that maintains hormone homeostasis through mechanistic computational modeling will aid the interpretation and quantitative prediction of the health outcomes of endocrine disrupting chemicals (EDCs). In this presentation, using the hypothalamic-pituitary-thyroid (HPT) axis as an example, we illustrate how the key design features help understand the thyroid effects of EDCs quantitatively. The circulating thyroid hormones (THs) are maintained in a narrow range (< 2 fold), whereas thyroid-stimulating hormone (TSH) can vary much more widely (> 10 fold). This contrasting variability profile indicates that the biochemical amplifier, required to achieve a high feedback loop gain, is located in the brain not in the thyroid gland. Multiple signaling events in the hypothalamus and anterior pituitary collectively contribute to a highly ultrasensitive motif that amplifies small changes in TH levels to regulate TSH synthesis and secretion. This design minimizes the chance of thyroid hormone alteration by protecting the sensitive signaling part within the blood-brain barrier. Depending on the molecular initiating event (MIE), EDCs affecting TH synthesis, metabolism, and action can exhibit different shape of dose-response curves for their effects on the hormone levels in the low-dose region. The inverse relationship between TSH and THs observed in the human population suggests that most sources of individual variabilities stem from the peripheral tissues whereas the pituitary system is relatively consolidated. Although this screening can be useful in examining the potential of chemicals to disrupt the hypothalamic-pituitary-thyroid axis, it provides mechanistic insights into the dynamic functioning of the hypothalamic-pituitary-thyroid (HPT) axis during the reproductive stage of women. The third talk presents the modeling work on in vitro to in vivo extrapolation (IVIVE) for the risk effects of EDCs on both the hypothalamic-pituitary-adrenal axis and male reproductive systems. By using in vitro data from thyroperoxidase and sodium-iodide symporter inhibition assays and a purified rat Leydig cells assay that detects alterations in testosterone production, the speaker illustrates quantitative adverse outcome pathway (qAOP) models that can extrapolate in vitro data to predict mammalian neurodevelopmental deficits. The fourth talk presents the models on the hypothalamic-pituitary-adrenal axis and how its interaction with the circadian rhythm can affect between-sex and within-sex variability. The model provides a computational tool that can be tapped to understand the heterogeneous responses in human populations to stress and to aid risk assessment of EDCs interfering with the physiological stress response. The final presentation includes a comprehensive modeling framework that links exposure, toxicokinetic, and ovarian cycle models. The work illustrates how modeling the exposure-to-outcome continuum through linking these models and incorporating ToxCast assay data can aid in the identification of putative inhibitors on menstrual cycle length and ovulation. In summary, the session will demonstrate that through integrating chemical and biological data from in vitro, in vivo, epitoxinology, and exposure studies, computational systems biology models of endocrine systems can play a key, bridging role in quantitatively understanding and predicting the health risks of EDCs.

**1040 Using Computational Approaches to Understand the Hypothalamic-Pituitary-Thyroid (HPT) Axis for Iodine Sufficient and Insufficient Conditions during Lactation**

Iodine insufficiency remains a public health concern in many regions of the world. Even for developed countries questions are raised about iodine sufficiency during pregnancy and lactation because of the critical importance of iodine during this sensitive life stage. Biologically-based HPT axis models for iodine sufficiency and insufficiency in lactating rats, nursing pups, lactating women and nursing infants revealed substantial compensatory actions, perhaps mediated by more than serum TSH. Iodine intake studies were undertaken with pregnant and lactating rats ranging from insufficient to excess. For lactating women several published studies were used to create a biologically-based computational model of the HPT axis for moderate iodine insufficiency. Iodine intervention studies, for which biomarker data exist on the status of the HPT axis, remain divergent, without a mechanistic understanding for how recovery from iodine insufficiency occurs. Our model, while generally successful, was unable to explain findings where increased dietary intake of iodine failed to ameliorate human iodine deficiency as measured by serum thyroid hormones and urinary excretion of iodide. These baseline nutritional studies serve as a first step in better understanding the complex interactions of chemicals on the HPT axis. This presentation provides mechanistic insights into the dynamic functioning of the HPT axis in rats and humans during lactation and iodine deficiency. With continued improvement this computational tool will be able to interpret chemical-induced disruption of the HPT axis in rat pups relative to the risks for HPT disruption in human neonates and infants.

**1041 Biologically Based Computational Models for Endocrine Disruption Incorporating Adverse Outcome Pathways and High-Throughput Toxicity In Vitro Testing**

H. El-Masri, US EPA, Research Triangle Park, NC.

An adverse outcome pathway (AOP) is a conceptual framework of biological relationships starting from modulations of molecular initiating events (MIEs) to key events (KEs) leading to pathological adverse outcomes. The process of constructing AOPs requires the accumulation of data and knowledge from experimental studies, literature and publicly available databases. The immediate application of AOPs is the screening of chemicals using information from in vitro high-throughput toxicity (HTT) experiments applied to specific MIEs. Although this screening can be useful in examining the potential of chemicals to cause adverse outcomes, it is not enough for estimating health hazards risks to humans. This inadequacy is due to differences in the behaviors and effects of chemicals in vitro vs. in vivo. For this reason, in vitro to in vivo (IVIVE) extrapolation of KEs in an AOP becomes an essential process to fully examine the hazard risks of environmental chemicals. Additionally, in the absence of chemical influence, AOPs provide the biological framework for developing computational predictive models (qAOPs) to quantitatively describe the sequence and timing of effects (key event relationships, KERs) leading to the pathogenesis of an AOP. In this manner, qAOPs are used to computationally estimate dose-response relationships where the effective dose can
be a chemical-independent biomarker (e.g. thyroid hormone levels in fetal brain) and the response is a pathological end point related to an adverse outcome (e.g. fetal brain heterotopia size). This presentation will provide details for the applications of biologically-based modeling to 1) conduct IVIVE of in vitro purified rat Leydig cell assay to predict chemical-induced alterations in testosterone production, and 2) develop qAOPs for thyperoxidease (TPO) and sodium-adrenyloxytoxin (NIS) inhibition leading to mammalian neuro-developmental deficits. The application of computational methods to predict dose-response relationships in view of in vivo biological mechanisms as outlined in an AOP construct is critical in the estimation of health risk estimates of environmental chemicals where data is not sufficient.

### W 1042 Personalized Adaptation to Stress and Physiological Trade-Offs in the Circadian Regulation of the HPA Axis: A Systems Biology Approach

Epidemiological studies established that exposure impairs the cardiovascular, respiratory and central nervous systems leading to a range of disease states. Exposure activates the hypothalamic-pituitary-adrenal (HPA) axis – a key component of the stress response – leading to increased levels of corticosterone/cortisol initiating systemic adverse effects. Evidence suggests that endocrine disruptors (pesticides, flame retardants and UV-filter chemicals) perturb circadian rhythm. The HPA exhibits complex dynamics resulting in robust circadian patterns driving the dynamics of glucocorticoid hormones. Persistent disruption of homeostatic glucocorticoid circadian rhythmicity due to chronic exposure is correlated with the incidence of a range of pathological conditions. A hallmark of HPA dynamics is its stress response disparity mediated by regulatory plasticity in its activity. Sex differences in HPA activity are prominent and thought to contribute to sex-specific disparity in the prevalence of stress disorders. We discuss mathematical models characterizing differences in regulatory properties controlling the circadian dynamics of the HPA axis contributing to sex-specific and inter-individual variability and stress-responsive functioning. We focus on understanding sex-dependent sensitivities in the dynamics of the HPA, hypothesizing that regulatory plasticity enables HPA adjustments to maintain homeostasis under stress and demonstrating that adaptation comes at a cost (allostatic load). We identify distinct sex-specific parameter spaces of greater adrenal sensitivity and weaker negative feedback in females indicative of the inter-individual variability in the HPA regulatory mechanisms. Allostatic habituation of HPA regulation provides fitness advantages by preventing the sustained dysregulation of glucocorticoid-responsive signaling pathways. Allostatic adaptation results in physiologic cost impairing the homeostatic stress-responsive and stress-responsive functioning. The HPA in the form of trade-off between the two objectives. Finally, the allostatic regulatory adaptations are predicted to cause time-of-day dependent sensitization of the acute stress response and impair the entrainability of the HPA. Our HPA model capturing individual variability provides a basis for a mechanistic tool that will allow health risk assessment of endocrine disruptors.

### W 1043 Computational Predictive Analysis of Ovarian Cycle Disruption by Mixtures of Endocrine Disruptors

N. Golbamaki. Lhasa Limited, Leeds, United Kingdom. Sponsor: Q. Zhang

The regulation of menstrual cycle in women is controlled by coordinated hormonal stimulation and inhibition along the hypothalamic-pituitary-ovarian axis. Exposures to endocrine disruptors that interfere directly or indirectly with any of the hormones responsible for this process can induce pathological outcomes such as infertility. In this context, the role of aromatase enzyme is critical as it reversibly converts testosterone to E2, and androstenedione to estrone, maintaining the dynamic balance between androgens and estrogens. In this talk a computational approach designed to predict the effects of exposure to large-scale (i.e., potentially real-life) mixtures of aromatase inhibitors on the dynamics of menstrual cycling in women will be presented. The approach was designed over four computational steps: step one, the ExpoCast database of exposure estimates were used to simulate random exposures to potential mixtures of aromatase inhibitors. In step two, a pharmacokinetic model was developed to estimate the intake and disposition of the chemicals and predict their internal concentrations as a function of time (up to 2 yr). The robustness of the PK model was validated. Successfully in step three, the extent of inhibition of aromatase by the chemical mixture was estimated by using the concentration-inhibition relationships provided in the ToxCast database (86 chemicals). The computed results served as an input for step four, an implementation of the ovarian cycle model. Results showed that the inhibition of estradiol synthesis by aromatase inhibitor mixtures was exceedingly higher than the effects of exposure to individual chemicals (more than 10% inhibition). In fact, no effects can be expected from typical exposures to individual chemicals when considered alone. The possibility to predict large-scale mixture effects for endocrine disrupters with a predictive toxicology approach that is suitable for high-throughput ranking and risk assessment will be introduced. Lastly, the consistency of the size of the predicted effects with an increased risk of infertility in women from everyday exposures to our chemical environment will be demonstrated.

### W 1044 MALDI Tissue Imaging: A New Tool for Making TK/TD Connections to Histopathology

L. Schnackenberg. US FDA/NCTR, Jefferson, AR.

Matrix-assisted laser desorption/ionization imaging mass spectrometry, or MALDI IMS, is an emerging label-free technology, which can provide the spatial distribution of drugs, drug metabolites, lipids, and other endogenous analytes in tissue samples. The analyte tissue distributions, when correlated with histopathology, provide detail that may allow a better understanding of a drug’s mechanism of action or the effects of a toxicological insult. MALDI IMS provides high spatial resolution (10 µm), is highly sensitive, and can be quantitative, qualities that have propelled the use of MALDI IMS across a variety of disciplines, including toxicological applications. This session will explore the recent incorporation of MALDI IMS to inform TK/TD drug decisions, a tool for identifying biomarkers related to histopathology and toxicity, and a method for identifying n-linked glycans across a variety of diseases and therapeutic models. Presenters representing government, academia, and pharmaceutical sectors will share recent MALDI IMS data from toxicology studies. The first presentation will provide a brief overview of MALDI IMS, including its strengths and limitations as a new tool for toxicology. The second presenter will discuss the role of MALDI-FTICR imaging to assist the United States Department of Defense at Fort Detrick to evaluate changes in metabolites in relation to infection from viral or bacterial pathogens. The third presenter will discuss the recent incorporation of MALDI IMS to assess drug, metabolites, and histopathological changes in a zebrafish model of drug-induced kidney toxicity. The fourth presentation will present case studies in drug development whereby MALDI IMS was utilized to better understand PK/PD relationships within a drug development pipeline. Finally, a cutting-edge and recent application of MALDI IMS will be presented, whereby n-linked glycan distributions can be identified in formalin-fixed paraffin-embedded (FFPE) tissues and microarrays from cancer biopsies. Use of this approach to further understand how glycan profiles and glycoproteins respond to therapeutics or xenobiotic exposures also will be discussed.

### W 1045 MALDI IMS: An Emerging Technology in the Field of Toxicology

L. K. Schnackenberg. US FDA/NCTR, Jefferson, AR.

Matrix assisted laser desorption/ionization imaging mass spectrometry (MALDI IMS) is a label free, robust and emerging technology which produces 2D ion density maps representing the distribution of an analyte across a tissue section in relation to tissue histopathology. Although MALDI IMS was initially developed to spatially profile proteins and peptides, the variety of analytes which are currently being evaluated have greatly increased and include: small molecule drugs and metabolites, lipids and glycans. Incorporation of high resolution Fourier transform ion cyclotron resonance (FTICR) MALDI mass spectrometry instruments within imaging workflows has also allowed for the detection of unique and lower abundant classes of analytes such as neurotransmitters to allow their placement into metabolomic pathways of interest. Although MALDI IMS has been used for some time to study different disease models, it has recently become an attractive technology in drug toxicity studies to complement standard quantitative techniques. While the technology has limitations including the ability to accurately quantify analytes of interest the value of MALDI IMS lies in the ability to provide a spatial component to a drug or metabolite rather than an average concentration within homogenized tissue; it is an analytical technique which directly links analyte distributions to histopathology and can provide functional detail can be obtained in relation to the distribution of an analyte highlighting the power of MALDI IMS in assessing toxicology.
MALDI-FTICR Mass Spectrometry Imaging Reveals Dysregulated Lipid and Small Molecule Metabolites in Tissues Harvested from Mice Infected with a Bacterial or Viral Pathogen

L. H. Cazares. US Army Medical Research Institute of Infectious Diseases, Fort Detrick, MD. Sponsor: L. Schnackenberg

Few studies have examined in-depth, the metabolic dysregulation and cross-talk which occurs between a pathogenic bacterium or virus and a mammalian host cell/tissue. To a considerable extent, this missing in-depth knowledge is due to the fact that historically, the investigation of metabolic alterations in the host and pathogen during infections posed major experimental challenges. Mass Spectrometry Imaging (MSI) is an analytical technique which can overcome some of these challenges. MSI add another dimension to metabolite profiling by providing in situ snapshots of the spatial distribution of biologically relevant metabolites in intact tissue sections. We sought to investigate the direct metabolic effects of bacterial or viral infection in mammalian tissues by employing matrix assisted laser desorption/ionization (MALDI-FTICR) Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry imaging. Brain tissue from an immunocompetent mouse model of Zika virus (ZIKV) infection which mirrors the neuropathophysiological properties of the virus in human hosts, and lung tissue from a mouse model of Francisella tularensis (Ft) infection was harvested from multiple animals at different times during infection. Sections from each tissue were cut and mounted on histology slides. Duplicate sections were utilized for in situ hybridization of ZIKV RNA in the case of the ZIKV infected brain sections, or Gram stained to detect bacterial lesions in Ft infected lung tissue. MSI revealed that the abundance of numerous metabolites, covering important metabolic pathways (Glycolysis, TCA cycle, lipid metabolism and fatty acid oxidation) were altered when compared to controls. Further, co-localization of brain sub-regions where ZIKV was actively replicating or areas of Ft colonization in the lung, allowed the direct examination of metabolite changes which occur at the host-pathogen interface. The data generated will be used in computational metabolic network reconstructions to provide a framework for the discovery of novel therapeutic targets or synergies and the prediction of key phenotypes of pathogenesis.

Matrix Assisted Laser Desorption Ionization Imaging Mass Spectrometry (MALDI IMS) of Drug-Induced Toxicity in a Zebrabfish Model

Determination of drug concentrations in tissue has historically been achieved using tandem mass spectrometry based platforms, however, without laborious dissections; traditional MS/MS does not offer any information concerning drug localization. Matrix assisted laser desorption ionization imaging mass spectrometry (MALDI IMS) is a label free approach in which the distribution of an analyte can be visualized across a tissue section in relation to the tissue’s histopathology. Zebrabfish (Danio rerio), are quickly becoming a popular model in toxicity studies due to their homogeneity with the human genome, small size, low cost, applicability to environmental studies and large breeding potential. Although a handful of MALDI IMS studies have been conducted in zebrafish, no one has assessed drug toxicity in a whole-body section, nor examined drug induced organ failure. Presented here is a pilot study in which a MALDI IMS method for the analysis of whole body zebrafish sections was developed. The method was further assessed in a zebrafish model dosed with 10mg/mL gentamicin. MALDI IMS images of both gentamicin and gentamicin metabolites will be presented, along with the overlap of drug distribution to tissue damage as an example of the power of this technology in further understanding drug induced toxicity.

MALDI IMS: Visualizing Pharmacologically Active Molecules “Breaking Bad” in Tissue

S. Castellino. GlaxoSmithKline, plc, King of Prussia, PA. Sponsor: L. Schnackenberg

Delivering safe and efficacious medicines is tied to our ability to understand the complex mechanistic relationships between molecular initiation events of pharmacologically active compounds and the cascade of biological consequences. The development and application of new technologies to investigate and interrogate biochemical events in tissue compartments is critical for unraveling the mechanistic pathways associated with drug-induced injury. Matrix-assisted laser desorption/ionization (MALDI) Imaging Mass Spectrometry (IMS) is an emerging technology which can determine the spatial distribution of a drug and its metabolites as well as endogenous compounds in tissue samples without the need for labeling. This methodology allows for the correlation of analyte tissue distributions with histology images, thereby integrating chemical structures with tissue morphology. MALDI IMS provides high spatial resolution (10µm), is highly sensitive, and can be quantitative. Furthermore, this imaging modality offers the potential to further our mechanistic understanding of drug disposition, disease progression and pharmacology including toxicity. This presentation will focus on our efforts to couple MALDI IMS and histology in drug development to better understand drug tissue disposition and gain mechanistic insights into drug correlated toxicities and efficacy. Case studies from early and late stage drug development, where MALDI IMS was employed to investigate the mechanisms of adverse events, provide insights into disposition, and PK/PD relationships will be presented.

R. R. Drake. Medical University of South Carolina, Charleston, SC. Sponsor: L. Schnackenberg

Glycoproteins account for approximately 80% of the proteins located at the cell surface and in the extracellular environment, and serve as binding ligands for cell adhesion, extracellular matrix molecules, signaling receptors, immune cells, lectins and pathogens. Alterations and changes in cell surface glyco- structure during carcinogenesis and other diseases have been documented, but the specifics in regards to which glycan and at what sites on glycoproteins are responsible for these changes is still poorly understood. Further, how glycan profiles and glycoproteins respond to therapeutics or xenobiotic exposures is even less characterized. To address this, we have recently optimized a MALDI mass spectrometry imaging method to spatially profile N-linked glycans in formalin-fixed paraffin-embedded (FFPE) tissue sections and tissue microarrays (TMAs). Tissues are incubated with a molecular coating of peptide N-glycosidase, and released N-glycans are detected using MALDI-FTICR imaging, linked directly with tissue histopathology. Two custom TMAs representing 20 different tumor types and other cancer models have been evaluated for systems glycomic comparisons. This in turn has generated a database of over 140 N-glycans derived from these tissues. Additional glycans representing different sialic acids detected in rodents, and ethylated derivatives of sialic acids are also included in the database. Using this methodology and data resources, the approach is proving informative for the comparative analysis of tissues in many model systems, including breast cancer drug resistance/sensitivity, gene knock outs of metabolic enzymes, tumor progression and patient derived tumor xenograft models. The goals are to link the disease or phenotypic changes identified for different N-glycan structural classes to metabolic, proteomic and genomic changes associated with each model.

Mechanisms and Effects of Diabetogenic Environmental Metals: Type II Diabetes mellitus and Diabetic Kidney Disease

J. Edwards. Midwestern University, Downers Grove, IL.

Complications arising from diabetes mellitus (DM) is the seventh leading cause of death in the US. Approximately 30.3 and 84.1 million Americans had type II DM or prediabetes, respectively, in 2015. The number of Americans with type II DM is projected to increase by nearly 20 million from 2015 to 2030. Lifestyle choices such as diet and exercise, in addition to genetics, are major factors in determining if someone will become type II DM. In addition to these factors, exposure to environmental metal and nonmetal substances (e.g., cadmium, arsenic, zinc, manganese, and selenium) may also play a significant role. Many epidemiological studies show a significant and positive association between exposure to toxic environmental metals and type II DM, prediabetes, or impaired fasting glucose. Experimental studies using animal models of metal toxicity show significant increases in fasting blood glucose levels or disruption of major mediators of metabolism. This session will examine the cellular and molecular mechanisms responsible for the diabetogenic effects of various metals. In addition, factors that may mitigate arsenic-induced dysglycemia, such as selenoproteins, will be discussed. Lastly, the session will review the synergistic or additive effects of cadmium-induced nephropathy in an in vitro model of diabetic nephropathy. This session will highlight the most recent experimental findings from presenters who are experts at the forefront of this field of study.
1051 Cadmium Accumulates within Pancreatic Islets at Levels Similar to the Renal Cortex in an Experimental Model of Long-Term Exposure

J. Edwards, Midwestern University, Downers Grove, IL.

Diabetes mellitus is a growing worldwide epidemic. Impaired pancreatic islet function is a hallmark of type 1 diabetes mellitus and for some, a key in the progression of type II diabetes mellitus. Multiple epidemiological and experimental studies show that exposure to the metal cadmium (Cd), is associated with diabetes mellitus and prediabetes. However, Cd is considered a classic nephrotoxicant that accumulates in the renal cortex at levels 8 to 20 times higher than any other tissue. The objective of this study was to quantify and compare the amount of Cd in the renal cortex to that of pancreatic islets. We also examined Zn because it is essential to normal pancreatic beta cell function and there is evidence that Cd and Zn may use the same transporters to gain entry into cells. Male Sprague Dawley rats were injected subcutaneously with either saline (control) or Cd (0.6 mg Cd/kg/day, 5 days per week). After 6 or 12 weeks of Cd treatment, kidney cortex tissue was collected and pancreatic islets were isolated. The freshly isolated islets were then either exposed to low (0.5 mg/ml) or high (3.0 mg/ml) glucose containing buffer for 4 hours. At the end of the incubation, islets were treated with lysing buffer and stored at -80 for later Cd and Zn determination. Kidney cortex tissue from 12 week treated animals had the highest Cd content at 11,007 ± 777 (nmol/g protein ± SE); in pancreatic islets isolated from 12 week Cd-treated animals and incubated in 0.5 mg/ml glucose the average Cd concentration was 7,305.2 ± 403. Surprisingly, at the same 12 weeks of Cd treatment there was significantly less Cd content in islets incubated at 3.0 mg/ml glucose compared to 0.5 mg/ml glucose. These results show that Cd accumulates within pancreatic islets to levels approaching that of the renal cortex. Overall, the study shows that pancreatic islets are sites of Cd accumulation, potential targets of Cd toxicity and likely involved in etiology of Cd-induced hyperglycemia.

1052 Methods of Investigating the Toxic Potential of Environmental Factors in Insulin-Producing Islets of Langerhans Illustrated Using the Example of Cadmium

M. El Muayed, Northwestern University, Chicago, IL.

Failure of insulin-producing β-cells in islets of Langerhans in the setting of insulin resistance is the underlying cause for type 2 diabetes mellitus (T2DM). Genetic susceptibility, age, lifestyle, and environmental factors contribute to β-cell failure in T2DM. Environmental contributors towards β-cell failure in T2DM are underexplored. Herein we illustrate epidemiologic and experimental methods aimed at exploring the association between environmental factors and β-cell failure in the setting of T2DM using the example of cadmium (Cd). To that end, we first illustrate epidemiologic studies by us and others showing evidence for a diabetogenic effect of Cd using the NHANES database. Others and we previously provided evidence for a correlation between cadmium (Cd) exposure and T2DM as well as the accumulation of Cd in insulin producing β-cells. We report findings from our newly established murine oral Cd exposure model for the study of Cd-induced dysglycemia. For this, male C57BL/6N mice were exposed to CdCl2 or vehicle in drinking water. Obesity and insulin resistance was simulated by placing the animals on a high fat diet (42% calories from fat). We exposed animals to CdCl2 for 19 weeks followed by a 19-week washout period to yield an islet Cd concentration of 80.9 ± 9.3 nmol/g protein. This concentration was within the range of human islet Cd concentration, thereby representing a relevant islet Cd concentration. Blood Cd concentrations returned to near baseline levels at the end of the study. We found significant impairment of glucose clearance and reduced insulin secretion in standard in vivo glucose stimulated insulin secretion testing. In examining the differences in physiology between islets from mice exposed to Cd vs control mice, we found a lower ratio of insulin to proinsulin, pointing towards an impairment in normal insulin processing. These results point to an impaired processing of insulin precursors into mature insulin and the accumulation of misfolded insulin-a known contributor to islet dysfunction in the setting of T2DM. Results from next generation sequencing of mRNA from islets exposed to CdCl2 in vivo for 6 weeks via drinking water showed changes suggesting an increase in markers of inflammation but no changes in ER stress. This may suggest an attenuated response to the impaired insulin processing.

1053 Dissecting Mechanisms of Metal-Induced Beta Cell Dysfunction: Arsenic, Cadmium, Manganese, and Zinc

M. Styblo. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Growing evidence suggests that exposures to environmental chemicals contributes to the current epidemics of diabetes. Several metals found in the environment have been implicated in diabetes risk, including inorganic arsenic (iAs), cadmium (Cd), manganese (Mn) and zinc (Zn). iAs and Cd are toxic heavy metals with no known physiological functions. On the other hand, Mn and Zn are essential micronutrients that play important roles in regulation of metabolic pathways and in antioxidant protection. Exposures to iAs and Cd have been consistently linked to compromised glucose homeostasis with impaired fasting glycemia or glucose tolerance, insulin resistance and/or beta cell dysfunction. In contrast, data on effects of Mn and Zn have been inconsistent. We used the rat insulinoma INS-1(832/13) beta cells, an established cell culture model in diabetes research, to compare the effects of iAs, Cd, Mn and Zn on glucose stimulated insulin secretion (GSIS) and on mechanisms involved in GSIS regulation, including mitochondrial metabolism and microRNA expression. We found that 24-hour exposures to non-cytotoxic concentrations of iAs, Cd and Mn inhibited GSIS, but only iAs impaired mitochondrial metabolism as demonstrated by decreased oxygen consumption rate, and by suppression of maximal respiration and spare respiratory capacity of mitochondria. Notably, no inhibition or activation of GSIS or mitochondrial metabolism was found in cells exposed to Zn. Exposure of INS-1(832/13) cells to iAs induced the expression of microRNA-146a, which is involved in beta cell function and survival, and suppressed expression of microRNA-217, which has been linked to apoptosis. Interestingly, exposures to Mn or Cd triggered the opposite response, decreasing microRNAs-146a expression and increasing expression of microRNA-217. Micro-RNA sequencing revealed a distinct small RNA profile associated with each metal exposure. Significant alterations were observed in the expression of a shared set of microRNAs with established targets along the insulin secretory pathway, as well as additional microRNAs unique to each metal exposure. These data suggest that iAs, Cd and Mn inhibit GSIS in beta cells; however, the mechanisms that underlie these effects may differ. Further analysis of microRNAs and their targets in beta cells may help to identify these mechanisms.

1054 Selenium and Selenoproteins Modulate Arsenic-Induced Metabolic Dysfunction

Diabetes is a devastating metabolic disease projected to afflict 693 million individuals worldwide by the year 2045. While caloric excess, physical inactivity, and genetic susceptibility all contribute to disease risk, these factors alone fail to fully account for the magnitude of the epidemic. Recently environmental toxicants acting as metabolism-disrupting chemicals (MDCs) have been implicated in the pathogenesis of diabetes. Based on the extent to which humans are exposed, one diabetes-linked MDC of significant importance is arsenic. Arsenic has been shown to disrupt the key pathways regulating glucose homeostasis, namely insulin secretion and insulin action, resulting in glucose intolerance in animal models. These effects are corroborated by epidemiologic evidence suggesting that arsenic exposure is associated with diabetes in human populations. Interestingly, arsenic and selenium have long been known to interact. Moreover, selenium-containing proteins (selenoproteins) have biological functions that are predicted to antagonize various aspects of arsenic toxicity. To test the hypothesis that selenoproteins protect against arsenic-induced metabolic dysfunction, male C57BL/6J mice were exposed to arsenic (sodium arsenite, As3+, 50 ppm) for 8-10 weeks on a selenium-deficient (0.01 ppm) or selenium-replete (0.1 ppm) diet. Body weight regulation and composition, glucose tolerance, and insulin secretion were examined. Identical studies were conducted in mice haploinsufficient for selenocysteine insertion sequence binding protein 2 (SBP2), a translation factor essential for the biosynthesis of all selenoproteins. Disruptions in either dietary selenium content and/or selenoprotein deficiency altered arsenic-induced effects on body composition and insulin secretion. These data suggest that selenium/ selenoproteins have mitigating role in arsenic-induced metabolic toxicity. Ongoing studies seek to define the specific selenoproteins mediating arsenic toxicity in order to both clarify the underlying mechanisms by which these factors preserve metabolic health as well as to identify populations who may be at enhanced risk of metabolic dysfunction from arsenic exposure.
Hyperglycemic Glucose and Cadmium Exposition: Two Loads Too Many for the Renal Proximal Tubule

S. Garrett, University of North Dakota, Fargo, ND.

The progression of chronic kidney disease (prevalence > 3% of adult population) to end-stage renal disease is a source of considerable morbidity and mortality in western populations. While pathological processes of the glomerulus are known to play a major role in this disease, it is the demise of the renal tubules, predominantly the proximal tubule, that is the major correlate to the progression to end-stage disease. Though diabetes is the largest contributor to this disease, the heavy metal cadmium is increasingly appreciated as a significant etiological factor, and with respect to this metal, the proximal tubule is the main target site for renal toxicity. Proximal tubule cells are also a major site for glucose toxicity due to the major role of the proximal tubule in glucose reabsorption. During hyperglycemia, the proximal tubule-glucose load increases and potentially saturates the reabsorption process eventually leading to the accumulation of sorbitol, a toxic metabolic side-product of glucose produced through the reduction of the aldehyde group by aldose reductases. Since the exposure and accumulation of cadmium in the proximal tubule cells occurs throughout the human population, the development of chronic kidney disease occurs with a high base line of metal exposure, thus the development of this disease most likely occurs through and interaction or collaboration of these two agents. Our model for study are cultures of immortalized human proximal tubule cells and recently the newly developed, telomerase-immortalized human proximal tubule cell line, RPTEC/hTERT. We recently discovered that an isoform of aldose reductase is induced by cadmium exposure and we are now investigating the contribution of this enzyme to glucose-induced sorbitol accumulation and toxicity. Exposures to the glucose can also lead to a loss of epithelial character having similarities to the epithelial-to-mesenchymal transition, a process that might contribute to the interstitial fibrotic process seen in this disease. We have been characterizing this process, with respect to both morphology and gene expression. It can be appreciated that multiple factors contribute to toxicity and disease processes, and with respect to the kidney, cadmium and hyperglycemic glucose concentrations are two agents that can initiate and accelerate chronic kidney disease.

Pharmaceutical Investigative Toxicology: Case Studies in Optimizing Drug Discovery and Guiding Human Risk Assessment

C. Scott, AstraZeneca Pharmaceuticals, Waltham, MA.

Toxicity and clinical safety have a major impact on drug development success. Moving toxicological studies into earlier phases of the research and development chain prevents drug candidates with a safety risk from entering clinical development. However, to identify candidates without such risk, safety has to be addressed proactively. Therefore, toxicology should ideally be integrated into the discovery process. Successful discovery phase drug safety assessment requires in-depth hazard identification and integrated experimental approaches to address target and lead compound risks to support target assessment. In order to identify a suitable candidate, selection, and derisking of safety flags from in vitro, animal, and clinical testing. Consequently, the application of innovative models and techniques that allow the identification of early hazards, prioritize chemical series, and steer chemical design and safety assessment should ideally be integrated into the early phases of the discovery process. Similarly, mechanistic insight into animal and clinical drug toxicities can be critical in developing informed human risk assessment. In this session, we will present case studies of innovative investigative discovery phase toxicology that have enabled mechanistic understanding and improved quantitative human risk assessment. Examples will include the use of recombinant proteins and antibodies to probe the effects of small molecule candidate drugs on in vivo safety biomarkers, use of 3D microphysiological models of human and animal organs, transcriptomics, drug metabolism, and modeling and simulation techniques to quantify translational risk assessment to humans.

Reduced Kupffer Cell Clearane Is Causing Elevation of Serum Toxicity Biomarkers in Rat and Monkey in Absence of Organ Injury

F. Pognon, Novartis, Basel, Switzerland.

Enzymatic serum biomarkers use to monitor drug safety in preclinical and clinical studies are sometimes not matching actual drug-induced organ injuries. Apparent toxicity biomarker elevations have been reported in animals treated with compounds affecting the proliferation and differentiation of Kupffer cells (KC), by inhibiting the macrophage colony-stimulating factor 1 (CSF1) pathway. Although KCs have been reported to play an important role in clearance of circulating enzymes, these co-incident observations have not formally established the causal link leading to elevated circulating biomarkers, as undetected organ damage could have been at the origin of this phenomenon. The purpose of the present studies was to explore the fate of exogenously injected histidine (His)-labeled recombinant enzymes ALT1 in rats treated with the CSF1 receptor antagonist BLZ945 and CKM (CK-MM isoform) in monkeys treated with MCS110, a CSF1-neutralizing monoclonal antibody. BLZ945 and MCS110 treatments resulted in elevations of endogenous serum ALT, AST or CK without causing histological detectable lesions or increase release of target organ specific micro RNAs (miRs). Additionally, both compounds were leading to a pharmacological reduction of KCs number. The elimination kinetics of injected His-tagged ALT1 and CKM were analyzed by non-comparmental (NCA) and a population analysis. Both analyses consistently demonstrated significant increase of the half-lives and delayed clearance rates of the His-tagged proteins after the BLZ945 and MCS110 treatment. The present data demonstrated that elevation of ALT and CK is independent of potential liver and muscle drug-induced toxicity by CSF1-pathway inhibitors, and likely resulting from reduced protein clearance by KCs in rats and monkeys.

Use of Early Phenotypic In Vivo Markers to Assess Human Relevance of an Unusual Rodent Non-Genotoxic Carcinogen In Vitro

A. Roth, F. Hoffman-La Roche Ltd, Basel, Switzerland.

Foci of altered hepatocytes (FAH) are considered putative, pre-neoplastic lesions that can occur spontaneously in aging rats or induced by chemicals or drugs. Progression of FAH to hepatocellular neoplasms has been reported repeatedly but increases in foci in rodents do not necessarily lead to tumors in carcinogenicity studies and the relevance for humans often remains unclear. Here we present the case of RG3487, a molecule which induced FAH and, later on, tumors in rats. Because the molecule was negative in genotoxicity assays it was classified as a non-genotoxic carcinogen. In order to assess the potential for liver tumor formation in humans, we analyzed treatment-induced changes in vivo to establish a possible mode of action (MoA). In vivo and in vitro gene expression analysis revealed that nuclear receptor signaling was unlikely to be the relevant MoA and no known mechanism could be established. We therefore took an approach comparing phenotypic markers, including mRNA changes, proliferation and glycogen accumulation, in vitro using models, including 3D MPS systems of different species to assess the human relevance of this finding. Since the alterations
observed in rats were not seen in the liver of mice or dogs in vivo, we could validate the relevance of the cell models chosen by use of hepatocytes from these species in vitro. This ultimately allowed for a cross-species comparison, which suggested that the formation of FAH and liver tumors was rat specific and unlikely to translate to human. Our work showed that phenotypic species comparison in vitro is a useful approach for assessment of the human relevance of pre-clinical findings where no known mechanism can be established.

1060 Characterization and Mechanistic Investigation of Hemolytic Anemia in Rats Induced by an Early Small Molecule Oncology Candidate

H. Mellor, Vertex Pharmaceuticals, Oxford, United Kingdom.

To ensure our candidate molecules have an appropriate safety profile, Discovery & Investigative Toxicology aims to identify liabilities early and support chemistry in optimizing molecules for safety. In a 14-day rat toxicology study, our lead compound induced hemolytic anemia. Key pathological features included extravascular hemolysis accompanied by a regenerative bone-marrow response. The presence of Heinz bodies indicated oxidative damage to erythrocytes. Exposure of rat erythrocytes (RBCs) to the compound in vitro revealed no direct toxicity. In vivo met-ID revealed a chloroaniline metabolite previously shown to trigger hemolysis via hepatic conversion to an N-hydroxy derivative. The N-hydroxy, but not parent or aniline, triggered met-ID and oxidation of RBCs. Further evaluation of other molecules in the series revealed they all exhibited the same hemotoxic propensity. These early investigative toxicology studies enabled a rapid decision to be made to de-prioritise this series.

1061 Complex Cell Models and TK/TD Modeling and Simulation Guide Drug Discovery and Enhance Translational Safety Risk Assessment

C. Scott, AstraZeneca, Waltham, MA.

3D human cell culture and microtissue models can recapitulate tissue biology at a more physiological level compared to conventionally used 2D static cell cultures, enabling improved biological understanding of candidate drugs and their potential for toxicity. In addition, more quantitative safety risk assessments can be achieved when in vitro data is coupled to pharmacokinetic/pharmacodynamic (PK/PD) models, which allow translation of time-course and magnitude across biological systems, accounting for differences between in vitro and in vivo physiology. Here we explore the use of primary cell and microtissue models to provide translational safety risk assessment of oncology drug candidates. In the first case study we utilize 3D human airway in vitro models to dissect the mechanism of degenerative bronchiolar epithelium pathology observed in vivo with a kinase inhibitor lead series. In a second case study we evaluate the suitability of a 3D human gastrointestinal microtissue to model human GI adverse effects reported with a candidate drug, to investigate the underlying toxicity mechanism(s) as well as to model dosing schedules with improved tolerability for in vivo validation. A final case study will describe the development and use of a microfluidics system to replicate in vivo PK profiles within cell-based assays to enable improved in vivo translation of drug actions. This system has the potential to minimize animal studies for both efficacy and safety studies and effectively guide clinical use of candidate drugs.

1062 UVA Photosensitization of Melanin Induces Oxidative DNA Damage, and B-RAF Mutational Hotspots Are Major Targets

M. Weng, and M. Tang, New York University School of Medicine, New York, NY.

Cutaneous malignant melanoma (CMM), the primary type of melanoma, occurs mainly at sunlight-exposed body regions, with 70% of CMM having B-Raf V600E mutations. It suggests that sunlight is a major CMM etiological agent that targets B-Raf codon 600. Intriguingly, the most frequent B-Raf V600E mutation ('GTG' to 'GAG') lacks UVB photo-damage signature; the exact mechanism of how sunlight induces melanogenesis remains unclear. In this study, we found that UVA induces a significant amount of oxidative DNA damage (ODD), particularly 8-oxo-deoxyguanosines (8-oxo-dG), in human melanocytes but not in non-pigmented normal human skin fibroblasts (NHSF). Also, UVA induces more 8-oxo-dG in African-American melanocytes (AAMC) than in European-American melanocytes (EAMC). In vitro, UVA sensitizes both eumelanin and pheomelanin to produce H2O2, which results in 8-oxo-dG induction. Mapping UVA-induced ODD in B-Raf, we found significantly more ODD in AAMC than in EAMC and discovered that both strands of codon 600 of B-Raf (AG-TGG-A/-TCA-TCT) are preferential sites for ODD formation. Furthermore, the ODD spectrum in B-Raf induced by UVA in melanocytes is the same as that induced by H2O2 in NHSF. We conclude that UVA sensitizes melanin to produce H2O2, which reacts with more genomic DNA to induce ODD. These results demonstrate that melanin plays a direct role in enhancing UVA-induced ODD formation and mutagenesis and that the B-Raf codon 600 is a major UVA target. We propose that UVA plays an important role in initiating melanogenesis.

1063 An Evaluation of the Cytotoxicity and Chromosome-Altering Effects of Vanadium Pentoxide and Sodium Metavanadate in Vitro

M. C. Vuong, L. S. Hasegawa, and D. A. Eastmond, University of California Riverside, Riverside, CA.

Vanadium compounds are found in mineral ores and have become increasingly important in industrial manufacturing. Vanadium exists in several oxidation states with vanadium pentoxide (V2O5) and sodium metavanadate (NaVO3) being among the more common. Previous studies by the National Toxicology Program have shown that vanadium pentoxide is carcinogenic in rodents inducing alveolar/bronchiolar neoplasms. However, the mechanism for the tumor promoting effect of vanadium pentoxide is not known. This study will describe the development and use of a microfluidics system to replicate in vitro drug action and to distinguish toxicity from genotoxicity. In vivo studies revealed no direct toxicity. In vivo met-ID revealed a chloroaniline metabolite previously shown to trigger hemolysis via hepatic conversion to an N-hydroxy derivative. The N-hydroxy, but not parent or aniline, triggered met-ID and oxidation of RBCs. Further evaluation of other molecules in the series revealed they all exhibited the same hemotoxic propensity. These early investigative toxicology studies enabled a rapid decision to be made to de-prioritise this series.

1064 Determination of the Molecular Target of Aneugenic Compounds by a Multiplexed, Flow Cytometric Assay

An efficient in vitro method for determining genotoxic mode of action (MoA) is commercially available under the trade name MultiFlow®. Based on several DNA damage response biomarkers, this multiplexed assay characterizes compounds as clastogenic, aneugenic or nongenotoxic. Here, we report modifications to the base assay that extend its capabilities to include the determination of aneugenic agents’ molecular targets. Specifically, we have designed a follow-up assay that discriminates between the two most common mechanisms of aneugenicity: tubulin binding and off-target inhibition of mitotic kinases, especially Aurora kinases. For these experiments TK6 cells were exposed to each of 27 aneugens over a range of concentrations and in the presence of fluorescent taxol. The aneugens consisted of 12 mitotic kinase inhibitors and 15 diverse tubulin binders. After 4 hrs at 37°C cells were added to MultiFlow base solution (detergent, nucleic acid dye, RNase and counting beads) supplemented with fluorescent antibodies against phospho-histone H3 (p-H3) and Ki-67. The resulting detergent-activated nuclei were then analyzed by flow cytometry. Alterations in taxol-associated fluorescence were only observed in the case of the tubulin binders—increases in the case of stabilizers, decreases for destabilizers. Pan-Aurora kinase B-specific inhibitor was the only agents that dramatically decreased the ratio of p-H3-positive to Ki-67-positive nuclei. Unsupervised hierarchical clustering based on taxol fluorescence and p-H3/Ki-67 ratios clearly distinguished 9/9 compounds with pan- or Aurora B-inhibiting activity, 12/12 tubulin destabilizers, and 3/3 tubulin stabilizers. These data demonstrate the adaptability of the MultiFlow platform to address not only genotoxic MoA, but also to elucidate specific molecular targets responsible for aneugenic...
Pig-a assay is a sensitive flow cytometry-based immunophenotypic method for detecting cells that have mutations in the endogenous X-linked Pig-a reporter gene. Instrumentally, phenotypically mutant cells measured in the assay are deficient in protein markers tethered to the cellular surface via glycosyl phosphatidylinositol (GPI) anchors. Pig-a assays can be established for nucleated cells and for nucleic acids-free red blood cells (RBCs) of various species. Rodent RBC Pig-a assay is useful in non-clinical safety evaluations of novel drugs; a regulatory-compliant test guideline for performing and interpreting the RBC Pig-a assay is under development. An outstanding issue for the RBC Pig-a assay was proving that the assay detects what it claims to detect, i.e., mutation in the Pig-a gene. We developed a Pig-a assay for precursors of rat RBCs, bone marrow erythroid cells (BMEs), and for lineage-related bone marrow granulocytes (BMGs). In rats treated with a prototypical mutagen, 7,12-dimethyl benz(a)anthracene (DMBA), the frequencies of phenotypically mutant marker- and GPI anchor-deficient BMEs and BMGs are increased. We sorted out the marker-deficient mutants in bulk and analyzed the Pig-a gene in them using next generation sequencing methodology. We determined that sorted BMEs have mutations in the Pig-a gene: mostly base-pair substitutions at dA and dG on the non-transcribed strand of genomic DNA, with dA to dT transversion being the predominant mutation. Such a spectrum is consistent with mutations induced by DMBA in vivo in other cell types (e.g., in the Pig-a and Hprt genes of rat T-cells). Recently, a similar relationship between the mutant phenotype and the spectrum of mutations in the Pig-a gene has been demonstrated for BMEs and BMGs from rats treated with another prototypical mutagen, N-ethyl-N-nitrosourea (ENU). ENU induced a different spectrum of mutations, mostly dt to dA transversions on the non-transcribed DNA strand. Mutant RBCs measured in the RBC Pig-a assay arise from mutant BMEs. Since phenotypically mutant BMEs in rats treated with two different compounds have agent-specific Pig-a mutations, the RBC Pig-a assay should measure true Pig-a mutant cells induced by agents of interest. Thus, the RBC Pig-a assay detects what it claims to detect, mutation in the Pig-a gene. The analysis of the spectrum of DMBA-induced rat BMG Pig-a mutations (currently in-progress) will further support such a claim.

\[P1\] 1065 Spectrum of DMBA-Induced Pig-a Mutations in Rat Bone Marrow Erythroid Cells

Pig-a assay is a sensitive flow cytometry-based immunophenotypic method for detecting cells that have mutations in the endogenous X-linked Pig-a reporter gene. Instrumentally, phenotypically mutant cells measured in the assay are deficient in protein markers tethered to the cellular surface via glycosyl phosphatidylinositol (GPI) anchors. Pig-a assays can be established for nucleated cells and for nucleic acids-free red blood cells (RBCs) of various species. Rodent RBC Pig-a assay is useful in non-clinical safety evaluations of novel drugs; a regulatory-compliant test guideline for performing and interpreting the RBC Pig-a assay is under development. An outstanding issue for the RBC Pig-a assay was proving that the assay detects what it claims to detect, i.e., mutation in the Pig-a gene. We developed a Pig-a assay for precursors of rat RBCs, bone marrow erythroid cells (BMEs), and for lineage-related bone marrow granulocytes (BMGs). In rats treated with a prototypical mutagen, 7,12-dimethyl benz(a)anthracene (DMBA), the frequencies of phenotypically mutant marker- and GPI anchor-deficient BMEs and BMGs are increased. We sorted out the marker-deficient mutants in bulk and analyzed the Pig-a gene in them using next generation sequencing methodology. We determined that sorted BMEs have mutations in the Pig-a gene: mostly base-pair substitutions at dA and dG on the non-transcribed strand of genomic DNA, with dA to dT transversion being the predominant mutation. Such a spectrum is consistent with mutations induced by DMBA in vivo in other cell types (e.g., in the Pig-a and Hprt genes of rat T-cells). Recently, a similar relationship between the mutant phenotype and the spectrum of mutations in the Pig-a gene has been demonstrated for BMEs and BMGs from rats treated with another prototypical mutagen, N-ethyl-N-nitrosourea (ENU). ENU induced a different spectrum of mutations, mostly dt to dA transversions on the non-transcribed DNA strand. Mutant RBCs measured in the RBC Pig-a assay arise from mutant BMEs. Since phenotypically mutant BMEs in rats treated with two different compounds have agent-specific Pig-a mutations, the RBC Pig-a assay should measure true Pig-a mutant cells induced by agents of interest. Thus, the RBC Pig-a assay detects what it claims to detect, mutation in the Pig-a gene. The analysis of the spectrum of DMBA-induced rat BMG Pig-a mutations (currently in-progress) will further support such a claim.

\[P2\] 1066 Similarities in the Transcriptomic Signatures in the Duodenum of Mice Exposed to Hexavalent Chromium, Captan, or Folpet Inform Mechanisms of Chemical-Induced Mouse Small Intestine Cancer
G. A. Chappell,1 J. E. Rager,1 J. C. Wolf,3 M. Babic,1 K. J. LeBlanc,3 C. L. Ring,4 M. A. Harris,1,2 and C. T. Thompson1,2.1Experimental Pathology Laboratories, Inc, Sterling, VA; 2BioSpyder Technologies, Inc., Carlsbad, CA; and 3ToxStrategies, Inc., Katy, TX.

Shared key events observed in intestinal cancers in mice exposed orally to hexavalent chromium (Cr(VI)) and the fungicides captan or folpet are the basis for similar non-motivated modes of action. Based on comparable histopathological findings in the duodenum (e.g. villus enterocyte cytotoxicity and crypt epithelial hyperplasia). Based on these similarities, we hypothesized that transcriptomic responses in the duodenum are also similar across these three agents. Such similarities at the molecular level would support a common adverse outcome pathway (AOP) for chromium and fungicides. A key hypothesis by evaluating transcriptomic responses in the duodenum tissues of B6C3F1 mice exposed to either Cr(VI) (180 ppm), drinking water), captan or folpet is whether there will be gene expression profiles similar between agents, with overall Pearson correlation coefficients >0.6. Second, gene-specific overlap comparisons revealed that 126/546 (23%) differentially expressed genes were altered in the same direction across all three agents. Third, gene set enrichment analysis was conducted using a broad range of curated gene sets, with 39 (23%) gene sets closely modulated between Cr(VI) and captan or folpet. A total of 25 upregulated gene sets were modulated by all three compounds, which were related to cellular metabolism, stress, inflammatory/immune cell response, and cell proliferation, including upregulation in HIF1- and AP1-signaling pathways (which are related to intestinal injury and angiogenesis/carcinogenesis). Transcriptomic profiles also differed between crypt and villus cells, indicating that alterations at the gene expression level are cell-type-specific. There was a lack of enrichment of DNA damage response-related gene sets. The similarities in Cr(VI)-, captan-, and folpet-induced effects at the molecular level support an AOP for mouse intestinal cancer that involves cytotoxic mechanisms.

\[P3\] 1067 Mammary Tumor Prevention Effects of Broccoli-Derived Sulforaphane in Rats Exposed to 17β-Estradiol Is Mediated by Multiple Cytoprotective Mechanisms
D. L. Palliyaguru1, and T. W. Kessler2,1.1University of Pittsburgh, Pittsburgh, PA; and 2Fred Hutchinson Cancer Research Center, Seattle, WA.

Although estrogens play a vital role in health and aging, elevated estrogens have been recognized as an important contributor to breast cancer risk. The receptor-independent, oxidative metabolism of estrogens is an important pathway for estrogen-mediated carcinogenesis that facilitates the formation of DNA-damaging adducts. In healthy cells, the formation of these adducts are controlled by cytoprotective enzymes such as catechol-O-methyltransferase (Comt) and NADPH:quinone oxidoreductase 1 (Nqo1). Pharmacologic activators of the Nrf2 signaling pathway such as broccoli-derived sulforaphane (SFN) have been shown to activate these enzymes. Further, SFN can also alter cellular metabolic pathways leading to cytoprotection. Thus, we hypothesized that administering SFN to animals exposed to 17β-estradiol (E2) would prevent mammary tumor formation via altered metabolism and reduced DNA damage. In our study, 4-6 week old female August Copenhagen Irish rats were implanted with E2 pellets (3 mg x 3) and were gavaged with either DMSO or 100 μmol/kg SFN for 56 weeks. The Kaplan-Meier curve showed that SFN-treated rats were significantly protected against mammary tumor formation compared to DMSO. Serum free fatty acid and triglyceride species were ~2-fold lower in SFN-treated rats. The mammary glands of SFN-treated rats showed ~2-fold higher Nqo1 and Comt as well as significantly lower Fatty acid synthase and Acetyl-CoA carboxylase 1 transcripts. SFN treatment also lead to ~2-fold lower phosphorylated γ-H2a.x and altered expression of DNA damage response markers in the mammary gland. This study indicated that SFN potently protects against breast cancer through multiple mechanisms in a clinically relevant chemical carcinogenesis model. \[P4\] 1068 Aflatoxin B1, Induces Fibrosis and Cirrhosis in Nrf2 Knockout Rats
K. Taguchi1, N. Osanai1, E. Naganuma1, T. W. Kessler2,1, and M. Yamamoto1, 1Tohoku University, Sendai, Japan; and 2Fred Hutchinson Cancer Research Center, Seattle, WA.

Aflatoxin B1 (AFB1), a mycotoxin produced by certain molds that contaminate foods, is a cause of liver cancer in humans. AFB1-induced hepatocarcinogenesis in rats is predicted by the focal burden of the glutathione S-transferase P (GSTP)-positive foci in livers well before cancers develop. GSTP gene expression is regulated by the transcription factor Nrf2. It has been reported that Nrf2 is constitutively activated in many kinds of human cancers. To examine roles of Nrf2 in AFB1-induced hepatocarcinogenesis, we dosed wild-type and Nrf2 knockout (Nrf2 KO) rats repeatedly with AFB1 (150 μg/kg/day, 5 d/week) for 12 weeks, followed by a one-month respite and then 2 weeks of 100 μg/kg/day, 5d/wk). Almost half of Nrf2 KO rats were sensitive to AFB1 and died between weeks 3 and 4; this dosing regimen had no effect on survival in wild-type rats. All surviving animals were sacrificed at 21 weeks. As reported previously, AFB1 induced substantial numbers of GSTP-positive foci in wild-type rats. However, GSTP-positive foci did not appear in the surviving Nrf2 KO rats, although bile duct cells and a few emerging single cells were positive for GSTP staining. Thus, GSTP expression in hepatocytes appears to be Nrf2-dependent. All surviving Nrf2 KO rats at 21 weeks showed cirrhosis in which most of the hepatocytes had disappeared. Some Nrf2 KO rats lived showed regenerative nodules surrounded by fibrosis. No fibrosis or cirrhosis was observed in the liver of wild-type mice at this timepoint. Clearly, Nrf2 plays a strong protective role against AFB1-induced liver injury. However, in AFB1-exposed Nrf2 KO rats, hepatocytes are damaged and disappear, leading to fibrosis and cirrhosis. Historically, it is well known that cirrhosis is not part of the etiopathogenesis of AFB1-induced hepatocarcinogenesis in wild-type rats. Whether chronic very low dose administration of AFB1 to Nrf2 KO rats could induce hepatocarcinogenesis driven through cirrhosis remains unknown. This research was supported by Fund for the Promotion of Joint International Research, JSPS KAKENHI 15KX0325, in Japan.
1069 Adverse Outcome Pathway of Ionizing Radiation Leading to Increased Risk of Breast Cancer

J. Helm, and R. Rudel, Silent Spring Institute, Newton, MA.

Knowledge about established breast carcinogens can support improved 21st century toxicological testing methods by identifying key mechanistic events. Ionizing radiation (IR) increases the risk of breast cancer, especially for women and for exposure at younger ages. We used the Adverse Outcome Pathway (AOP) framework to outline and evaluate the evidence linking ionizing radiation with breast cancer from molecular initiating events (MIE) to the adverse outcome (AO) through intermediate key events (KE). We identified prospective key events using recent literature on ionizing radiation and carcinogenesis, focusing on review articles. We searched PubMed for each key event and ionizing radiation, and used references cited in the resulting papers and targeted searches with related key words to identify additional papers. We manually curated publications and evaluated data quality. The AOP specifies that ionizing radiation directly and indirectly causes DNA damage and increases production of reactive oxidative and nitrosative species (RONS), and these are designated as MIEs. RONS lead to DNA damage (MIE) and both lead to mutations (KE) and proliferation (KE) leading to the AO, but RONS and DNA damage also increase inflammation (KE). Inflammation contributes to direct and indirect effects (effects in cells not directly reached by IR) via positive feedback to RONS and DNA damage, and separately increases the AO through pro-carcinogenic effects on cells and tissue. These MIEs and KEs overlap at multiple points with events characteristic of “background” induction of breast carcinogenesis, including hormone-responsive proliferation, oxidative activity, and DNA damage. These overlaps make the breast particularly susceptible to ionizing radiation and reinforce the importance of these MIEs and KEs as part of toxicological panels for carcinogenicity. The AOP identifies areas for additional research, including better description of the time and dose-dependence of MIEs and KEs in many tissues directly and indirectly exposed to IR. The AOP will inform development of new assays, and offers new applications and context for existing assays addressing these KEs. Ultimately, this AOP will improve methods that predict chemical breast carcinogens so that exposure can be reduced.

1070 Phosphatidic Acid Enhances Liver Regeneration after Acetaminophen Hepatotoxicity by Promoting Phosphorylation and Inhibition of GSKβ3

M. Clemens,1 S. Kennon-McGill,1 U. Apté,2 B. Finck,1, and M. McGill,1 1University of Arkansas for Medical Sciences, Little Rock, AR; 2University of Kansas Medical Center, Kansas City, KS; and 1Washington University School of Medicine, St. Louis, MO.

Acetaminophen (APAP) overdose is the primary cause of acute liver failure (ALF) in the US. The current treatment is N-acetylcysteine (NAC). However, NAC is only effective at ≤16h post-overdose, and approximately half of all patients present later. Clearly, new treatments are needed. One approach is to enhance liver regeneration. We recently discovered that phosphatidic acid (PA) promotes liver regeneration, but the mechanism is not known. The Wnt-GSKβ3-β-catenin signaling pathway is known to be important for regeneration after APAP overdose. Thus, we hypothesized that PA activates that pathway. Male C57BL/6J mice were treated with 300mg/kg APAP (i.p.) followed by vehicle (Veh) or 20mg/kg FSG67 (PA synthesis inhibitor) 2, 24, and 48h later. Some mice received 600 nmol of the GSK3 inhibitor L803-mts in addition to APAP and FSG67. Liver and blood were harvested at 0, 6, 24, and 52h post-APAP. Liver injury (plasma ALT, histology) and regeneration markers (PCNA, Cyclin D1) were measured, as well as Wnt, GSKβ3 and β-catenin. FSG67 post-treatment reduced PCNA protein (mean±2SE. 10±1 vs. 7±0.7 fold over 0 h for Veh vs. FSG67, respectively). Wnt and β-catenin increased. GSKβ3 phosphorylation (which inhibits GSKβ3 and promotes regeneration) was almost completely prevented in the FSG67 group at 24h post-APAP (26±9 vs. 3±1 fold over 0 h for Veh vs. FSG67). To confirm that loss of PA affects regeneration through increased GSKβ3 activity, we performed a rescue experiment in which mice were co-treated with FSG67 and the GSK3 inhibitor. Messenger RNA for PCNA (1±0.2 vs. 0.6±0.2, Veh vs. FSG67) and the β-catenin target cyclin D1 (1±0.1 vs. 0.3±0.2, Veh vs. FSG67) decreased with FSG67 treatment, but were restored by the GSK3 inhibitor (0.8±0.1 and 1.3±0.2 for PCNA and cyclin D1 mRNA, respectively). PA enhances regeneration through Wnt-independent effects on GSKβ3 and β-catenin. Additional research is needed to determine how PA alters GSKβ3 phosphorylation. Support: AASLD Foundation and NIGMS T32 GM106999.

1071 De Novo Fibrinogen Synthesis Promotes Liver Repair after APAP Overdose in Mice

A. Pant,1 A. K. Kopiec,1 K. S. Baker,1 H. Cline-Fedewa,1 A. Revenko,2 and J. P. Luyendyk1 1Washington University School of Medicine, St. Louis, MO; and 2Ionis Pharmaceuticals, Carlsbad, CA.

Acetaminophen (APAP) overdose is the leading cause of acute liver failure (ALF) in the United States. The coagulation protein fibrinogen relocates from plasma to the injured liver after APAP overdose, and hepatic fibrinogen (fibrinogen) deposits promote liver repair. Induction of de novo fibrinogen expression is also evident in APAP-challenged liver. Whether fibrinogen induction regulates plasma fibrinogen levels and liver repair after APAP overdose is unknown. We hypothesized that hepatic fibrinogen induction restores plasma fibrinogen after APAP overdose. To test this hypothesis, we used an N-acetylgalactosamine (GalNAc)-conjugated fibrinogen β (Fgbβ)-targeted anti-sense oligonucleotide (ASO). C57BL/6j mice were pretreated with GalNAc-Fgb-ASO or GalNAc-control-ASO (30 mg/kg) 24 hours prior to administration of APAP (300 mg/kg). Coincident with increased hepatic necrosis (38.6%), plasma fibrinogen levels were reduced and hepatic fibrinogen deposits were evident 24 hours after APAP challenge in mice given control-ASO. By 48 hours, plasma fibrinogen levels were restored and liver repair was evident (6.4% necrosis). Fgb-ASO-pretreated mice had equivalent plasma fibrinogen levels and were unaffected by APAP induced necrosis. To confirm that loss of PA affects regeneration through Wnt-independent effects on GSKβ3 and β-catenin. Additional research is needed to determine how PA alters GSKβ3 phosphorylation. Support: AASLD Foundation and NIGMS T32 GM106999.
Hepatic in vitro systems require phenotypic characteristics of liver cells which mimic those in vivo in humans. In addition to parenchymal hepatocytes, non-parenchymal cells (NPCs) accounting for approximately 30% of the total liver cell population, prominently contribute to the progression of liver diseases. Here, 3D primary human hepatocyte (PHH) spheroids were generated using Corning ULA plates (Bell et al., 2016) with or without the addition of crude NPC fractions (Baze et al., 2018) to produce co-culture spheroids from both matching and non-matching PHH and NPC pairs (6 PHH and 5 NPC donors). Phenotypic characterization of hepatocyte-specific markers in the co-culture spheroids revealed abundant expression of CYP3A4 and albumin at levels comparable to monoculture spheroid counterparts. Analyses of the cellular composition of the spheroid co-cultures at the mRNA level showed increased expression of mRNA markers for Kupffer cells (CD68, CD163), hepatic stellate cells (Cytogobulin, Vimentin, Vinculin) and liver sinusoidal endothelial cells (PECAM1) compared to corresponding parenchymal hepatocyte monocultures. Incorporation of NPCs was further confirmed by immunostaining which demonstrated variable incorporation of NPCs based on specific donors and PHH-NPC pairings. The plasticity of monoculture and co-culture spheroids was evidenced by time-dependent changes in the mRNA expression of NPC markers over time. Co-cultures demonstrated potential applications in modelling liver diseases as evidenced by increases in the response to IL-6 following lipopolysaccharide stimulation and increases in LOX and COL1A1 expression in response to transforming growth factor β (TGF-β) which could be negated in the presence of a TFG-β receptor inhibitor. High concentrations of free-fatty acids (480 µM) were also able to induce stress responses and pro-fibrogenic expression of COL1A1 almost exclusively in co-culture spheroids. In conclusion, a time course of 3D spheroid co-cultures of PHH combined with crude NPC fractions was characterized. This indicated dependence on suitable donor combinations to form and maintain co-culture spheroids and the requirement for NPCs to induce features related to pro-fibrotic outcomes.

An in vitro system requires phenotypic characteristics of liver cells which mimic those in vivo in humans. In addition to parenchymal hepatocytes, non-parenchymal cells (NPCs) accounting for approximately 30% of the total liver cell population, prominently contribute to the progression of liver diseases. Here, 3D primary human hepatocyte (PHH) spheroids were generated using Corning ULA plates (Bell et al., 2016) with or without the addition of crude NPC fractions (Baze et al., 2018) to produce co-culture spheroids from both matching and non-matching PHH and NPC pairs (6 PHH and 5 NPC donors). This indicated dependence on suitable donor combinations to form and maintain co-culture spheroids and the requirement for NPCs to induce features related to pro-fibrotic outcomes.

Environmental disasters such as the flooding that impacted Houston, Texas after Hurricane Harvey may lead to the redistribution of contaminants from both sediment as well as industrial/hazardous waste sites, resulting in exposure and potential health risks to residents who live in close proximity. Traditional hazard identification methods are not suitable to determine the chemical composition and potential hazard of the exposures to hazardous mixtures after environmental emergency events. Therefore, new methods are urgently needed to enable faster responses to emergency events. This study aimed to test whether a panel of physiologically-relevant human cell populations, prominently contributing to the progression of liver diseases, can be used to identify key events and molecular mechanisms used to understand the underlying key events and molecular mechanism used to develop putative AOPs for hepatic lipid dysfunction. This abstract does not necessarily reflect US EPA policy.

Environmental disasters such as the flooding that impacted Houston, Texas after Hurricane Harvey may lead to the redistribution of contaminants from both sediment as well as industrial/hazardous waste sites, resulting in exposure and potential health risks to residents who live in close proximity. Traditional hazard identification methods are not suitable to determine the chemical composition and potential hazard of the exposures to hazardous mixtures after environmental emergency events. Therefore, new methods are urgently needed to enable faster responses to emergency events. This study aimed to test whether a panel of physiologically-relevant human cell populations, prominently contributing to the progression of liver diseases, can be used to identify key events and molecular mechanisms used to understand the underlying key events and molecular mechanism used to develop putative AOPs for hepatic lipid dysfunction. This abstract does not necessarily reflect US EPA policy.

Addressing inter-individual variability is a critical but challenging step in health risk assessments. Most environmental toxicants, including tetrachloroethylene (PERC), lack experimental data on inter-individual variability, hence default uncertainty factors are applied to account for inter-individual variability in toxicokinetics (UF Toxicokinetics (UF TK) = 2.43-3.51) and toxicodynamics (UF Toxicodynamics (UF TD) = 3.16). One of the important contributors to inter-individual variability in toxicity of chemicals is variability in their metabolism. Specifically, kidney toxicity of PERC has been associated with generation of glutathione conjugation metabolites; however, a low flux of PERC metabolism through glutathione conjugation (<0.5%) has raised concern on this mode of action in vivo. In this study, we aimed to better characterize the variability in glutathione conjugation and kidney toxicity of PERC and their underlying molecular mechanisms by using the Collaborative Cross (CC) mouse population. Male mice from 45 CC strains were intragastrically dosed with PERC (1000 mg/kg) or vehicle (5% Alkamuls-EL 620 in saline) and euthanized at various time points up to 12 hours (n=1/strain/time). Concentration-time profiles showed wide variability among strains in toxicokinetics of S-(1,2,2-trichlorovinyl)glutathione (TCVG, UF TK = 1.35-2.66) among liver, kidney and serum, S-(1,2,2-trichlorovinyl)-L-cysteine (TCVC, UF TK = 2.43-3.51), and N-acetyl-S-(1,2,2-trichlorovinyl)-L-cysteine (NACTCVC, UF TK = 2.62-3.25) in mouse serum, liver, and kidney. Acute treatment with PERC (24 hrs) had significant effects (paired t-test, p<0.05) on kidney weight loss, increased kidney to body weight ratio, induction of fatty acid metabolism-associated genes (Acot1, Fabp1, and Ehhadh), and markers of proximal tubular injury (expression of Kim1/Havn1). Expression of Kim1 in kidney was positively correlated with formation of TCVG in liver (r=0.60). In conclusion, our results demonstrate that the default uncertainty factor for toxicokinetic variability may be marginally adequate to protect 95% of the population for kidney toxicity mediated by PERC. Further refinement of the characterization of inter-individual variability can be accomplished by incorporating these data into in silico population models both for toxicokinetics (such as a physiologically-based pharmacokinetic model) as well as for toxicodynamic responses.
1077 mRNA-Sequencing Identifies Liver as a Potential Target Organ for Triphenyl Phosphate in Embryonic Zebrafish

Triphenyl phosphate (TPHP) is a commonly used organophosphate flame retardant and plasticizer in the United States. Over the past decade, there has been a marked increase in the use of TPHP due to the phase-out of certain brominated flame retardants. Using zebrafish as a model, previous studies have shown that TPHP exposure from 24 to 72 hours post fertilization (hpf) results in severe cardiac looping defects by 72 hpf - a phenotype that is dependent on exposure during pharyngula (24-48 hpf) and mitigated by pre-treatment with non-toxic concentrations of a pan-retinoic acid receptor (RAR) agonist (fenretinide). Therefore, the objectives of this study were to 1) rely on mRNA-sequencing to identify pathways before and after cardiac looping (30 and 48 hpf, respectively) that may be impacted following exposure to 10 µM TPHP from 24-48 hpf and 2) determine whether pre-treatment with 2 µM fenretinide from 24-30 hpf mitigates cardiotoxicity-related pathways within embryos exposed to TPHP from 30-48 hpf. Based on mRNA-sequencing, TPHP exposure from 24 to 30 hpf and 24 to 48 hpf significantly affected the abundance of 305 and 274 transcripts, respectively, relative to vehicle (0.1% DMSO) controls. In addition, minor effects on cardiotoxicity- and nephrotoxicity-related pathways, Ingenuity Pathway Analysis (IPA) of significantly affected transcripts from 30- and 48-hpf embryos revealed that hepatotoxicity-related pathways were strongly affected following exposure to TPHP alone. Moreover, while pre-treatment with fenretinide mitigated TPHP-induced cardiac looping defects at 72 hpf, IPA revealed that fenretinide was unable to block TPHP-induced effects on hepatotoxicity-related pathways at 30 and 48 hpf, suggesting that, unlike the heart, TPHP-induced hepatotoxicity may be RAR-independent. Overall, our mRNA-sequencing-based data suggest that, in addition to the heart, the embryonic liver may be highly susceptible to TPHP exposure during early development. Therefore, our ongoing studies are focused on confirming that TPHP exposure alters the normal trajectory of liver development (based on phenotypic data) within zebrafish embryos and 2) identifying the mechanism of action that leads to potential TPHP-induced effects on hepatocytes within zebrafish and human cell-based systems.

1078 The Cross-Laboratory Testing and Comparison of a Liver Microphysiological System
C. Sakolish, Y. Liu, C. Reese, R. DeBiasio, L. Vernetti, and L. Taylor. Texas A&M University, College Station, TX; and University of Pittsburgh, Pittsburgh, PA.

Drug-induced liver injury (DILI), and a poor understanding of human pharmacokinetics have long been cited as the major reasons for drug failure in clinical trials or post-marketing. This is in part due to the limitations of existing animal and in vitro models to accurately predict drug toxicity and efficacy in humans. To address these limitations, microphysiological system (MPS) models of the liver are being actively developed; however, the adoption of these models, with 3D cultures? exploration of best practices with human hepatocyte models over time in culture

1079 Acute In Vitro Nephrotoxicity of Three Brominated Flame Retardants
L. Barnett, N. Siddiquie, and B. S. Cummings. University of Georgia, Athens, GA.

Brominated flame retardants (BFRs) are a class of organohalogens commonly added to commercial products such as computers, electronics, textiles, and furniture to reduce their flammability. BFRs have significant environmental persistence and are reported to be detected in human blood and breast milk. In particular, tetrabromobisphenol A (TBBPA), hexabromocyclododecane (HBCD), and polybrominated diphenyl ethers (PBDEs) occupy 17 percent of the global flame retardant market and have been reported to have adverse effects on humans and wildlife. As such, the mechanisms of BFR-induced toxicity are actively being explored under the US EPA Toxic Sub stance Control Act. Previous research shows that these compounds cause nephrotoxicity in rats and mice; however, the mechanisms mediating this nephrotoxicity are unknown. In the present study, we determined the effects of TBBPA, HBCD, and BDE 47 on cell viability in rat (NRK), human embryonic (HEK-293), and adult human (HK-2) kidney cells after 48 hours. We observed a concentration- and species-dependent effect on MTT staining, with IC50 values of 58, 38, and 3 µM for TBBPA; 20, 16, and 7 µM for HBCD; and 46, 40, and 14 µM for BDE 47 in NRK, HEK-293, and HK-2 cells, respectively. We assessed the mechanisms of cell death by measuring annexin V staining and propidium iodide (PI) staining as markers of apoptosis and necrosis, and by studying changes in nuclear morphology via DAPI staining. Significant increases in both the percentage of annexin V- positive cells and the percentage of annexin V and PI double-positive cells suggested that all compounds were inducing apoptosis. These data suggest that BFRs induce species-dependent toxicity in renal cells, with higher levels of toxicity being induced in human cells. The mechanisms mediating this differential toxicity is the subject of future studies.

1080 What’s So Special about 3D Spheroid Cultures? Exploration of Best Practices with Human Hepatocyte Models over Time in Culture
K. S. Larvich, S. C. Ramaiahgari, M. J. Devito, R. S. Paules, and S. S. Ferguson. NIEHS, Research Triangle Park, NC.

Advances in organotypic, three-dimensional (3D) cell culture models for human liver hold great promise for high throughput toxicology screening due to their enhanced physiological relevance. However, the development and evaluation of these models for predictive toxicology research has relied largely upon basic assumptions borrowed from two-dimensional (2D) hepatocyte culture systems (e.g., high glucose media, corticosteroids, fetal bovine serum), with insufficient characterization of the impact of these factors on spheroid maturation and stability over time. To address these shortcomings, we investigated the dynamics of metabolic competence and gene expression of 3D HepaRG spheroids over time, and compared transcriptomic profiles between 2D and 3D culture models to explore distinguishing molecular characteristics of 3D HepaRG spheroids. Our findings revealed the enzymatic activities of major drug metabolizing enzymes, including CYP3A4, initially decay over time in 3D culture with a half-life of ~12-24 h during cell aggregation. As spheroids mature from this “developmental” liver state over time, enzymatic activities rise and eventually exceed their initial 2D-differentiated levels after ~7-10 days in culture. Comparing transcriptomic signatures with mature 3D spheroids to their differentiated and proliferated 2D comparators revealed characteristic cellular pathways, including glycolysis and fatty acid metabolism. Bioenergetic differences were functionally apparent between 2D and 3D models, with 3D models exhibiting increased oxidative metabolism over time in culture and shifting away from glycolytic 2D cultures. Further exploration using varied culture media composition (e.g., serum, glucose, corticosteroid) revealed unique requirements with 3D spheroids for optimal maturation, stability, and reduced variability. To characterize how these factors influence liver modeling, high throughput transcriptomics and cell viability assays were performed in response to exposures with a focused panel of prototypical liver effectors, including menadione, tamoxifen, aflatoxin B1, rifampicin, omeprazole, phenobarbital, and acetaminophen. Altogether, our findings identified key factors important for organotypic, 3D spheroid models and establish best practices for their use in predictive toxicology screening.
Air pollution, particularly smoke produced from biomass combustion, is pneumotoxic. However, the mechanisms underlying the toxic effects of these materials on lung epithelial cells is not fully understood. Transient receptor potential (TRP) ion channels are a family of proteins that mediate some of the pro-inflammatory and cytotoxic effects of air pollutants, typically via disruption of intracellular calcium homeostasis. We hypothesized that TRP ion channels that are activated by wood smoke particles might regulate cytocytotoxicity in lung epithelial cells treated with wood smoke particles via mechanisms involving disruption of intracellular calcium homeostasis; specifically causing endoplasmic reticulum stress and E1FαK3/PERK-dependent signaling. Using fluorescent calcium imaging and various human TRP channel expression assays, it was found that TRPV3 resides on the endoplasmic reticulum of human lobular bronchial epithelial cells. Consistent with the induction of endoplasmic reticulum stress and E1FαK3/PERK activation in lobar cells, treatment with pine wood smoke particles promoted the time-dependent induction of pro-apoptotic DDIT3 and ATF3, biomarkers of E1FαK3/PERK activation during ER stress. As above, both TRPV3 and TRPA1 antagonists substantially attenuated these responses. Collectively, these data show that activation of TRPV3 and TRPA1 by wood smoke particles triggers ER stress in primary human lung epithelial cells, and that these events contribute to the acute cytotoxic effects of pine wood smoke particles on bronchial epithelial cells. These findings expand our understanding of how wood smoke adversely affects the lung.

**1084 Air Quality: An Interface between Environment, Climate Change, and Public Health**

S. Mack, K. Bein, Q. Zhang, and K. Pinkerton, University of California Davis, Davis, CA.

In recent years, Imperial County has consistently ranked as the top California County with the highest asthma rate in children. Community members are concerned their breathing problems are due to one or more of many sources of pollution that contaminate Imperial Valley (IV). Of particular interest is the potential toxicity of particles rising from the Salton Sea. With polluted runoff as the only water source, the Salton Sea has become increasingly polluted and is rapidly shrinking. No one has differentiated the sources of particulate matter (PM) in IV or their connection to asthmatic symptoms. Our goal is to investigate the differences between, and potential harmfulness of airborne particles to which IV residents are exposed. A state-of-the-art mobile sampling unit has been designed to collect PM of various size fractions, from ultrafine (<0.1 μm) to PM10. The geography and meteorological conditions in IV expose the community to a unique combination of natural and man-made pollutants. These sources include agriculture, industrial plants, and large cities across the border of Mexico, as well as the Salton Sea. To account for seasonal changes and source variation, our sampler collects particles from different wind directions over the course of a year. Each PM sample is chemically characterized and screened in an in vitro system to before moving into an in vivo model of asthma. Due to the high incidence of asthma in youth in IV, we are specifically interested in how this PM may modulate sensitization of the immune system to house dust mite (HDM) allergen, and in turn, how this impacts subsequent encounters with the allergen. Our initial chemical characterization indicates organic species dominate IV particles (58%) followed by ammonium sulfate (37%). The chemical composition of the organic particles from IV is highly complex and likely composed of hundreds of carbon-containing compounds. An in vitro screening in a human macrophage cell line demonstrates a significant increase in gene expression of COX-2, CYP1a1, IL-8 and IL-1B cytokines, as well as a similarity between IV PM and other agricultural regions in California. The high average degree of variability in the high organic nitrogen content suggest that ultrafine PM in IV is likely toxic and could be a major culprit for the health problems in the region. The increase of inflammatory cytokines when exposed to IV PM in vitro suggests the need for further testing in a murine model of asthma.
The Effects of Inhalation Exposure to Traffic-Generated Air Pollutants on Angiotensin II Receptor Expression and Signaling of Monocytes/Macrophages in the Vasculature and Kidney of Wildtype Mice on a High-Fat vs. Low-Fat Diet

B. Phipps, J. Lucero, J. D. McDonald, and A. K. Lund. University of North Texas, Denton, TX; and Lovelace Biomedical Research Institute, Albuquerque, NM.

While multiple studies have reported a positive correlation between exposure to traffic-generated air pollution and exacerbation of cardiovascular disease (CVD), and more recently kidney diseases, very few studies have focused on the effects of these exposures in a healthy animal model. Furthermore, little is known on whether these exposure-related effects are exacerbated by concurrent consumption of a high fat diet. The renin-angiotensin system (RAS), when dysregulated, is known to mediate pathogenesis in the renal and cardiovascular system through Angiotensin (Ang) II signaling via the Ang II Type 1 (AT1) and/or Type 2 (AT2) receptors. We have previously reported that plasma Ang II levels are increased in C57Bl/6 wildtype mice exposed to traffic-generated pollutants. Thus, we hypothesized that inhalation exposure to traffic-generated pollutants results in altered inflammation in the vasculature and/or kidneys. To test this hypothesis, 3 mo old male C57Bl/6 mice on either a high-fat “Western” diet (HF, 21% fat) or standard (LF, low fat) mouse chow were randomly assigned to inhalational exposure of either filtered-air (FA n=10 per diet) or a mixture of 70 µg PM2.5/m3 diesel exhaust + 30 µg PM1/m3 gasoline exhaust (MVE: n=10 per diet) for 6 hr/day for 30 days. MVE exposure resulted in increased expression of the AT1 receptor in the vasculature, as determined by RT-qPCR and immunofluorescence, which was further exacerbated in MVE+HF exposed mice. In contrast, CYP1A1 mRNA levels were decreased with either HF diet or MVE-exposure, compared to FA+LF. No statistical change was observed in renal AT-2 levels across groups. Such findings indicate that inhalation exposure to traffic-generated pollutants can promote induction of RAS signaling, associated with factors that mediate the initiation and progression of vascular and kidney disease. Funded by NIH R15ES026795 (AKL) and an UNT Undergraduate Research Grant (BP).

Traffic-Generated Air Pollution-Mediated Alterations in Cerebral AhR and CYP Enzyme Expression Dependent upon Age and Diet in C57Bl/6 Wild Type Mice

C. Kennedy, J. Lucero, J. D. McDonald, and A. K. Lund. University of North Texas, Denton, TX; and Lovelace Biomedical Research Institute, Albuquerque, NM.

Inhalation exposure to traffic-generated air pollutants have been reported to have deleterious effects on the central nervous system (CNS), including blood brain barrier (BBB) disruption and neuroinflammation, and neurodegenerative diseases. Cytochrome P450 enzymes (CYPs) are one of the main classes of biotransforming enzymes present in the body, which mediate reactions of thousands of endogenous and exogenous substances. Altered expression of certain CYP enzymes are associated with neurodegenerative disorders, thus we chose to investigate the effects of inhaled traffic-generated air pollutants on expression of these enzymes in the CNS on the BBB. Additionally, we investigated the expression through speculative and experimental regulation of cerebral hydrocarbons and AhR regulates transcription of CYP1A1 and 1B1, we analyzed its expression in the cerebrum and microvasculature, as well. Young (2 mo) or aged (18 mo) male C57Bl/6 wild type mice were placed on either a “Western” high fat (21% fat by content) or low fat diet, and subsequently exposed to either 300 µg/m3 of mixed exhaust (MVE: 250 µg/m3 PM diesel engine + 50 µg/m3 PM gasoline engine emissions) or filtered air (FA, controls) for 6 hr/day, 7 days/wk, for 50 days. Brain tissue was collected at the end of the exposure period, and prepared for either real time RT-qPCR or double immunofluorescence, to detect variation in AhR and CYP enzyme expression in the cerebrum and/or BBB. MVE-exposure resulted in significant increases in CYP2D (1.5-fold), CYP2E1 (2-fold) enzymes, with trending increases in AhR and CYP1B1 enzyme expression in the CNS of aged mice on a low fat diet, while the expression of these same enzymes had the opposite trends in expression (decreased with MVE exposure) in the CNS of young C57Bl/6 mice on a low fat diet. There was no significant change observed in expression of CYP1A1 in either young or old mice. In the high-fat fed C57Bl/6 mice, MVE-exposure resulted in a significant decrease in CYP1B1, with trending decreases in CYP2D, CYP2E1, and CYP3A1 mRNA in the aged mice. Inverse (increasing) trends in expression in CYP2D, CYP2E1, and CYP3A1 were observed in the young mice on a high fat diet, compared to FA controls. Thus, our preliminary findings suggest that inhalation exposure to traffic-generated pollutants altered cerebral expression of AhR and CYP enzymes in the young vs. aged differently (typically inversely), that is further complicated with concurrent consumption of a high fat diet. Research funded by NIEHS R00ES0126586 (AKL).

Angiotensin II Receptor Type 1 (AT1) Mediates Alterations in Blood Brain Barrier Integrity and Inflammation in Wildtype Mice, on Either a High- or Low-Fat Diet, Exposed by Inhalation to Vehicle Emissions

U. Suwannasula, J. Lucero, J. D. McDonald, and A. K. Lund. University of North Texas, Denton, TX; and Lovelace Biomedical Research Institute, Albuquerque, NM.

Exposure to traffic-generated air pollutants has been associated with detrimental outcomes in the central nervous system (CNS), including exacerbation of neuroinflammation, neurodegeneration, and cerebrovascular disorders (stroke). We have previously reported that inhalation exposure to mixed vehicle exhaust (MVE) results in altered blood brain barrier (BBB) integrity and permeability in C57Bl/6 mice. The purpose of this study was to investigate whether Angiotensin II receptor Type 1 (AT1) signaling mediates alterations in BBB integrity, related to MVE-exposure, as well as whether concurrent consumption of a high fat (HF) diet exacerbates such outcomes. To investigate the aims of this study, we utilized both in vivo and in vitro (BBB co-culture) methodology. 3 mo-old male C57Bl/6 mice on either an HF or low fat (LF) diet were randomly assigned to inhalational exposure of either filtered-air (FA) or 30 µg PM/m3 gasoline exhaust + 70 µg PM/m3 diesel exhaust (MVE) for 6 hr/day for 30 d. Exposure to MVE + HF diet resulted in a significant increase in plasma Ang II, associated with increased BBB permeability (Na-F transport into the CNS), decreased tight junction (TJ) protein expression and increased expression of AT1 in the cerebral microvasculature. BBB co-cultures treated with plasma from mice in the exposure study showed significantly increased transendothelial electrical resistance (TEER), a measure of membrane integrity, and reduced TJ protein expression in the MVE+HF group, compared to FA+LF or FA+HF groups. However, when pre-incubated with the AT-1 inhibitor, Losartan, TEER and TJ protein expression in BBB co-cultures treated with plasma from mice were not statistically altered in MVE+HF vs. control groups. Both interleukin-6 and transforming growth factor-β were also observed to be statistically increased in astrocytic media from BBB co-cultures treated with plasma from MVE+HF groups, compared to plasma from control animals. Our results indicate that inhalation exposure to traffic-generated air pollutants, coupled with an HF diet, results in altered BBB integrity, mediated through Ang II-AT1 signaling, and increased CNS inflammation. Funded by NIH R15ES026795 to AKL.

One Year Urban Nanoparticle Concentration Monitoring in Queens, New York

R. Luo, and R. J. Jaeger. Columbia University, New York, NY; and CH Technologies (USA) Inc., Westwood, NJ.

Particulate matter in air is regulated in the United States by the Clean Air Act of 1970 and subsequent amendments. Standards exist for PM10 and PM2.5 particulate concentrations. These standards are supplemented by regulations and controls for other gaseous pollutants. However, as of this time, no regulations exist for airborne nano-particle concentrations such as those from mobile combustion sources, i.e. motor vehicle emissions. Further, other than black carbon measurement devices, few instruments exist that can document the prevalence of nano-particles in the global environment. To help diminish this environmental data gap, several instruments have been developed to measure urban as well as indoor nano-particle pollution. These can document the prevalence of nano-particles in the global environment, further, those from mobile combustion sources, i.e. motor vehicle emissions. Additional to the above, recent regulations and controls for other gaseous pollutants. However, as of this time, no regulations exist for airborne nano-particle concentrations such as those from mobile combustion sources, i.e. motor vehicle emissions. Further, other than black carbon measurement devices, few instruments exist that can document the prevalence of nano-particles in the global environment. To help diminish this environmental data gap, several instruments have been developed to measure urban as well as indoor nano-particle pollution. These are measurements most often made using passive charging of particulates in the under 10 to 300 or more nanometer size range. From the charge measurements, particulate surface area estimates may be calculated and expressed as Lung Deposited Surface Area (LDSA) from urban and residential atmospheres. Particulates in this size range are out of the usual optical and gravimetric measurement range. Two devices, the Naneos Partector and the Pegasor Urban air monitor are commercially available. To document LDSA in urban air, three Pegasor Urban units were co-located at the New York State DEC monitoring station at Queens College, Queens, New York. The units would be operated in an unattended manner for one full year. As of July, 2018, after 9 months of operation and using a proprietary algorithm to estimate PM2.5, the units agreed with each other within ±20% for 95% of the time. This level of agreement between the 3 units had an R2 value of 0.64 to 0.66. Agreement between the 3 units had an R2 value of 0.64 to 0.66. Data analysis continues until the end of the 2018 year since other co-located gravimetric instruments report their data with delays of up to 90 days. In comparison to the TEDM...
and gravimetric instruments requiring daily or weekly attendance, the passive charge devices employed here, once located in the field and supplied with an internet or cell phone connection, required no maintenance, no human intervention and reported their observations to the cloud. This allowed minute display of urban air LDSA concentrations with controlled or open global access. Additional data analysis as well as other comparisons are ongoing and will be reported. This work was self funded and supported by Pegaso Oy, who supplied the measuring devices. The cooperation and hospitality of the staff of the NY DEC is gratefully acknowledged.

1089 Developmental Traffic-Related Air Pollution Exposure and Autism-Related Neurotoxicity in Mice
Y. Chang1, T. Cole1, and L. G. Costa1,2,3,1 University of Washington, Seattle, WA;2 Gradient, Seattle, WA; and 3 University of Parma, Parma, Italy.

Epidemiological findings have suggested that developmental exposure to traffic-related air pollution (TRAP) may be associated with an increased risk of autism spectrum disorders (ASD). In order to further assess this association mechanistically, we carried out a series of studies in C57Bl/6J mice developmentally (EO to PND21) exposed to 250-300 µg/m3 of diesel exhaust (DE) or filtered air (FA) in a controlled environment. A series of behavioral, molecular, and brain histological assessments relevant to ASD were carried out in both male and female pups and young adults. Behavioral testing indicated changes consistent with ASD, namely increased repetitive behavior, disrupted social behavior and impaired social communication. Elevated levels of the inflammatory cytokine interleukin-6 (IL-6) were found in fetal brains and placenta of mice exposed to DE. Prompted by findings obtained in the maternal immune activation model of ASD, we also explored a possible biochemical pathway relevant for ASD which may be disrupted by developmental DE exposure. Additionally, increased levels of phosphorylation of STAT3, as well as increased expression levels of DNMT1 (DNA methyltransferase 1) and reelin (RELN) were found to be associated with DE exposure. DNMT1 is a target gene of activated transcription factor STAT3 and has been shown to bind directly to the promoter region of the RELN gene via epigenetic modification. The RELN gene encodes for extracellular protein reelin, which plays a major role in guiding the neuronal migration process during CNS development. Downregulation of RELN due to DE exposure persisted in cortical samples of PND60 male mice. An immunohistochemical analysis was performed with the lamina-specific markers RELN and calretinin to examine the cortical organization in PND60 brains of mice exposed to either DE or FA during development. Significant differences were seen in the cortical distribution of both RELN- and calretinin-positive cells, suggesting a disruption of cortical layering. Altogether these studies suggest that developmental exposure to DE causes behavioral, biochemical and histological changes in mice which are similar to those observed in ASD. Supported in part by NIEHS grants RO1ES22949, and RO1ES028273.

1090 Mouse Pulmonary Response Induced by Exposure to Dust from Sawing Corian, a Solid-Surface Composite Material
W. Mandler1, J. Sisler1, C. Qi2, L. Battelli1, M. Orandle1, K. Sarkisian1, R. Mercer2, A. Stefanaki1, A. Knepp1, L. Bowers3, and Y. Qian1. 1NIOSH, Morgantown, WV; and 2NIOSH, Cincinnati, OH.

Corian®, a solid-surface composite (SSC), is composed of a proprietary blend of powdered alumina trihydrate, methyl methacrylate, and other binders and colorants. The present study evaluated the murine pulmonary toxicity from exposure to dust generated from sawing of SSC. The particle number-based geometric mean diameter and geometric standard deviation $\sigma$ of the airborne fraction SSC sawing dust following suspension in saline was 1.16 µm, $\sigma = 2.18$, which is similar to the number-based geometric mean aerodynamic diameter to aerosolized SSC sawing dust of 1.05 µm, $\sigma = 1.78$. Inductively coupled plasma and energy dispersive X-ray spectroscopy analyses confirmed that aluminum was the principle inorganic component of SSC sawing dust particles as well as microbiome and chemical composition of the dust, with different doses (25, 50 and 100 µg/ml) of farm dusts. Toxicological and immunomodulatory potential of the dusts was measured. Dusts were also collected from farm 1 differed more significantly from each other than matrices. The results were dependent of the farm, as responses from samples collected from farm 2, were more significantly different from each other than matrices. The adsorption of proteins reelin in alveoli at all doses at day 1 post-exposure, and fibrosis in the 1000 µg dose at day 14 post-exposure. Darkfield imaging indicated alveolar cell deposition and granulomatous mass formation persisting to 14 days post-exposure in all exposure groups. Taken together, these findings suggest that SSC sawing dust exposure may induce pulmonary inflammation and damage that warrants further investigation.

1091 Effect of Vinyl Chloride on HNF4α Expression in a Model of Nonalcoholic Steatohepatitis (NASH)
N. T. Peterson1, I. Huck2, J. L. Beier1, and U. Apte3,1 Pennsylvania State University, State College, PA; 1University of Kansas Medical Center, Kansas City, KS; and 3University of Pittsburgh, Pittsburgh, PA.

Vinyl Chloride (VC) is an organochlorine compound which is known to cause hepatic steatosis, fibrosis, necrosis and hepatocellular carcinoma. Occupational exposure has been directly associated with hepatic angiosarcoma. Recent studies have shown that inhalation exposure to VC at levels below current Occupational Safety and Health Administration exacerbates liver injury, steatosis and inflammation in mice fed a high fat diet suggesting that VC is a Toxicant Associated Steatohepatitis (TASH) causing agent. Previous studies from our laboratory have shown that decrease in expression and activity of Hepatocyte Nuclear Factor 4 alpha (HNF4α) an orphan nuclear receptor produces NASH like pathology in the liver. We hypothesized that VC might be causing these effects by targeting HNF4α. To test this hypothesis, HNF4α promoter/mRNA and protein expression and activity was measured in livers from mice with and without inhalation exposure to vinyl chloride and fed either normal chow (LFD) or high fat diet (HFD). Western Blot and RT-PCR analyses were used to determine HNF4α protein expression and activity. Western blot analysis for adult isoforms (P1) of HNF4α showed no difference in protein expression between treated and untreated LFD fed animals. Interestingly, the adult P1 HNF4α protein levels were decreased in untreated HFD fed mice but returned to normal levels with VC treatment. Expression of fetal P2 HNF4α isoforms were not affected by VC treatment but were induced in all mice fed HFD. RT-PCR analysis of HNF4α and its target genes did not reveal any changes in HNF4α activity measured using target gene expression except CD36, a lipid importer, which significantly increased in mice on a high fat diet. VC treatment decreased CD36 expression in mice on HFD, but expression was still significantly greater than VC treated and untreated fed LFD. In conclusion, HFD decreased HNF4α expression and VC exposure along with HFD prevented this decrease. Further, the HFD treatment with and without VC induced expression of the fetal P2 isoform in HFD. Further studies are required to determine the mechanisms behind these observed effects.

1092 The Effect of Farm Dust Collection Method on the Toxicological Responses in Lung Co-Culture Model
M. Martikainen1, T. Tossavainen, K. Wolczkiewicz, and M. Roponen. University of Eastern Finland, Kuopio, Finland. Sponsor: M. Viluksela

Early life exposure to farm environment has been shown to protect from asthma and allergies, whereas exposure during adulthood can increase the risk of respiratory syndromes. To assess the immunological mechanisms behind these phenomena, the focus of research has shifted to in vitro stimulations with farm dust. However, the use of authentic farm dust raises questions about the collection methods as different methods might affect the composition of the dust and furthermore alter toxicological and immunological responses. Detailed characterization, such as data on the size distribution of dust particles as well as microbiome and chemical composition of the dust, could also support a better identification of cause effect relationships. The aim of our study was to assess the impact of dust collection methods on cellular responses. Farm dust samples were collected from 3 different Finnish dairy farms by 1) mechanical scraping (sample matrix 1), 2) settled dust sampling (sample matrix 2), and 3) utilizing DGI impactor (sample matrix 3). Scraped sample was further filtered into two size-fractions (63-125 µm). DGI filter samples were extracted and different size fractions were pooled to obtain sufficient mass of particles for the experiments. Co-cultures of lung epithelial cells (A549) and macrophage-like cells (THP-1) were stimulated with different doses (25, 50 and 100 µg/ml) of farm dusts. Toxicological and immunomodulatory potential of the dust was measured. Dusts were also analysed for particle size distribution, microbiome and chemical composition. Cell membrane integrity was not affected by the collection method, whereas oxidative stress and metabolic activity responses were distinct between matrices. The results were dependent of the farm, as responses from samples collected from farm 1 differed significantly from each other than matrices from other farms. The secretions of IL-6 and TNFa were slightly dependent on matrix. The response profiles were similar whereas the absolute levels
were slightly lower in matrix 2 and higher in matrix 3. Our results indicate that the method of collection slightly affects the toxicological and immunological responses induced by farm dust. This should be taken into account when interpreting the results and comparing findings of different studies as well as when searching for causative components.

1093 Nanjing Youth Olympic Games 2014 Air Quality Intervention: Changes in the Chemical Composition and Toxicological Characteristics of Size-Segregated Urban Air Particulate Matter

T. J. Rönkkö, P. I. Jalava, M. S. Happo, O. Sippula, A. Leskenen, K. Kompulaa, J. Jokiniemi, and M. Hirvonen.1 University of Eastern Finland, Kuopio, Finland; and 2Finnish Meteorological Institute, Kuopio, Finland. Sponsor: M. Vilkuska

The global health risk presented by ambient air particulate matter (PM) calls for efficient emission reduction strategies, especially in areas with dense population and high PM concentrations, such as Chinese megacities with high traffic and industrial activity. In August 2014, Nanjing, a megacity of over 8 million inhabitants in Eastern China, held the Youth Olympic Games (YOG). To provide cleaner air for the event, Nanjing and several surrounding cities enacted temporary emission control measures, including shutting down industries and construction sites, and limiting traffic. In this study, our aim was to assess how this air quality intervention affected the chemical composition of PM and the induced cytotoxic and oxidative stress responses in a co-culture model of alveolar epithelial cells and macrophages. We collected day- and nighttime size-segregated urban air PM in Nanjing before (June), during (August), and after (October) the YOG emission control period, followed by extensive chemical characterization. Co-cultures of A549 cells and THP-1 cells differentiated into macrophage-like cells were exposed to three doses (SO2, 100, 200 μg/mL) of PM in each size range (PM0.25, 0.25–1.0 μm, PM1.0, 1.0–2.5 μm, PM2.5, 2.5–10 μm). After 24 hours, cellular metabolic activity (CMA), cell membrane integrity, intracellular oxidative stress, and thiold redox state were measured. In general, PM0.25 elicited high oxidative stress response and a moderate reduction of CMA, yet showed little to no changes in cell viability and generally modest thiold redox state changes. For the three smaller size ranges, the role of oxidative stress diminished compared to PM2.5, while the thiold redox status and CMA showed similar or greater detrimental effects compared to PM0.25. For all end-points, the August samples showed lower detrimental effects compared to June samples, while the effects returned to higher levels for October samples. In conclusion, we observed changes in chemical composition of PM due to the emission control measures in August, which were reflected as less severe responses in many toxicological endpoints. Thus, air quality intervention not only reduced the ambient concentration of airborne PM, but also decreased its toxicity. However, some of the greatest toxicological responses were seen for October PM, indicating loss of beneficial effects of the temporary emission control period.

1094 Assessment of Cured-in-Place Pipe Worksite Emissions and Toxicity

L. Kobos, S. Sendesi, A. Whelton, and J. Shannahon. Purdue University, West Lafayette, IN.

The U.S. water infrastructure is in need of widespread repair due to age-related deterioration. Currently, the cured-in-place pipe (CIPP) procedure is the most common and cost effective method for water pipe repair. This method involves the on-site manufacture of a new polymer composite plastic pipe within the damaged pipe. This curing process, however, results in the release of emissions into the environment. Our recent investigation of public records has determined public health incidences near CIPP installation sites in at least 29 states resulting building evacuations and health agency responses. Field investigations at 5 CIPP installation sites revealed transient chemical plumes characterized to contain a variety of compounds (styrene, acetylene, toluene, benzaldehyde, phenol, etc.) at differing concentrations. To understand hazards associated with exposure, an in vitro toxicity assessment was performed utilizing mouse lung epithelial and macrophage cell lines and emission samples collected at 4 worksites. All samples were normalized based on the major particulate species, and CMA, a marker that corresponds with lung disease severity, was determined to be up-regulated in all cells exposed to CIPP emissions but down-regulated in styrene controls. Further, vascular cellular adhesion molecule-1, a marker of inflammation, was induced following all exposures except for site 3, which was determined as the least cytotoxic. The immune mediator, transforming growth factor-β and heme oxygenase-1, a marker of oxidative stress, were elevated only after CIPP emission exposures but not by styrene alone. Together our findings demonstrate risks associated with exposure to the CIPP process and the need for worksite interventions in regards to emissions and toxicity. This suggests the need for adjustments in operational procedures to reduce potential public adverse health effects.

1095 Co-exposure of Air Pollutants in Human Lung In Vitro Models

Background Long-term exposure to air pollution including diesel exhaust particles (DEP), nitrogen oxides (mainly NO2), and sulfur dioxide (SO2) has been associated with adverse effects to human health. Most studies are epidemiologically based and often lack methodologies to establish exposure-effect relationships. Aim To develop new exposure systems to allow for repeated co-exposures of gases (NO2, SO2, and DEP) with human bronchial mucosa in vitro lung models at the air-liquid interface (ALI) to assess inflammatory responses that are important for respiratory disease development. Method Bronchial mucosa models were developed using human primary bronchial epithelial cells (PBEC) cultured at ALI and co-cultured with or without macrophages (PBEC-ALI/MQ and PBEC-ALI, respectively). Single and repeated gas exposures (low: 0.1 ppm NO2, 0.2 ppm SO2; high: 0.2 ppm NO2, 0.4 ppm SO2) with and without DEP (12.5 μg/cm2) were carried out at, including clean air (sham) exposure. Changes in gene expression and protein levels were measured as markers for pro-inflammatory (CXCL8) and tissue injury (MMP9) responses. Cell viability was assessed using the lactate dehydrogenase assay. Results More than 90% of the cells were viable before and post repeated and combined exposure to gases and DEP. Sham exposure significantly increased release of CXCL8 in PBEC-ALI/MQ compared to in PBEC-ALI after 24h post exposure. High NO2 and SO2 exposure significantly increased release of CXCL8 in PBEC-ALI. However, 48h repeated exposure to both low and high concentration of both gases resulted in reduced release of CXCL8 in PBEC-ALI compared to sham. Similarly, release of CXCL8 was also significantly reduced in PBEC-ALI/MQ at both 24h and 48h post-repeated exposure to gases. Further, significantly increased release of MMP9 (tissue injury marker) was detected in PBEC-ALI after combined exposure to DEP with gases. Conclusion Combining the newly developed exposure system, which allows for repeated and combined exposure of gases and diesel exhaust, with the physiologically relevant multicellular in vitro lung models, pro-inflammatory and tissue injury responses could be investigated. This approach would be useful to further investigate the underlying mechanistic toxicity aspects of known air pollution components.

1096 Evaluation of Tire and Road Wear Particles in Air in Delhi, India

Tire and road wear particles (TRWP) are formed at the frictional interface of the tire and the road surface, and include contributions from both the tire and the pavement. In a previous international sampling campaign to quantify TRWP in environmental media, TRWP were found to be ubiquitously present in ambient air, detectable in both the PM10 (particulate matter less than 10 μm) and PM2.5 (particulate matter less than 2.5 μm) fractions; although at low concentrations relative to other PM in the air. However, previous sampling was executed in developed countries, where ambient particulate matter concentrations are well-managed. The purpose of this study was to understand the TRWP concentrations and contributions to ambient particulate matter in a developing country with known challenges associated with ambient air particulate. As a city with one of the highest concentrations of ambient PM, Delhi, India was selected for investigation in this study. Both PM10 and PM2.5 air samples were collected over consecutive days at six locations throughout Delhi. Total suspended particulate (TSP) samples were also collected at two of the six locations. Study sites were selected to represent a wide variety of human receptors with close proximity to a traffic source; samples were collected within 10 m of the roadside. These air samples were then evaluated for the presence of TRWP using a previously-established pyrolysis gas-chromatography-mass spectrometry method, which measures pyrolys products of the rubber polymer to ensure specificity to TRWP. Mean TRWP air concentrations across the six sampling sites were 0.45, 2.1, and 6.2 μg/m3 for PM2.5, PM10, and TSP, respectively.
respectively. These concentrations represented 0.40%, 0.58%, and 0.50% of total particulate in these respective size ranges, indicating that TRWP is only a minor contributor to ambient particulate matter in Delhi. This finding is consistent with sampling in developed countries, where TRWP represented less than 0.3% of total PM2.5 and less than 0.6% of total PM10 on average. That said, the concentration of TRWP in Delhi was higher than found elsewhere; though the underlying reasons for this are unknown, differences in traffic volume, road surfaces, and tires may be potential contributors.

### 1097 In Vivo Toxicity Assessment of Metal Contaminated Wind Blown Particulate Matter from an Abandoned Uranium Mine on the Navajo Reservation

J. Begay,1 Y. Ordonez,2 S. Lucas,3 B. Sanchez,4 A. Wheeler,5 F. Baldwin Jr.,6 G. Herbert,7 C. Shuey,8 J. Harkema,1 J. Wagner,9 M. Morishita10, B. Bleksie11, and M. Campen12
1University of New Mexico, Albuquerque, NM; 2Dine College, Tsaile, AZ; and 3Michigan State University, East Lansing, MI.

Studies have shown that particulate matter (PM) adversely affects the respiratory and cardiovascular systems, and that specific metals are important modifiers of PM toxicity. We recently found that PM derived from the sediments surrounding an abandoned uranium mine (AUM; Claim 28) in northern Arizona showed to be more toxic than PM from non-impaired sites. Here, we address the extent to which uranium-contaminated PM is present in ambient air of the community and further assess cardiopulmonary toxicity in acute and subchronic exposures. C57BL/6 and ApoE−/− (a model of vascular inflammation) mice were exposed to concentrated ambient PM (~80 µg/m3) in the Mobile Air Research Lab for 1 or 28 days for 4 hours/day. The mobile laboratory was located 1 km SW of the AUM. Wind stations were positioned on the mobile laboratory and on the AUM to determine wind directions and speed. Lungs and aortas were obtained and analyzed for inflammatory disease marker transcripts (TNF-β, TGF-β, CXCL1, and IL6). Bronchoalveolar lavage was conducted to examine influx of macrophages and neutrophils into the lungs. QPCR for lung 1-day exposure showed an increase in TNF-α, IL6, and TGF-β in PM groups versus filtered air (FA)-exposed mice, and CXCL1 levels slightly decreased as seen in both 1- and 28-day mice. In the 28-day exposures, CXCL1, TGF-β, and TGF-β levels were lower in PM mice than FA mice. QPCR for aorta 1-day exposure showed a slight decrease in CXCL1 in PM mice compared to FA mice, and a small increase in IL6. In the 21-day exposures, slight increases were seen in all probes of PM mice compared to FA mice. Average wind direction over the mobile laboratory traveled from SW to NE, and mostly north over the AUM, away from the mobile laboratory and community. Interim results show minimal inflammatory or toxic outcomes from concentrated ambient PM in the region adjacent to the AUM, but also minimal metals contamination, largely due to predominant wind flow. The next step will be to fully assess the metal content of the PM by ICP-MS and associate with daily wind direction patterns.

### 1098 Evaluating Toxicity of Inhalation Exposure to Unconventional Natural Gas Drilling-Related Chemicals

B. Rivera1, L. Tidwell1, C. Donald1, Y. Chang1, B. Siddens1, K. Mullen1, D. Ainsworth2, K. Anderson1, and S. Tilton1
1Oregon State University, Corvallis, OR; and 2Cornell University, Ithaca, NY.

Over the past two decades, an effort towards reducing reliance on imported fossil fuels has resulted in the rapid expansion of natural gas drilling in the United States. Shale gas made up 40% of U.S. gas production in 2012, compared to 2% in 2000, and is projected to grow fourfold by 2035. The rapid expansion of unconventional natural gas drilling (UNGD) has resulted in drilling moving closer to rural and urban communities, however the chemical composition and toxicological relevance of UNGD-related chemical mixtures is largely unknown. Studies show that residents living less than 0.5 miles from an UNGD site are at higher risk and have higher exposure to UNGD-related chemicals than individuals living more than 0.5 miles from an UNGD site. Air, water, and personal passive sampling devices around the respiratory zone of mares, serving as a sentinel for humans, were deployed at two farm locations with the same proprietor. The affected farm in Pennsylvania had an UNGD site 0.25 miles from its location and another five within a 2.5 mile radius, the New York location served as a control site with no UNGD sites in its vicinity. Over the 18 month sampling period, approximately 56% of full-term neonatal foals born at the Pennsylvania location were dysphagic (difficulty swallowing), compared to 12% at the New York location. These findings suggest that UNGD-related chemical exposure may be associated with the adverse health outcome seen in equine and should be explored for the potential toxicity in a human inhalation model. Quantification of polycyclic aromatic hydrocarbons (PAHs) from passive samplers identified dibenz(ghi)chrysene, phenanthrene, and benzo[a]pyrene, at higher concentrations in PA compared to NY. Exposure to these individual PAHs (1-500 µg/ml) in a 3D human bronchial epithelial cell (HBEc) culture model resulted in significant (q<0.05) induction of transcriptional biomarkers associated with oxidative stress, DNA damage, barrier function and xenobiotic metabolism indicating potential mechanisms for toxicity. Surrogate mixtures identified from a classification approach used to identify chemical exposure profiles associated with location will be tested in the HBEc and assessed to identify the potential adverse effects associated with inhalation exposure to UNGD-related mixtures.

### 1099 Genetic Injury Caused by LINE-1 Retrotransposition following Intratracheal Instillation of Benzo(a)pyrene in ORFeus1,2 Transgenic Mice

A. A. Hassanin1,2, M. Tavares-Garcia1, P. Bojang1, and K. S. Ramos1
1University of Arizona, College of Medicine, Tucson, AZ; and 2Suez Canal University, Ismailia, Egypt.

Long interspersed nuclear elements (LINE-1) are a group of non-LTR-retrotransposons in the human genome. LINE-1 is involved in both disease initiation and progression via retrotransposition dependent and independent mechanisms. Benzo(a)pyrene (BaP) is a widespread polycyclic aromatic hydrocarbon known to be mutagenic and to alter the lung epigenome via mechanisms linked to LINE-1 retrotransposition. These alterations may contribute to heightened rates of lung cancers; cancer types often diagnosed in late stages and displaying the highest cancer mortality rate in the United States. As such, there is need to identify potential biomarkers relevant to the diagnosis and management of patients with lung cancer. The experiments described here focused on the study of genetic injury caused by LINE-1 retrotransposition in ORFeus1,2 mice treated with the lung carcinogen BaP. Eight groups of ORFeus mice, including four male and four female mouse groups were examined. The carcinogen was administered via intratracheal instillation with or without CRE recombinase for conditional activation of a single-copy LINE-1 transgene in the mouse lung. Significantly higher expression of ORFeus LINE-1 mRNA was observed in both male and female lung glands combined and BaP treatment compared to either BaP alone or vehicle. Interestingly, the lung carcinogen alone was capable of inducing LINE-1 mRNA expression in the lung of treated mice. LINE-1 expression was higher in female lungs compared with males, suggesting that females are more susceptible to epigenetic disturbances by BaP. Furthermore, RT-PCR analysis of eight genetic targets within an in silico predicted LINE-1 regulatory network showed increased expression, establishing LINE-1 as a key regulator of genome integrity in the murine lung. These findings are now being used for testing precision-based therapies that can neutralize the genetic injury caused by toxic environmental exposures in vivo that activate LINE-1. We conclude that the ORFeus mouse is a sensitive model to evaluate complex biological interactions that occur during the course of chemical lung carcinogenesis in vivo.

### 1100 Investigating the Role of TRPV3 in Lung Epithelial Cell Repair

K. L. Burrell and C. Reilly
University of Utah, Salt Lake City, UT.

Transient receptor potential vanilloid-3 (TRPV3) is a Ca2+ ion channel. In the skin, TRPV3 regulates keratinocyte proliferation and cornification during wound repair. Our laboratory recently characterized the expression of TRPV3 in human lung epithelial cells, and its contributions to the pneumotoxic effects of wood smoke particulate matter (PM). Over-expression of TRPV3 in primary human bronchial epithelial cells sensitized these cells to cytotoxicity by wood smoke PM, which was partially blocked by a TRPV3 antagonist. Additionally, mice treated sub-acutely with pine PM via oropharyngeal delivery exhibited increased airway resistance that was blocked by TRPV3 inhibition. In mice, histological changes in the major airways, consistent with active wound repair, were observed and was TRPV3-dependent. Transcriptomic profiling of BEAS-2B and BEAS-2B TRPV3-overexpressing cells with and without wood smoke PM or agonist treatment demonstrated significant differences in the regulation of EMT-specific genes including N-cadherin, collagen I, the structural protein vimentin, and numerous genes in the EGFR network. Notably, we have found that TRPV3 overexpression as well as TRPV3 agonists and antagonists appear to “lock” cells into a non-migratory epithelial phenotype, in part through an apparent attenuation of EGF activation following epithelial cell/membrane damage. These data suggest that TRPV3 activation not only contributes to the acute cytotoxic effects of wood smoke PM to lung epithelial cells but also plays a role in coordinating signaling events involved in epithelial wound repair following damage. The mechanism by which TRPV3...
regulates lung epithelial wound repair is unknown, but the consequences of stimulation or inhibition of this process by TRPV3 agonists and antagonists has both toxicological and therapeutic significance.

### 1101 Apoptosis Resistance of Fibroblasts Precedes Progressive Scarring in Pulmonary Fibrosis and Is Partially Mediated by Toll-Like Receptor 4 Activation

K. Hanson, and J. Finkelstein, University of Rochester Medical Center, Rochester, NY.

Inhalation of environmental toxicants such as cigarette smoke, metal or wood dust, silica, or asbestos is associated with increased risk for idiopathic pulmonary fibrosis (IPF). IPF involves progressive scarring of lung tissue, which interferes with normal respiration and is ultimately fatal. To develop therapies to reverse or prevent IPF, it is crucial to clarify the complex cellular mechanisms of IPF pathogenesis. Fibroblast apoptosis is essential in normal wound healing but is dysregulated in IPF. Recent studies suggest that Toll-like receptor 4 (TLR4) is key in the onset of IPF. Mutations in TOLLIP (TLR4 inhibitor) are associated with increased risk for IPF, and TLR4-defective or -deficient mice are fibrosis resistant. Moreover, TLR4 activation causes pro-survival signaling, potentially helping cells evade apoptosis. We hypothesized that epithelial damage leads to the endogenous TLR4 agonist HMGB1, which causes fibroblast apoptosis resistance and thus interferes with wound resolution, contributing to IPF development. Radiation-induced PF was used as a model for IPF because it very closely mimics the progressive and intractable nature of IPF. Female C57BL/6J (WT) and C57BL6/J B6.10S0CN-Tlr4<sup>del/del</sup> (TLR4KO) mice were exposed to 13 Gy whole-thorax ionizing radiation (rt), a fibrosis-inducing dose in WT mice. At 24 hr, 8 wk, and 22 wk post-irradiation (PI), samples collected included plasma, right lungs for primary mouse lung fibroblast (1<sup>st</sup> MLF) expansion, and left lungs for histology. Plasma samples showed increased HMGB1 by ELISA during the inflammatory phase of rt response at 8 and 12 wk PI in both WT and TLR4KO strains. However, TLR4KO lungs exhibited less fibrosis than WT lungs at 22 wk PI, assessed by modified Ashcroft scoring. Furthermore, apoptosis of 1<sup>st</sup> MLFs was induced and the robustness of the apoptotic response was quantified. It was determined that WT 1<sup>st</sup> MLFs were not apoptotic resistant at 24 hr; however, this phenotype was found as early as 8 wk PI and persisted at 12, 16, and 22 wk PI timepoints. These findings expand current knowledge of PIF by indicating that apoptosis resistance occurs earlier in the rt response than previously assumed. Furthermore, apoptosis resistance was not detected in TLR4KO 1<sup>st</sup> MLFs, suggesting that TLR4 plays a key role in fibroblasts acquiring this detrimental phenotype. Future studies will explore TLR4 pro-survival signaling in vitro to further characterize the mechanisms of pulmonary fibrosis.

### 1102 The Effect of Enriched vs. Inadequate Housing Conditions on Biomass Smoke-Induced Cardiovascular Dysfunction in Mice

M. E. Harmon<sup>1</sup>, Y. Kim<sup>2</sup>, C. King<sup>3</sup>, B. Martin<sup>4</sup>, N. H. Coates<sup>2</sup>, M. J. Gilmour<sup>1</sup>, A. K. Farrar<sup>1</sup>, and M. S. Hazari<sup>1</sup>.

University of North Carolina at Chapel Hill, Chapel Hill, NC;<sup>2</sup>US EPA, Research Triangle Park, NC; and<sup>3</sup>Oak Ridge Institute for Science and Education, Oak Ridge, TN.

Air pollution increases the risk of cardiovascular (CV) morbidity and mortality, even with short term exposures. Extrinsic factors that cause psychosocial stress may increase susceptibility to the CV effects of air pollution. Lower socioeconomic status, lack of physical activity and green spaces (i.e. urbanization) is associated with deleterious CV changes. Noise, extreme temperatures, and inadequate social environment lead to stress and CV changes in rodents. In addition, wildfires increasingly threaten public health as they become more widespread and occur more frequently at urban/wildland interfaces. Biomass smoke is an understudied air pollutant. We hypothesized that socioeconomic status, lack of physical activity and green spaces (i.e. urbanization) may take place. To shed light on such interactions we used our established in vitro model of isolated trigeminal ganglion (TG) neurons of CD1 mice (PDNS) that predicts the potency of chemicals to interact with chemoreceptors by using Fura-2-AM based Ca<sup>2+</sup> imaging. To reduce the variety of VOCs we restricted our experiments to (a) prototypical emissions from oriented strand boards (OSB), (b) the five VOCs with the highest concentrations, and (c) one representative mixture of these five compounds. The TG-neurons were stimulated in ascending concentrations of OSB, of the single compounds (i.e. α-pinene, β-pinene, isopropyl-n-hexanal, and trans-2-octanal. Based on the percentage of responding neurons the EC<sub>50</sub> values were: α-pinene: 59.5 mM, β-pinene: 3.6 mM, limonene: 5.2 mM, hexanal: 1.9 mM, and trans-2-octanal: 0.3 mM. The five compounds were mixed in ratios derived from representative air sample taken in the test chambers at the Thünen Institute. Using the same ratios, the EC<sub>50</sub> values of the single compounds predicted a pure additive EC<sub>50</sub> of 6.8 mM for the mixture. The experimental evaluation of the synthetic mixture yielded an EC<sub>50</sub> of 4.9 mM. These results confirmed that the aldehydes are more potent in causing sensory irritation than the selected terpenes. Moreover, using in vitro assay no additive of a mixture representing emissions from OSB-boards could be detected. However, this novel approach as some limitations that need to be considered when extrapolating the results to indoor air exposures of humans.
1105 Baroreflex Sensitivity and Cardiovascular Responses to Acute Peat Smoke Inhalation in Rats

1US EPA, Research Triangle Park, NC; and 2Oak Ridge Institute for Science and Education, Oak Ridge, TN.

Exposure to air pollution elicits disruptions to internal homeostatic controls, the abnormal functioning of which may increase risk for adverse cardiovascular events. The purpose of this study was to assess the concentration-dependent impacts of acute exposure to peat smoke (PS), a key wildland fire-related air pollution source, on cardiovascular function and sensitivity of the baroreflex (BRS), which maintains homeostatic control of blood pressure. Three-month-old male Wistar-Kyoto rats implanted with radio-telemeters to monitor heart rate (HR), blood pressure (BP), and the electrocardiogram, were exposed once, for 1 hr, to filtered air (FA) or low (LP: 0.36 mg/m³ fine particulate matter (PM)) or high (HP: 3.76 mg/m³ PM) concentrations of smoldering PS, generated using a tube furnace system. Spontaneous baroreceptor sensitivity was assessed via the sequence method, which analyzed sequences of fluctuations and corresponding changes in pulse interval using custom software. Exposure to HP, but not LP, caused increases in systolic (11.6%; p=0.053) and diastolic BP (15.6%; p=0.02) and a decrease in HR (p=0.065) during exposure relative to FA. At hour 2 after exposure, HP caused a significant positive linear trend in systolic BP (p=0.059) and a significant increase in diastolic BP relative to both FA and LP. For the first 3 hours after exposure, HP caused an increase in diastolic BP relative to FA and LP (both with p<0.05). By contrast, only exposure to LP increased BRS (i.e. increased gain of all sequences) relative to FA during exposure (LP: p=0.052, FA: p=0.87), previously determined to increase sensitivity to triggered cardiac arrhythmias. Interestingly, PM size (LP = 0.7 microns vs. HP = ~1.3 microns) and proportion of organic carbon (LP = 77% vs. HP = 67%) varied with exposure level. In summary, exposure to air pollution may cause homeostatic shifts, the exact consequences of which are not known, but may contribute to increased cardiovascular risk.

1106 Multiple Comparison of Combustion Emission Toxicity of Wood, Diesel and Aged Equivalents on Novel Thermophoretic Air-Liquid Interface Exposure System

1University of Eastern Finland, Kuopio, Finland; 2Savonia University of Applied Sciences, Kuopio, Finland; 3Finnish Meteorological Institute, Kuopio, Finland; and 4Helmholtz Virtual Institute of Complex Molecular Systems in Environmental Health (HICE), München, Germany. Sponsor: M. Vilukkaela

In attempt to lower fossil fuel usage, the European Union has encouraged among other renewable sources, wood to be used as a heating source. However, biomass combustion increases particulate matter (PM) levels in many regions and heating has become one of the biggest sources of PM especially in winter time. Effects of wood combustion and especially in aged aerosols on health are still largely unknown even many diseases have been connected to PM exposure. We measured several different smoke emissions with and without aging. Used aging conditions were created using LP = 77% vs. HP = 67%) which not only may contribute to increased cardiovascular risk. Moreover, the precise reason for the divergent BRS and BP responses among exposure levels is unclear, but may relate to physicochemical factors specific to each exposure level. Disclaimer: This abstract does not reflect US EPA policy.

1107 Inflammatory Responses in Mouse BALF after Exposure to Fresh or Aged Spruce or Lignite Combustion Aerosol

1University of Eastern Finland, Kuopio, Finland; 2Finland; 3US EPA, Research Triangle Park, NC; and 4Finnish Meteorological Institute, Kuopio, Finland. Sponsor: M. Vilukkaela

Lignite and wood smoke produced due to residential heating are sources of fine particulate matter (PM), which have a consistent effect on human disease, for example exacerbation of cardiovascular diseases and respiratory diseases. The purpose of this study was to model the subchronic effect of wood and lignite smoke exposure on pre-challenged mouse lung. In this study, LPS instilled or healthy C57BL/6J mice (8-9 weeks old) (n=6) were exposed to combustion aerosol in a whole body inhalation chamber for 4 hours for three consecutive days. Four different aerosols were produced in a light stove: wood smoke (spruce), flow tube aged wood smoke (spruce), lignite smoke, or flow tube aged lignite smoke. The control group for both LPS mice (n=11) and healthy mice (n=12) were kept in the animal room separate from the exposure room throughout the experiment, and they were used as controls for all four exposure groups. From collected bronchoalveolar lavage fluid (BALF) total cell count, cell differential count, cell assay, and cytokine analysis (IFNγ, IL-10, IL-12p70, IL-1b, IL-2, IL-4, IL-5, IL-6, TNFα, and KC) were made. An increase can be seen in BALF cell number of LPS mice in contrast to the healthy mice in all aerosol exposed groups and in the control group. Macrophage number seems slightly higher in LPS treated groups, whereas lymphocyte and neutrophil number seems slightly higher in LPS treated groups. Were seen inside alveolar macrophages in BALF samples of fresh wood smoke and aged wood smoke exposed mice and, in less quantity, fresh lignite and aged lignite smoke exposed mice. Genotoxicity in BALF cells shows slight variation between different exposure groups and there is some differences between LPS instilled and healthy mice as well. All ten cytokines measured (IFNγ, IL-10, IL-12p70, IL-1b, IL-2, IL-4, IL-5, IL-6, TNFα, and KC) were low in concentration. Signs of neutrophil driven acute inflammation in LPS treated mice was expected since the LPS instillation induced inflammation is widely reported technique. Engulfed carbon agglomerates inside BALF alveolar macrophages, in both LPS and healthy mice, indicates the activation of inflammation immune response due to wood or lignite smoke exposure.

1108 Zebrafish Locomotor Responses Reveal That Irritant Effects of Biomass Smoke Are Influenced by Fuel Type, Burn Conditions, and Byproduct Chemistry

1University of North Carolina at Chapel Hill, Chapel Hill, NC; and 2US EPA, Research Triangle Park, NC.

Human exposures to wildfire-derived particulate matter (PM) have been linked to increased incidences of adverse heart and lung health outcomes. However, little is known about the influence of biomass fuel type and burn conditions on toxicity. The purpose of this study was to assess the irritant potential of extractable organic material (EOM) of PM derived from biomass smoke condensates from 5 fuels (Eucalyptus, Pine, Pine Needle, Peat, or Red Oak), representing various fire-prone regions of the USA, burned at 2 temperatures each (flaming at ~640 °C and smoldering at ~500 °C) in a locomotor assay in 6-day post-fertilization (dpf) zebrafish. We hypothesized that locomotor responses, measures of irritant effects, are dependent on fuel type and burn conditions and that these differences would relate to combustion byproduct chemistry. To test this, locomotor activity was tracked for 60 minutes in the dark in 6 dpf zebrafish embryos (28-32/group) exposed acutely to 0.4% DMSO vehicle or EOM from biomass smoke (0.3-0.3 µg EOM/ml half-log intervals from each of the 10 condensates in 96-well plates). All condensates elicited concentration-dependent responses. Linear regression analysis (of the first 20 minutes of concentration-response data) to derive rank order potency indicated that on a µg PM basis, flaming Pine and Eucalyptus demonstrated the greatest irritant effects. By contrast, on an emission-factor basis, which normalizes responses to the amount of PM produced/kg of fuel burned, smoldering smoke condensates showed a much greater capacity (~100-fold) to elicit irritant responses than flaming condensates, with smoldering Pine being the most potent. Importantly, irritant responses strongly correlated with polycy-
clic aromatic hydrocarbons (PAH) content (n=0.95, r²=0.90, p<0.0001), but not organic carbon or methoxyphenols. These results indicate that fuel type and burn conditions impact toxicity, and differences in responsiveness are likely determined by the quantity and chemical composition of PM. Furthermore, these results corroborate findings in mouse lung toxicity and PAH-sensitive Salmonella mutagenicity assays. Disclaimer: This abstract does not reflect US EPA policy.

1109 Health Effects of Wildfire Smoke Exposure

The recent wildfire season in the western United States has resulted in increasing levels of particulate matter (PM). This study examined the health impacts of these high exposure levels in rural communities. The US Environmental Protection Agency (US EPA) has established a set of standards that are designed to protect human health. The standard for optimal air quality is 0 to 35.4 PM₂.₅ with anything above being rated from unhealthy to hazardous. Seeley Lake, MT experienced unprecedented levels of smoke exposure from July 31 to September 18, 2017. Seeley Lake had 35/50 days with > 200 PM₂.₅ with 70% of days between the range of very unhealthy (150.5 to 250.4 PM₂.₅) and 9 days of > 1000 µg/m³ which exceeds hazardous levels (250.5 to 500.4 PM₂.₅). Though there has been some literature evaluating the health effects of wildfire smoke in the wildland firefighting context, there have not been a lot of studies evaluating the effects on local communities. The present study is designed to assess long-term effects of wildfire smoke through a series of screenings. We used a variety of tests including spirometry, blood pressure, serum markers of inflammation and a variety of other tests to measure changes in human health. The Seeley Lake cohort consisted of 95 participants all of which lived in Seeley Lake and had an average age of 63 years old. Spirometry was one of the main tests used to access changes between the screening in 2017 to the screening in 2018. The FEV1/FVC ratio is commonly used in studies as a good measurement of lung function as it is able to determine the difference between an obstructive or restrictive lung disease. The FEV1/FVC ratio is the amount of air exhaled in the first second divided by all of the air exhaled during a maximal exhalation. Overall, we found that there was a significant decrease in the FEV1/FVC ratio for all participants. A decrease in FEV1/FVC indicates that there is some airway obstruction. We are currently still reviewing the other data collected and assessing potential correlations with the spirometry data. The findings thus far have implications that wildfire smoke can have long lasting effects on human health.

1110 PM₂.₅ Characterization in Biomass and Non-biomass Burning Households
C. Roper, A. Perez, D. Barrett, P. Hystad, S. Simonich, and R. Tanguay. Oregon State University, Corvallis, OR.

Exposure to indoor air pollution is a global public health disparity issue. Nearly 3 billion people are exposed to biomass smoke with women and children of low socioeconomic status disproportionately impacted. Fine particulate matter (PM₂.₅) is a component of indoor air pollution with well-established health effects and is significantly elevated in residences burning biomass fuel compared to homes using a non-biomass fuel source. Thus far there is limited exposure-response data establishing reduced health impacts from alternative fuel use compared to biomass burning and the characterization of these complex environmental mixtures beyond concentration is poorly understood. We are preforming a robust characterization of PM₂.₅ from biomass and non-biomass burning households through concentration, composition, oxidative potential, and bioactivity assessments. As part of the Prospective Urban and Rural Epidemiological (PURE-Air) study, PM₂.₅ was collected with a stationary monitor in the kitchen and personal monitors on female and male participants in 24 households in Belupalle and Kheri, India. Filters were stratified between 24 households in Belupalle and Kheri, India. Filters were stratified between 24 households in Belupalle and Kheri, India. Filters were stratified between 24 households in Belupalle and Kheri, India. Filters were stratified between 24 households in Belupalle and Kheri, India. Filters were stratified between 24 households in Belupalle and Kheri, India. Filters were stratified between 24 households in Belupalle and Kheri, India. Filters were stratified between 24 households in Belupalle and Kheri, India.

1111 High-Carbohydrate Oral Load Increases Arrhythmia and Alters Cardiovascular Function One Day after a Single Eucalyptus Smoke Exposure in Sprague-Dawley Rats
M. Hazari¹, B. Martin², M. Harmon¹, Y. Kim¹, C. King¹, L. Thompson¹, K. Martin¹, M. Gilmour², and A. Farraj¹. ¹US EPA, Research Triangle Park, NC; ²ORISE, Research Triangle Park, NC; and ³University of North Carolina at Chapel Hill, Chapel Hill, NC.

Multiple studies have demonstrated the severe health effects of a single exposure to wildfire smoke. Stemming from underlying physiological changes, these effects include not only acute respiratory complications but also adverse cardiovascular events. Notwithstanding the brevity of exposure and lack of data on the many of these changes, a recent report sheds light on the host susceptible to subsequent stressors. As such, consumption of a high-carbohydrate (HC) meal has been shown to increase stress in the body. Therefore, this study was conducted to determine the cardiovascular effects of a single exposure to eucalyptus smoke and subsequent priming to a HC meal challenge. Adult male Sprague-Dawley rats (14-26 weeks) were exposed to either filtered air (FA) or 0.7 mg/m³ of flaring eucalyptus smoke (ES) for one hour. Animals were fasted starting 15 hours after exposure and then 21 hours later challenged with either vehicle (Veh) or HC emulsion via oral gavage to mimic a high-carbohydrate meal. One hour after gavage, rats were anesthetized and implanted with an intraventricular Millar probe. Rats were then treated with phenylephrine (pressor) followed by sodium nitroprusside (depressor) to determine cardiac and arterial function, and baroreflex sensitivity (BRS). Baseline aortic blood pressure was significantly decreased in ES-Veh rats, whereas left ventricular pressure (LVP) was significantly increased only in ES-HC rats. On the other hand, only the FA-HC group had increased arrhythmogenicity. Lastly, although the BRS pressor response showed a trend towards decreased sensitivity in ES-Veh and FA-HC rats, there were no significant differences. In contrast, both ES-Veh and ES-HC caused a significant blunting of the BRS depressor response when compared to FA-Veh. These results demonstrate that a HC meal increases cardiac pressure and decreases BRS one day after ES exposure. Although these findings of HC after ES smoke exposure indicate heightened cardiovascular risk, it appears that HC and ES on their own also cause cardiovascular dysfunction. In addition, these results suggest that even though ES and HC are likely deleterious on their own, their combined effect is probably most pronounced in hosts with underlying cardiovascular disease. 1112 Acute Eucalyptus Smoke Inhalation Sensitizes Rats to the Postprandial Effects of a High Carbohydrate Oral Load
B. L. Martin¹, L. C. Thompson², Y. H. Kim², S. Snow², M. C. Schladweiler², P. Phillips³, C. King¹, J. Richards³, W. K. Martin¹, N. Haykal-Coates², M. L. Gilmour³, U. P. Kodavanti¹, M. S. Hazari¹, and A. K. Farraj¹. ¹Oak Ridge Institute for Science and Education, Oak Ridge, TN; ²US EPA, Research Triangle Park, NC; and ³University of North Carolina at Chapel Hill, Chapel Hill, NC.

Previous studies have shown that air pollution exposure primes body systems to heightened responses to everyday activities that stress the cardiovascular (CV) system. The goal of this study was to investigate the impacts of a one-time exposure to eucalyptus smoke (ES) on the postprandial CV effects after a single high carbohydrate (HC) challenge, a cardiometabolic stressor long used to predict CV risk. Three-month-old male Sprague Dawley rats were exposed once (1 hr) to filtered air (FA) or ES (700 µg/m³ fine particulate matter), a key wildland fire air pollution source, generated by burning eucalyptus in a quartz tube furnace. Rats were then fasted overnight, and subsequently administered an oral gavage of either water or a HC suspension (70 kcal% from carbohydrate), mimicking a HC meal, 24 hr post-exposure. Two hours post gavage, cardiac and superior mesenteric artery function, circulating lipids and hormones, and pulmonary and systemic inflammatory markers were assessed. ES inhalation alone caused an increase in glucose, serum interleukin (IL)-13, and keratinocyte chemoattractant (KC)/growth-regulated oncogene (KC-GRO) compared to water in both FA- and ES-exposed animals. By contrast, only ES-exposed and HC-challenged animals had an increase in serum IL-4 and IL-6 compared to FA-exposed animals that received water. Echocardiography data is currently being analyzed. In summary, exposure to eucalyptus smoke can heighten cardiovascular risk, it appears that HC and ES on their own also cause cardiovascular dysfunction. In addition, these results suggest that even though ES and HC are likely deleterious on their own, their combined effect is probably most pronounced in hosts with underlying cardiovascular disease. Disclaimer: This abstract does not reflect US EPA policy.
Inhalation of Ozone (O₃), a main component of smog, adversely affects lung function. We have shown that O₃ exposure leads to activation of pulmonary macrophages toward an M1/pro-inflammatory phenotype, which is dependent on NF-κB function. Nitric oxide is a known regulator of NF-κB function, either via direct nitrosylation of the p65 subunit or indirectly via regulation of translocation. However, there were a number of other targets for NO within the lung that exacerbate inflammation. Here we investigated the effects of 3 different S-nitrosothiole (SNO) donors (ethyl nitrite, ENO, S-nitroso-N-acetyl cysteine, SNAC, and S-nitrosopropanamide, SNOPPM) on inflammatory cell recruitment and activation. In addition, we have developed a human exposen model to examine macrophage activation. Female mice were exposed to 0.8 ppm of O₃ or air for 3 hours and given 0.0125% ENO (50µg), or 50 ng of SNAC or SNOPPM intranasally 1hr following exposure. Mice were sacrificed 48hr following dosing. Alveolar and tissue associated macrophages were obtained via bronchoalveolar lavage and lung digestion. Lung lobes were either inflamed for histology or snap frozen. Immunohistochemical staining of paraffin-embedded tissue sections allowed for assessment of lung injury and inflammatory signaling. O₃ increased BAL protein, which was opposed by ENO and SNOPPM but not SNAC. O₃ did not significantly alter the cell content of either the tissue or the BAL, but all SNO donors increased total recruitment and particularly within immature unactivated macrophages. ENO reduced the expression of markers of epithelial cell damage, lipid peroxidation, and downstream inflammatory signals. All SNO donors reduced O₃ induced expression of the pro-inflammatory marker Ly6C in alveolar and tissue associated macrophages. All donors reduced the O₃ induced appearance of YM1 in tissue associated macrophages. These studies imply that SNO donor administration inhibits macrophage activation with SNOPPM being the most effective. This conclusion is supported by in vitro work that shows SNOPPM can oppose LPS-mediated induction of NF-κB activity. In our human studies, we have examined the effects of low dose O₃ exposure while exercising for 3 hours on pulmonary inflammatory activation. Examination of induced sputum reveals an inflammatory activation pattern that we have not seen in our mouse model. Our data show O₃ increases pro-inflammatory signaling in humans and animals and that inhaled SNO donors may be able to oppose this process, leading to decreased epithelial injury.

Wood smoke exposure causes airway inflammation and oxidative stress, which contributes to cardiopulmonary disease and early mortality; however, the molecular mechanisms responsible for these adverse effects are unclear. To date, epithelial cell monocultures have been widely used for identifying the molecular mechanisms involved in toxicity. While epithelial cells serve as the barrier between the host and the environment, they are only one of many cell types within the airway that cooperatively affect lung function. We hypothesized that exposure to wood smoke condensate (WSc) would induce both the oxidative stress and pro-inflammatory response in airway fibroblasts, which reside immediately beneath the airway epithelium and play a critical role in maintaining tissue homeostasis. To test this hypothesis, we developed a low-serum Transwell-based in vitro organotypic model that recapitulates in vivo exposures in which airway epithelial cells (16HBE) are directly exposed and airway fibroblasts (IMR90) are indirectly exposed. We determined that exposure to WSc at 20 µg/cm² did not decrease trans-epithelial electrical resistance (TEER) or increase permeability of the epithelial layer to fluorescein-labeled dextran (20kDa) following 24 hours of exposure, indicating that our exposure conditions do not disrupt epithelial barrier functions. We then assessed the effects of WSc dose (10 and 20 µg/cm²) and the kinetics of the exposure response (2, 4, 6, 8, 10, 12, and 24 hours) on the expression of the sentinel pro-inflammatory and oxidative stress genes interleukin-8 (IL-8) and heme oxygenase (HMOX1), respectively. Direct exposure of epithelial cells induced peak IL-8 (3-fold) and HMOX-1 (15-fold) gene expression at 6 and 8 hours of exposure, while the indirectly exposed fibroblasts exhibit peak IL-8 (2.5-fold) and HMOX-1 (25-fold) gene expression at 8 and 4 hours of exposure, respectively. These results demonstrate distinct gene expression kinetics of epithelial cells and fibroblasts in response to WSc exposure. The discrepancy in gene expression kinetics may suggest that epithelial cell signaling influences the stress response of underlying fibroblasts. The influence of signaling between cells in this organotypic model facilitates new insights into the origins of cardiopulmonary diseases in response to wood smoke exposures.

Human exposure to ozone at peak ambient levels is associated with an accumulation of activated macrophages in lung and airways. How these cells influence ozone-induced pulmonary morbidity and neutrophilic inflammation remains unclear. Following exposure of rodents to ozone, a persistent increase in proinflammatory macrophages is observed in the lung. Moreover inhibiting the activity of these cells mitigates toxicity. We hypothesize that proinflammation macrophages play a similar role in human toxicity. To address this, we assessed the phenotype of macrophages in induced sputum following ozone exposure. Healthy men and women were exposed for 3 hr to clean air and to 0.2 ppm ozone two weeks apart in a randomized cross-over design. During exposures mild to moderate exercise was performed. Subjects were initially screened for their ability to produce sputum, which was used as a baseline for comparison with induced sputum collected 24, 48 or 72 hr after exposure. Mucus plugs were manually separated from sputum, weighed, and incubated in 0.1% dithiothreitol. After counting, recovered cells were processed for histological analysis and flow cytometry. A gating strategy using successive bivariate scatter plots of forward/side scatter, CD45⁻/⁺, live/dead analysis, and relative CD14/CD16 positivity identified 3 discrete populations of cells: macrophages, monocytes and neutrophils. Cell uniformity in each region was verified by cell sorting and microscopy. In contrast to paired baseline and room air control, a significant increase in mature proinflammatory (M1) CCR2+ Macrophages was observed in samples collected from subjects 24 and 48 hr after ozone exposure in 5 of 6 subjects, a response which was reduced at 72 hr. This was correlated with increases in neutrophils and immature macrophages. These findings demonstrate that CD11b/CCR2 expression on macrophages after non-invasive sputum collection can iden-
1117 Differential Gene Expression in Alveolar versus Intratissial Macrophages during Ozone-Induced Pulmonary Inflammation

M. Hodge1, S. Reece1, R. Tighe1, B. Luo1, J. House1, E. Browder1, R. Kilburg2, and K. Gowdy1.1 East Carolina University, Greenville, NC; 2Duke University, Durham, NC; and 3North Carolina State University, Raleigh, NC.

Ozone (O3) is a criteria air pollutant that causes pulmonary inflammation and injury. Lung resident macrophages termed ‘alveolar macrophages’ (AMs) contribute to the O3-induced pulmonary inflammatory response. However, pulmonary macrophages are a heterogeneous population and it is currently unknown how the other macrophage populations contribute to and/or mitigate O3-induced inflammation. Intratissial macrophages (IMs) are a population of pulmonary macrophages present in the lung parenchyma. However, the role of IMs in O3-induced pulmonary inflammation and injury is unknown. We hypothesized that IMs attenuate O3-induced pulmonary inflammation by upregulating pathways important for resolving lung injury. Female C57/Bl/6j mice were exposed to filtered air (FA) or O3. Whole lung tissue was excised 24 hr and 48hr after exposure to isolate macrophage populations. Using fluorescence activated cell sorting (FACS), we performed quantitative PCR (qPCR) in whole lung macrophages (CD11b+Ly6G+Ly6C+CD11b+SiglecF+) and IMs (CD45−CD124+Ly6GCD64+CD41b+). Macrophage RNA was isolated to analyze expression of receptors known to be important in O3-induced pulmonary inflammation (Scarb1, Cd36, Cd163) and expression of markers known to participate in the resolution of lung injury (Merk, Tgfb, Cd36). CD163 expression was unchanged after O3; however, IMs had increased baseline Il10 expression when compared to AMs that was significantly upregulated after O3. Scarb1 and Cd163 expression in AMs was unchanged after O3 whereas IMs had significantly higher expression of Scarb1 and Cd163 compared to AMs that was augmented after O3. Neither AMs nor IMs had alterations in expression of Merk, Tgf-β, and Cd36 after O3 compared to FA controls. These data indicate that IMs are involved in the pulmonary inflammatory response to O3 through upregulated expression of Il-10 and scavenger receptors. Future RNA sequencing studies will determine the molecular pathways responsible for these alterations in gene expression in IMs.

1118 Pathologic Effects of Depletion of CD11b+ Monocytic Cells in Mouse Lung following Ozone Inhalation

C. R. Gardner1, J. Radbel2, K. Vayas1, S. Taylor3, J. A. Cervelli1, H. Chang1, S. Koo1, J. M. Lee1, D. L. Laskin1, and P. Silveyra2. 1Rutgers The State University of New Jersey, Piscataway, NJ; and 2Robert Wood Johnson Medical School, New Brunswick, NJ.

Ozone (O3) is a ubiquitous urban air pollutant known to cause lung inflammation, alveolar epithelial damage and oxidative stress. CD11b+ macrophages have been shown to accumulate in the lung following ozone exposure; these cells have been characterized as Ly6C+ proinflammatory and Ly6C− anti-inflammatory. To assess the role of CD11b+ macrophages in ozone toxicity, we used mice with a transgenic diphertheria toxin (DT) receptor under the control of the CD11b promoter (CD11b-DTR). Mice were treated i.p. with 25 μg/kg DT to deplete CD11b+ monocytes. After 18 h, mice were exposed to air or 0.8 ppm O3 for 3 h. IL-10, TNFα, IL-6, and LPS were elevated when compared to LPS treated mice; conversely, the percentage of resident alveolar macrophages (CD45+CD11b+SiglecF+CD44+) was reduced. These results suggest that pre-exposure to ozone primes the lung for sepsis-induced ALI in mice. The ALI appears to be mediated, in part, by loss of resident alveolar macrophages and infiltrating neutrophils and monocytes are pro-inflammatory macrophages into the lung. Supported by NIH ES004738, ES005022, SOT Donald E. Gardner Inhalational Toxicology Education Award.

1119 Ozone Exposure Predisposes Mice to Sepsis-Induced Lung Injury

J. Radbel1, K. Vayas2, O. Le-Hoang1, V. Sunil2, A. Gow1, and D. L. Laskin2. 1Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ; and 2Rutgers Ernest Mario School of Pharmacy, Piscataway, NJ.

Ozone is a ubiquitous urban air pollutant known to cause alveolar epithelial barrier dysfunction. Recently, US Environmental Protection Agency (US EPA) compliant levels of ozone exposure have been directly linked to increased incidence of human acute respiratory distress syndrome (ARDS), a severe form of acute lung injury (ALI). While sepsis is a well-established cause of ARDS, it is unknown why only certain individuals develop ARDS as a consequence of sepsis. Our goal was to analyze the potential role of ozone pre-exposure in the development of sepsis-induced ARDS. Male C57/Bl/6j mice were exposed to 0.8 ppm ozone or air in a whole-body exposure chamber for 3 hr followed 24 hr later by i.v. administration of lipopolysaccharide (LPS) (2.4-3 mg/kg) to model bacterial sepsis, or phosphate buffered saline (PBS) control. Mice were euthanized 24 hr later and bronchoalveolar lavage fluid (BAL) fluid and cells collected and analyzed for markers of lung damage (protein, IgM) and leukocyte phenotype. BAL protein content and IgM levels from mice exposed to ozone and LPS were elevated when compared to LPS or ozone alone. Flow cytometric analysis of BAL leukocytes revealed a significant increase in activated neutrophils (CD45+CD11b+Ly6G+Fla480-Ly6Ch1) in the ozone/LPS group relative to the other groups. A greater percentage of mature pro-inflammatory macrophages (CD45+CD11b+Ly6G-Fla480+CD11c+Ly6Ch1) was also observed in the ozone/LPS treated mice, conversely, the percentage of resident alveolar macrophages (CD45+CD11b+SiglecF+Fla480+) was reduced. These results suggest that pre-exposure to ozone primes the lung for sepsis-induced ALI in mice. The ALI appears to be mediated, in part, by loss of resident alveolar macrophages and neutrophils and monocytes are pro-inflammatory macrophages into the lung. Supported by NIH ES004738, ES005022, SOT Donald E. Gardner Inhalational Toxicology Education Award.

1120 Estrogen Regulation of Ozone-Induced Lung Inflammation

N. Fuentes1, L. Rivera1, M. Nicoleau1, S. DiAngelo1, and P. Silveyra2. 1Penn State College of Medicine, Hershey, PA; and 2University of North Carolina at Chapel Hill, Chapel Hill, NC.

Aspiration is a lung disease characterized by exaggerated lung inflammation that is exacerbated upon air pollution exposure. The risk of an asthma exacerbation requiring a hospital admission is almost twice as high for women than men. Environmental and physiological factors, including exposure to ozone and circulating levels of sex hormones, have been shown to increase the risk of asthma exacerbations. However, the mechanisms involved remain unknown. Our lab has recently challenged male and female C57/Bl/6j mice with 2 ppm of ozone for 3 h and identified sex differences in lung inflammation and airway hyperresponsiveness. To test the hypothesis that circulating estrogen levels can regulate lung function in response to ozone, we performed gonadectomy and hormone replacement (17β-estradiol, 2 weeks) in adult male and female mice. In control females, the stages of the estrous cycle were monitored by daily by vaginal smear, and confirmed by serum sex hormone levels. We exposed animals to 2 ppm ozone or filtered air (FA) for 3 hours, and we compared lung function parameters at 24 h after exposure by methacholine challenge using the FlexiVent system. We found significant changes in respiratory parameters in males and females, and in females exposed to ozone at different stages of the estrous cycle. Gonadectomized males exposed to ozone had increased resistance (Rs) and elastance (Es) than females and males exposed to FA, and treatment with estradiol decreased lung expansion in both sexes. Female mice exposed to FA in the metestrus and diestrus stages exposed had higher Rs and Es values than when compared to the proestrus and estrus stages. Contrarily, exposure to ozone caused a decrease in these parameters during metestrus and diestrus, but a slight increase in the proestrus and estrus. These results suggest that pulmonary function following ozone exposure is affected by circulating hormone levels. This information could lead to better individualized treatment options for men and women suffering from asthma, and identification of sex-specific environmental and hormonal triggers that lead to severe disease symptoms.
1121 Neuroendocrine Stress Axis and Adaptation after Repeated Daily Ozone Exposure

1US EPA, Research Triangle Park, NC; and 2University of North Carolina at Chapel Hill, Chapel Hill, NC.

After repeated daily ozone exposure for more than 2 days, rodents demonstrated total/circulation/circulation from internal lung injury, inflammation, and functional alterations. The mechanisms of adaptation to ozone, other pollutants, or non-chemical stressors are not well known. We hypothesized that since ozone-induced lung injury and inflammation are mediated through the activation of neuroendocrine pathways, the adaptive response to initial lung injury and inflammation might involve the lack of neuroendocrine response, and that low level 1-month exogenous glucocorticoid treatment might result in steroid resistance and impairment of adaptation. Male Wistar Kyoto rats (12-week old) were treated with saline or dexamethasone sul fate (DEX, 0.01 mg/kg/day; 7 days/week for 4 weeks); ip prior to and during daily exposure to air or 0.8 ppm ozone for 2 or 4 days followed immediately by injury/inflammation and systemic neuroendocrine changes were assessed post-exposure. Body, thymus and spleen weights were lower in animals treated with DEX when compared to saline controls. DEX reduced circulating adrenocorticotropic hormone in all animals, however, it had no effect on prolactin (PRL), luteinizing hormone (LH) or thyroid stimulating hormone (TSH) levels. Ozone exposure for 2, but not 4 days, was associated with a remarkable depletion of PRL, LH and TSH regardless of DEX treatment. DEX-treatment was associated with ~80% depletion of circulating corticosterone in all air-exposed rats. Ozone exposure for 2, but not 4 days, reversed this depletion, suggesting that adaptation was associated with reduction of glucocorticoid hyroid. Ozone-induced hypoxic, glucose intolerance and inhibition of insulin release in response to glucose noted after 2 days were not present after 4 days, indicating adaptation of metabolic response. This adaptation was not influenced by DEX. The lung injury/inflammation and increased lavege fluid IL-6 levels noted after the 2nd day of ozone exposure was not observed after the 4th day of exposure in saline-pre-treated rats, however, this adaptation was less pronounced in DEX-treated rats. These results demonstrate that adaptation to repeated ozone exposure is not in only pulmonary but also neuroendocrine pathways, and that long-term steroid pretreatment had a small effect on the adaptation to lung injury and inflammation. Disclaimer: Does not reflect US EPA policy.

1122 Dynamic Changes in Neuroendocrine Hormones and Inflammatory Cell Egress following an Acute Ozone Exposure in Rats

S. J. Snow1, A. R. Henriquez2, M. C. Schladweiler1, M. M. Hargrove4, C. N. Miller1, W. Williams1, and U. P. Kodavanti1.

1US EPA, Durham, NC; and 2ORISE, Durham, NC.

Acute exposure to ozone leads to multi-organ alterations through activation of the sympathetic-adrenal-medullary and hypothalamic-pituitary-adrenal axis, which control the synthesis and release from adrenal glands of epinephrine and glucocorticoids, respectively. These hormones regulate and maintain homeostasis through modulating changes in two fundamental survival processes in the body: metabolism and immune response. The purpose of this study was to elucidate the temporal sequence behind ozone-induced metabolic alterations and innate immune responses in the lung by constructing a time line of events for stress hormone release and egress of immune cells. Male, 12-14 weeks old Wistar-Kyoto rats were exposed to filtered air or ozone (0.4 or 0.8 ppm) for 30 min, 1h, 2h, or 4h followed immediately by necropsy to collect blood and tissues for analysis. Circulating hormones were measured in plasma or serum samples. The levels of thyroid stimulating hormone, luteinizing hormone, and prolactin steadily decreased with increased exposure times to 0.8 ppm ozone. Adrenocorticotropic hormone, which stimulates the release of corticosterone from the adrenal cortex, was increased at 30 min (p=0.0759), 1h, and 2h. This was prior to the elevation of corticosterone at 1h, 2h, and 4h-post-exposure to 0.8 ppm ozone. Ozone exposure (0.8 ppm) led to significant increases in epinephrine levels at the 1h, 2h, and 4h timepoints, illustrating the rapid response of these stress response pathways. These findings corresponded with significant increases in free fatty acids (1h, 2h, and 4h), total cholesterol (1h; and blood glucose levels (4h) following exposure to the high dose of ozone. Furthermore, ozone exposure at 0.8 ppm led to significant decreases in circulating white blood cells and lymphocytes at the 4h timepoint. Neither apoptotic nor necrotic white blood cell subpopulation levels were altered, suggesting mobilization into tissues rather than cell death was responsible for the decreased count. Collectively, these findings illustrate the temporal pattern of effects that lead to the release of neuroendocrine hormones, metabolic alterations, and immune responses following ozone exposure. These dynamic datasets are critical for the accurate characterization of injury mechanisms as well as the development of adverse outcome pathways associated with exposure to environmental stressors. Disclaimer: Does not reflect US EPA policy.

1123 Ozone Increases Plasma Kynurenine and Impacts Hippocampal Serotonin Receptor and Neurotrophic Factor Expression: Role of Stress Hormones

E. Thomson1, M. Rose1,2, A. Filatreault1, A. Williams1, and J. Guénette1.

1Health Canada, Ottawa, ON, Canada; and 2University of Waterloo, Waterloo, ON, Canada. Sponsor: A. Nong.

Air pollution is associated with increased incidence of neurological and mental health disorders, but underlying mechanisms remain unclear. Recent work has shown that air pollutants activate the hypothalamic-pituitary-adrenal (HPA) axis, releasing stress hormones (glucocorticoids) that exert profound effects on many biological systems. Stress can affect cognition, mood, and behavior, and chronic stress can produce biochemical and structural changes that contribute to disease processes in the brain. However, the role of stress hormones in mediating impacts of air pollutants on the brain is unknown. The objective of the present study was to assess effects of ozone on biological factors relevant to depression and dementia, notably serotonin signaling and neurotrophic factor expression, and examine the role of stress hormones in mediating these effects. Male Fischer-344 rats (n=5/group) were exposed by nose-only inhalation to air or 0.8 ppm ozone for 4 h with or without metyrapone, a drug that blocks production of the glucocorticoid corticosterone. Plasma levels of the serotonin precursor tryptophan and the tryptophan metabolite kynurenine, and changes in gene expression in the hippocampus, a stress-sensitive region of the brain implicated in memory, cognition, and depression, were assessed. Ozone increased the ratio of kynurenine to tryptophan (2.7-fold, p<0.001), a feature of a number of brain, inflammatory, and metabolic disorders. Serotonin receptor genes were differentially affected by ozone, while mRNA levels of neurotrophic factors were decreased. Some, but not all, of these effects were blocked by metyrapone (Ozone x Metyrapone factor interactions, p<0.05) and reproduced by administration of corticosterone (r=0.83, p=0.01), establishing a role for stress hormones in mediating effects of ozone on the brain. The findings show that short-term exposure to a commonly air pollutant implicated biological processes implicated in depression and cognitive disorders, and contribute to the weight of evidence linking exposure to air pollutants and effects on the brain.

1124 The Impact of Ozone Exposure and Sedentary Lifestyle on Microglia and Mitochondrial Bioenergetics of Female Long-Evans Rats

M. C. Valdez1,2, D. L. Freeborn2, A. F. Johnstone1, A. Tennant1, and P. R. Kodavanti1.

Ozone is a widespread and highly reactive air pollutant that produces cardiovascular and pulmonary dysfunction. We sought to assess neurological changes in glial morphology and mitochondrial bioenergetics in response to both sedentary lifestyle and ozone exposure. Astrocytes work intimately with neurons to sustain functioning synapses as well as preserve the blood brain barrier. Microglia are highly plastic and aid in safeguarding the brain by removing damaged neurons, plagues, and xenobiotics. Microglia are key regulators of cellular energy homeostasis and may play a role in mechanisms that regulate the temporal sequence behind neurodegeneration. To develop an animal model in which female Long-Evans rats were either sedentary or active (exercise on running wheels) starting at postnatal day (PND) 22 until the age of PND 100 and then exposed to O3 (0.0, 0.25, 0.5 or 1.0 ppm) 5 h/day for two consecutive days. Immediately following O3 exposure, the rats were sacrificed and brains were either fixed and stored at 4°C or dissected on ice, quick frozen, and stored at -80°C until analysis. For astrocytes (GFAP) and microglia (Iba1) immunohistochemistry, we measured the area of coverage and reactive morphology, respectively, in the hypothalamus (HYP) and hippocampus (HIP), two brain regions with known roles in coordinating stress responses. We found more reactive microglia within the hippocampus (HYP) and hippocampus (HIP), two brain regions with known roles in coordinating stress responses. We found more reactive microglia within the hippocampus (HYP) and hippocampus (HIP), two brain regions with known roles in coordinating stress responses. We found more reactive microglia within the hippocampus (HYP) and hippocampus (HIP), two brain regions with known roles in coordinating stress responses. We found more reactive microglia within the hippocampus (HYP) and hippocampus (HIP), two brain regions with known roles in coordinating stress responses. We found more reactive microglia within the hippocampus (HYP) and hippocampus (HIP), two brain regions with known roles in coordinating stress responses. We found more reactive microglia within the hippocampus (HYP) and hippocampus (HIP), two brain regions with known roles in coordinating stress responses.
Acute ozone (O3) inhalation in rats induces firing of catecholaminergic neurons in the nucleus tractus solitarius (NTS) in the brainstem as well as paraventricular nucleus (PNV) of hypothalamus. O3 exposure increases circulating stress hormones through activation of sympathetic-adrenal-medullary and hypothalamic-pituitary-adrenal axes. Adrenalectomized (AD) rats lacking circulating stress hormones epinephrine (EPI) and corticosterone (CORT) have attenuated pro-inflammatory responses to O3. We hypothesized that O3-induced changes in the circulating levels of pituitary-derived and other neuroendocrine hormones will correlate with changes in global gene expression in the brainstem and hypothalamus. Additionally, based on our previous pulmonary findings, we investigated the effects of AD on modifying O3-induced changes in pituitary hormones as well as gene expression. Male Sprague-Dawley rats (12 wks) that underwent sham surgery (SH) or AD were exposed to O3 (0.8 ppm) or filtered air, 4 hr/day for 1 day. Serum pituitary hormones were quantified, and mRNA from brainstem and hypothalamus was isolated, purified and sequenced. O3 exposure decreased the serum levels of thyroid-stimulating hormone (TSH), prolactin (PRL), and luteinizing hormone (LH) in SH rats. O3-induced TSH and PRL but not LH reductions were prevented in AD rats. AD increased ACTH nearly 5-fold in all animals. O3-exposure in SH rats significantly changed gene expression in the brainstem and hypothalamus (303 and 568 genes, respectively). Virtually no genes were changed after O3 exposure in AD rats. AD in air-exposed rats changed only ~18 genes in the brainstem and hypothalamus. O3 induced enrichment of genes involved in activation of hedgehog signaling, response to alpha interferon, response to low oxygen levels, and activation of mTORC1, among others. Gene expression altered in both tissues was analogous to those altered by glucocorticoids and L-dopa, suggesting a pivotal role of CORT and neurotrophins. These findings suggest that O3 inhalation promotes a rapid rearrangement of gene expression in the brainstem and hypothalamus, which reflects changes in biological processes such as hypoxia and/or inflammation; and results in activation of neuroendocrine axes. Elimination of circulating stress hormones abolishes O3-induced changes in brain gene expression and neuroendocrine activation. Disclaimer: This abstract does not reflect US EPA policy.

Ozone (O3) is one of The US EPA’s six “criteria air pollutants” due to its association with adverse effects on human health including the exacerbation of existing respiratory diseases and heightened susceptibility to respiratory infections. Inhalation to O3 rapidly reacts with airway lining fluid constituents to form biologically active molecules that trigger inflammation and impair host defense by altering innate immune responses. Beyond the initial O3-airway surface reactions, the mechanisms by which O3 elicits inflammation and impairs host defense are not known. Extracellular vesicles (EVs) are nano-scale lipid membrane bound particles known to function as intercellular messengers and carry cargo such as microRNAs (miRNAs) that can regulate mRNA expression in recipient cells. We hypothesized that O3 alters miRNAs carried by EVs between airway cells (e.g., epithelia and macrophages), thereby altering gene expression in the airways in a manner that contributes to inflammation and innate immune dysfunction. In this study, we exposed female C57BL/6 mice to O3 (~10x ambient) or filtered air (FA) for 3 h in whole body chambers. Bronchoalveolar lavage fluid (BALF) was collected, EVs isolated and their content assessed. We found that MVs and Exos were released into BAL following O3 exposure. Flow cytometric analysis showed that MVs were mainly derived from type I epithelial cells (ATI), while Exos were from type II epithelial cells (ATII). Furthermore, the majority of the cargo carried by ATI cell-derived MVs (ATI-MVs) consisted of smaller RNAs. In contrast, there were negligible amounts of small RNAs in ATII cell-derived Exos. In ATI-MVs, small RNAs, but not proteins or large RNAs, were robustly increased after O3 exposure. Using microRNA (miRNA) arrays, epithelial MVs generated following ozone exposure were found to encapsulate a selected miRNA repertoire. These findings suggest a pathway for selective loading of miRNAs into MVs in response to O3. We also found that MV-miRNA-derived miR-185 induces ATI cell necroptosis via augmenting caspase 8-mediated signaling pathways. Collectively, these findings demonstrate that O3 induces the generation of miRNA containing by lung epithelial cells; moreover these play a role in epithelial cell death. Air pollution (AP) is a leading global risk factor for cardiovascular and metabolic-related morbidity and mortality. Particulate matter that is <2.5 micrometers (PM2.5) is a persistent pollutant and is monitored by environmental agencies around the world using satellite and ground-level methods. Populations in areas with high levels of ambient air pollution likely have increased risk of developing metabolic syndrome. Understanding the molecular mechanisms underlying this multifactorial disease is critical for developing population level preventive approaches. We have previously demonstrated that chronic exposure to PM2.5 causes insulin resistance in mice. Here, we modeled early childhood PM2.5 exposure using 3-week-old C57BL/6J mice (male and female). Mice were exposed through inhalation to concentrated PM2.5 (~10x ambient) 3 h/day, 5 days/week, over 14 weeks. The control mice received filtered air (FA) from the same concentration system. All mice were randomized to a normal or high-fat diet in order to model air pollution with the background of an increased body weight and high fat intake. We found that mice that experienced 14-weeks of PM2.5 exposure had impaired glucose metabolism, compared to FA, as measured by glucose and insulin tolerance testing. In contrast, female mice exposed to PM2.5 did not exhibit similar metabolic perturbations. Using a comprehensive and systematic transcriptome map, we identified differentially expressed genes in the liver, visceral white adipose, brown adipose, and skeletal muscle. By incorporating open chromatin signatures, we have discovered widespread decrease of chromatin accessibility in liver upon the PM2.5 exposure. We also performed transcriptome mapping on brain tissue, particularly on the hypothalamus and rostral ventrolateral medulla (RVL/M) tissue, which is both associated with the cardiovascular function. The male mice exhibited phenotype reversal 8 weeks after cessation of PM2.5 exposure, and we conducted transcriptome and chromatin accessibility analysis to find the potential mechanism of transcription reprogramming. DEGs discovered in PM liver and WAT have been majorly
1129 Behavioral Alterations with Ambient Ultrafine Particulate Matter Exposure in Aged Alzheimer’s Disease Mice

Alzheimer’s disease (AD) is a neurodegenerative disorder that diminishes memory and cognitive skills as well as movement and olfactory function. The major pathological components of AD are sparsely distributed amyloid plaques and neurofibrillary tangles. Environmental factors like air pollution may contribute to the overall risk of disease development. Of concern is exposure to ultrafine particles (UFP, <0.1 μm in aerodynamic diameter), as they deposit efficiently in all regions of the respiratory tract, evade clearance, and can translocate to secondary organs, where they may induce inflammation. We hypothesized that triple transgenic AD mice (3xTgAD) exposed to concentrated ambient UFPs undergo accelerated AD progression and altered performance in tests of cognitive function, as well as non-memory-related behavioral tasks. UFPs from ambient air were concentrated using the Harvard Ultrafine Concentrated Ambient Particle System (HUCAPS). Cohorts of male mice were exposed at 12.5–13 months of age, when AD pathology is present, for 2 weeks (4 hours/day, 4 days/week) to filtered air or HUCAPS (number concentration 1.22E+5/cm³, count median diameter 79 nm, geometric standard deviation 1.5). Following exposure, behavioral testing was performed to assess spatial learning and memory, recognition memory, locomotor and olfactory function, and motivation. Radial arm maze testing showed that 3xTgAD mice had diminished spatial learning and working memory as compared to non-transgenic (NTg) mice; no dependence on exposure was found. No effects were observed with reference memory, recognition memory, or locomotor activity. 3xTgAD mice also showed diminished olfactory discrimination compared to NTg mice. Progressive ratio testing of motivation showed a significant interaction between genotype and treatment such that motivation was diminished in 3xTgAD mice with HUCAPS exposure but enhanced in NTg mice. While there was a significant effect of HUCAPS-exposure on motivation, our overall results show that the predominating effect observed at this age - when pathology is present - is AD-related and detectable in multiple behavioral domains (spatial learning, working memory, olfactory discrimination). The inability to detect HUCAPS related effects in other behavioral paradigms indicates that HUCAPS doesn’t alter the cognitive trajectory of AD progression in this mouse model. 1130 The Effects of Ultrafine Particulates from Air Pollution on the Progression of Amyloid Pathology in Alzheimer’s Disease

Currently, 44 million people are affected by Alzheimer’s Disease (AD) worldwide and the number continues to rise. While a small percentage of cases can be accounted for by specific gene mutations, the majority are thought to arise from gene-environment interactions. Exposure to air pollution has been identified as a possible environmental factor contributing to the disease. We hypothesize that exposure to ultrafine particulates (UFP, <100nm) from air pollution enhances the progression of amyloid pathology and the formation of amyloid-β plaques, an important indicator of disease. Two cohorts of 3xTgAD mice, a model for AD, and non-transgenic mice were exposed to concentrated ambient UFP (Harvard Ultrafine Concentrated Ambient Particle System, HUCAPS). Each cohort was exposed for 4 hours a day, 4 days per week for 2 weeks at 12 months of age. The mean particle concentration ranged from 3.39x10⁵/cm³ to 9.01x10⁵/cm³ and the count median diameter from 81±12 nm to 84±4 nm (Geometric Standard Deviation 1.45-1.53). One cohort of mice was sacrificed immediately after exposure, while the other recovered for 2 months. One half of each cohort was used to harvest brain tissue via microdissection, while the other half was perfused and dedicated to immunofluorescence analysis. The sectioned brains were stained with 6E10, which detects mature amyloid-β and precursors like amyloid precursor protein (APP). There was no indication of lung inflammation based on bronchoalveolar lavage fluid cellular and biochemical analyses. No significant changes in 6E10 hippocampal staining were found between 3xTgAD mice exposed to concentrated UFP and the control 3xTgAD mice exposed to filtered air in either cohort. When insoluble amyloid-β42 protein was measured in the microdissected hippocampi, the 3xTgAD HUCAPS mice trended towards increased levels (p=0.053) in comparison to the 3xTgAD filtered air mice within the immediate cohort. This trend was not sustained in mice that were allowed to recover for 2 months. These findings suggest that short-term, near-ambient exposures to concentrated UFPs do not directly alter amyloid pathology once plaques have already formed. 1131 Traffic-Generated Air Pollution Exposure Mediates Adipocyte Hypertrophy Associated with Increased Angiotensin II Signaling in C57Bl/6 Wildtype Mice

J. Lucero¹, J. D. McDonald², and A. K. Lund³. 'University of North Texas, Denton, TX; and Lovelace Biomedical Research Institute, Albuquerque, NM.

Recent studies have reported a positive correlation between exposure to environmental air pollution and metabolic syndrome and/or obesity in both children and adults. Additionally, at least a few of these studies have reported traffic-generated pollutants are associated with increased incidence of obesity, associated with cardiovascular disease (CVD). To date, very limited information exists on the effects of inhaled pollutants on adipocytes. The renin-angiotensin system (RAS), when dysregulated, is known to mediate pathogenesis in the cardiovascular system, and in adipocytes, through Angiotensin (Ang) II signaling via the Ang II Type 1 (AT1) or Type 2 (AT2) receptor(s). We have previously reported that inhalation exposure to mixed vehicle emissions (MVE) results in increased plasma Ang II and adipocyte AT-1 expression in C57Bl/6 wildtype mice. Thus, we hypothesize that MVE-exposure results in altered RAS signaling in adipocytes, associated with adipocyte hypertrophy and/or altered adipocyte signaling. To test this hypothesis, 3 mo old male C57Bl/6 mice on either a high-fat “Western” diet (HF, 21% fat) or standard (LF, low fat) mouse chow were randomly assigned to inhalation exposure of either filtered air (FA) or a mixture of 70 µg PM/m³ diesel exhaust + 30µg PM/m³ gasoline exhaust (MVE n=10 per diet) for 6 hr/day for 30 days. MVE exposure resulted in adipocyte hypertrophy, which was associated with increased expression of angiotensinogen (AGT), and the AT1 receptor in adipocytes in MVE-exposed mice compared to FA controls, as determined by immunofluorescence (IF) and immunoblotting. These outcomes were further exacerbated in MVE+HF diet animals, compared to MVE+LF or FA controls. Furthermore, MVE-exposure resulted in increased adipocyte expression of the inflammatory marker, TNF-α, and monocyte/macrophage infiltration (MOMA-2), and a decrease in expression of glucose transporter (GLUT)-4, compared to FA controls. These findings indicate that inhalation exposure to traffic-generated pollutants can promote induction of adipocyte Ang II signaling, macrophage recruitment, and inflammation that are associated with decreased GLUT-4 receptor expression (and possibly impaired glucose uptake), which are further exacerbated by concurrent consumption of a high fat diet. Funded by NIH R01ES020795 to AKL.

1132 DEP-Induced Airway Epithelial Barrier Dysfunction Involves a Reduction in the Tight Junction Protein Tricellulin

Perturbations in the epithelial barrier have been increasingly linked to the pathogenesis of asthma. While airborne particulate matter (PM) has been linked to asthma development and exacerbation, its impact on the function of the epithelial barrier has not been fully assessed. Of particular interest is Tricellulin, a tight junction protein in the same family of Occludin, which localizes specifically to points of tricellular contact and is hypothesized to regulate the permeability of macromolecules across the epithelium at these points. In order to test the impact of diesel exhaust particles (DEP), a major component of PM, on epithelial barrier function and Tricellulin expression, Standard Reference Material (SRM®) 2975 Diesel Particle Matter (DEP) (National Institute for Standards and Technology, Gaithersburg, MD) was suspended in culture media and exposed to nonmonolayers of the human bronchial epithelial cell line 16HBE140. Six-hour treatment with DEP significantly reduced 16HBE barrier function as determined by increased permeability of four ka Da FITC-Dextran (28.2±4.0 versus 19.6±4.34 µg, n=4, p<0.05) and decreased transepithelial electrical resistance (523±6 versus 602±5 Ohms, n=4, p<0.05). This corresponded with a decrease in Tricellulin as measured by Western blot (61±17% normalized band intensity versus vehicle, n=3, p<0.05) without reducing Occludin. To test the impact of DEP on developing lungs, neonatal Balb/c mice (postnatal day 5-7) were exposed to 25±50 µg/m³ aerosolized DEP or filtered air by whole body inhalation for two hours per day for five consecutive days, and sacrificed 2 weeks later. Following these whole-body inhalation exposures, Tricellulin expression was significantly reduced in the lungs as measured by Western blot (65±20% normalized band intensity ver-
sus filtered air, n=7, p<0.05). Taken together, in vitro exposure to DEP caused a significant reduction in epithelial barrier function with a corresponding reduction in Tricellulin expression. A similar reduction was seen in whole lungs of neonatal mice two weeks following exposure to aerosolized DEP. Overall, these results suggest that early life exposure to DEP may have lasting impacts on epithelial barrier structure and function.

1135 Marco Regulates In Vivo Response to Low Molecular Weight Hyaluronan Fragments

A. Birukova, T. Espenschied, and R. M. Tighe. Duke University, Durham, NC.

Ozone is criterion air pollutant, which enhances cardiorespiratory morbidity and mortality and exacerbates pre-existing respiratory diseases. Prior work demonstrates that macrophage scavenger receptor (Marco) is critical for the clearance of O3-derived oxidized lipid species. We hypothesize that Marco also regulates biological response to O3-derived low molecular weight hyaluronan (sHA) fragments. We challenged 8-10 weeks old CS7BL6 (WT) and Marco-/- mice with 2ppm O3 or filter air for 3 hours. 24h after exposure mice underwent BAL for total cell count, differentials and hyaluronan measurement. We observed significantly increased level of BAL hyaluronan in O3-exposed Marco-/- mice. Moreover, at 6h following oropharyngeal instillation of sHA (1.5mg/ml) versus saline in Marco-/- or CS7BL6 mice, we observed that Marco-/- mice had increased cell count and neutrophil influx with increased BAL cytokines (IL6, TNF alpha, MCP1 and KC) in comparison to WT. Alveolar macrophages harvested from sHA instilled WT mice significantly increased their Marco expression. Moreover, in time course experiments with alveolar macrophages harvested from naive WT and Marco-/- mice using Rhodamine labeled sHA, we observed enhanced sHA binding in WT vs Marco-/- after 2h of treatment by confocal microscopy. In these same experiments, we observed a positive correlation between level of binding sHA and Marco receptor expression at the cell surface. Finally, we evaluated baseline levels of TR4 and CD14 expression in Marco-/- and WT mice by RTPCR and observed increased RNA for TR4 and CD14 in the Marco-/- alveolar macrophages. In summary, our data suggest a central role for Marco receptor in biological response to low molecular weight hyaluronan. Deletion of this scavenger receptor lead to accumulation of hyaluronan in respiratory system. In vivo stimulation with sHA caused increase expression of Marco receptor in WT and more exacerbated inflammation with increased level of cytokines and neutrophil influx in Marco-/- mice. Lack of Marco receptor causes less binding of sHA and balance baseline expression of TLR group proteins, which suggests a potential mechanism for this response.

1136 Comparison of Precision Cut Lung Slices and Whole Lungs in Particle-Induced Inflammation

Y. Kim, and M. Gilmour. US EPA, Durham, NC.

Precision cut lung slices (PCLS) have been widely used as a 3D organotypic lung tissue model to provide physiologically relevant responses to whole animal exposures while requiring few animals. We previously assessed lung toxicity of airborne particles in both PCLS and mice and sought here to determine whether the responses observed were linear between the two systems. The particles were categorized into three types: indoor airborne particles from an electronic recycling plant (mechanical process emissions; inorganic-rich particles; IRP), outdoor airborne particles (wildfire smoke; organic-rich particles; ORP), and engineered nanoparticles (SiO$_2$, CeO$_2$, and TiO$_2$; poorly soluble particles; PSP). PCLS were exposed to 22 µg/mL of IRP or ORP and 132 µg/mL of PSP under submerged conditions and assessed for lung toxicity at 24 h post-exposure. Mice were exposed to 100 µg of all the particle samples by oropharyngeal aspiration and assessed for lung toxicity at 4 and 24 h post-exposure. The relationship of proinflammatory cytokine levels (TNF-α, MIP-2, and IL-6) between PCLS and in vivo bronchoalveolar lavage fluid of mouse lungs was then examined. We found that ORP exposures show a strong correlation for all cytokines between the two models (TNF-α: r$^2$ = 0.9997, MIP-2: r$^2$ = 0.9953, and IL-6: r$^2$ = 0.9790), followed by IRP exposures (TNF-α: r$^2$ = 0.9957, MIP-2: r$^2$ = 0.7150, and IL-6: r$^2$ = 0.9390). PSP exposures however only showed a strong correlation for IL-6 (r$^2$ = 0.7948) between PCLS and whole lungs models (TNF-α: r$^2$ = 0.0075 and MIP-2: r$^2$ = 0.0605). These results suggest that inflammatory responses between PCLS and whole lung models are highly associated with concentrations of organic matter (ORP > IRP > PSP) and water-soluble materials (ORP > IRP > PSP) in the particular samples. In addition, IL-6 appears to be a more sensitive biomarker in PCLS than other cytokines. Overall our findings demonstrate good concordance in proinflammatory responses between PCLS and whole lung studies following exposures to different types of airborne particles. Notably, PCLS may better predict in vivo responses to chemicals (e.g., water-soluble organic matter) released from particles. This information can be used to understand the uses and limitations of PCLS as a screening tool for the lung toxicity of airborne particles. This abstract does not represent US EPA policy.
Extensive evidence indicates that exposure to ambient air fine particulate matter (PM) is associated with an increased risk of developing cardiovascular disease (CVD). Our previous studies have shown that PM exposure decreases circulating endothelial progenitor cell (EPC) levels in humans. In mice, exposure to concentrated PM (CAP) induces the depletion of circulating EPCs, decreases the function of ex vivo expanded bone marrow derived EPCs, and impairs EPC-mediated revascularization after hind limb ischemia. However, it is unclear whether PM exposure similarly affects cardiovascular processes in vivo. Hence, we tested whether exposure to CAP impairs angiogenesis by using matrigel implants. For this, male C57BL/6J mice were exposed to HEPA-filtered air or CAP for 4 days prior and 9 days after the matrigel implantation (500 μL containing 20 ng/mL VEGF, subcutaneous at the left dorsal posterior flank). CAP exposure decreased hemoglobin levels in the matrigel implants and the number of circulating EPCs (Fk-1+/Sca-1− cells). While CAP exposure decreased plasma nitrite levels, levels of plasma stem cell factor (SCF) or vascular endothelial growth factor (VEGF) were unchanged in plasma of CAP-exposed mice. Using the fluorescence reporter monochlorobimane (MCE), we observed increased permeability, suggesting that they result from the release of epithelial/fibroblasts (TEER) and small molecule (20kDa fluorescein isothiocyanate (FITC)-dextran) transporters. Upon DEP exposure, we identified a variety of oxidative stress responses in H441 cell monolayers of H441 cells, grown on the apical surface of Transwell permeable membranes, to the ubiquitous air pollutant, diesel exhaust particulates (DEP), with human lung fibroblasts on the underside of the Transwell membrane and human microvascular lung endothelial cells (HLEC) in the basal compartment. Upon DEP exposure, we identified a variety of oxidative stress responsive genes induced in the directly exposed H441 cells and in the indirectly exposed HLEC, including heme oxygenase 1 (HMOX1) and NADPH dehydrogenase (quinoxaline) 1 (NQO1). These changes in gene expression occurred despite a lack of change in trans-epithelial electrical resistance (TEER) and small molecule (20kDa fluorescein isothiocyanate (FITC)-dextran) permeability, suggesting that they result from the release of epithelial/fibroblast-derived mediators and/or compounds/metabolites that traverse the epithelial cells. Collectively, these data suggest that induction of oxidative stress in nearby endothelial cells may be mediated by epithelial cells, and may be an important mechanism of API-CVD. We conclude that we have developed a relevant, in vivo model of the AEB-cardiovascular system interface which can be used to identify the elusive molecular mechanisms driving API-CVD. Ultimately, data derived from this model can be used to identify therapeutic targets, biomarkers of both susceptibility and exposure effects, and can encourage the continued development of similar biomimetic models resulting in a reduction of non-essential animal testing.
1141 Pulmonary Fibroblasts Influence Epithelial Cells Response to Air Pollution

1University of Puerto Rico at Cayey, Barraquitas, Puerto Rico; 2University of North Carolina at Chapel Hill, Chapel Hill, NC; and 3US EPA/NHEERL, Research Triangle Park, NC.

The World Health Organization estimates that 8 million people die from air pollution every year. In addition to reducing the air pollution abundance and limiting the bad effects it is necessary to understand how inhaled chemicals affect tissues. Part of developing this understanding involves characterizing the relationship between air pollutants and their adverse effects, such as inflammation and oxidative stress, at the cellular level. While nearly every study to date has examined airway epithelial cells, the normal function of these cells is influenced by their interactions with other airway cell types as is referred to as the “airway epithelial microenvironment”. As a result, we hypothesize that fibroblast (IMR90) play a role in regulating the response of airway epithelial cells to air pollution exposures. We have developed an in vitro coculture model that allows us to determine whether the presence of airway fibroblasts, a key cell type in the airway microenvironment, alters the way that epithelial cells respond to air pollution exposure. 

1142 Cytotoxicity of Low Doses of Ultrafine Diesel Exhaust Particles in Endothelial and Microglial Cell Monocultures and Mixed Co-Culture

E. Aquino, A. Dabi, and E. Bruce. Baylor University, Waco, TX.

Diesel exhaust particles (DEPs) are a recognized risk factor for several health conditions including neurodegenerative diseases. However, information regarding the toxicity of low doses of ultrafine DEPs in the brain is limited. While in vitro studies of cerebral capillary endothelial cell monocultures provide insight into the cellular mechanisms by which particulate matter (PM) cause toxicity, they do not account for the effects of cell-cell interactions on PM toxicity. The goals of this study were to evaluate the cytotoxicity of low doses of ultrafine (UF) DEPs and to investigate if cell-cell interactions mitigate or aggravate the effects of UF DEP exposure using rat brain microvascular endothelial cells (BMVECs) as a simple blood-brain barrier model and microglia as the model immune cells of the brain. Lactate dehydrogenase assay was used to determine cytotoxicity of endothelial and microglial monocultures, and in mixed co-culture exposed to UF DEPs for 24 hours. Results indicated that low doses of UF DEPs significantly decreased cell viability in a dose-dependent manner in the monocultures, but not in the mixed co-culture. Additionally, cell-cell interactions in the co-culture appear to have a protective effect compared to the microglial monoculture but not the endothelial monoculture. This study shows that exposure to low doses of UF DEPs can disrupt the function of BMVECs and microglia, and that cell-cell interactions can have the potential to mitigate cytotoxic effects from environmental toxins. Future studies involve repeating this experiment using a complete in vitro neurovascular unit model to further investigate the effect of cell-cell interactions on cytotoxicity of UF DEPs.

1143 Bronchial Epithelial Cells Exposure to Airborne Particulate Matter Results in the Expression of CIITA and an Increase of Bronchial Asthma Inflammatory Mediators

Inhalation of airborne particulate matter (PM) is associated with an increased risk of bronchial asthma in our population. PM composition includes low-toxicity minerals derived from natural and anthropogenic sources, and inorganic salts. Toxic metal levels are enriched in PM from polluted urban and industrial areas. Its organic constituents include polycyclic aromatic hydrocarbons (PAHs) which are considered to be widespread environmental contaminants and known for their carcinogenicity and mutagenicity. PM constituents are known to generate reactive oxidative species and thus alter gene expression. Furthermore, exposure to PM can induce respiratory and cardiovascular adverse effects by altering the available frequency, exposure and reactivity of lung antioxidant systems (ROS). Oxidative Stress in lung tissue caused by PM associated compounds correlates with an increase in asthma, airway fibrosis and COPD in urban populations. The exact mechanism describing bronchial epithelium (BE) exposure to PM and its contribution to inflammation remains unknown. Here we provide evidence of mRNA expression of the Major Histocompatibility Complex (MHC) class II and its major regulator, CIITA, in bronchial epithelial cells after exposure to organic PM extracts. Even though epithelial cells are non-professional antigen presenting cells (APC), bronchial epithelial cells express these pro-inflammatory mediators. Furthermore, induction of CIITA in BE results in an increased mRNA expression of pro-inflammatory mediators IL-6 and IL-8, characteristic of bronchial asthma. Our data thus provides evidence for an alternate inflammatory pathway upon exposure to airborne particulate matter in bronchial epithelial tissue.

1144 Afghanistan Particulate Matter Increases Mouse Airway Hyperresponsiveness Partially through IL-33 Signaling

An increasing number of soldiers returning from tours of duty in Afghanistan have reported asthma symptoms and other respiratory illnesses, possibly caused by inhaled nanoparticles from particulate matter (PM). However, it remains uncertain whether Afghanistan PM (APM) increases airway hyperresponsiveness (AHR), a key feature of airway diseases such as asthma. The IL-33 pathway, including its receptor ST2, has been implicated in the pathogenesis of lung diseases, but its role in PM-mediated airway dysfunction is uncertain. The goal of this work is to determine whether APM promotes AHR and inflammation in mice, and if the IL-33/ST2 axis is involved. Wild-type (WT) BALB/c and ST2 knockout (KO) mice (on a BALB/c background) were instilled with either a single dose of APM (1.25 or 2.5 mg/kg body weight) and euthanized 24 hours post-exposure. AHR was measured on live, anesthetized mice using the Flexivent animal physiology apparatus. Bronchoalveolar lavage fluid (BALF) and lung tissue were collected for analysis of inflammatory cells, cytokines, and gene expression. APM significantly increased AHR in WT mice, but not ST2 KO mice. Interestingly, both strains demonstrated significant increases in neutrophilic inflammation: 12-fold increase in WT mice and 3-fold in KO mice (p<0.0001 for all control vs. APM combinations). KC protein levels, a neutrophil chemoattractant, were significantly increased in BALF of WT and KO mice after the high dose of APM (p=0.01 and p=0.03, respectively). In WT mice, the high dose of APM significantly increased IL-33 mRNA expression in lung tissue (p=0.02), but not IL-33 protein in BALF. APM did not increase IL-33 protein levels in KO mice. APM increased inflammation in both WT and KO mice, but without ST2, there is no significant induction of AHR following APM exposure. The ST2/IL-33 axis may be essential for neutrophilic inflammation-mediated downstream events involved in AHR. Alternatively, AHR in the APM exposure model may be related to ST2-mediated tissue injury and repair processes, including mucus production or epithelial permeability.

1145 OH Formation from Fulvic Acid-Fe(II) Complexes in Human Lung Fluids

D. A. Diaz1, D. H. Gonzalez2, and S. Paulson2. 1California State University, Granada Hills, CA; and 2University of California Los Angeles, Los Angeles, CA.

Epidemiological studies show strong correlations between fine particulate matter (PM2.5) inhalation and increased mortality, cardiovascular and respiratory health effects. However, the biological mechanisms and PM2.5 components contributing to these health effects are poorly understood. A hypothesized mechanism contributing to these health effects is PM2.5 deposits in the lungs creating reactive oxygen species (ROS) and inducing oxidative stress. Out of all ROS we measure hydroxyl radicals (OH) due to its ability to oxidize lipids, proteins and DNA. Fe in the presence of lung antioxidants produces ROS, however the impact of Fe chelating lung fluid proteins (albumin and transferrin) on this ROS chemistry is poorly understood. It is accepted that albumin and transferrin can reduce ROS formation; however no studies measure OH formation from Fe(III)-albumin or Fe(III)-transferrin. Humic-like substances (HULIS) found in PM2.5 from biomass burning and cigarette smoke are capable of chelating with Fe(III). However the impacts of ROS formation in the presence of lung antioxidants is not fully understood. This study uses
Airborne fine particulate matter (PM2.5) derived from livestock farming is a unique mixture of dusts, biogenic materials and anthropogenic emissions. Susceptible individuals working in or living near high density animal operations may be at risk for adverse health effects associated with inhalation exposure to the ambient pollutants associated with these airsheds. To compare the potency of livestock farm-derived PM to exacerbate allergic airway responses in laboratory rodents, we collected PM2.5 from two chicken farms, two pig farms and two goat farms in the Netherlands. Female BALB/c mice (6-8 weeks old) were sensitized and boosted with ovalbumin (OVA; days 0, 10, respectively), and then challenged with intranasal saline or OVA for 2 consecutive days. OVA challenge was performed prior to a single intranasal exposure to OVA, 0.9 or 3 µg of farm-derived PM2.5. Twenty-four hours later mice were euthanized and bronchoalveolar lavage fluid (BALF) was collected for differential cell analysis and lung tissues were processed for light microscopy. All PM samples elicited significant, dose-dependent increases in BALF neutrophils in saline-challenged mice, with pig farm induced 2- to 6-fold greater inflammatory responses than other sources (rank potency goat PM >> pig PM > chicken PM). OVA sensitization and challenge induced allergic airway inflammation, as indicated by significant accumulation of inflammatory cells in BALF, mucous cell metaplasia in conducting airways, and alveolitis and bronchiolitis. In OVA-challenged mice, PM from both chicken and goat farms induced inflammation more potently than other sources (rank potency chicken PM >> pig PM > goat PM) compared to OVA challenged mice treated with saline. Both doses with 0.9 or 3 µg goat PM were equally potent. By comparison, treatment of OVA-challenged mice with PM from either of the chicken farms failed to alter the BALF inflammatory cell accumulations elicited by OVA. Lastly, PM from one of the pig farms produced a similar magnitude of airway responses as that elicited by the goat farm PM, whereas PM from the remaining pig farm induced non-significant changes similar to that induced by chicken farm PM. Our results suggest that the exacerbation of allergic airway inflammatory responses by livestock farm PM is dependent on the source of PM, and that physicochemical characterization of PM is needed to identify the specific components that might be responsible for the enhancement of allergic inflammation.

**Oxidative and Inflammatory Potential of PM2.5 from the San Joaquin Valley: Seasonal Trends and Molecular Marker Associations**

D. S. Antkiewicz1, A. Al Hanao1, A. Lai1, M. Olson1, M. Bae2, J. Hemming2, M. Shafer2, and J. Schauer3

1. University of Wisconsin-Madison, Madison, WI; and 2. Mokpo National University, Muan, Korea, Republic of.

Adverse health effects of ambient air particulate matter (PM) include respiratory and cardiovascular diseases, as well as cancer; contributing to an estimated 3.2 million premature deaths each year. Oxidative stress due to excess reactive oxygen species (ROS) production and inflammatory processes are hypothesized to be the main mechanisms underlying the adverse health effects associated with PM exposures. This study evaluated oxidative and inflammatory potential of the monthly PM2.5 compositions from a year-long sampling campaign conducted at two distinct locations in California’s San Joaquin Valley: Fresno and Bakersfield. The oxidative potential of the full dataset of PM2.5 samples was assessed using a broad-spectrum ROS probe (DCFH-DA), while the inflammatory potential was assessed via cytokine induction (TNFa by ELISA), both using an in vitro alveolar macrophage model. Furthermore, a subset of 0.9 µg PM composite samples from both sites was examined by RT-PCR for 28 different markers of inflammatory and oxidative signaling on the mRNA level. Relationships between PM-induced ROS and TNFa protein production, as well as PM chemical composition was examined using Pearson correlation. The chemical analysis of PM2.5 included organic carbon (OC), elemental carbon (EC), water soluble organic carbon (WSOC) and a large suite of organic molecular markers. A strong seasonal pattern was observed in both oxidative potential as well as cytokine production outcomes, with the latter having a more pronounced pattern at both sampling locations that correlated with PM chemical composition. Interestingly, no correlation has been found between the two measures of PM-induced toxicity suggesting that different chemical components drive each of these measures in the alveolar macrophage model. In addition, the mRNA cell signaling marker analysis revealed a distinct gene expression profile at each sampling site, with Fresno showing higher upregulation of the anti-inflammatory response markers.
in the NOR task 2 weeks before exposure ended and the OIP task on the last week of exposure. Mice were sacrificed for tissue harvesting the following week. Brain tissue was processed using standard techniques for immunofluorescent section staining, protein probing, and RNA analysis. UF PM exposed mice had decreased performance in both the NOR and OIP tasks compared to mice exposed to filtered air. Levels of amyloid deposition as measured by plaque burden were not affected, nor were amyloid peptide levels or APP gene expression. Conclusion: Behavior task results indicate that PM exposure can exacerbate memory impairment in AD model mice. However, this impairment does not appear to coincide with changes in amyloid pathology. These results suggest that alternative pathways leading to cognitive impairment, such as CNS inflammation state, are responsible for the decreased performance observed in this rodent model when exposed to ultra-fine particulate matter.

1150 Organosulfates Identified in Traffic-Related Air Pollution Are Neurotoxic in Primary Rat Hippocampal and Cortical Neuron-Glia Co-Cultures

R.K. Morgan1, D.R. Cart1, H. Lehmler1, E.A. Stone2, and P.J. Lein1
1University of California Davis, Davis, CA; and 2University of Iowa, Iowa City, IA

There is increasing evidence that traffic-related air pollution (TRAP) is an environmental risk factor for adverse neurodevelopmental outcomes, including neurodevelopmental disorders such as autism. Fine particulate matter (PM2.5) may especially contribute to neurologic disease. As defined by the United States Environmental Protection Agency, PM2.5 is comprised of several constituents including organic chemicals, metals, pollen and acids. Among the acidic atmospheric aerosols are organosulfates, which are estimated to comprise a significant fraction of PM2.5 mass. Organosulfates are abundant in TRAP in both rural and urban locations, but whether these compounds contribute to the neurotoxic effects of TRAP has not been addressed. The objective of this study was to screen organosulfates identified in PM2.5 for neurotoxicity in primary neuron-glia co-cultures dissociated from the hippocampus and neocortex of postnatal rats. Phenyl sulfate (PS), benzyl sulfate (BS), biphenyl 4-sulfate (9S), 3,4-nitrophenyl sulfate (4NS), 3-methylphosphoryl sulfate (3MS), glycolic acid sulfate (GAS) and hydroxyacetone sulfate (HS) were tested at concentrations ranging from 10 pM to 10 µM for effects on: (1) cell viability as measured by LDH release and uptake of calcein AM and propidium iodide; (2) neuronal morphogenesis determined by morphometric analyses of axonal outgrowth and dendritic arborization; (3) apoptosis measured by caspase-3 and -7 activities; and (4) mitochondrial function as measured by MTT. While none of the organosulfates altered cell viability, several were found to have biological activity that varied between hippocampal and cortical cultures. Significant increases in dendritic arborization were observed in cortical neurons exposed to 1 nM PS, 10 pM BS, or 10 µM HS; whereas, in hippocampal neurons, 100 nM HS, 1 nM GAS and 100 nM GS increased, but 100 nM 4NS decreased dendritic arborization. Apoptosis was decreased in hippocampal cell cultures by GAS at all concentrations, and in both hippocampal and cortical cell cultures by 10 µM BS. Overall, this study suggests that organosulfates may contribute to the neurotoxicity associated with TRAP exposures. Supported by NIH (P30 ES023513-03S1).

1153 Wastewater Reuse, Exposure Risk, and Fish Endocrine Disruption in the Shenandoah River Watershed

A.M. Vajda1, L. Barber1, J.L. Rapp2, C. Kandel3, S. Keeve4, J. Rice5, P. Westerhoff2, and D. Bertolatus1
1University of Colorado Denver, Denver, CO; 2US Geological Survey, Boulder, CO; 3US Geological Survey, Richmond, VA; 4University of North Carolina at Charlotte, Charlotte, NC; and 5Arizona State University, Tempe, AZ. Sponsor: A. Vajda, Society of Environmental Toxicology and Chemistry

Reuse of municipal wastewater treatment plant (WWTP) effluent is an important component in augmenting global freshwater supplies. One of the challenges associated with reuse of municipal wastewater is the presence of biologically active contaminants, such as endocrine-disrupting compounds (EDCs), which not only influence human consumption of re-used wastewater but also impact ecosystems which provide hydrologic connectivity between WWTP discharge locations and intakes for drinking water treatment plants. Risk assessment for potential endocrine disruption requires a landscape-based approach that allows investigations from river reach to continental scales. Widespread fish endocrine disruption, in the form of intersex and elevated plasma vitellogenin in male smallmouth bass, has been reported in the Shenandoah River Watershed (SRW). Detailed studies were conducted on the relationship between EDC exposure pathways and biological endocrine disruption effects incorporating wastewater reuse modeling, field sampling of water chemistry, and on-site fish exposure experiments. The amount of WWTP effluent in each river reach (calculated wastewater treatment plant discharge ratio - ACCWRatio) was determined and used to predict environmental concentrations for select WWTP derived EDCs, including the steroidal estrogens estrone, 17β-estradiol, estriol, and 17α-ethynylestradiol. Mobile laboratory fish exposure and water characterization experiments were conducted at 9 locations to assess different source waters for the presence of EDCs and fish endocrine disruption using vitellogenin induction in male fathead minnows as the biomarker. Although the various source waters had complex mixtures of chemicals, the measured and predicted environmental concentrations of select steroidal estrogens resulted in 17ß-estradiol equivalency quotients ranging from <0.5 to 5 ng L⁻¹, indicating low-to-moderate risk of fish endo-

1152 Wildlife Toxicity Assessment for 3-Nitro-1,2,4-Triazol-5-One (NTO)

3-Nitro-1,2,4-triazole-5-one (NTO) is a triazole and is comparatively less sensitive to toxic component that is used in many conventional formulations. NTO was developed recently as a potential replacement for energetic military munitions. The explosive nature of NTO was reported in 1985 and is now a key formulation component in the "insensitive munition explosive" (or IMX) series. When fielded, NTO use could be released to the environment and be found in soil, water and sediments at manufacturing facilities or training operations. We have reviewed acute and sub-chronic toxicity data of NTO in mammalian, avian, reptilian and amphibian species. Despite limited wildlife exposure data in animal studies, we have attempted to derive No Oberved Adverse Effect Level (NOAEL) and Low Observed Adverse Effect Level (LOAEL)-based Toxicity Reference Levels (TRVs) from dose-response end-points from target organ-specific studies. US Army Public Health Center Technical Guide 254 - Standard Practice for Wildlife Toxicity Reference Values (TRVs), guided our development of class-specific TRVs. Recently developed data is available for mammals and birds. By contrast, amphibian data are limited, and data relevant to reptiles are absent altogether. Tentative TRVs were derived from an oral sub-chronic study conducted in rats, and Benchmark Dose (BMD) values were derived from mammalian studies on exposure to NTO by ingestion. A BMD (ED10) of 70 mg/kg-day, and a lower-bound BMDL10 (LED10) value of 44 mg/kg-day was determined for the class Mammalia. For avian species, an ED10 for male quail was estimated at 62 mg/kg-day, based on brain lesions with a corresponding LED10 of 35 mg/kg-day. Using neuromuscular effects, an ED10 of 348 mg/kg-day was derived for male and female quail that corresponded to an LED10 of 151 mg/kg-day on oral exposure to NTO. For amphibian species, a NOAEC TRV of 334 mg/L and a LOAEC of 838 mg/L were derived following a 70-day exposure to NTO. These tentative TRVs are based on data from the most sensitive species available, and may be protective of the entire class of wildlife species with broad utility in ecological risk assessment applications.
was selected in order to assess the effects of mixtures of Oryzias latipes
1158 Effects of Low, Subchronic, Exposure of sperm from untreated adult zebrafish was incubated for 30 to 240 min with both experiments, sperm quality (after activation was observed for Erythromycin, followed by Propranolol. Sotalol was found to be affected for all mixtures, except two mixtures. The greatest main effect the scope of the particular study was to perform a chronic test with mixtures of APIs in order to evaluate some adverse effects towards an aquatic organism. The range of concentration was chosen based on the concentrations have been found in the environment mainly because they end up ubiquitously into the water cycle. Even at low concentrations, most of APIs can cause unrevealed toxicity to aquatic organisms. Usually, the behavior of APIs in a mixture may vary depending on the mixture composition, concentration and the chosen test to evaluate the results. It is well stated that even if a compound is not individually toxic, it may act in an antagonistic, additive or synergistic way with other drugs or metabolites, thus a toxic effect possibly takes place. The scope of the particular study was to perform a chronic test with mixtures of APIs in order to evaluate some adverse effects towards an aquatic organism. The range of concentration was chosen based on that populations of microorganisms are not exposed to pharmaceutically different mixtures, the immobilization percentage was found to be statistically different compared to the control. The total number of nauplii was found to be affected for all mixtures, except two mixtures. The greatest main effect was observed for Erythromycin, followed by Propranolol. Sotalol was found to have the least effect, followed by Diclofenac. The results are arguably realistic, based on that populations of microorganisms are not exposed to pharmaceutical mixtures in a fixed proportion.

2019 SOT Annual Meeting

1157 Evaluation of Skin Mucus Vitellogenin (VTG) in a Japanese Medaka Fish Sexual Development Test (OECD TG 234) with 17a-ethynylestradiol (EE2) as Contribution to 3Rs Animal Welfare Concept
V. Strauss, E. Salinas, M. Braun, S. Gröters, S. Pawlowski, and B. van Ravenzwaay, BASF SE, Ludwigshafen am Rhein, Germany.

Vitellogenin is regarded as sensitive biomarker to detect exposure to endocrine active chemicals in fish and provides mechanistic mode-of-action information. The current OECD Tgs 229, 234 and 240, recommend measuring VTG in the liver or head/tail homogenate of sacrificed fish. In the OECD TG 240 an extra cohort is used for whole body VTG measurement. VTG measurement in skin mucus of living fish is possible and may save individuals for other investigations. Implementing VTG measurement in skin mucus in an OECD TG 234 positive control study and comparison to established recommended procedures. The fish sexual development test was performed generally according to the OECD TG 234 with two replicates of 30 fertilized eggs each, in the chosen group and in the treatment group (0.1 µg/L EE2) in a flow-through system. Medaka fish (Oryzias latipes) were raised until day 60 post hatch. All recommended endpoints were measured. This poster focuses on secondary sex characteristics (stereomicroscopic investigation after modified Davidson’s fixation of the dorsal and anal fin), genotypic sex ratio (dmy gene with PCR), VTG levels in skin mucus and head/tail homogenate (ELISA) and histological evaluation of gonads, liver, and kidney in the midsection cut after fixation in Davidson’s solution. In this poster we present that the EE2 group all fish were phenotypically females as confirmed by histological investigation of the gonads. The test group and in the control group the phenotype and the genetic sex ratio in the EE2 group was not statistically different to the control. Female fish from the control and EE2 group could be differentiated from male controls by VTG levels in skin mucus as well as in head/tail homogenate. However, the coefficient of variation in each group was higher among the VTG in mucus compared to the head/tail VTG. Vitellogenin in skin mucus can be used as parameter especially for in interim measurements from living fish during the course of a study. However, the mucus sampling procedure should be further standardized to minimize variation and increase the power of this Parameter.

1156 Endocrine Disruptors Screening Analyzing Zebrafish Sperm Quality
M. J. Mazón, A. Muriana, and A. Alday. Biobide, San Sebastian, Spain.

Endocrine disruptors (EDCs) are chemicals that by interfering with the endocrine system can have an adverse effect at developmental, neurological, immune and reproductive level. The negative impact of EDCs is becoming a real public health issue, therefore the necessity of tests to assess the potential risk of new chemicals before they are marketed is increasing. The zebrafish is currently used as a model for the evaluation of acute and developmental toxicity, and also for the screening and testing of potential endocrine disruptors as described in the OECD Guidelines. However, the two major endpoints used to evaluate endocrine disrupting chemicals, vitellogenin concentration and change in sex ratio, have several limitations. With the purpose of expanding the number of tests available to identify xenobiotics with endocrine disrupting activity, we developed an assay that evaluates the reproductive performance of zebrafish (after in vivo or in vitro exposure to EDCs) by measuring sperm quality using a computer-assisted sperm analysis (CASA). For in vivo experiments, adult zebrafish (aged between 6-12 months) were exposed to heavy metals (copper or mercury), herbicide (N-[phosphonomethyl] glycine) and bisphenol A for a period ranging 2-15 days. At the end of the exposure period the testes were excised, placed in tubes with immobilization solution and the sperm was released by gently shake. For in vitro experiments, sperm from untreated adult zebrafish was incubated for 30 to 240 min with four concentrations of copper, methyl mercury, N-[phosphonomethyl] glycin and bisphenol A. In both experiments, sperm quality (after activation with system water) was evaluated using a microscope with a negative contrast objective connected to a computer-assisted sperm analysis system (CASA) system (Proiser R + D., S.L., Paterna, Spain). Parameters such as progressive motility, curvilinear velocity and linearity were evaluated and compared to DMSO treated control. The assay here proposed with these two in vitro and in vivo approaches, can discriminate between compounds with a direct cytotoxic effect (reducing sperm motility) and compounds that might generate, after long exposure, a reduction in fertility by disrupting the overall process of spermatogenesis.

1154 Daphnia magna Chronic Toxicity Testing towards Using Widely Found Pharmaceuticals in the Aquatic Environment
M. Tarapouliou1, M. I. Vasquez2, and D. Fatta-Kassinos1,2. 1University of Cyprus, Cyprus; 2Nerea-International Water Research Center, University of Cyprus, Cyprus. Sponsor: M. Ines Vasquez, Society of Environmental Toxicology and Chemistry

The rationale of the particular study was based on the fact that numerous mixtures of Active Pharmaceutical Ingredients (APIs) exist in the aquatic environment after wastewater treatment plants fail to reduce or eliminate them. APIs are considered as an enormous threat for the environment mainly because they end up ubiquitously into the water cycle. Even at low concentrations, most of APIs can cause unrevealed toxicity to aquatic organisms. Usually, the behavior of APIs in a mixture may vary depending on the mixture composition, concentration and the chosen test to evaluate the results. It is well stated that even if a compound is not individually toxic, it may act in an antagonistic, additive or synergistic way with other drugs or metabolites, thus a toxic effect possibly takes place. The scope of the particular study was to perform a chronic test with mixtures of APIs in order to evaluate some adverse effects towards an aquatic organism. The range of concentration was chosen based on that populations of microorganisms are not exposed to pharmaceutically different mixtures, the immobilization percentage was found to be statistically different compared to the control. The total number of nauplii was found to be affected for all mixtures, except two mixtures. The greatest main effect was observed for Erythromycin, followed by Propranolol. Sotalol was found to be affected for all mixtures, except two mixtures. The greatest main effect was observed for Erythromycin, followed by Propranolol. Sotalol was found to have the least effect, followed by Diclofenac. The results are arguably realistic, based on that populations of microorganisms are not exposed to pharmaceutical mixtures in a fixed proportion.

1158 Effects of Low, Subchronic, Exposure of Commercial 2,4-D Formulation on Early Life Stages of Native Wisconsin Game Fish Species
G. K. Dehnert1, M. Freitas2, T. Barry1, and W. Karasov1. 1University of Wisconsin-Madison, Madison, WI; and 2University of Viçosa, Viçosa, Brazil. Sponsor: G. Dehnert, Society of Environmental Toxicology and Chemistry

Aquatic herbicides are used worldwide to eradicate nuisance and invasive plants despite limited knowledge of their toxicity to non-target organisms. 2,4-Dichlorophenoxyacetic acid (2,4-D) is a common active ingredient in commercial herbicide formulations, which triggers plant cell death by mimicking the plant specific hormone auxin. Application practices with 2,4-D commercial herbicides typically coincide with yearly freshwater fish spawning periods, exposing fish to xenobiotics at their vulnerable larval stages. However, the physiological impacts of 2,4-D on larval fish remain poorly understood, and hence, whether it may alter larval performance, fish populations, and ecosystem dynamics. We conducted a series of experiments to determine the effects of low concentrations (0.05, 0.50 and 2.00 ppm 2,4-D) of commercial amine salt herbicide formulation DMA®4IVM on the development and survival of nine freshwater fish species at various life stages. We observed reduced survival in embryo assays for 4 out of 9 species tested, reduced survival in 30-day larval assay for 4 out of 6 species tested, and no reduced survival in a 90-day juvenile assay in the 2 species tested. Altogether, the results indicate that the use of 2,4-D herbicide DMA®4IVM for weed control in aquatic ecosystems at current recommended concentrations (< 2 ppm whole lake; ≤ 4 ppm spot treatment) could reduce fitness and survival of freshwater game fish species.

**1159 Examination of the Avian Acute Oral versus Sub-Acute Dietary Testing in Ecological Risk Assessment**

The United States Environmental Protection Agency (US EPA), as well as other international regulatory agencies, require pesticide registrants to submit toxicity data that are used to conduct ecological risk assessments. While the US EPA has required both an acute oral and sub-acute dietary tests in birds, trends over the past 20 years have suggested that the avian sub-acute dietary test generally does not drive ecological risk assessment conclusions. To address this question, a retrospective analysis was conducted to evaluate 119 pesticides with publicly available ecological risk assessments that were registered into commerce between 1998 and 2017. New pesticides (i.e., registered in the US within the past 20 years) were chosen for the retrospective analysis to show utility of these tests for modern pesticide chemistries. Risk quotient (RQ) values (a point estimate of exposure divided by a deterministic toxicity endpoint) from the avian acute oral and dietary tests, as well as risk assessment conclusions, were compared to determine which test(s) drove the risk assessment findings. The RQ values were chosen as the data point for comparison in order to assess total risk (i.e., exposure and toxicity). After comparing RQ values from avian acute oral versus sub-acute dietary tests, there was only one case in which an avian sub-acute dietary RQ was greater than the acute oral RQ. In all other cases (greater than 99%), risks were not identified based on the results of both studies or the acute oral RQ was higher than the sub-acute dietary RQ. Based on the results of the retrospective analysis, it is concluded that in most cases avian risk can confidently be assessed without conducting the sub-acute dietary test.

**1160 Comparative Analysis of Potential Endocrine Effects of Triclosan in Three Model Fish Species and Xenopus laevis**

Triclosan (TS), a widely used antibacterial compound, was investigated for potential to interact with the endocrine system using US EPA and OECD test guidelines. A modified fish short-term reproduction assay (FSTRA) used three model fish species (Fathead Minnow (FM), Japanese Medaka (JM), and Zebrafish (ZF)), and the larval amphibian growth and development assay (LAGDA) used the amphibian model species, Xenopus laevis. All assays tested four concentrations along with a negative control. The FSTRA is used to identify compounds that may have potential to interfere with the normal structure and function of the hypothalamic-pituitary- gonadal axis. Thyroid histopathology was added to evaluate potential thyroid axis effects. In TS-exposed FM (average measured concentrations (amc) of 1.0, 2.7, 6.2, or 14 μg/L) at 14 μg/L mortality/morbidity was observed in males though not in females but fecundity was decreased. Histopathological findings (HF) in ovaries and testes at ≥6.2 and ≥2.7 μg/L, respectively, were not necessarily indicative of an endocrine system effect. In TS-exposed JM (amc of 4.7, 15.5, 57.5, or 179 μg/L) mortality was observed at 179 μg/L in both sexes. Decreased fecundity and ovarian HF were noted at 57.5 μg/L, suggesting possible endocrine system perturbation. In TS-exposed ZF (amc of 0.34, 1.3, 4.9, or 16 μg/L), in females, increases in standard length, gonadal weight, gonadal somatic index, and plasma vitellogenin were noted at ≥4.9 μg/L alone with decreased fecundity, increased body weight, and ovarian HF at ≥1.3 μg/L. Potential hormonome system disruption could not be dismissed. There were no thyroid gland HF attributed to TS in any of the species. ZF appeared to be the most sensitive to TS. The LAGDA is designed to evaluate apical effects of chronic chemical exposure on growth, thyroid-mediated amphibian metamorphosis and reproduction throughout multiple life stages. X. laevis embryos were exposed to TS (amc of 4.23, 13.8, 39.7, or 111 μg/L) until 10 weeks post-metamorphosis. Exposure to TS did not decrease survival, alter sex ratios or growth. However, median metamorphosis time was delayed at 111 μg/L. There were significant HF in gonadal ducts, testes, and kidneys predominantly at 39.7 and 111 μg/L, but not in ovaries, thyroid, and liver. TS effects in X. laevis and fish may support endocrine-mediated mechanisms that impair reproduction. This abstract does not necessarily represent US EPA policy.

**1161 Mitochondrial Dysfunction in Early-Staged Zebrafish Embryos Exposed to Chlorinated Persistent Organic Pollutants**

The exposure of chlorinated persistent organic pollutants (POPs) was known as one of important risk factors for metabolic syndrome (e.g., diabetes and insulin resistance), associated with impairment of mitochondrial function. An embryonic zebrafish has been applied into research on metabolic adverse effects, due to similar organ system and high genetic homology for disease with human. To investigate the effect of mitochondrial function on exposure of chlorinated POPs, we exposed individual zebrafish (i.e., 4.4'-DDT, Chlordane (technical mixture), Heptachlor, beta-HCH (be- ta-Hexachlorocyclohexane), Hexachlorobenzene (HCB)) and their mixture with 0.1% dimethyl sulfoxide (DMSO), to dechlorinated zebras fish embryos from 6 to 120 hpf (hours post-fertilization). We measured the oxygen consumption rate (OCR) and indirect indicators of the mitochondrial function, at sublethal concentrations of 0.05, 0.1, and 0.5 μg/mL, by using Seahorse XFe Extracellular Flux Analyzer at 24 hpf. In addition, we evaluated oxidative phosphorylation reaction rates on mitochondrial complex I to IV in isolated mitochondria, and analyzed mRNA expression of transcription factors (i.e., pparα, acox1, sda, acadm, and cs) regulating mitochondrial metabolism at 72 hpf. In our results, the OCR was reduced to the exposure of chlorodane and beta-HCH. In particular, OCR in zebrafish embryos exposed to the mixture decreased remarkably at lower concentrations. Dysregulation of oxidative phosphorylation in the mitochondria was identified on the complex I and III POPs, and the expression of sda, acadm, and cs genes were altered following exposure of p,p-DDT, chlordane, heptachlor and mixture. Consequently, the exposure of either individual and mixed chlorinated POPs impaired mitochondrial function biogenestically and bioenergetically.

---

**1162 Toxicity Study of Perfluorohexanoic Acid (PFHxA) and Its Salts in Aquatic Animals**

Z. Guo, and H. Iwai.

Daikin Industries, Ltd., Osaka, Japan.

Perfluorohexanoic acid (PFHxA) belongs to polyfluoroalkyl substances (PFAS). It is an environmental degradation product of C6-based fluorotelomer intermediates, used to produce various kinds of polymers. PFHxA is considered as a low toxic chemical compared to PFAS. Therefore, PFHxA is used as a replacement for long chain PFAS in industry site. However, the concerns of its ecotoxicity still remain. Therefore, we performed exposure experiments by using two kinds of aquatic animals, medaka (Oryzias latipes), rainbow trout (Oncorhynchus mykiss). To investigate the potential effects to fish reproduction of perfluorohexanoic acid, ammonium salt, we first performed experiment by using medaka (Oryzias latipes). We found that NOEC of PFHxA-NH4 and PFHxA-Na for the reproduction of medaka were both above100 μg/L. The spawning in the exposure levels was active the same as control, and decreasing trend was not observed compared with the control. Although the fertility tended to decrease in 100 μg/L PFHxA-NH4 and PFHxA-Na exposure levels, it kept more than 90% and there was no significant difference. Furthermore, VTG production was not detected in any male fish. Therefore, it was indicated that PFHxA-NH4 or PFHxA-Na has no estrogenic activity. Next, we examined the effect of APF on growth and development of embryos and larvae of the freshwater fish species, rainbow trout (Oncorhynchus mykiss), in a Fish Early-Life Stage Toxicity Test (ELS). Hatching success in the control group was 74%. As this exceeded 66%, the validity criterion for hatching success was satisfied. First egg hatch in treatment and control vessels occurred in the 24-hour period between the Day 25 and Day 26 pre-hatch observation timepoints. This indicated no difference in time to first hatch across all treatments when compared to the control group. Larval survival until Day 28 post-hatch in the control group exceeded 70% (93%) thereby satisfying the validity criterion for hatching success. Post-hatch survival, average daily weight gain, and percentage of fish that grew ranged between 96 and 100%. Additionally, exposure groups did not show significant difference with control group in both fish total lengths and wet weights. The NOEC and LOEC for hatching success, larval survival, fish total lengths and wet weights are considered to be 9.96 and over 9.96 mg/L respectively. The NOEC and LOEC for post-hatch larval survival until Day 28 are 2.96 and considered to be low. In conclusion, PFHxA and its salt have no estrogenic activity and no effect on reproduction to aquatic animals in the test concentration.
Silicones—Do They All Behave the Same Way in the Environment Regarding Biodegradability/ Degradability?

T. Creusot, G. Louvet, A. Bellemain, B. Combourieu, B. Page, S. Soum, S. Catoire, and H. Ficheux. "THOR Personal Care, Compiègne, France; and Rovaltain Research Company, Aixian, France.

Many molecules are found under the generic name of silicones. Applications are numerous and silicones are found in industrial, pharmaceutical, medical device and personal care products. Revisiting the concept of biodegradability and degradability in such a complex family is challenging. Biodegradability was investigated using in silico tools (Epiwin and QSAR toolbox) and it was concluded that silicon-based molecules are hardly handled with these softwares. From our literature survey and our experience, we recommend that a non-conventional approach can be taken with the aim of studying potential relevant effects such as a solar simulator to study UV effects combined with abiotic degradation in wet and dry soils. Physico-chemical properties, in part driven by the polymerisation level, play a crucial role as they influence the physical state: solid, liquid, volatile, gel. Functionalisation of alkyl dimethicone compounds is also a key parameter for both entry in the environment and degradation. Silicones in cosmetics should be considered separately because of particular conditions of use of these products and the fact that they are found in wastewater in which it is treated in consequences. Abiotic processes can be important steps in the degradation of man-made chemicals in the environment (clay acts as a catalyst of degradation of silicones); usually only primary degradation occurs but the products formed may be biodegraded further by microorganisms. The ultimate stage, represented by the siloxane backbone degradation, may be obtained by the combined effect of bacteria, clay and UV light leading to formation of silicates. A low level of polymerisation leads to easily hydrolysed silicones by enzymatic and non-enzymatic reactions of the grafted carbon chain. A higher level of polymerisation provides greater protection against degradation. Consequently (bio)degradability should be approached on a case-by-case basis and the approach should consider parameters which are specific to silicones. Even if (bio)degradation, with respect to the OECD definition for very high molecular weight silicones, is not totally achieved, a degradation of lower molecular weight silicones, as used in the personal care industry, is achieved by other means such as UV and abiotic transformation.

Reconstituted Mining Effluent Reduces Neuronal Proliferation in the Developing Brain and Slows Growth of Body and Facial Features in Wild-Caught Wood Frog Tadpoles

Mining has been a dominant industry in rural Appalachia for more than 150 years, but the impact of mining on aquatic animal health is not well understood. This is an important issue because Appalachia is home to an enormous diversity of organisms, including a huge array of amphibians that live in streams that receive mining effluent from operating and abandoned mines. We examined the effects of reconstituted mining effluent on the development of wood frog (Lithobates sylvaticus) tadpoles. We collected day-old fertilized eggs from a creek near Blacksburg, VA in early March, 2018 and raised them to hatch. Tadpoles were then assigned to either sulfate or chloride-based reconstituted mining effluent diluted to six different conductivities (100 µS/cm - 2,400 µS/cm). After 7 or 14 days of treatment, tadpoles were euthanized and fixed in paraformaldehyde. We imaged the heads and bodies of tadpoles for morphometric analysis before dissecting out brains and immunostaining them for phospho-histone3, which labels dividing progenitor cells in the brain. We found that sulfate-based reconstituted mining effluent significantly lowered progenitor cell division at 1200 µS/cm at Day 7 and at 600 µS/cm at Day 14 relative to control. Chloride-based reconstituted mining effluent was less impactful, with no significant differences observed at Day 7 and significantly lowered progenitor cell division at 2400 µS/cm at Day 14. In addition, both treatments slowed growth of morphological features, including body length, head size, and interocular distance. In contrast to the neuronal data, higher concentrations of effluent appeared to increase variability within each treatment. These experiments suggest that mining effluent that has high concentrations of sulfate is particularly likely to negatively impact the development of amphibians.

PBDE-47 Can Affect the Embryonic-Larval Development of Zebrafish but Not BDE-99 and BDE-154

F. R. Abe, A. A. Oliveira, M. Pazin, D. P. Oliveira, and D. J. Dorta. University of São Paulo, Ribeirão Preto, Brazil.

Polybrominated diphenyl ethers (PBDEs) are widely used as flame retardants that have been detected in samples of humans and wildlife animals. Their physical and chemical properties favor their bioaccumulation and provide high resistance to environmental degradation. The congeners BDE-47, BDE-99 and BDE-154 are between the most used and present high toxic potential, such as induction of endocrine disruption, neurotoxicity and hepatotoxicity to humans. It is known that PBDEs can be accumulated in the environment, especially in aquatic organisms, thus we evaluated the toxicity of these compounds in an ecotoxicological model. Zebrafish (Danio rerio) was used to evaluate the toxicity of these environmental contaminants on its embryonic and larval stages. Endpoints of lethality (e.g. coagulation, hatchling), sub-lethality (e.g. eye development, pericardium and yolk edemas) and teratogeneticity (e.g. delayed growth, inflated swimming bladder) were assessed after embryo exposure to BDE-47, BDE-99 and BDE-154. The highest tested concentration of BDE-47 (12.1 mg/L) was able to cause toxic effects, such as pericardium and yolk edema induction, however most of them were reabsorbed until 144 hours post fertilization (hpf), thus not culminating in lethal effects on zebrafish embryos/larvae. Teratogenetic effects have been observed to those BDEs, but we did not significantly detect in zebrafish embryos/larvae after BDE-47, BDE-99 and BDE-154 short-term exposure. Therefore, the exposure of zebrafish to BDE-47, but not BDE-99 and BDE-154, can impair zebrafish development with slight toxic effects.

Developmental Exposure to Fluoxetine Induces Higher Mortality but Not Gross Anomalies in an In Ovo Chicken Model

J. R. Meadows, Q. Hu, and J. C. DeWitt. East Carolina University, Greenville, NC.

Fluoxetine is a pharmaceutical pollutant of emerging concern as it is detected in trace amounts in myriad water sources. Several studies have demonstrated that environmentally relevant concentrations of fluoxetine impact behavior, reproduction, and survival of aquatic species. Fluoxetine has been shown to impact the stress axis in small aquatic animals and plants at concentrations similar to those found in the environment. It is well known that developmental and early life stress from environmental contaminants profoundly affect physiological regulation throughout life. Previously, we investigated phenotypic anchors associated with modulation of the stress axis by fluoxetine in an avian model of developmental toxicity. We found that fluoxetine induced molecular changes in the stress-axis of newly-hatched chickens exposed in ovo. These data led us to hypothesize that developmental changes induced by fluoxetine exposure will persist and lead to detectable effects in two-week old chickens. Prior to incubation, fertilized chicken eggs were injected with environmentally relevant concentrations of 0, 1, 10, or 100 ng/mL of fluoxetine in DMEM. Eggs were incubated until hatch and hatchlings were kept until 13 days of age. Hatchlings were monitored for growth throughout the study and tissues were collected and weighed after necropsy. Body and organ weights, and general growth, as measured by increases in body weight and crown-rump length, did not differ among groups. However, all treated groups exhibited at least 5% higher embryonic mortality than vehicle controls. Together, our findings indicate that developmental exposure to fluoxetine can affect survival and induce molecular changes relevant to the stress axis, but does not impact less-sensitive endpoints, such as growth. Because developmental impacts to the stress axis are often not apparent until a secondary insult, our additional work investigated how individuals responded to an inflammatory challenge. Here, we assessed for an inflammatory response using a PHA skin test, which showed a dampened response in animals treated with the lowest concentration of fluoxetine, and increased variability in those treated with the highest. Further analyses will determine relationships imperative to the stress axis, including glucocorticoid receptor concentrations, corticosterone level and other immune function parameters, that could help explain pollutant-induced mortality.
1167 Monitoring Reproductive and Immunological Effects in Colonial Waterbirds to Support Management Decisions at Contaminated Great Lakes Sites

This monitoring program assessed effects of contaminants, primarily PCBs and PCDDs, on immune function and reproduction in fish-eating birds in the Saginaw Bay and River Raisin Areas of Concern (AOCs) and Grand Traverse Bay in 2010-18 under the Great Lakes Restoration Initiative and AOC programs of the US Fish and Wildlife Service and US Environmental Protection Agency. Saginaw Bay sites included two herring gull colonies (Confined Disposal Facility (CDF) and Little Charity Island), two Cassip tern colonies (CDF and Charity Reef/L. Charity Island) and one black-crowned night heron colony (CDF). Herring gulls were studied in the River Raisin AOC at the Detroit Edison Monroe Power Plant on the western shore of Lake Erie and on Bellow Island in Grand Traverse Bay. Reference sites were in the lower St. Mary’s River (gulls on Pipe Island Twins and terns on Two Tree Island), on Tahquamenon Island in Whitefish Bay (terns), and on Chantry Island, Lake Huron (herons). Gull embryos were assessed during late incubation using a viability detector sensitive to heartbeat and movement. Relative risk ratios for embryonic nonviability were significantly elevated two to three-fold at contaminated sites compared to the reference site (2.2 for the Saginaw Bay AOC, 2.7 for the River Raisin AOC, and 3.4 for Grand Traverse Bay). Infertility was the primary cause of nonviability at the reference site. Elevated infertility and mortality contributed to nonviability in contaminated sites. Deformities associated with PCBs and PCDDs were found in several individuals at contaminated sites (3 gull chicks on Monroe, 2 tern chicks on L. Charity, 3 gull embryos on the CDF, 1 gull embryo on L. Charity, and 1 gull embryo on Bellow). Chick productivity in terms of Saginaw Bay (mean of 0.76 chicks/nest) was significantly below that of reference sites (1.2 chicks/next). In the River Raisin AOC, productivity of gull chicks was poor for 4 of 9 years, with complete reproductive failure in 2010. In gull chicks the mean phynohemagglutinin (PHA) skin response for T-cell mediated immunity was suppressed 54-56% at both AOCs and 50% in Grand Traverse Bay. This response was suppressed 48% in terns and 39% in herons in Saginaw Bay. Mean antibody responses in gull chicks at the River Raisin AOC and in Grand Traverse Bay were two- three-fold lower than at the reference site. Ongoing immunological and reproductive impairments at these contaminated sites are consistent with the effects of persistent pollutants such as PCBs and PCDDs.

1168 Tebuthiuron and Trifluralin Affect Locomotor Activity of Zebrafish (Danio rerio) Embryos and Larvae Body Length

A. A. de Oliveira, and D. P. de Oliveira. "Univerdade de Sao Paulo, Ribeirao Preto, Brazil."

Tebuthiuron (TFL) and tebuthiuron (TBR) are herbicides commonly applied in sugarcane culture leading to environmental occurrence, as reported by several studies. However, little is known about TFL and TBR toxic potential on non-target organisms. In this study, we analyzed effects of TFL and TBR exposure on embryo locomotor activity and larvae body length of zebrafish (Danio rerio). For this purpose, five concentrations of TFL and TBR analytical standards (0.1, 1, 10, 100, and 1000 µg/L) were tested. Dimethyl sulfoxide (DMSO) 0.01% was used as solvent control. During exposure, embryos and larvae were kept at 28 ± 0.5°C with constant light-dark (14:10h) cycle (only for TBR treatment group but not for TFL). Within 27 to 30 hours post-fertilization (hpf), embryos locomotor activity (n=90) was monitored for 3 minutes. Data were analyzed by DanioScopeTM (Noldus) software, quantifying percentage of burst activity, burst count, mean burst duration and total burst duration. Larvae body length (n=60) was measured at 96 hpf. Analysis of variance (ANOVA) followed by Dunnett’s Multiple Comparison Test (p <0.05) was performed by SPSS Statistics (IBM). Results showed that TFL at highest concentration (1000 µg/L) has decreased larvae body length in comparison to control group (F3,564 = 42.95, p<0.001), but did not affect embryos locomotor activity. On the other hand, TBR strongly decreased embryos locomotor activity inducing less locomotor activity even at lowest concentration tested (0.1 µg/L). Additionally, decreasing of locomotor activity was dependent on the concentration tested (highest concentration led to lowest locomotor activity). Our findings allow us to evidence TBR ability to interact with biological organisms such as zebrafish at early life stages, as well TFL capacity to induce teratogenic effects.

1169 Yeast Atlas, Diversity of Wild Yeast Collected from North and South American Regions

J. Barney, and J. Gallagher. "West Virginia University, Morgantown, WV."

The ecology of wild strains of Saccharomyces cerevisiae from around the globe is poorly understood. Early domestication by human kind and ubiquitous use of a select few strains has led to an ambiguous origin, although relatively new data suggests an out of Asia theory and importance of insect vectors in yeast mobility. Glyphosate is an herbicide which is commercially used as the main ingredient in Roundup®. Prolonged use has increased glyphosate resistant plants, which may affect human health. In this study, urban and rural isolates were obtained through phenol-chloroform extraction of genomic DNA and amplification of their internal transcribed spacer (ITS) gene of the ribosomal DNA. Sanger sequencing was employed and used in conjunction with NCBI databases for identification of yeast genus. Using species specific multiplexing primers, species level identification has been resolved. Development of The Yeast Atlas as resource to better understand mechanisms of response, adaptation, and evolution to stimulants such as chemicals including glyphosate is a tool for yeast researchers to harness the genetic diversity of wild strains with ease. This effort is currently on going: genetically diverse wild yeast are being both processed and identified. Once identified, the collected S. cerevisiae samples will be categorized by location and evaluated for phenotypic responses to chemicals. Greater than 623 samples have been amassed and 538 isolates recorded. PCR amplification of 421 amplicons aided in 329 species being matched in the NCBI database. Phylogenetic diversity of the isolates varies to include Pichia, Lanchancea, Candia, and more families of yeast other than Saccharomyces. North and South American isolates of S. cerevisiae will be assayed against chemical stressors, including glyphosate, as a screening process for phenotypic traits of wild yeast.

1170 An Overview of the Properties MCHM Exhibits on Multiple Yeast Strains

Z. N. Sherman, M. C. Ayers, A. Pupo, and J. E. Gallagher. "West Virginia University, Morgantown, WV."

In 2014 a chemical spill occurred in the Elk River, West Virginia releasing approximately 10,000 gallons of the coal washing chemical, 4-MCHM (NIIH, 2015). The contaminated water affected aquatic organisms, local plant and animal species, and nearly 300,000 residents residing in the Charleston, WV area (Pusey and West, 2015). In this study we had selected multiple yeast strains that were grown in constant exposure to MCHM. Our goal is to develop yeast strains resistant to MCHM and analyze their DNA sequences to detect specific mutations at perspective genes. Serial dilutions on solid as sayso presented numerous strains presenting resistant-like properties. Further genetic analysis revealed similarities in the polymorphisms between some of the resistant strains. The mutations range from non-synonymous point mutations to addition/deletion frameshift mutations ~40 base pairs long. Similarly, on numerous occasions the same mutations occurred between two parallel strains. MCHM may cause DNA replicative stress. Mechanisms of possible DNA damage and the promotion of protein aggregation are a few of the leads thus far. Further analysis of the mutations will guide our understanding to the toxicological effects of MCHM.

1171 Analysis of Emerging Contaminants in Maryland Coastal Bays Using In Vitro Bioassays as Biological Screening Tools

R. A. Elfadul, R. Jesien, A. El Nabawi, P. Chigbu, and A. Ishaque. 1

1University of Maryland Eastern Shore, Princess Anne, MD; and -Maryland Coastal Bays Program, Berlin, MD.

Emerging contaminants (ECs) with estrogenic or estrogen-like activity have been increasingly detected in aquatic environments and have been an issue of global concern due to their potential adverse effects on wildlife and human health. ECs include pharmaceuticals, personal care products, natural and synthetic hormones, nanomaterials, food additive, plasticizers. These chemicals and their bioactive metabolites are usually introduced to the aquatic environment as a complex mixture through wastewater treatment systems. This study was aimed to investigate the fate and occurrence of ECs in the Maryland Coastal Bays (MCB) and to assess their estrogenic activity profile. Fish samples were collected from four sites as well as water and sediment samples were collected from 13 sites along the MCBs in addition to influx and effluent samples from Ocean Pines and Princess Anne Wastewater Treatment Plants (WWTPs). In this study, Stripped killifish (Fundulus majalis), and Mummichog (Fundulus heteroclitus) were used as bioindicators for spatial contamination. Samples were analyzed using vitellogenin (VTG) assays as biomarker for the presence of ECs in the environment and MCF-7 cell prolifer-
1172 Mapping Nutrient and Heavy Metal Concentrations in Greens Bayou

T. H. Johnson, J. Johnson, T. Bukunmi-Omidiran, and M. S. Bhaskar. Texas Southern University, Houston, TX.

Houston is the fourth largest and one of the fastest growing cities in the United States. The rapid population growth of the greater Houston area has caused major urbanization to its local watersheds. The Greens Bayou Watershed is located in north Harris County and encompasses portions of the cities of Houston and Humble. The watershed covers about 341 kilometers (212 miles) across the city. One of the main waterways connected to the watershed is Greens Bayou. As the population increase in the greater Houston area, the heavy metal waste and pollution increases. Waste runoff is also growing rapidly in the city of Houston. During September of the year 2017, a major hurricane named Hurricane Harvey flooded the city of Houston. The goal of this study is to monitor the changes in the nutrient and metal concentrations in the water and flood plain soils of Green Bayou during the pre- and post-Harvey event. Water and soil samples were collected from Greens Bayou during the pre- and fall of 2017. The instruments used to identify the nutrient and metal concentrations in the water and soil samples were total organic carbon and nitrogen (TOC), inductively coupled plasma mass spectrometry (ICP-MS), and the hand held X-ray fluorescence analyzer (XRF). Our water sample analysis indicates that the TC, TN, P, K, Ca, Na and Mg is significantly higher in the upstream locations compared to the downstream locations during the pre-Harvey sampling. On contrast to the other elements, Fe concentration increased significantly in the downstream locations compared to the upstream locations during pre-Harvey sampling. The N, P, Ca, Na, Mg, Fe and Zn concentrations in the downstream locations increased following the Harvey flooding. The total N and total P concentrations in our water samples as well as the historical data exceeds the US EPA nutrient criteria for rivers and streams which is 0.76 ppm for total N and 0.128 ppm for total P. All the metal concentrations in the water were found to be below the critical limit while the N and P concentrations exceeds the critical limit. Future research involves identifying the non-point sources of contaminant, which can be better managed to preserve the health of the urban watershed ecosystem.

1173 Culture System Differences in Growth and Hematological Profiles of Juveniles and Adults Clarias gariepinus

N. Achilike1, and A. D. Wusu2, 1Nigerian Institute for Oceanography and Marine Research, Lagos, Nigeria; and 2Lagos State University, Lagos, Nigeria.

Clarias gariepinus, a typical freshwater clariid species in the coast of Africa is an essential fish species given its immense contribution to the nutritional needs, economic growth and development of any African nations including Nigeria. Knowledge of current health status of Clarias gariepinus reared in different culture media is lacking. Therefore, this study was conducted in six randomly selected fish farms (concrete tanks and earthen ponds) in three agricultural zones in Lagos State, South Western Nigeria. Growth and blood indices for hematological variation in the upstream locations of Greens Bayou were compared to the downstream locations during the pre-Harvey sampling. The results showed that water quality characteristics of earthen ponds recorded significantly (p < 0.05) higher level of ammonia concentrations, lower values of dissolved oxygen, pH and transparency than in concrete tanks indicating poor water quality. Haematological indices: red blood cells, packed cell volume and hemoglobin increased significantly (p < 0.05) in fish reared in concrete tanks with highest mean red blood cells and packed cell volume and hemoglobin increased significantly (p < 0.05) in fish reared in earthen ponds are diagnostic elements, predisposing factors for microcytic fish anemia, a health phenomenon in cultured catfish in Nigeria.

1174 An ‘Omics Approach to Unraveling the Paradoxical Effect of Diet on PFOA- and PFNA-Induced Non-Alcoholic Fatty Liver Disease (NAFLD)

M. Pfohl, E. Marques, H. Ma, N. Seeram, and A. Slitt. University of Rhode Island, Kingston, RI.

Obesity, diabetes, and insulin resistance are all risk factors associated with the development of hepatic steatosis and non-alcoholic fatty liver disease (NAFLD). It is estimated that 20-30% of the population present with NAFLD in the United States alone. The role of environmental exposures as risk factors for fatty liver disease is not well known. Perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFNA) are widespread environmental toxicants that persist in over 98% of the general population. The aim of this study was to evaluate whether PFOS or PFNA exposure in combination with a moderately high-fat diet, augmented hepatic lipid content and biomarkers associated with NAFLD. Six-week-old male C57BL/6 mice were fed either a 10% kcal low-fat diet (LFD) or 45% kcal high-fat diet (HFD), with or without 0.0003% PFOS or PFNA (LFD-PFOS, LFD-PFNA, HFD-PFOS, and HFD-PFNA, respectively) for twelve weeks. The HFD increased liver weight by about 30% and body weight compared to the LF control. Both HFD-PFOS and HFD-PFNA administration significantly increased liver and body weights when compared to the LF control. PFNA induced significant liver weight increase over both the control groups, as well as PFOS-exposed mice. Internal hepatic PFOS and PFNA content was quantified by LC-MS and the impact of diet on hepatic tissue was assessed through various histological and H&E techniques. PFOS and PFNA were compared and the additional impact of diet on these mechanisms was assessed. Both PFOS and PFNA treatment resulted in significantly increased expression of fatty acid uptake genes cluster of differentiation 36 (CD36) and solute carrier family 27 member 1 (Slc27a1), while PFOS-exposed mice showed an opposite effect. Both PFOS and PFNA exposure resulted in more profound effects on gene and protein expression overall when compared to PFOS. Diet exerted an additional impact on the mechanisms and potency of PFOS and PFNA in the liver. The data suggests that PFOS and PFNA at an exposure relevant dose (0.0003%) may have an adverse effect on hepatic lipid accumulation when combined with a LFD. The paradoxical impact of diet on the mechanism and potency of PFOS and PFNA is described herein.

1175 Comparative Analysis of International and Domestic Points of Departure and Uncertainty Factors Contributing to Disparate Oral Reference Doses for PFOA

J. V. Miller1, D. G. Kouguias2, M. A. Abramson1, M. A. Maddaloni1, and M. L. Kreidel1, 1Cardno ChemRisk, Pittsburgh, PA; 2Cardno ChemRisk, Chicago, IL; and 3Cardno ChemRisk, Brooklyn, PA.

Perfluorinated aliphatic carboxylic and sulfonic acids have been widely used in consumer and industrial products, such as firefighting foams, surfactants, chemical treatments for stain resistance, and key components for the manufacture of fluorinated polymeric materials. Since the 1950s, this category of compounds contain very stable C-F bonds, making them resistant to metabolism, phototransformation, biodegradation, and hydrolysis, with a human half-life of approximately 3.8 years. One of the most prevalent perfluoroalkyls is perfluorooctanoic acid (PFOA). PFOA has been detected in various environmental matrices (e.g., soil, surface and ground water, air, and food) and is biopersistent. As such, PFOA has been widely scrutinized for regulatory oversight and several agencies have established screening values for use in risk assessment of PFOA. This work presents a comparative analysis of International and US federal- and state-level recommended oral reference doses (RfDs) and the underlying variance in the approaches used to determine these RfDs, including selected points of departure (POD), treatment of pharmacokinetics, and uncertainty factors (UFs). Currently, international and domestic regulatory agencies' RfDs for PFOA range from 0.0015-0.2 µg/kg/d and are based on varying UF s, PODs, species, and endpoints. These values are based on human equivalent dose (HED) pharmacokinetic models that use lowest observed adverse effect level (LOAEL), no observed adverse ef-
flect level (NOAEL), and/or BMDL10 (benchmark dose level associated with 10% risk of adverse effect in exposed test animals). We have also performed rigorous study selection analysis of the 20+ studies relied upon for RfD calculations. From these analyses, we have found that more conservative RfD values are primarily due to post-study selection treatment of UFs and use of LOAEL as POD. Interestingly, some of the more conservative RfD values have a narrower exposure range for common organisms (e.g., mice, rats, monkeys) and critical effects (hepatotoxicity, developmental toxicity, and reproductive effects), suggesting significant inconsistencies between various regulatory agencies. The heterogeneity of international and domestic recommended RfDs will continue to be a significant issue for future PFOA regulatory action.

1176 Approaches for Assessing Perfluoralkyl Acid Mixture Toxicity: A Case Study with PFOA and PFHxS

A. Luz1, J. Anderson2, and P. Goodrum3. 1Integral Consulting, Inc, Annapolis, MD; 2Integral Consulting, Inc, San Antonio, TX; and 3Integral Consulting, Inc, Syracuse, NY.

The relative potency factor (RPF) method is one approach for addressing mixtures that focuses on deriving a set of toxicity values that are normalized to a reference compound. This approach has been used to assess the toxicity of complex mixtures of PCBs and dioxin-like compounds that share the same mode of action (MoA) for eliciting an adverse effect. Interest in RPF methods for perfluorinated alkyl substances (PFASs) is growing given developments from in vitro studies and non-mammalian models in understanding potential MoAs of PFASs, both individually and as mixtures. Criteria for assessing whether or not the RPF method is applicable to specific PFASs include: 1) identifying if responses are mediated through a single receptor; 2) evaluating species differences in receptor responsiveness; 3) determining if differences in dose-response are consistent across relevant dose ranges. In this presentation, we demonstrate that PFASs do not satisfy these criteria by comparing perfluorooctanoic acid (PFOA) and perfluorohexanoic acid (PFHxS), which differ in structure by only two fluorinated carbons. Studies demonstrate that, unlike PFOA, PFHxS is a weak carcinogen, hepatotoxicant, developmental or repro- ductive toxicant, or an endocrine disruptor. The only human-relevant adverse effect reported for PFHxS is histopathological changes in the kidney of female rats in a 2-year study, which yields NOAEL and LOAEL values of 30 and 200 mg/kg-day, respectively. This LOAEL is 200-fold higher (i.e., less toxic) than reported LOAELs for PFOA (i.e., approximately 1 mg/kg-day) in mice. Low levels of PFHxS in the kidney may be due to lower dose, differences in receptor responsiveness, or other factors. Analysis of high-throughput Tox21 data demonstrates that both PFOA and PFHxS are PPARα agonists, however, unlike PFHxS, PFOA exhibits binding to additional nuclear receptors, which may contribute to its MoA. Quantitative dose-response relationships for PFASs and PFHxS do not exhibit consistent proportional differences in response across relevant dose ranges. The RPF approach is contrasted with the conventional hazard index method to demonstrate how these approaches, if applied in a risk assessment context, may support very different risk management decisions depending on exposure ranges, differences in human relevancy of endpoint selection, and different potency factors applied in deriving mixture toxicity criteria for reference doses. Collectively, these results demonstrate that even highly structurally similar PFASs may not satisfy minimum criteria for the RPF method.

1177 PFOA and PFOS Interfere with Hepatocyte Differentiation in a Human iPSC to Hepatocyte Model

I. Huck, J. Draper, J. L. Vivian, and U. Apte. University of Kansas Medical Center, Kansas City, KS.

Perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) are persistent organic pollutants with significant concerns for health of humans and the environment. PFOA/OS cross the placental barrier and accumulate in fetal liver. In utero exposure to these compounds is associated with decreased birth weights in humans. We hypothesized that PFOA/OS exposure inhibits hepatocyte differentiation during embryonic liver development. To test this, we used a human induced pluripotent stem cell (iPSC)-derived hepatocyte model, which recapitulates various stages of embryonic hepatocyte differentiation in vitro. An iPSC line (K3) was differentiated to hepatocytes using a culturing protocol that directs differentiation of the cells into definitive endoderm (Day 0 - 5), specified hepatic endoderm (Day 6 - 10), immature hepatocytes (Day 11 - 15), and mature hepatocytes (Day 16 - 20). Gene expression analysis confirmed activation of mature hepatocyte markers (AFP, ALB, CYP2C19, F7, GSTA1, HNF4A, TP) and downregulation of developmental and stem cell markers (CXC4, GATA4, SOX17) following completion of the differentiation protocol. Next, 10 μM PFOA, PFOS, or vehicle was added to culture media from days 6, 11 or 16 of iPSC to hepatocyte differentiation and samples were obtained at day 20. PFOA treatment was more effective than PFOA in disrupting the iPSC to hepatocyte differentiation. Treatment from days 16 to 20, which correlates with immature to mature hepatocyte differentiation was the most affected stage by both PFOA and PFOS. Day 6-20 treatment of PFOA resulted in reduced CXC4 expression and sustained expression of SOX17 expression. Day 16-20 PFOA treatment enhanced CYP2C19 expression but blocked expression of CXC4. PFOA treatment upregulated hepatocyte cell markers (CXC4, SOX17) and also reduced expression of hepatocyte markers (ALB, CYP3A4, F7, HNF4A). In conclusion, these data indicate that PFOA and PFOS have significant effect on embryonic hepatocyte maturation and that this iPSC to hepatocyte model of in vitro hepatic differentiation is an effective method to identify the underlying mechanisms.

1178 Concentration of 19 Perfluorinated Compounds in Processed Seafood Analyzed by Liquid Chromatography-Tandem Mass Spectrometry

Y. Jeong1, J. Kim2, Y. Joo2, and K. Lee1. 1Korea University, Seoul, Korea, Republic of; and 2Dongguk University, Seoul, Korea, Republic of. Sponsor: J. Lee

Perfluorinated compounds (PFCs) that are kind of anthropogenic contamination materials existed in ubiquitous environments such as water, soil, air, and foods. PFCs are accrued in the human body and hard to discharge. Recently, there were studies about monitoring PFCs in seafood. In this study, 19 PFCs were monitored by in-house developed liquid-liquid extraction methods after homogenizing samples and analyzed by liquid chromatography-tandem mass spectrometry (LC-MS/MS). The validation of our analysis method was performed by accuracies and precisions using inter-day and intra-day. The accuracies were between 80% and 120% and the precisions were within 20%. The limit of quantitation (LOQ) of 19 PFCs was ranged from 0.04 to 0.18 ng/g. Our samples were composed of 302 processed seafood that was directly in consumption form to the consumer. These samples were divided 5 categories such as processed fish products, dried seafood, salt seafood, canned food, and seasoned laver. In this study, the results showed that PFOA was the highest concentrated in processed seafood (40-100 ng/g) in canned food and salt seafood, PFOA in dried seafood, and PFPeA in seasoned laver. Although there were the different patterns of the highest PFCs in each category, PFOA and PFOS were mainly detected in all categories. The dried seafood (including seasoned laver) and salt food were detected a high level of PFOA and PFOS compared with other categories. Also, the present study show that the distribution of the PFCs’ concentration were different as per biological classification, the raw material of samples, and habitat of the raw fish samples using statistical analysis. The result was that crustaceae, sea squirt and demersal organisms were the highest level in PFOA and PFOS.

1179 PFAS Tissue Distribution in Cattle

R. Drew1, T. G. Hagen1, D. Champness2, and A. Sellier1. 1ToxConsult Pty Ltd, Darling South, Australia; 2Agriculture Victoria, Melbourne, Australia; and 3AureQuality Limited, Wellington, New Zealand.

Deciding when PFAS in beef cattle has declined sufficiently after exposure is stopped, such that the tolerable daily intake by high end meat consumers is not violated, requires information on clearance of PFAs from tissues (experimental) and a model for dietary intakes for cattle or from serum to tissue partitioning data. Belted Galloway beef cattle that had accumulated PFASs from water had blood sampled (tail vein) prior to stunning and exsanguination (as per standard abattoir practice) by a veterinarian. Animals were hung from water had blood sampled (tail vein) prior to stunning and exsanguination. Although there were the different patterns of the highest PFCs in each category, PFOA and PFOS were mainly detected in all categories. The dried seafood (including seasoned laver) and salt food were detected a high level of PFOA and PFOS compared with other categories. Also, the present study show that the distribution of the PFCs’ concentration were different as per biological classification, the raw material of samples, and habitat of the raw fish samples using statistical analysis. The result was that crustaceae, sea squirt and demersal organisms were the highest level in PFOA and PFOS.
The Interaction with and Transport of Three Perfluoroalkyl Sulfonates by Renal Organic Anion Transporters

P. J. Sandoval, J. D. Zitzow, S. Chang, and B. Hagenbuch. University of Kansas Medical Center, Kansas City, KS; and 3M Company, St. Paul, MN.

Perfluoroalkyl substances (PFAS) are environmentally resilient compounds that have been used in many industrial applications. Some PFAS have long serum elimination half-lives in humans with the transport activity of multi-drug transporters having a significant role in the retention and reabsorption of these compounds. We have demonstrated in the past that several of the renal organic anion transporters are involved in the disposition of perfluoroalkyl carboxylates. However, little is known regarding perfluoroalkyl sulfonates. Therefore, the aim of this study is to determine whether the human kidney organic anion transporters (OAT1, OAT3, OAT4, URAT1, and OATP1A2) influence the disposition of these compounds. We undertook this study by expressing different transporters transiently in HEK293 cells and measured the uptake of radiolabeled model substrates in the absence or presence of either perfluorobutane sulfonate (PFBS), perfluorohexane sulfonate (PFHxS), or perfluorooctane sulfonate (PFOS). The uptake of these compounds was also directly quantitated by LC-MS/MS. We observed that both PFBS and PFHxS inhibited transport activity of these selected transporters to a greater extent than PFOS, with the greatest inhibition observed in the transport activity of both OAT3 and OAT4. We determined that PFBS and PFHxS are substrates of OAT3 and OAT4 while PFOS is not a substrate of these transporters. This observation is consistent with the role of the kidney in handling and eliminating small (<450 MW) organic compounds. Within the limits of our study design, these results demonstrated that, in addition to perfluoroalkyl carboxylates, renal organic anion transporters preferentially interact and transport certain perfluoroalkyl sulfonates, suggesting a possible role in the retention and distribution of these compounds.

Accessing Toxicity Data for Per- and Polyfluoroalkyl Substances Using the US EPA CompTox Chemicals Dashboard

EPA’s National Center for Computational Toxicology is developing automated workflows for curating large databases within the DSSTox project, and providing access to chemical structure and toxicity data. The CompTox Chemicals Dashboard (https://comptox.epa.gov/dashboard), a publicly accessible web site providing access to data for ~760,000 chemical substances, the majority of these represented as chemical structures. The web application delivers a wide array of computed and measured physicochemical properties, in vitro high-throughput screening data and in vivo toxicity data, as well as integrated chemical linkages to a growing list of literature, toxicology, and analytical chemistry websites. In addition, several specific search types are in development to directly support the mass spectrometry non-targeted screening community, enabling cohesive workflows to support data generation for the detection and assessment of environmental exposures to chemicals contained within DSSTox. The application provides access to segregated lists of chemicals that are of specific interest to relevant stakeholders, including, for example, scientists interested in Per- and Polyfluoroalkyl Substances (PFAS). Added lists include those sourced from the European Union as well as developed in-house and now containing thousands of chemicals. A procured testing library of hundreds of PFAS chemicals, with a portion of the list annotated into chemical categories, has been integrated into the dashboard with a number of resulting benefits: a searchable database of chemical properties, with hazard and exposure predictions, and links to the open literature. This presentation will provide an overview of the dashboard, the developing library of PFAS chemicals and associated categorization, and efforts underway to develop new physicochemical property and environmental fate and transport Qsar prediction models developed for these chemicals. This abstract does not necessarily represent the views or policies of the US Environmental Protection Agency.

Development of a Maximum Allowable Dose Level for Perfluorooctane Sulfonate and Assessment of Exposures from Drinking Water in California

K. M. Scaife, S. Pham, S. West, J. M. Cybulski, and L. A. Haighton. Intertek Scientific & Regulatory Consultancy, Mississauga, ON, Canada.

Perfluorooctane sulfonate (PFOS), a polyfluoroalkyl substance with uses in stain-resistant coatings and fire-fighting foam, is known to be a prevalent contaminant in the environment as it is resistant to degradation. The US Environmental Protection Agency (US EPA) concluded that PFOS may be developmentally toxic to humans based on toxicology studies. Given these findings, PFOS was recently added to the California (CA) Proposition 65 list via the scientific mechanism. As there is now a Safe Harbor Level (SHL or Maximum Allowable Dose Level, MADL) for PFOS, the current work was undertaken to (i) derive a MADL and to (ii) determine if PFOS in drinking water is likely to exceed the MADL. CA Proposition 65 requires businesses to provide a clear and reasonable warning if they sell products that would result in chemical exposures above a SHL and it also prohibits a business from discharging effluent into drinking water sources if consumption of the drinking water would exceed the SHL. From the most sensitive and relevant PFOS reproductive study, a No-Observed-Effect Level (NOEL) of 0.1 mg/kg/d was identified with the critical effect being decreased weights in offspring. A MADL of 5.8 micrograms/d was calculated from the NOEL (0.1 mg/kg/d/1000 x 58 kg x 1000 µg/mg). Data from the Unregulated Contaminant Monitoring Rule were used to determine potential exposures to PFOS from drinking water in CA. PFOS was reported at an average and maximum concentration of 0.057 and 0.156 µg/l in CA, respectively, and a maximum concentration of 1.8 µg/l in all US. The higher concentrations are associated with industrial sites that manufacture or use polyfluoroalkyl substances, and are significant predictors of historical PFOS uses. Using exposure defaults from the CA Proposition 65 regulations (2 L/d), these concentrations would correspond to daily exposures of 0.114, 0.312 and 3.6 µg/d, respectively, which are all below the MADL. Thus, while the maximum concentrations would exceed the current US EPA lifetime drinking water health advisory of 0.07 µg/L (which was very conservatively derived and included a 20% relative source contribution adjustment), the MADL for PFOS for reproductive effects would not be exceeded. Based on the present work, the drinking water in CA from any source, which is reflective of historical uses of PFOS, would not be expected to exceed the calculated MADL for developmental toxicity.

Exposure of Nrf2-Deficient Astrocytes to PFOS and PFOA Results in Increases in ROS and Apoptosis

S. Alharty, and D. Hardej. St. John’s University, Queens, NY.

Perfluoroalkyl substances (PFAS) include perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) are environmentally persistent compounds used in many industrial and consumer products, such as fire-fighting foams, paints, and adhesives. These chemicals are found in measurable concentrations in human, animal and environmental samples. PFOS and PFOA have been detected in contaminated drinking water which could potentially cause long-term effects in humans and animals. Toxicity of these compounds, including hepatotoxicity, nephrotoxicity, and neurotoxicity has been demonstrated in several studies in various experimental models. The aim of this study was to determine the role of Nrf2 in protection against the neurotoxicity of these agents. Oxidative stress has been implicated in the activation of Nrf2, a transcription factor responsible for induction of antioxidant enzymes, such as superoxide dismutase, glutathione peroxidase and reductase, and catalase. The in vitro models used in the study were Nrf2-/− and wild type C57BL/6 mouse astrocytes. Previous work in our laboratory has determined cytotoxicity using the Lactate dehydrogenase (LDH) Assay and morphological changes of exposed astrocytes by phase contrast light microscopy. Cytotoxicity was significantly greater in Nrf2−/− treated astrocytes as compared to wild type treated astrocytes via these methods. Current studies have now determined that the apoptosis was significantly induced in Nrf2−/− astrocytes as compared to wild type astrocytes after exposure to high doses (600µM and 800µM) of PFOS and PFOA, respectively, via caspase-3 assay. Additionally, the Nrf2−/− treated group exhibited higher ROS than the wild type group at the highest concentrations of PFOS and PFOA as determined by DCFDA fluorescent technique. These results indicate that Nrf2−/− astrocyte exposure to PFOS and PFOA results in significantly greater toxicity than matched wild type astrocytes suggesting a role for oxidative stress in the observed neurotoxicity.
Perfluorobutane sulfonate, PFBS, is a perfluorooctylated substance and a shortened (4-carbon) alternative of PFOS, perfluorooctane sulfonate (8-carbon). PFBS has a shorter half-life and lower reported toxicity than PFOS. Exposures in zebrafish embryos have shown it to affect pancreatic islet morphology and other developmental endpoints, but the critical exposure window prior to conception has not yet been examined. Using the zebrafish model (Danio rerio), this pilot study aims to investigate the effects of a maternal, prenatal exposure to PFBS during early developmental endpoints. Three adult female fish, Tgβ-gal/Fgf, were stripped to remove existing eggs and exposed to 0.25 µg/mL PFBS or 0.01% DMSO for 1 week during a cycle of oocyte maturation. Following exposures, female fish were bred daily with unexposed male fish for a period of two weeks. Embryos were imaged daily through 20 days post fertilization, hpf, via live brightfield and fluorescence microscopy, and total larval length, yolk sac area, and pancreatic beta cell area were measured. Additionally, pooled samples of 25 embryos (3 hpf) or larvae (120 hpf) were assessed for total protein, triglycerides, cholesterol, and glucose using commercially available kits. In newly fertilized eggs (3 hpf), there was a significant 7% reduction in yolk sac area in the embryos collected from the 0.25 µg/mL PFBS-exposed maternal group compared to controls. These embryos also had a significant 50% decrease in cholesterol. At 24 hpf, embryos from PFBS-exposed females had significantly decreased yolk sac area (8%), which persisted at 5 dpf (11% reduction). In addition, at 5 dpf, the 0.25 µg/mL PFBS larvae had a significant 13% increase in pancreatic beta cell area that corresponded with a trend towards lower larval glucose content, as would be expected with increased islet size and capacity. This study demonstrates that embryos are developmentally impacted by maternal exposures to PFBS during oocyte maturation. The exposure in female fish may impact the nutritional deficit that is known to occur during development, which is evident in the effects on cholesterol and yolk sac area in the early developmental stages. This nutritional deficit, which is possibly coupled with loading of toxicant into the eggs, may explain the persistence of effects at 5 dpf. Together this suggests that there may be alterations in oocyte maturation and metabolic homeostasis in larvae associated with maternal, preconception exposure to PFBS. This work was supported by R01ES028201.

### 2019 SOT Annual Meeting

### 1184 Maternal Preconception Exposure to PFBS Alters Nutrition and Growth of Offspring

K. Annunziato, M. Marin, and A. Timme-Laragy, University of Massachusetts Amherst, Amherst, MA, MA.

Legacy per- and polyfluoroalkyl substances (PFAS) have been shown to affect development and puberty in mice. This pilot study was conducted to compare the effect of a replacement PFAS, GenX (ammonium perfluoro-2-methyl-3-oxahexanoate), with effects of a legacy compound, perfluorooctanoic acid (PFOA) on developmental end points and mammary gland morphology in female mice offspring. Time-pregnant CD-1 mice were dosed with either 1 or 5 mg/kg PFOA, or 2 or 10 mg/kg GenX (blindly allocated) from gestation days 1.5 to 17.5. Litter weights were recorded at PND 0.5, and at PND 2.5, when litter size was equalized to 10 pups. Individual pup weights were recorded on PND 6, 9, 12, 21, and 36. The PND of fur appearance, eye opening, and incisor eruption were recorded. Pups were necropsied at either PND 21 or 36 for tissues and serum. Dams were euthanized at PND 21 and uteri were analyzed for implantation sites for calculation of resorptions. Compared to the control group, body weights were significantly decreased in the 5 mg/kg PFOA group at PND 0.5, 2.5, 6, and 9. 1 mg/kg PFOA reduced pup body weight at PND 2.5, and 10 mg/kg GenX reduced pup body weight at PND 6, with no further weight changes noted. Relative liver weights were similar to control at PND 21 and 36. Eye opening was delayed in the 5 mg/kg PFOA group. Puberty delays were evident in female pups in both PFOA and 10 mg/kg GenX groups. Mammary gland development was stunted in all dose groups of GenX and PFOA. Mammary glands were scored blinded to treatment on a scale of 1 to 4 by two reviewers for stage of development, with 4 being the most fully developed glands. At PND 21 control glands were scored an average of 3.5. 2 mg/kg and 10 mg/kg GenX and 1 mg/kg PFOA averaged scores between 1.5 and 2 and displayed limited branching, lack of ductal growth, and fewer terminal end buds. Weaning 5 mg/kg PFOA glands were scored as a 1 and 1.5 had very limited ductal growth. At PND 36, controls averaged a 3.5 score and all PFAS dose groups averaged a 2.5. Even though GenX is thought to exhibit rapid elimination in mice and PFOA persists for weeks, the doses tested here suggest that GenX is more toxic than PFOA on a mg/kg exposure basis when assessed during development.

### 1185 PFAS Clearance in Cattle

R. Drew, T. G. Hagen, D. Champness, and A. Sellier, 1ToxConsult Pty Ltd., Darling South, Australia; 2Agriculture Victoria, Melbourne, Australia; and 3AsureQuality Limited, Wellington, New Zealand.

Farms are often located near sources where PFAS firefighting foams were used (e.g., training grounds of rural fire services, defence bases, buffer areas of oil/gas refineries). However, there is limited information available that facilitates management of PFAS affected farms or the animals. The objectives were to gather robust information on serum clearance of PFAS from beef cattle, tissue distribution, partial partition coefficients, and GIT absorption. A herd of Belted Galloway beef cattle (16 heifers and 3 steers) were exposed to PFAS in water for 2 years. - All had access to the same water, constant PFAS concentration, no other water source. 1. All animals bred on property, or larvae (120 hpf) were assessed for total protein, triglycerides, cholesterol, and glucose using commercially available kits. In newly fertilized eggs (3 hpf), there was a significant 7% reduction in yolk sac area in the embryos collected from the 0.25 µg/mL PFBS-exposed maternal group compared to controls. These embryos also had a significant 50% decrease in cholesterol. At 24 hpf, embryos from PFBS-exposed females had significantly decreased yolk sac area (8%), which persisted at 5 dpf (11% reduction). In addition, at 5 dpf, the 0.25 µg/mL PFBS larvae had a significant 13% increase in pancreatic beta cell area that corresponded with a trend towards lower larval glucose content, as would be expected with increased islet size and capacity. This study demonstrates that embryos are developmentally impacted by maternal exposures to PFBS during oocyte maturation. The exposure in female fish may impact the nutritional deficit that is known to occur during development, which is evident in the effects on cholesterol and yolk sac area in the early developmental stages. This nutritional deficit, which is possibly coupled with loading of toxicant into the eggs, may explain the persistence of effects at 5 dpf. Together this suggests that there may be alterations in oocyte maturation and metabolic homeostasis in larvae associated with maternal, preconception exposure to PFBS. This work was supported by R01ES028201.

### Do Perfluoroalkyl Carboxylic Acids Interact with the Bile Acid Transporter NTCP?

H. Miller, M. Ruggiero, J. D. Zitzow, S. Chang, and B. Hagenbuch, 1University of Kansas Medical Center, Kansas City, KS; and 2AsureQuality Limited, Paul, MN.

Sodium/taurocholate cotransporting polypeptide (NTCP) is a sodium-dependent bile acid transporter located at the basolateral membrane of hepatocytes. NTCP plays an important role in the enterohepatic circulation of bile acids and this mechanism has been suggested to be a possible explanation as to why certain perfluoroalkyl substances have long serum elimination half-lives in humans. We had previously demonstrated that some perfluoroalkyl sulfonates can be transported by NTCP, however, little is known about perfluoroalkyl carboxytes. Therefore, the purpose of this study was to determine if perfluoroalkyl carboxylic acids would interact with NTCP and potentially act as NTCP substrates. Human embryonic kidney cells (HEK293) stably expressing NTCP were plated on poly-D-lysine-coated 24 well plates, and uptake of sodium-dependent 1H-taurocholate was measured between 24 and 48 hours after plating in the absence or presence of perfluoroalkyl carboxylic acids with varying chain lengths from 3 to 18 carbons at either 10 or 100μM. Direct uptake was also quantitated by LC-MS/MS. Protein concentrations were determined by BCA assay. Perfluorooctanoic acid (PFOA), perfluoromonoanoic acid (PFNA), and perfluorodecanoic acid (PFDA) are the strongest inhibitors of NTCP-mediated taurocholate uptake with IC50 values of 8.7, 12.0 and 9.2μM, respectively. All three compounds are also transported by NTCP. Interestingly, decanoic acid, the C10 medium-chain fatty acid analogue of PFDA, inhibited NTCP-mediated transport only by about 30% and is not a substrate of NTCP. Similar to perfluoroalkyl sulfonates, certain perfluoroalkyl carboxylic acids can interact and inhibit NTCP-mediated taurocholate uptakes. The strongest inhibitors are ones with longer than 12 carbons and act as substrates of NTCP. Under the study conditions, our data provided evidence that longer chain perfluoroalkyl carboxylic acids such as PFOA, PFNA, and PFDA can undergo enterohepatic circulation.
Perfluoroalky acid (PFHxA) is a short-chain, six-carbon perfluoroalky acid (PFAA) and is a primary impurity, degradant, and metabolite associated with the short-chain fluorotelomer-based chemistry used in the United States and Europe today. The transition to short-chain fluorotelomer-based products as a cornerstone in replacement fluorochemistry raises questions regarding potential human health risks associated with exposure to fluorotelomer and PFHxS. Here, we present a critical review of data relevant to such a risk assessment, including epidemiological studies and in vitro and in vivo toxicity studies that examined acute, subchronic, and chronic toxicity of PFHxA. Key findings from toxicokinetic and mode of action studies are also evaluated. Sufficient data exist to conclude that PFHxA is not carcinogenic, is not a selective reproductive or developmental toxicant, and does not disrupt endocrine activity. A chronic human-health-based oral reference dose (RfD) for PFHxA of 0.2 mg/kg-day was calculated using benchmark dose modeling of renal papillary necrosis from a chronic rat bioassay. This RfD is four orders of magnitude greater than the chronic oral RfD calculated by the US Environmental Protection Agency for perfluorooctanoic acid (PFOA). The PFHxA RfD can be used to inform public health decisions related to PFHxA and fluorotelomer precursors for which PFHxA is a terminal degradant. Examples provided herein include calculations of protective human health-based screening levels, including a lifetime health advisory and threshold limit value, that provide protective screening level protective of sensitive subpopulations. Occurrence studies demonstrate that the range of environmental concentrations of PFHxA at sites with identified sources of PFAA contamination are at least an order of magnitude lower than screening levels. Furthermore, human serum and urine biomonitoring studies demonstrate that low serum PFHxA levels and rapid elimination kinetics of PFHxA and fluorotelomer precursors contribute to a high margin of safety for the general population. The analyses herein can support site-specific risk assessments as well as product stewardship initiatives for current and future fluorotelomer-based chemistries.

Perfluorooctane sulfonate (PFOS), a commonly used ingredient in aqueous film forming foams, fabric protectors, stain repellents, and other surface-coating products, has the highest environmental and biological persistence among per- and polyfluoroalkyl substances (PFAS). In fact, PFOS is ubiquitously detected in wildlife and the general human population across the world due to its biopersistence and bioaccumulation. Furthermore, given the growing scientific concern regarding its potential toxicity, there have been international regulations, advisories, and guidelines to limit exposure that are constantly evolving based on current scientific knowledge. Thus, in this presentation, we critically evaluate international and domestic regulatory values, and their corresponding methodologies, in order to gain insight into the dose response assessment approaches that have been adopted for PFOS to date. Here, we found that the international and domestic regulatory values, there are large differences in the reference doses (RfD) determined, ranging from 0.0018 to 0.3 µg/kg bodyweight (BW)/day. This was due to a range of aspects, including differences in study selection and thus species, as well as pharmacokinetic considerations and applied uncertainty factor(s). In particular, a total of 23 studies from the international and domestic regulatory agencies that selected the same study, some still had distinct RfD values due to differences in the application of uncertainty factors and pharmacokinetic considerations. Furthermore, it was found that the lowest regulatory value based on a study in mice generated the most conservative RfD, whereas in general regulatory values based on studies in rats were less conservative and those based on studies in monkeys were the least conservative. Overall, while the range of RfDs identified for determination of the regulatory values was considerable, there was a much narrower range for the point of departure in animal studies, indicating that the treatment of values after study selection is the most significant factor accounting for the large range of RfDs. This critical analysis may be used to identify the best practice for the evaluation of dose response for PFAS.

C. Nyberg1, R. Krisko1, A. Eveland1, J. Hart1, G. Olsen1, J. Butenhoff1, and S. Chang1. 13M Company, St. Paul, MN; and 2Salutox, LLC, Lake Elmo, MN.

Perfluoroalkanesulfonate (PFHxSs) and perfluorooctanoate (PFOA) are perfluoroalkyl compounds that are persistent and bioaccumulative. Some toxicological studies had reported reductions in the measurements of serum free thyroxine (FT4) in rodents with exposure to either PFOA or PFHxS; however, these studies did not take into account the possible binding competition that would result in a negative bias associated with the analog FT4 immunoassays used. Several PPARα agonists, including perfluorooctanesulfonate (PFOS), have been shown to compete and displace serum thyroxine (T4) from binding proteins. Given their structural similarity to PFOS, it is plausible that PFHxS and PFOA can also compete and displace T4. We tested this hypothesis in vitro by incubating mouse, rat, and human sera with 0 - 500 µM of PFHxS or PFOA. Serum FT4 was directly quantitated with LC-MS after equilibrium dialysis. Serum FT4 levels positively correlated with increasing PFHxS concentrations in mouse and rat sera. At 500 µM, they were approximately 200% and 650% over controls, respectively. FT4 levels also positively correlated with increasing PFOA concentrations in mouse and rat sera (~ 250% and 1000% over controls, respectively, at 500 µM). While there was no significant concentration-dependent increase in FT4 in human sera with PFHxS, there was a slight FT4 increase with PFOA. The degree of T4 displacement by PFOA in human sera (~ 30% over control at 500 µM) was much lower in magnitude than rodents. Compared to PFHxS, the higher displacement of T4 by PFOA appeared to be serum specific; whereas the higher displacement with PFHxS was species independent.

Using high PFHxS or PFOA concentrations that are several orders of magnitude higher than the general population, our data demonstrated that (1) PFHxS and PFOA can displace serum FT4 from binding proteins in vitro; and (2) rodents are more prone to serum T4 displacement than humans.

Integrating genomic data from short-term exposure to identify the mode of action (MoA) and point of departure (POD) for a compound’s quantitative risk assessment requires the evaluation of both dose-response and time-course results for the MoA key events. We performed a hepatic transcriptomic analysis on rats treated with PFOA to unravel the potential molecular mechanisms underlying the observed key events. We also investigated the dose-response and time-course concordance of transcriptional and apical liver effects. Male SD rats were treated with 0, 1, 5 or 15mg/kg PFOA by oral gavage for 7, 14, and 28 days. Hepatic total RNA were isolated for RNA sequencing experiments. Ingenuity and KEGG pathway analyses suggested that PFOA modulated the PPARα signaling (the first key event) in a dose-dependent manner at all time points studied. Using a William trend test, a total of 779, 829, and 743 genes showed dose-response pattern after 7, 14, and 28 days of PFOA treatment, respectively. Only 16 genes differentially expressed in the low dose PFOA treatment after 7d compared to control. The repression of Cyp4a11, Aco1, Aco2, Vnn1, and Nr1d1 showed a dose-response and time-dependent upregulation trend, suggesting these transcripts as potential biomarkers for screening for PPARα mediated compounds. The median benchmark dose estimates (BMDL50) of Aco1 were concordant with apical benchmark doses (BMDL50) for acyl-CoA oxidase activity at all time points studied. However, the median BMDL50 in the whole “peroxisome lipid metabolism” pathway appeared to underestimate the potency of PFOA on the PPARα activation. No dose-dependent change was found on the proto-oncogene expression including Myc, Mki-67, and Pcn1. Interestingly, Reactome pathway analyses identified a subset of genes with dose-responsive behavior that related to the S phase in the cell cycle. These data correlate with our previously observed increased hepatocytes DNA synthesis at 7d (BrDU) but lack of cell division (Ki67). The median BMDL50 of these genes was 2-fold higher than the BMDL50 for BrDU labeling index. Taken together, results from both apical endpoints and transcriptomic analyses demonstrated that PFOA induced a clear dose- and time-dependent activation of PPARα. However, PFOA only induced a transient increase in DNA synthesis in rat liver without any sign of driving cell proliferation, suggesting that further investigation is needed for the second key event in the MoA of PFOA induced rat liver tumor formation.
Perfluorooctanoic acid (PFOA) is a synthetic, fluorinated organic acid previously used in the production of fluoropolymers in the United States, and is a byproduct found in a variety of consumer products that contain fluoropolymers or have fluoropolymer coatings. PFOA has been a recent focal point for regulation due to the widespread presence of the chemical in drinking water wells throughout the United States. Water resources impacted by PFOA have been associated with releases from manufacturing sites, municipal wastewaters, and industrial or municipal landfills where treated products have been disposed. In 2016, the US EPA issued a lifetime drinking water Health Advisories (HA) for PFOA of 0.07 micrometers per liter (µg/L). The goals of the current study were to: 1) determine the basis for the health-based guidelines (state and federal) for PFOA in drinking water, and 2) evaluate the assumptions used by the US EPA in setting the drinking water advisory limit. A total of nine PFOA and biofluids. We reviewed the acute, sub-chronic and chronic toxicity of PFOA in mammalian, avian, reptilian and amphibian species to derive toxicity reference values (TRVs) that could be protective for species in those classes. Despite limited wildlife exposure data, available laboratory animal studies enabled identification of target organs, dose-response endpoints, and NOAEL and LOAEL values. The US Army Public Health Center Technical Guide 254 - Standard Practice for Wildlife Toxicity Reference Values, guided our development of class-specific TRVs. Although considerable mammalian toxicity data were available, comparatively few data were available for avian, amphibian species, and severely limited data was available for reptiles - limiting meaningful TRV derivation for these classes. Tentatively derived oral TRVs were based on the most sensitive mammalian species. For murine immunological effects, a LOAEL of 3.75 mg/kg/day and a NOAEL of 1.88 mg/kg-day were derived. Benchmark dose (BMD) analysis of antigen-specific IgM responses, indicative of suppressed immunity, gave a BMD of 3.06 mg/kg-day. Further, one standard deviation (1SD) from the control mean was selected as the benchmark response (BMD(1)) level for continuous data to give a lower bound 95 percent confidence limit (BMDL) of 1.75 mg/kg-day. Selected inhalation TRVs for the class Mammalia gave a NOAEL of 0.1 mg/m³ and a LOAEL of 1 mg/m³ with moderate confidence from sub-chronic studies conducted in rats. By comparison, selected dermal TRVs for the class Mammalia gave a NOAEL of 0.075 mg/kg and a LOAEL of 0.125 mg/kg with very low confidence. The available toxicity data on avian, amphibian and reptilian species were insufficient to develop TRVs. These initial TRVs were based on the most sensitive species available, which might be formally protective of the entire class of mammalian wildlife species in ecological risk assessment.

Bioaccumulation patterns for persistent organic pollutants (POPs) in humans are influenced in part by diet, lifestyle and socio-economic factors. Moreover, persistence and bioaccumulation in hepatic metabolic pathways. Including ingestion of POPs in lipid metabolism, oxidative stress, inflammation, TCA cycle, glucose and amino acid metabolism. Changes in the metabolome correlated with changes in genes that regulate these pathways. Integrative analyses also demonstrated a strong correlation between the alterations in microbiota composition and hepatic metabolic pathways. The main findings from the study demonstrated that the molecular and biochemical changes induced by PFOS are mediated in part by the gut microbiome, which alters gene expression and the host metabolome in mice.

Perfluorooctane sulfonate (PFOS) is a persistent environmental chemical whose biological effects are mediated by multiple mechanisms. Recent evidence suggests that the gut microbiome may alter the fate and effects of environmental chemicals in the host. Thus, the aim of this study was to determine whether PFOS influences the gut microbiome and host metabolism. Male C57BL/6 mice were fed a control diet with and without 0.003%, 0.006% or 0.012% PFOS. 16S rRNA gene sequencing, metabolomic, and molecular analyses were used to examine the gut microbiota of mice after dietary PFOS exposure. Dietary PFOS exposure caused a marked change in the gut microbiome compared to controls. Dietary PFOS also caused dose-dependent changes in hepatic metabolic pathways. Including integration of gut microbial expression and exposure, and the results indicates that ACHS females had higher POPs body burden. The occurrence of liver disease in participants of the Anniston Community Health Survey (ACHS), a historic cohort with exposures to multiple POPs, primarily polychlorinated biphenyls (PCBs). The current study aims to investigate if sex differences exist with serum POPs levels in the ACHS baseline (I) and follow-up (II) samples. The study also investigated if associations between POPs and liver disease biomarkers in the ACHS population are sex-dependent. Structural and functional groupings of PCBs congeners were tested for differences across sex with adjustment for lipids only or adjusted for age, BMI, total lipids, race/ethnicity, diabetes, drinking and smoking status for ACHS I (517 females, 221 males) and II (245 females, 93 males). Sex differences for levels of organochlorine pesticide (OCPs) and liver disease biomarkers were also assessed in ACHS I. Generally, females had higher levels of PCBs compared to males. Total mono-ortho PCB levels were higher for females in both ACHS I and II. Further, the non-ortho, dioxin-like PCBs (e.g. 81, 126, 169, 189) were higher in females at follow-up. Additionally, females in ACHS II had higher estrogen-like (types 1 and 2), anti-estrogenic and thyroid-like PCB levels. In terms of disease biomarkers, females from ACHS I exhibited higher leptin, adiponectin and total cholesterol vs. males. Importantly, these females had higher levels of OCPs including hexachlorobenzene, oxychlordane and DDT. Generally, in terms of PCB load, females had higher concentrations of PCB congeners with lower chlorine substitutes while males had higher levels of congeners with higher number of chlorine substitutes. Taken together, the results indicated that ACHS females had higher POPs body burden. The findings warrant further investigations into sex-based disease outcomes with pollutant exposures.
Persistent organic pollutants (POPs) including 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), 2,3,7,8-tetrachlorodibenzofuran (TCDF), and polychlorinated biphenyls have been extensively studied. However, how the intestinal microbiome and the systemic effects of POPs in rodent models to better clarify the host-microbiome relationship in the toxicity response, we explored connections between changes in the microbial metatranscriptome and metabolome with host toxicity. Metatranscriptomic analysis of the mouse intestinal cecal microbiome after a 5-day exposure to low dose TCDF (5 µg/kg) or high dose TCDF (24 µg/kg) was conducted. SAMSA2 (Simple Annotation by Metatranscriptomes by Sequence Analysis) identified enzymes and pathways directly enriched or depleted after treatment of TCDF including increased amino acid metabolism (LDA score = 2.94, P Value < 0.05) increased serine-glycine-oxytate cycle (LDA score = 3.03, P Value < 0.05) and decreased glycogen metabolism (LDA score = 3.06, P Value < 0.05) after TCDF treatment in the microbiome. Additionally, 16S rRNA and metagenomics sequence analysis were integrated with 1H NMR and high resolution Orbitrap mass spectrometry metabolomics data to predict the changes that were seen with the metatranscriptomic analysis. This investigation not only elucidated the systemic metabolic changes that were directly caused by TCDF modulation of the intestinal microbiome but also provided validation for the predictive techniques used to understand the toxic interaction with the microbiome. Importantly, this study provides convincing evidence that establishing microbiome toxicity endpoints may help to better inform risk assessment.

Physiologic and Metabolic Impact of Persistent Organic Pollutants on Gut Microbiota

Y. Tian1, J. Cai1, W. Gu1, and A. D. Patterson1. 1Pennsylvania State University, University Park, PA; and 2Wuhan Institute of Physics and Mathematics, University of Chinese Academy of Sciences, Wuhan, China.

Emerging evidence supports that exposure to persistent organic pollutants (POPs) can impact gut microbiota-host metabolic homeostasis, leading to metabolic disorder. Here, we examined the direct effects of POPs including 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), 2,3,7,8-tetrachlorodibenzofuran (TCDF), and polychlorinated biphenyl (PCB)-123 on the gut microbiota using in vitro models. Mouse cecal microbiota were incubated with three doses of TCDD (high: 0.2 µg/ml, middle: 0.02 µg/ml, and low: 0.002 µg/ml), TCDF (high: 2 µg/ml, middle: 0.2 µg/ml, and low: 0.02 µg/ml), and PCB (high: 2 µg/ml, middle: 0.2 µg/ml, and low: 0.02 µg/ml) for 4 h in an anaerobic chamber. NMR- and mass spectrometry-based metabolomics combined with flow cytometry was used to evaluate the direct physiologic and metabolic impact of TCDD, TCDF, and PCB on the microbiota. TCDD, TCDF, and PCB treatment all resulted in significant decreases in microbial metabolic activity following POPs treatment in a dose-dependent manner (decrease from 62.7 ± 6.4% [vehicle] to 53.6 ± 1.6% [TCDD], 55.0 ± 0.6% [TCDF], and 52.9 ± 1.1% [PCB]). Global and targeted 1H NMR analyses revealed significant changes in microbial metabolites including dose-dependent increases in microbial lipids (increase 1.18-fold [TCDD], 1.16-fold [TCDF], and 1.19-fold [PCB]) and decreased amino acids, lactate, and lactate after TCDD, TCDF, and PCB treatment. These data provide new insights into the direct role of POPs on the gut microbiota and begin to establish possible microbial toxicity endpoints which may help to better inform risk assessment.

Chronic Exposure to Tetrabromobisphenol A Potentially Alters Circadian Rhythm in Rats

S. J. Coulter1, G. A. Knudsen1, and L. S. Birnbaum1. 1National Cancer Institute, Research Triangle Park, NC; and 2NIEMS/NTP, Research Triangle Park, NC.

Tetrabromobisphenol A (TBBPA) is a brominated flame retardant used as a component in the epoxy resin of circuit boards for electronic devices. It has been found at higher levels inhous dust, and thought initially to be not present in health risks, more recent studies have indicated a potential link between higher exposure levels and uterine tumors in rats, as well as suggesting that it may have endocrine disrupting function. The International Agency for Research on Cancer (IARC) determined in 2016 that there was sufficient evidence to list TBBPA as probably carcinogenic to humans (Group 2A). Previous studies in our lab using Wistar Han rats treated with 250 mg/kg/d for 5 days linked TBBPA exposure to disruption in estrogen homeostasis and potentially thyroid and immune system function. RNA-Seq analysis of liver and uterus from the TBBPA and vehicle-treated rats also indicated a possible effect on expression of the genes controlling circadian rhythm. To investigate this, expression levels of the core circadian genes Clock, Arntl (Bmal1), Npas2, Period (Per) 1, 2, and 3, and Cryptochrome (Cry) 1 and 2 were measured in liver and uterus from these rats using droplet digital PCR (ddPCR). After accounting for differences in time of euthanasia, results showed a possible shift of the gene expression in the uterus but not the liver of the animals treated with TBBPA. For the genes that were expected to alter the estrus cycle and are representative of possible pathways for perturbation of estrogen levels in the uterus, as well as affecting expression of numerous other genes which are reliant on circadian signals to regulate expression. This research was supported by the Intramural Research Program of NIH/NIC (Project ZIA BC 011476).

Mitigating the Health Consequences of Paternal Exposure to Arctic Pollutants with Folic Acid

P. L. Charest1, M. Lessard1, P. M. Herst1, P. Navarro1, A. MacFarlane2, S. Kimmins3, J. Trasher3, M. Dalval1, M. Benoît-Biancamano4, and J. L. Bailey4. 1Université Laval, Quebec City, QC, Canada; Health Canada, Ottawa, ON, Canada; 3McGill University, Montreal, QC, Canada; and 4Université de Montréal, St-Hyacinthe, QC, Canada.

Traditional diets of Inuit people result in low folate intake and high body burdens of Persistent Organic Pollutants (POPs), known to have negative health effects. Indeed, Inuit have more adverse pregnancy outcomes and shorter life expectancies than non-Inuit Canadians. Recent studies have shown that the father’s lifestyle influences his offspring health. Therefore, we hypothesized that Folic acid (FA) supplementation might protect paternal health in the presence of POPs. In this study, we evaluated the direct physiologic and metabolic impacts of POPs at the intestinal level of the father and male offspring and explored the potential relationship between the paternal POP burden, FA supplementation, and fetal development. The study provided evidence that FA supplementation may protect against POP-associated health effects in the offspring of fathers with high POP burdens.

Telomeres as a Potential Target for the Chronic Toxicity of Polychlorinated Biphenyls (PCBs)

S. VanEtten1, M. Bonner1, X. Ren1, L. Birnbaum2, P. Kostyniak3, and J. Olson4. 1University at Buffalo, Buffalo, NY; and 2NIH/NTCP, Research Triangle Park, NC.

Telomeres are DNA-protein complexes found at the ends of chromosomes that help protect the genome from degradation and interchromosomal fusion. Telomere length (TL) can be affected by various factors, including age and increased oxidative stress. TL has been associated with higher risks for several types of cancer. The National Toxicology Program (NTP) conducted two year studies exposing female Sprague Dawley rats to various doses of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), the dioxin-like compounds (DLC) PCB 126 and PCB 118, the non-DLC PCB 153, and a mixture of PCB 126 and PCB 153. Relative telomere length (RTL) is a biomarker that may be associated with neoplastic and/or non-neoplastic responses observed with chronic exposures.
to PCBs. DNA was isolated from banked liver and lung tissue obtained from the NTP studies and RTL was assessed by quantitative PCR. Relative to time-matched vehicle controls, liver RTL increased 3-10% and 15-24% in rats given various doses of TCDD for 13 weeks and 52 weeks, respectively. Similarly, RTL increased 7-13% and 17-27% in the liver and increased 6-15% and 14-33% in the lung following exposure to PCB 126 for 13 weeks and 52 weeks, respectively. Rats dosed with PCB 118 showed increases in liver RTL of 2-17% and 15-30% and increases in lung RTL of 8-20% and 15-18% following 13 week and 52 week exposures, respectively. Following 13 weeks of exposure to the mixture of PCB 126 and PCB 153, RTL increased 9-11% in the liver and 12-16% in the lung. After 52 weeks of exposure to the mixture of PCB 126 and PCB 153, liver RTL increased 24%, while lung RTL increased 6-28%. In contrast, RTL decreased from 4-9% in the liver of rats receiving PCB 153 alone. The association between RTL and test compound is congener-specific and associated with the varying toxicological activity of PCB congeners. An increase in RTL was observed in rats treated with the DLCs, TCDD, PCB 126, and PCB 118, and the mixture of PCB 126 (DLC) and PCB 153 (non-DLC). These rats also showed an increased incidence of cancer and other non-neoplastic lesions in the liver, lung, and other organs. In contrast, a general reduction in RTL was observed in rats treated with PCB 153 alone, which exhibited hepatic hypertrophy and other non-neoplastic lesions. Increases in RTL may be an early indicator of carcinogenesis that occurs following two years of exposure to DLCs. Supported in part by the intramural research program of NCI/NIH.

1201 Transcritomic Analyses of Ortho-PCB Exposures in Larval Zebrafish

Developmental effects of PCBs are among the most important and least well-understood concerns in PCB toxicology. Ortho-substituted PCBs are far more abundant than the dioxin-like planar non-ortho-PCBs, and consequently are still found in significant concentrations in human maternal samples. In this study, we used zebrafish larvae to investigate the transcritomic effects of neurotoxic PCBs developing vertebrata. PCB52, PCB95, and PCB153 were not acutely toxic to zebrafish in nominal water-borne concentrations up to 1 μM. However, ortho-substituted PCB153 and PCB95 alter the behavior of 6 days post-fertilization (dpf) zebrafish larvae in standard light-dark movement assays. Both PCBs caused an increase in light-stimulated freezing, and a decrease in dark induced activity following exposures from 4 hours post-fertilization (hpf). To examine more acute effects of ortho-PCB exposure, transcriptomic analyses of zebrafish larvae exposed from 48-72 hpf were performed. Similar numbers of genes were differentially regulated by PCB153 and PCB95 after 24 hrs. PCB153 dysregulated 265 genes (90 up- and 175 down-regulated), while PCB95 altered 89 genes. PCB153 down-regulated CYP activity, glycosylation/glucogenesynthesis, and lipid binding and transport, and CYP2A4s were prominently down-regulated. PCB95 strongly dysregulated expression of apolipoprotein (apoA and M) and up-regulated genes for fatty acid and cholesterol binding and transport. In contrast, these short exposures to moderate concentrations of PCB95 significantly altered only 5 genes, with only zona pellucida glycoprotein expression being significantly up-regulated. The low number of genes dysregulated by PCB95 and 52 in this study may be a result of significant variation in the control, DMSO-exposed fish. Ongoing work on targeted transcritomic analyses of larvae will provide important information on the mechanisms of these environmental toxicants. NIH SPA2ES007381. The Boston University Superfund Research Program.

1202 Skeletal Toxicity of Co-planar Polychlorinated Biphenyl Congener 126 in the Rat Is Aryl Hydrocarbon Receptor-Dependent

A. Williams1, J. Watt1, L. Robertson1, M. Osborn1, M. Soares1, and M. Ronis1. 1Louisiana State University Health Sciences Center, New Orleans, LA; 2University of Iowa, Iowa City, IA; 3Louisiana State University, Baton Rouge, LA; and 4University of Kansas Medical Center, Kansas City, MO.

Polychlorinated Biphenyls (PCBs) are persistent organic pollutants which bioaccumulate up the food chain. There is epidemiological evidence linking this to decreased bone mineral density, however mechanisms whereby PCBs produce bone loss are poorly studied. PCBs are complex mixtures of ortho- and co-planar congeners. The toxicity of co-planar PCBs have been suggested to be associated with activation of aryl hydrocarbon receptor (AhR). The hypothesis underlying this study is that co-planar PCB 126 acts on the skeleton via the AhR. PCB 126 (5 umol/kg) or corn oil control was administered to N=3-6 male and female, Wild Type (WT) and AhR-/- rats via intraperitoneal injection. Animals were sacrificed after four weeks, bone length was measured and bone morphology was assessed by micro-computed tomography.

WT rats exposed to PCB126 had reduced serum calcium, tibia length, cortical total area and medullary area relative to vehicle controls (P<0.05), with an increased effect in females relative to males. There were no significant effects on cortical thickness or trabecular parameters. Reduced bone length was the only genotype specific effect (P<0.05). In contrast, the effects of PCB126 on bone parameters was abolished in AhR-/-animals. The data suggests that effects on cortical bone loss may be mediated by AhR.

Studies will clarify importance mechanisms underlying skeletal toxicity of dioxin-like PCBs and highlight potential therapeutic targets to combat bone loss. Supported in part of PREP R25GM12189 and NIH-R37AA10282 (MJR).

1203 Toxicity of PCB126 in Adult Male and Female Rats, Including Timed Pregnant Rats

N. Eti1, V. E. Klenov1, S. Flor1, K. Ikal2, J. Watt3, W. H. Watson3, A. F. Keating3, K. N. Gibson-Corley4, M. J. Ronis5, M. J. Soares5, G. Ludewig5, and L. W. Robertson1. 1University of Iowa, Iowa City, IA; 2University of Kansas Medical Center, Kansas City, KS; 3Louisiana State University Health Sciences Center, New Orleans, LA; 4University of Louisville, Louisville, KY; and 5Iowa State University, Ames, IA.

PCB126 is the most potent dioxin-like toxicant among PCBs. It binds to the aryl hydrocarbon receptor (AhR), a ligand-activated transcription factor involved in the regulation of biological responses to planar aromatic hydrocarbons. The AhR regulates many xenobiotic-metabolizing enzymes, such as CYP1A1. PCB126 is not only hepatotoxic, but also a reproductive and developmental toxin. Our hypothesis is that PCB126 is more toxic in utebro than in adult male rats. To test this, we used AhR/- only (AhR KO) rat model created using CRISPR/Cas9, and a timed pregnant rat study. Comparisons were made between wild type (WT) and AhR KO male and female Holtzman Sprague Dawley rats and Sprague Dawley pregnant rats (dams). In AhR KO study, rats received a single IP dose of corn oil (5ml/kg) or PCB126 (.5umol/kg) in corn oil and necropsied the next day 12 and 24 h. In pregnant rat study, dams were injected with a single IP dose of corn oil (5ml/kg) or different doses of PCB126 (0.5, 1.0, 2.0, 5.0, 5μmol/kg) on gestation day 12 and necropsied after 6 days. Both, PCB126 exposed WT rats and dams had significant weight loss (P<0.05) compared to AhR KO rats. Similarly, relative thymus weights were lower (P<0.05) and relative liver weights were higher (P<0.05) in WT rats and dams compared to PCB126 exposed AhR KO rats. In addition, PCB126 exposed WT rats had decreased serum glucose levels, while there was no effect on serum glucose in the AhR KO rats and dams. Also, relative ovarian weight was decreased in female WT rats exposed to PCB126, but no significant change was seen in exposed AhR KO rats and dams. In contrast, serum estradiol level was unaffected by PCB126 in WT and AhR KO female rats, while PCB126 exposed dams had significantly increased serum estradiol. Moreover, the high dose of PCB126 (5μmol/kg) decreased average fetal number, and increased the implantation sites, suggesting fetal death and loss, but no adult rats died within the first 2 weeks after receiving the same dose. All effects in the dams were dose-dependent. These data suggest that most, if not all, toxic effects of PCB126 are mediated through the AhR and that even short time (6 days) in utebro exposure is extremely toxic, possibly due to a dysregulation of the estradiol homeostasis. Funded by NIHES P24ES053661; HD020676; HD079363.

1204 Beneficial Effect of Resveratrol in Combined Treatment with Cisplatin on Growth Inhibition and Apoptosis Induction in Gastric Cancer SGC-7901 Cells

Y. Xu1, X. Wu1, Q. Liu1, W. Zheng2, and G. Zhao1. 1Hubei University of Chinese Medicine, Wuhan, China; and 2Purdue University, West Lafayette, IN.

Cisplatin, also known as cis-dichlorodiammine platinum (DDP), is a commonly used chemotherapy drug in clinical treatment of gastric cancer; however, the drug has been shown to have a dose-dependent toxicity to body systems. To reduce its toxicity and enhance chemotherapeutic efficiency, it is desirable to co-administer non-toxic compound(s) to reduce the dosage of cisplatin while maintaining its anti-cancer effect. Resveratrol (RES) is a polyphenol compound isolated and extracted from grapes, blueberries and other Chinese herbal plants such as polygonum giant knotweed and mulberry. This study was designed to use cultured gastric cancer SGC-7901 cells to test the hypothesis that co-treatment of RES with cisplatin may enhance the latter’s efficacy in inhibiting the cancerous growth and in induction of apoptosis in SGC-7901 cells. Experiments were divided into 6 groups: control without drugs, RES-only (50 μM), RES combined with low and medium-cisplatin groups (50 μM RES+1 μg/mL and 4 μg/mL DDP, respectively), mid-dose cisplatin-only (4 μg/mL DDP), and high-dose cisplatin only (6 μg/mL DDP). Twenty-
four hours after various treatments in cultured cancer cells, the MTT assay showed that the growth inhibition in the low-dose DDP group treated with RES was significantly higher than that of the mid-dose DDP alone. Similarly, the RES treatment in the mid-dose DDP group achieved a more significant inhibition of cancer cell growth than the high-dose DDP alone. Data by the flow cytometry indicated that the apoptosis in the low-dose DDP treated with RES was significantly higher than that by the mid-dose DDP alone, and the effect of RES in the mid-dose DDP was higher than that of the high-dose DDP alone. Results of cell cycle detection further showed that RES in the low-dose DDP group blocked SGC-7901 cells in G0/G1 phase, which was similar to the effect of the treatment by the mid-dose DDP alone; the combination treatment with RES and the mid-dose DDP achieved the similar effectiveness by the high-dose DDP alone. Taken together, our results suggest that RES appears to show a beneficial anti-cancer therapeutic effect in combined treatments with cisplatin; the effect is due to RES’s enhancement of cisplatin’s inhibiting growth and inducing apoptosis in cancerous SGC-7901 cells.

1205 Metformin Scavenges Methylglyoxal to Form a Product That Improves Endothelial Cell Function: Potential Novel Mechanism of Metformin Action

H. Nguyen, S. Lau, and T. Monks, Wayne State University, Detroit, MI.

Reactive dicarbonyls, such as methylglyoxal (MG), are highly elevated in type-two diabetes mellitus (T2DM) patients. These endogenous electrophiles covalently react with proteins to form non-enzymatic advanced glycation end products (AGEs), which are major causes of cellular damage and dysfunction during diabetic cardiovascular complications. The T2DM first-line drug therapy, metformin (MF), significantly reduces adverse diabetic endpoints more effectively than other antihyperglycemic agents. The exact mechanism(s) by which metformin inhibits cardiac maladies is far from well characterized. We previously discovered that metformin scavenges MG to form a novel imidazoline (IMZ) metabolite, thus reducing MG-related AGEs. Many compounds that possess an imidazoline act as ligands for imidazoline receptors (IR) and the alpha-2 adrenergic receptor (α2R). IMZ, the product of the MF and MG reaction as a novel imidazolinone (IMZ) metabolite, is a potent IR and α2R antagonist that initiates a cascade of processes, including vasodilation. We therefore hypothesize that IMZ improves endothelial cell function and contributes to the therapeutic effects of MF. In the current studies we examined the in vitro effects of IMZ on endothelial cell function using HUVECs and characterized potential signaling pathways. We show that IMZ at physiological relevant concentrations induces the production of the potent endothelial derived relaxation factor (EDRF), NO, concomitant with an increase in the activation of endothelial nitric oxide synthase (eNOS). IMZ-induced NO production was blunted by pretreatment with I1R and α2R antagonists, suggesting that IMZ action is receptor mediated. We also observed that IMZ cause the activation of Akt and ERK1/2, in both a concentration and time-dependent manner. IMZ-induced activation of Akt, ERK1/2, eNOS was inhibited in the presence of a PI3K inhibitor. Interestingly, ERK1/2 phosphorylation mediated by IMZ was also reduced in the presence of Akt1/2 specific inhibitors, suggesting that ERK1/2 might lie downstream of Akt during IMZ-initiated activation. The effects of IMZ on angiogenesis function were also evaluated. In co-culture experiments, IMZ treatment significantly increased tube length compared to untreated controls. Collectively, the data demonstrate that IMZ might contribute to the protective effects of metformin on endothelial cell function by activating I1R and/or α2R-Akt-ERK1/2-eNOS-NO pathway. Studies are ongoing to further elucidate and confirm the effects of IMZ in vivo models.

1206 A Novel Metformin-Methylglyoxal Imidazoline Metabolite Sensitizes Cells to Insulin: A Potential Role in Alleviating T2DM Complications

T. Hargraves1, N. Mastranord2, S. Lau, and T. Monks, 1University of Arizona, Tucson, AZ; and 2Wayne State University, Detroit, MI.

Reactive dicarbonyls, such as methylglyoxal (MG), are elevated in type-two diabetes mellitus (T2DM) patients. These endogenous electrophiles covalently modify proteins, which may contribute to diabetic complications. The T2DM first-line therapy, metformin (MF), significantly reduces adverse diabetic endpoints and mortality more effectively than other antihyperglycemic agents, the mechanism(s) of which remain unclear. We have identified and characterized the product of the MF and MG reaction as a novel imidazoline (IMZ) metabolite. IMZ was detected via LC/MS in MF-treated T2DM patients, and MF urinary levels directly correlated with urinary IMZ. Scavenging of MG by MF represents a possible alternative mechanism of MF drug efficacy, in addition to its antiglycogenesis properties. Imidazoline receptors (IR) are novel targets for drug development in disorders associated with T2DM because they are involved in insulin secretion/sensitization and glucose homeostasis. Thus, we examined the ability of IMZ to modulate insulin-mediated cell signaling pathways, via western blot in PC12 (express high levels of I1R and lack the α2-adrenergic receptor) and HepG2 (a common cell model for insulin signaling) cells. Combination treatment of insulin and IMZ at physiologically relevant concentrations (1 pM and 1nM) increased AKT and ERK1/2 phosphorylation above levels seen with insulin treatment alone. Moreover, IMZ also restored high glucose-induced decreases in AKT and ERK1/2 phosphorylation and AKT signaling pathway. This potentiation was not observed in the presence of I1R and α2-AR antagonists. Therefore, IMZ may enhance insulin action in the insulin-dependent AKT and ERK pathways through I1R and α2-AR activation. Preliminary in vivo pharmacokinetic studies show that IMZ (IP, 10mg/kg and 20mg/kg) is rapidly absorbed and quickly eliminated. In addition, IMZ enhanced hepatic pAKT after 40 minutes. In summary, the formation of IMZ in T2DM patients provides evidence that MF scavenges MG, potentially reducing detrimental protein modifications. This property of MF may play a role in the reduction of diabetic complications and represents a potential alternative mechanism of MF drug efficacy. Further, research in diabetic (db/db) mice are ongoing to assess whether IMZ has the ability to improve glycemic control and insulin responsiveness in vivo.

1207 In Vivo and In Silico Evaluation of Anti-diabetic Effect of White Butterfly (Clerodendrum volubile) Leaves

O. Molehin1, O. Elekofehinti2, and O. Oloyede1, 1Ekiti State University, Ado-Ekiti, Nigeria; and 2Federal University of Technology, Akure, Nigeria.

White Butterfly (Clerodendrum volubile) leaf is commonly used in traditional medicine for the management of various diseases including diabetes in Nigeria. This study sought to propose the possible mechanism underlying the anti-diabetic effect of C. volubile leaves in streptozotocin (STZ)-induced diabetic rats using in vitro and in silico approach. Aqueous extract of C. volubile was prepared and its effect assessed on relevant enzymes associated with diabetes. Fifty Male Wistar rats (n=5) were randomly separated into ten groups. The induction of diabetes in rats was by a single intraperitoneal injection of STZ (65 mg/kg body weight), which C. volubile extract was administered orally to diabetic and non-diabetic animals, at the doses of 50, 100, and 200 mg/kg body weight for 14 days. Also the interaction of compounds identified from C. volubile (HPLC-DAD) on Takeda-G-protein-receptor-5 (TGR5), peroxisome proliferated activated receptor gamma (PPAR gamma) and dipeptidyl-peptidase 4 (DPP-4) was also investigated through molecular docking. Administration of C. volubile extract significantly reduced the elevated plasma glucose level and body weight, improved kidney functions, attenuated oxidative stress by decreasing MDA levels, enhancing superoxide dismutase, catalase and glutathione peroxidase activities, reinstated the lipid profile to normal level and restored pancreatic histological integrity in diabetic rats. Rutin ranked highest among all the compounds identified in C. volubile with -8.3 kcal/mol binding energy with TGR5 with Glu343 and Glu291 -7.9 kcal/mol (PPAR gamma) and -9.5 kcal/mol (DPP-4). Glu77, Arg125, Tyr240, Glu343, Tyr 662 are among residues enhancing rutin binding to these proteins. The results revealed that C. volubile possess anti-diabetic effects through the modulation of TGR5, PPAR gamma, and DPP-4. Rutin and other compound responsible for the anti-diabetic effect of C. volubile justifying the use of this plant in traditional medicine.

1208 TGF-β1 Modulates G Protein-Mediated cAMP Generation in Human Airway Smooth Muscle (HASM) Cells

F. Chung1, C. A. Ojiaku2, G. Cao2, B. Deeneey2, V. Parikh3, C. Koziol-White1, and R. A. Panettieri Jr.2, 1Rutgers, The State University of New Jersey, New Brunswick, NJ; and 2Rutgers Institute for Translational Medicine and Science, New Brunswick, NJ.

G protein coupled receptor signaling modulates human airway smooth muscle (HASM) relaxation through the β3-adrenergic receptor (β3AR/G/adenylyl cyclase axis, inducing dilation of the airways in asthma. Our previous studies showed that the pro-fibrotic cytokine, transforming growth factor beta 1 (TGF-β1), enhanced contractility of HASM. Accordingly, we hypothesize that TGF-β1 attenuates β3AR agonist-induced relaxation of HASM through modulation of G protein. HASM cells were stimulated in serum-free F12 media with TGF-β1 (10 ng/mL) overnight. Subsequently, HASM cells were treated with cholera toxin (CTX) (0.25 μg/mL; 30-60 min), the β3-agonist ISO (1 μM; 5 min), or the adenylyl cyclase direct activator, FSK (10 μM; 15 min). HASM were lysed and intracellular cAMP levels were determined by chemiluminescent immunoassay. In addition, phosphorylated myosin light chain (MLC) and total MLC were determined by immunoblot after HASM cells were stimulated with CTX (0.25 μg/mL; 30-60 min) or ISO (1 μM; 10 min) in the presence and absence of carbachol (CCh) (20 μM; 12 min) or TGF-β1. Data is represented as mean ±
Selenium plays an essential role in redox biology and redox toxicology. It is found at the active site of redox enzymes such as, glutathione peroxidases (GPx) and thioredoxin reductases (TrxR). Cell culture media is typically deficient in selenium; this deficiency could limit seleno-enzyme expression and activity, compromising the translation of data from in vitro experiments to in vivo settings. The level of selenium in cell culture media should always be a consideration. However, any supplementation must be within a range to overcome deficiency and yet not induce toxicity. The optimal level of supplementation has not been well characterized. To determine optimal levels of Se-supplementation of cell culture media we introduced varying levels of sodium selenite (Na2SeO3) or seleno-L-methionine (SLM). We established, that the window to avoid potential toxicity can be widened by using SLM instead of selenite. We assessed the expression and activity of GPx1 and GPx4 to determine the level of optimal selenium supplementation for a variety of cells. Supplementation cell culture media containing 10% FBS with 100 - 300 nM SLM, we were able to maximize GPx1 and GPx4 enzyme expression and activity. Interestingly, data from a clinical trial at The University of Iowa indicates that supplementing Se in humans does not increase GPx1 activity in blood. Subjects received ~30x the RDA (35 μg d-1) of Se as SLM daily for more than 7 mo. The level of total Se in blood increased about 50-fold. However, the activity of GPx1 in blood remained constant. Our cell culture data show the importance of supplementing cell culture media with Se to insure full activity of these enzymes. This simple maneuver will increase the rigor and reproducibility of cell culture experiments and may lead to better translation of data addressing basic redox biology.
Poisoning is a significant global and national public health problem; and the leading cause of injury death in the United States. According to the World Health Organization, an estimated 193,460 people died of intentional poisoning, and 47,478 deaths were attributed to unintentional poisoning in the United States. Approximately 60,000 emergency department (ED) visits, annually, result from unintentional medication overdoses among children under the age of 5. The purpose of this study was to examine the US trends in fatal pediatric poisonings, and to examine the recorded circumstances of fatalities from poisoning in children under 5 years old. The investigators reviewed ten years of American Association of Poison Control Centers (AAPCC) annual reports examining pediatric fatalities from years 2007–2016. Exposures to children over age five years, adults, and animals were excluded from the review. In total, there were 419 deaths in children 5 years and under, during the 10-year period. In cases where intent was known, forty percent of pediatric fatalities were due to unintentional exposures, and 14% were attributed to malicious intent. Fifty-one percent of cases were attributed to non-pharmaceutical exposures, including 20 cases of carbon monoxide poisoning, and 17 cases of disc battery ingestions. Forty-nine percent of exposures attributed to pharmaceuticals included categories such as opioids, analgesics, cough and cold preparations, antidepressants, and amphetamines and street drugs. The findings indicate an opportunity and mandate for toxicologists to participate in inter-professional collaboration for prevention measures on significant public health issues to prevent tragic poisoning deaths in young children.

Carbon monoxide is a colorless, odorless gas, the inhalation of which can be fatal. There is only one report on CO poisoning in cats in the literature. Two adult Singapura brown ticked cats were submitted to the San Bernardino branch of CAHFS for necropsy. These animals had been found dead in an apartment along with their two deceased owners. At necropsy, gross lesions were similar in both cats and consisted of multifocally large and irregular, bright red spots on the skin of the abdomen and the inner surface of ear pinna, bright red muscles and blood. The carcasses, and tissues fixed in formalin retained the bright red discoloration for up to two weeks. Microscopic lesions were also similar in both cats and included diffuse pulmonary congestion and edema, and multifocal intense basophilia of cardiomyocytes. The latter was seen mostly affecting whole fibers but it was occasionally affecting only a portion of the fiber, with a clear transverse line of demarcation from the rest of the fiber. Van Kossa staining of these fibers was unrewarding. Rarely, discrete areas of hypercontraction bands were seen in individual cardiomyocytes. Based on the clinical history, gross and microscopic changes, carbon monoxide poisoning was suspected, and frozen muscle and blood from the two animals were submitted for toxicological analysis. The muscle samples were negative for cyanide by distillation method. The blood samples were analyzed for carbon monoxide by a modification of the Compac® electrochemical gas meter. The blood carboxyhemoglobin (COHb) was measured as % saturation, and values of 57 % and 41 % were found for both cats, respectively. Twenty-five percent of serum samples were positive for carbon monoxide, and the blood hemoglobin (Hb) was significantly lower in both cats, compared to the normal values for the species. The presence of CO in the blood was confirmed by gas chromatography. The results of this study suggest that CO poisoning is a significant public health issue in cats, and that routine screening for COHb should be performed in cases of unexplained death in cats. The findings of this study also highlight the importance of inter-professional collaboration for prevention measures on this significant public health issue.

Acetaminophen (paracetamol) overdose is the commonest cause of acute liver failure. Calfamafodipin (CaM) is a superoxide dismutase mimetic that prevents acetaminophen toxicity in mice. The POP Trial was a phase 1, open label, rising dose, randomised study which explored the safety and tolerability of CaM in patients with acetaminophen overdose. The POP Trial had ethical and regulatory approval. Patients were recruited in the Emergency Department of the Royal Infirmary of Edinburgh, UK, from 8 June 2017 to 10 May 2018. The inclusion criterion was: adults within 24 h of a single or staggered acetaminophen overdose that required NAC treatment. Patients were randomly assigned with a 1:1 allocation ratio to one of three sequential dosing cohorts of 8 patients (n=6 for NAC+CaM; n=2 for NAC alone). The intravenous dosages of CaM were 2, 5 and 10 µmol/kg, administered over 5 min between NAC bags. All participants experienced at least one adverse event (AE). The numbers experiencing at least 1 serious adverse event (SAE) were: NAC alone, 2/6; NAC+CaM (2 µmol/kg), 4/6; NAC+CaM (5 µmol/kg), 2/6; NAC+CaM (10 µmol/kg), 3/6. In assessing causality, there were no AEs or SAEs probably or definitely related to CaM. ALT was similar across groups. Median FLK18 rate at 20h was: NAC alone, 306 U/L (range 118-2606); NAC+CaM (2 µmol/kg), 212 U/L (98-572); NAC+CaM (5 µmol/kg), 163 U/L (100-287); NAC+CaM (10 µmol/kg), 155 U/L (103-508). The median fold increase in FLK18 (baseline to 20h) with NAC alone was 1.71 (1.24-3.57). By comparison, with NAC+CaM treatment the
fold increase in FLK18 was smaller (2μmol/kg: 1.41 (0.53-2.80); 5μmol/kg: 1.02 (0.43-1.45); 10μmol/kg: 1.07 (0.74-4.34)). The change in mir-122 across groups was comparable to FLK18. CaM was tolerated in patients treated with NAC for acetaminophen overdose and may reduce hepatocyte injury. Clinicaltrials.gov NCT03177395. Funder PledPharma AB.

1217 Delayed Treatment with 4-Methylpyrazole Protects against APAP Hepatotoxicity by Inhibition of C-Jun N-Terminal Kinase

J. Akakpo1, A. Ramachandran1, W. Ding1, B. Rumack2, and H. Jaeschke1.
1University of Kansas Medical Center, Kansas City, KS; and 2University of Colorado School of Medicine, Aurora, CO.

Acetaminophen (APAP) overdose is a major cause of hepatotoxicity and acute liver failure in the United States. N-acetylcysteine (NAC) is the only antidote available against APAP hepatotoxicity, but is only effective within a narrow therapeutic window. 4-Methylpyrazole (4MP) is a US FDA approved drug for methanol and ethylene glycol poisoning. We have previously shown that co-treatment with 4MP effectively protects against APAP-induced liver injury by inhibiting cytochrome P450-dependent metabolic activation. Since a post-treatment regimen is clinically more relevant, we tested the hypothesis that delayed treatment with 4MP is still protective against APAP hepatotoxicity and this involves novel mechanisms. Male C57BL6/J mice were treated with 300 mg/kg APAP, followed by either 50, 100 or 200mg/kg 4MP, 90 min later (when almost all APAP metabolism is completed in the mouse). Animals were then sacrificed at 2, 6, and 24 hrs and stored at -40°C. Analysis of 4MP indicated that 4MP can bind to the ATP binding site of JNK. Downstream events of JNK activation such as mitochondrial oxidant stress and the release of apoptosis-inducing factor from mitochondria were also effectively prevented. Importantly, protein adduct formation was not affected, indicating that protection from delayed 4MP treatment is independent of its effect on APAP metabolism. Further investigation revealed that 4MP treatment also promoted autophagy and the removal of protein adducts but autophagic flux experiments suggested that this is only a minor contribution to the overall protection. We conclude that delayed treatment of 4MP effectively protects against APAP hepatotoxicity through the novel mechanism of being a competitive inhibitor of JNK. Thus, 4MP can be a useful complementary antidote to NAC with different therapeutic targets.

1218 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) Dysregulation of Hepatic One Carbon Metabolism during the Progression of Steatosis to Steatohepatitis with Fibrosis in Mice

R. R. Fling1, C. M. Doskey1, K. A. Fader1, R. Nault1, and T. Zacharewski1.
Michigan State University, East Lansing, MI.

TCDD has been linked to the development of numerous metabolic diseases including non-alcoholic fatty liver disease (NAFLD). One carbon metabolism (OCM) gene expression and metabolites levels, most notably S-adenosylmethionine (SAM) and S-adenosylhomocysteine (SAH), are often altered in NAFLD. Changes in the SAM/SAH ratio affect methylation reactions and this involves novel mechanisms. Male C57BL/6 mice were treated with 0.33, 1.0, or 3.3 μg/kg TCDD (0.3-30 μg/kg) every 4 days for 8 or 28 days. At 28 days, histopathology showed increased hepatic fat accumulation, Immune cell infiltration, bile duct proliferation and collagen deposition. TCDD dose- dependently repressed adenosylhomocysteine hydrolase (AcH; EDS0 10.4 μg/kg), betaine-homocysteine S- methyltransferase (BHMT; EDS0 11.2 μg/kg), cystathionine-β-synthase (CBS), glycine N-methyltransferase (Gmmt; EDS0 11.2 μg/kg), and methionine adenosyltransferase 1A (Mat1a; EDS0 4.5 μg/kg). Accordingly, protein levels of AcH, BHMT, CBS, Gmmt and Mat1a were decreased with increased levels of betaine, homocysteic acid, and methionine, while cystathionine (cyste), dimethylglycine (dmg), and sarcosine were decreased. Absence of protective dioxin response elements (pore) within AhR enriched regions of most OCM genes following 2hrs of TCDD exposure suggests non-canonical AhR regulation. A time-course study revealed modest Mat1a and CBSexpression at 168 hrs following a single bolus dose of TCDD indicating OCM disruption maybe a delayed response. At 8 days, repression of Mat1a and AcH resulted in decreased cyst and dmg levels, and the SAM/SAH ratio. These results suggest persistent AhR activation by TCDD leads to OCM disrup-

1219 Masitinib Induces Apoptosis in Human Hepatic and Cardiac Cells

Q. Shi1, L. Ren1, L. Pang1, J. J. Greenhaw1, X. Yang2, and W. B. Mattes1. 1US Food and Drug Administration, Rockville, MD; and 2US Food and Drug Administration, Silver Spring, MD.

Masitinib is a tyrosine kinase inhibitor that was temporarily approved by US FDA for veterinary use. Though masitinib is no longer approved for animal use, it is currently under phase 3 clinical trials for treating mastocytosis, rheumatoid arthritis, various types of cancers and nervous system diseases in humans. Clinically apparent acute hepatotoxicity has been associated with masitinib administration, but the mechanisms are unknown. Here we examined the short-term (6 to 24 h) cytotoxicity of masitinib in primary cultured rat, canine and human hepatocytes at concentrations normalized to human blood levels. Mode of cell death and mitochondrial functions were determined. We found that masitinib started to induce significant apoptosis and adenosine triphosphate (ATP) shortage at 4.5 μM, a concentration that equals to 1.5-fold the peak blood levels (Cmax) of masitinib in humans. At 10-fold Cmax, masitinib caused 100% lactate dehydrogenase (LDH) release in primary cultured hepatocytes, indicating that all cells were killed. Similar findings were obtained with human induced-pluripotent stem cell (iPS)-derived hepatocytes. However, in human iPS-derived cardiomyocytes (iPSC-CMs), significant cytotoxicity was not observed until the concentration was increased to 4-fold Cmax, suggesting that cardiomyocytes might be less sensitive to masitinib toxicity than hepatocytes. The apoptosis-inducing effect of masitinib was at least partially due to its capacity to induce mitochondrial cytochrome c release. These data indicate that direct hepatocyte cytotoxicity might contribute to masitinib associated hepatotoxicity.

1220 CYP2A5 Absence in PPARα-/- Mice Develop Less Obesity but More Severe NAFLD in Response to High Fat Diet

X. Chen1, P. Gao2, and Y. Lu3. 1East Tennessee State University, Johnson City, TN; and 3University of Dali, Dali, China.

Cytochrome P450 2A6 (CYP2A6) and its mouse ortholog CYP2A5 are mainly expressed in liver. CYP2A6 is associated with obesity and its hepatic expression is increased in patients with non-alcoholic fatty liver disease (NAFLD). High fat diet (HFD)-induced obesity and NAFLD were more severe in CYP2A5 knockout (cyp2a5-/-) mice than in wild type mice, suggesting that CYP2A5 protects against obesity and NAFLD. Very interestingly, peroxisome proliferator activated receptor α (PPARα) is upregulated in cyp2a5-/- mice. PPARα regulates lipid metabolism and glucose homeostasis in liver. To examine the possible role of PPARα in the enhanced HFD-induced obesity and NAFLD in cyp2a5-/- mice, we created CYP2A5 and PPARα double knockout (ppara/-/cyp2a5-/-) mice by crossing PPARα knockout (ppara-/-) mice with cyp2a5-/- mice. The littermate including cyp2a5-/- mice and ppara-/- mice were used as control. After 14-week HFD feeding, serum alanine transaminase (ALT) was increased in ppara-/- and cyp2a5-/- mice but not in cyp2a5-/- mice and ppara-/- mice. Haematoxylin and eosin staining in liver sections showed that hepatosteatosis was more severe in ppara-/-/cyp2a5-/- mice than in cyp2a5-/- mice and ppara-/- mice, more inflammatory foci were observed in ppara-/-/cyp2a5-/- mice than in cyp2a5-/- mice and ppara-/- mice; satellitosis (inflammatory cells surrounding big lipid droplets) and inflammation-associated nodules were observed in ppara-/-/cyp2a5-/- mice but not in cyp2a5-/- mice and ppara-/- mice. Immunohistochemistry staining showed that lipid droplet protein perilipin-2 was more extensive in ppara-/-/cyp2a5-/- mice than in cyp2a5-/- mice and ppara-/- mice. Sirius red staining and Trichrome Masson staining indicated that fibrosis was developed in ppara-/-/cyp2a5-/- mice but not in cyp2a5-/- mice and ppara-/- mice; consistently, expression of collagen and α-smooth muscle actin was increased in ppara-/-/cyp2a5-/- mice. However, body weight was increased in cyp2a5-/- mice to a greater extent than in ppara-/- mice and ppara-/-/cyp2a5-/- mice; consistently, expression of collagen and α-smooth muscle actin was increased in ppara-/-/cyp2a5-/- mice more than in cyp2a5-/- mice. Glucose tolerance test indicates that ppara-/- mice and ppara-/-/cyp2a5-/- mice were more tolerant to glucose than cyp2a5-/- mice. These results suggest that PPARα may enhance the protective effect of CYP2A5 on NAFLD but suppress the anti-obese effect of CYP2A5.
The disease burden of liver diseases is high and despite years of research much remains to be explored in the molecular mechanisms behind liver regeneration and hepatocellular carcinoma (HCC). The liver has a unique and intrinsic regenerative capacity which could be triggered by, but not limited to hepatotoxins and surgical removal of liver tissue. Several animal studies demonstrated spontaneous liver regeneration after partial hepatectomy and hepatocellular carcinoma after exposure to chemicals such as diethylnitrosamine (DEN). Interestingly, osteopontin and Wnt/β-catenin pathway independently play important roles in liver regeneration after partial hepatectomy and chemical-induced HCC in mice. Furthermore, osteopontin is a Wnt target gene. Our group previously observed a dramatic increase in the number of hepatocytes in S-phase in the transgenic mice overexpressing beta-catenin at 40 hours and 72 hours in the wild type mice following partial hepatectomy in mice. We therefore hypothesize that “Partial hepatectomy stimulate the Wnt/β-catenin pathway to potentiate liver regeneration by inducing osteopontin”. Osteopontin expression in liver tissue samples from wild type (WT), Serine-45 mutant β-catenin transgenic (TG) and β-catenin conditional knockout out mice (KO) after partial hepatectomy was assessed by immunohistochemistry. In addition, advanced imaging was performed on the stained sections. The time points post-hepatectomy considered include: 6 hours, day zero, 20 hours, 40 hours, 72 hours and 14 days. Our results showed a peak expression of osteopontin in the TG mice at 40 hours post-partial hepatectomy. In addition, there is greater expression of osteopontin in the TG mice compared to the WT mice 40 hours post-partial hepatectomy. Finally, our observation suggests that the deficiency of beta catenin suppresses the expression of osteopontin following partial hepatectomy in mice. In conclusion, Peak expression of osteopontin at 40 hours post-hepatectomy coincides with the previously observed peak proliferation of hepatocytes at the same time point in TG mice. Therefore, Wnt/β-catenin pathway may potentially regulate osteopontin expression following partial hepatectomy in mice. The interaction between Wnt/β-catenin pathway and osteopontin may play an important role in regenerative medicine and the pathogenesis of chemical-induced hepatocellular carcinoma.

Biochemical and Histological Studies on the Effect of African Iba, a Herbal Purgative, in Albino Rats

K. Ushedo1, M. Adegbola2, and C. Otuecher3. 1Redeemer’s University, Ede Town, Nigeria; and 2Federal Polytechnic, Ede Town, Nigeria.

Limited data is available about the toxicity of herbal remedies used for self-medication. Since a popular herbal remedy, African Iba Herbal Mixture (AFRIM), contains various bioactive molecules, the present study aimed to observe the biochemical and histological changes in the hepato-renal system of albino rats. Four groups of six male rats per group were used for the study. To group A was administered distilled water and served as control, while groups B, C and D were respectively administered with 100, 200 and 400 mg/kg body weight of AFRIM via gastric intubation for 14 days. Thereafter, animals were anesthetized and sacrificed by cervical dislocation; blood samples were collected for biochemical assays while the liver and kidney were processed for histopathological studies. While the administration of AFRIM did not significantly alter the levels of calcium, potassium and alanine aminotransferase across all treatment groups, aspartate aminotransferase, albumin, blood urea nitrogen were significantly (p < 0.05) reduced, especially at 200 and 400 mg/kg doses. Furthermore, there was a significant (p < 0.05) elevation in uric acid levels at the higher doses of AFRIM. Liver sections revealed mild to severe infiltration of inflammatory cells in zone 2 at 100 and 200 mg/kg of AFRIM. Kidney sections illustrated engorged glomeruli which appear shrunk with hyper-cellularity of mesangial cells at the 200 mg/kg dose. In light of this, caution and adherence to dosage prescription is strongly advised. This study is a contribution to scientific knowledge on the safety/toxicity profile of African Iba Herbal Mixture among the growing list of Nigerian herbal remedies.
Predicting drug metabolism and drug induced liver injury (DILI) remains challenging as all in vitro models, including cultured primary human hepatocytes (PHH), hepatoma cells and pluripotent stem cell (PSCs)-derived hepatocyte-like cells (HLCs) do not recapitulate many hepatic functions. We here created a robust protocol to generate PSC-hepatic progeny that significantly better approach mature PHH functions. PSC were engineered to overexpress 6 transcription factors (named HC6X). This, combined with metabolomics-based medium optimisation (named Med5), generated hepatic progeny that was gluconeogenic and used OxPhos to levels similar to PHHs. RNAseq demonstrated that the PSC-hepatic progeny were significantly more similar to PHHs than most if not all other PSC-derived hepatic cells. Among the top normalized pathways were xenobiotic metabolism, PPAR signaling, glycolysis and amino acid metabolism. An unbiased metabolomics profile of the cells is being completed. A repeated dose toxicity study with the 13 gold-standard training compounds described by the MIP-DILI Consortium (Sison-Young et al., 2017), demonstrated that HC6X-Med5 cells correctly identified 6 of 9 hepatoxins (IC50/LOEC = 10), without detecting false positive hits, which is similar to fresh PHHs, and significantly better than HepG2 or HepaRG cells. In line with their PHH-like mitochondrial activity, HC6X-Med5 cells were exquisitely sensitive to the mitochondrial toxin, Rotenone. Finally, CYP450 and UGT drug biotransformation studies demonstrated that the biotransformation capacity of HC6X-Med5 cells approximated that of the PHH-based Hepatopac system and surpassed that of HepG2 and HepaRG cells. Of note, drug toxicity and drug biotransformation were stable until at least d50 in vitro. To conclude, we developed a robust in vitro culture system consisting of genome edited PSC derived hepatic progeny cultured in optimised medium, which display drug biotransformation characteristics and accurate drug toxicity detection at levels similar to fresh PHHs, which remains stable until at least d50. This project received funding from the EU Horizon 2020 research and innovation programme, grant agreement No 681002.

Polychlorinated biphenyls have been characterized as epidermal growth factor (EGF) and transforming growth factor (TGF)-alpha secretory inhibitors in vivo. We identified a PSC hepatocytic line that can promote a fibrotic associated steatohepatitis (TASH) in exposed human populations and animal models. Current therapeutics for TASH or other subsets of NAFLD are nonexistent but are high priority due to the 25% prevalence of non-alcoholic fatty liver disease (NAFLD) worldwide. A PBC-mediated TASH animal model (C57BL/6 male mice fed a HFD) followed by epidermal growth factor (EGF) (0.2 μg/g) injections after 10 weeks post PBC exposure was conducted. Physiological liver, adipose, and serum samples were taken to measure therapeutic efficacy. Western blot, qPCR, and phosphoproteomic analyses were conducted to evaluate the mechanism of action for EGF and PBC exposure. EGF administration prevented PBC-mediated inhibition of hepatic EGF signaling. EGF also attenuated PBC-induced hepatic steatosis and bridging fibrosis, accompanied by decreased levels of steatois markers including plasminogen activator (PAI-1) and resistin. EGF administration also reduced PBC-induced elevation of hepatic free fatty acids by facilitating lipid export from the liver to the adipose tissue for storage. While EGF promoted hepatic gluconeogenesis, it however had no effect on glucose uptake. Mechanistically, EGF elicited its protective effects through EGF signaling which appeared to negatively regulate PBC-induced CAR activation. Additionally, EGF signaling positively regulated HNF4 α, a transcription factor crucial for hepatocyte function as well as LXRα and Nr2 expression and activity. Taken together, the results demonstrated that EGF administration ameliorated metabolic features caused by PBC exposures in a diet-induced obesity setting. Furthermore, EGF acted via multiple mechanisms such as phosphoregulation, nuclear receptor activity and adipokine secretion to protect mice against PBC-induced steatosis and fibrosis. These data strongly implicate the role of EGF signaling as a pharmacological target for TASH.
1229 Hepatic Fibrosis Is Induced by Ochratoxin A through SMAD Pathway in LX-2 Cells and Mice
S. Chae1, M. Pyo1, H. Lee2, J. Bae2, and K. Lee1. 1Korea University, Seoul, Korea, Republic of; and 2Korean National Food Cluster FOODPOLIS, Iksan, Korea, Republic of. Sponsor: J. Lee

Ochratoxin A (OTA) is a mycotoxin produced by some species of Aspergillus and Penicillium. It occurs mainly in the process of storing cereals and spices in a high temperature and high humidity environment. OTA is the most common and toxic substance among Ochratoxins. Food product which contains OTA can cause fatal damage to kidneys and liver. This study was conducted to investigate the causal mechanism between OTA and fibrosis. We assume that liver cells exposed to OTA express TGF-β1 by its TGF-β1 receptor on the cell membrane. Then, Smad2 and Smad3 are phosphorylated in the cytoplasm and transported into the nucleus, which induces Epithelial mesenchymal transition (EMT) leading to fibrosis. LX-2 cells were treated with OTA to determine proper cell viability. With in vitro and in vivo experiment, major liver fibrosis markers such as fibronectin, E-cadherin, and α-SMA were expressed in mRNA and protein level. Especially in vivo, it is observed that OTA induces pathological damage through Masson’s Trichrome staining in mouse liver tissue. Also, the hepatic fibrosis index in serum such as albumin, ALP, ALT, AST, and bilirubin showed the degree of liver damage. The expression of TGF-β1, Smad2, and Smad3 in mRNA and protein levels is increased. These results showed the relationship between liver fibrosis by OTA and TGF-β1, and Smad pathways.

1230 Distribution of Acetaminophen Protein Adducts following Repeat Administration of Subtoxic Doses in Fed Mice
N. Nguyen, J. Weemhoff, J. Akakpo, A. Ramachandran, and H. Jaeschke. University of Kansas Medical Center, Kansas City, KS.

Acetaminophen (APAP) is a widely used analgesic and is safe at therapeutic doses. APAP hepatotoxicity is initiated by formation of a reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI) which depletes cellular glutathione and binds to mitochondrial proteins to form protein adducts (APAP-CYS). Though APAP-CYS adducts have been identified as biomarkers in APAP hepatotoxicity and are also the focus of a recent bioassay in plasma to measure severity of APAP overdose, it is well recognized that circulating adducts also appear after therapeautic doses of APAP, indicating that their release at lower doses is independent of liver injury. Since multiple doses of APAP are typically taken over time, especially in situations of chronic pain, we hypothesized that the development of liver injury could be dictated by accumulation of adducts over time, especially within the mitochondria. This was tested in the mouse model by repeated sub toxic doses (75mg/kg and 150mg/kg) in fed mice to reproduce clinical use of the drug, followed by measurement of adducts within the liver, mitochondria and in plasma. Since autophagy has been shown to be involved in handling of cellular adducts, the effect of their perturbation was also analyzed. Our data shows that APAP-CYS was formed in mitochondria in the absence of liver injury, though this occurred in parallel with adduct accumulation in the whole liver. Despite detectable adducts within liver and mitochondria at lower doses, release into plasma was only evident when the dose was increased, suggesting the existence of a threshold effect for plasma release of adducts. Interestingly, interference with the removal of adducts through blocking autophagy consistently increased intracellular adduct levels and exacerbated liver injury. In conclusion, repeated administration of subtoxic doses of APAP result in accumulation of APAP-CYS within the liver and mitochondria, and its appearance in plasma seems to be concentration dependent. Any interference with adduct removal through autophagy elevates addsuct levels both in mitochondria and the liver and exacerbates liver injury.

1231 Differential Activation of Hepatocyte Tissue Factor Procoagulant Activity by Necrotic and Apoptotic Cell Death

Tissue factor (TF) is the transmembrane receptor for coagulation factor VIIa and the primary activator of the coagulation cascade. The TF:VIIa complex expressed by liver parenchymal cells (i.e., hepatocytes) lacks procoagulant activity under normal conditions. However, when the liver is injured, the TF:VIIa complex initiates intrahepatic coagulation. The mechanisms required to activate TF:VIIa procoagulant function are not known. We tested the hypothesis that hepatocyte TF:VIIa procoagulant activity is increased by hepatocyte injury and functionally connected to the mode of cell death. Necrosis of primary mouse hepatocytes was induced by the toxicant acetaminophen (APAP, 0.5 mM) and c-Fos-dependent apoptosis was induced using J02 antibody (0.5 mg/ ml). APAP treatment increased outer membrane permeability consistent with necrotic cell death, indicated by release of alanine aminotransferase (ALT). A slight, but significant (~1.7 fold) increase in hepatocyte TF procoagulant activity occurred 7 hours after APAP treatment, but did not increase concomitantly to near complete cell death observed after overnight treatment. In contrast, induction of apoptosis with J02 caused a dramatic increase in TF activity prior to loss of outer membrane integrity, and this continued to increase over time. These results indicate that loss of outer membrane permeability, as in necrotic cell death, is insufficient to elicit large increases in TF procoagulant activity. By comparison, apoptotic cell death elicits rapid and robust increases in TF procoagulant activity. Overall, these results suggest that apoptotic cell death, as opposed to necrosis, is a more procoagulant form of hepatocyte cell death.

1232 Perfluorobutanesulfonic Acid (PFBS) Promotes Fat Accumulation in HepG2 Cells
W. Oj, J. Clark, A. Timme-Laragy, and Y. Park. University of Massachusetts Amherst, Amherst, MA.

Nonalcoholic fatty liver disease (NAFLD) is one of the most prevalent chronic liver diseases. Per- and polyfluoroalkyl substances (PFASs), especially perfluorooctanesulfonic acid (PFOS), have been extensively used in food packaging, non-stick cookware, and textiles for over 50 years. However, in the past decade, a growing body of evidence has emerged, demonstrating the potential adverse effect of PFASs, including its effect on the development of NAFLD. On the other hand, there is no report investigating the effect of perfluorobutanesulfonic acid (PFBS), the major replacement for PFOS, on NAFLD. Therefore, we aimed to examine the effects of PFBS exposure on fat accumulation in HepG2 human hepatocytes. HepG2 cells were exposed to PFBS with or without 300 μM fatty acid (FA) mixture conjugated by bovine serum albumin (oleic acid:palmitic acid = 2:1) as an inducer of steatosis for 48 hours. Compared to the control, 200 μM PFBS significantly increased the triglyceride level with or without FA. FA interacted with PFBS and potentiated the fat accumulation induced by PFBS. Moreover, PFBS treatment promoted the production of reactive oxygen species (ROS) and the expression levels of genes regulating lipogenesis; acetyl-CoA carboxylase (ACC), fatty acid synthase (FAS), and sterol regulatory element-binding protein 1 (SREBP1). Moreover, HepG2 treated with fatty acid uptake was also implied by the upregulation of key genes modulating the capacity of FA trafficking to liver, including peroxisome proliferator-activated receptor gamma (PPARγ) and fatty acid translocase (CD36). C/EBP homologous protein (CHOP), which is activated by endoplasmic reticulum (ER) stress, was increased after PFBS treatment. In conclusion, PFBS may promote fat accumulation in HepG2 cells by inducing lipogenesis, fatty acid uptake, oxidative stress, and ER stress. This project was supported in part by NIH R01ES028201.

1233 The Double-Hit Toxicity of Obstructive Jaundice on Liver
A. Engin, A. Engin, L. Memis, and N. Bukan. Gazi University, Ankara, Turkey.

Bile is crucial for the maintenance of the integrity of intestinal barrier. Obstructive jaundice (OJ) causes intestinal barrier dysfunction leading to endotoxin translocation to portal circulation due to intestinal gram-negative bacterial overgrowth and decreased tight junction protein expression. Although studies indicate a marked decrease in the hepatic glycogen content in OJ, the mechanism of this process could not be well characterized. Sixty-nine guinea pigs were randomly assigned to six experimental groups. In the OJ group common bile duct (CBD) was identified and ligated, whereas in sham operated (SO) CBD was only identified. In both groups blood glucose, insulin, glucagon and IL-1β levels were measured at 24 or 72 hours of postoperative period, while oxidative stress in liver and terminal ileum was determined by the levels of nitric oxide, reduced glutathione (GSH) and malondialdehyde. The results of glucose consumption rate were expressed in percentage per minute. Histological assessment of cholangitis, necrosis, inflammation and quantification of hepatocyte necrosis were made at 24 and 72-hour following OJ. Intestinal mucosal barrier dysfunction was documented by subepithelial edema, sporadic mucosal denudation and portal endotoxin translocation. Excessive endotoxin exposure via portal circulation creating first-hit toxicity in hepatocytes stimulated the production of IL-1β, nitric oxide and superoxide anions in the liver, provoking focal hepatic necrosis. Thereby, biliary obstruction was accompanied by increased levels of lipid peroxidation in intestinal and hepatic tissues as well as the depletion of GSH. Second hit toxicity due to excessive bile acid accumulation in liver provoked the hepatic fibro-
sis, while inducing G protein-coupled cell surface receptor (TGR5)-mediated cholangiocyte proliferation, as well as alterations in pancreas. After first-hit related IL-1β expression, bile acid-induced proliferation of cholangiocyte, and protection of cholangiocytes from apoptosis indicated the increased expression of TGR5 in cholangiocytes, in response to bile acids. Seven-fold increase in serum glucagon levels and 2.8-fold higher insulin under normoglycemic conditions confirmed the TGR5 activation and its effect on glucagon-GLP-1 pathway.

1234 Acute Liver Injury Drives Fibrin(ogen) Cross-Linking Independent of Thrombin-Catalyzed Fibrin Polymerization

A. K. Kopec, H. Cline-Fedewa, L. G. Poole, A. Pant, M. J. Flick, and J. P. Luyendyk.1 Michigan State University, East Lansing, MI; and 2Cincinnati Children’s Hospital, Cincinnati, OH.

Acute liver injury following acetaminophen (APAP) overdose is associated with activation of the blood coagulation cascade and deposition of fibrinogen in the liver. We previously documented that hepatic fibrinogen deposition is central to promoting repair of the APAP-injured liver. The traditional view of blood coagulation presents an entrenched hypothesis that fibrinogen deposition is driven by a canonical pathway wherein thrombin-catalyzed fibrin polymer formation is a prerequisite for fibrin cross-linking by the transglutaminase factor XIII (FXIII). However, a lack of specific tools to differentiate the functions of soluble fibrinogen and fibrin polymer in vivo has left this hypothesis largely untested. To directly address this longstanding assumption, we analyzed fibrinogen (Fib465m) which expresses normal levels of soluble fibrinogen incapable of thrombin-mediated fibrin polymer formation (i.e., a form of the molecule locked in the soluble form), following acute liver injury with APAP overdose (300 mg/kg). APAP-challenged Fib465m mice displayed a reduction in plasma fibrinogen and increased hepatic fibrinogen deposition that was identical to APAP-challenged wild-type (WT) mice. Moreover, hepatic levels of high-molecular-weight cross-linked fibrinogen were identical in Fib465m mice and WT mice after APAP challenge. Comparably, APAP challenge significantly reduced plasma fibrinogen in both WT and FXIII–/– mice, but fibrinogen cross-linking was significantly reduced in livers of APAP-challenged FXIII−/− mice compared to APAP-treated WT mice. These results offer the first evidence that thrombin-mediated polymerization is in fact not required for fibrinogen (cross-linking in vivo). Rather, the deposition of fibrinogen in the APAP-injured liver appears to occur by a mechanism distinct from traditional blood coagulation that occurs within injured vessels.

1235 High-Throughput Screening for Evaluating Drug-Induced Inhibition of Bile Acid Transporters Using Humanized Hepatocytes Generated from Chimeric Mice

Cholestasis which results from inhibition of hepatic bile-acid efflux transporters has been proposed to play a role in drug-induced liver injury (DILI), one of the most frequent safety-related reasons for drug attrition and withdrawal. To better understand risks associated with cholestasis, we have developed a high-throughput cell-based in vitro assay which can be used during different phases of drug discovery. We firstly compared two candidate cell sources; PBX-cells, freshly isolated human hepatocytes from humanized mouse liver, and HepaRG cell line in terms of gene expression, membrane polarity, and response to cyclosporine. A. PBX-cells showed more transcriptomic, structural and functional characteristics, and provide a capability for high throughput screening and a robust and consistent drug response. Fluorescent bile acid derivative cholyl-L-lysyl-fluorescein (CLF) was used to quantify drug-induced efflux transport inhibition in these hepatocytes. Accumulation of CLF in apical bile-canicular lumen was inhibited by cyclosporine A in a dose-dependent manner. Forty-five pharmaceutical compounds with or without cholestatic potential were examined to investigate the predictive power of the assay system. Over 90% of the compounds (21 of 23) with cholestatic potential exhibited safety margin (IC100/IC90) > 35, resulting in sensitivity of 91.3%, specificity of 86.4%, and a balanced accuracy of 88.9%. Our assay system demonstrated increased predictive power than industry standards cell-free bile salt export pump (BSEP) membrane vesicle assay and rat hepatocyte-based CLF efflux assay, possibly by the potential involvement of other efflux transporters, metabolic pathways and/or species differences. The combination of high-throughput CLF efflux and the 3D liver spherical cytotoxicity assays enhanced DILI risk predictability. Our CLF efflux assay can be used as a surrogate for BSEP MVA. When it is combined with other cytotoxicity endpoints, it can also improve drug candidate prioritization.

1236 Exposures to Polychlorinated Biphenyls Altered the Hepatic Proteome

J. Jin,1 H. Shi,1 J. E. Hardesty,1 K. C. Falkner,1 M. Merchant,1 R. A. Prough,1 and M. C. Cave1 University of Louisville, Louisville, KY; and 2Northwestern University, Chicago, IL.

Polychlorinated biphenyls (PCBs) are associated with non-alcoholic fatty liver disease (NAFLD) in human subjects and animal models. Based on their structure and ability to activate the aryl hydrocarbon receptor, PCBs are classified as: dioxin-like (DL PCBs) and non-dioxin-like (NDL PCBs). Both types of PCBs are known to disrupt hepatic metabolism and modulate NAFLD; however, the exact mechanisms are still unclear. In the study, PCB mechanisms were investigated using transcription factor analysis of proteomics data in a diet-induced obesity mouse model of NAFLD exposed to both DL and NDL PCBs. Mice were fed a 42% fat diet and exposed to low-dose PCBs by gavage, PCB exposure included Aroclor1260 (20 mg/kg, a DL PCB mixture); PCB126 (20 μg/kg, a DL PCB congener); or Aroclor1260 (20 mg/kg)+PCB126 (20 μg/kg). After 12 weeks, the mice were phenotyped and hepatic proteomics was performed (LC/MS/MS following TMT metabolic labeling and reverse high pH separation of peptides). Spectra were matched to mouse protein database. PEAKS Studio 8 software quantitated the normalized abundance of select peptides. 2-way ANOVA was performed using R software and transcription factor analysis (TFA) was performed using MetaCore. Aroclor1260 mediated a transition from diet-induced steatosis to steatohepatitis; and PCB126 prevented this progression. PCB126 increased mice. PCB 126 reduced free fatty acids and decreased serum lipids. 8,355 hepatic proteins were identified by proteomic analysis. Protein abundance was altered by Aroclor1260 (190 proteins); PCB126 (1529 proteins); and the interaction of Aroclor1260 with PCB126 (87 proteins). TFA predicted the following alterations in transcription factor function: Aroclor1260-Hnf4α, Erry, and 5 others; PCB 126-Hnf4α, Lxrα/β, Srebp1/2 and 7 others including Nf-kb1 and CREB1; interaction of Aroclor 1260 and PCB 126-Hnf4α, Erra, and 3 others. PCB exposures differentially modulated diet-induced NAFLD and the hepatic proteome. PCB 126 altered 18.3% of all identified liver proteins. Importantly, these effects occurred 12 weeks after a single low-dose exposure.

1237 Restoration of Cellular Circadian Rhythm by FGF15/19 in Prevention of Non-Alcoholic Fatty Liver Disease

Z. Yang1,2, K. Bendinelli1,2, B. Kong3, G. Guo4, H. Zarbl1, and M. Fang4. 1Rutgers, The State University of New Jersey, Piscataway, NJ; 2Norman Bethune Medical College, Jilin University, Changchun, China; 3Dickinson College, Carlisle, PA; and 4Ernesto Mario School of Pharmacy, Piscataway, NJ.

Long-term disruption of circadian rhythm by shift-work, jet-lag, and light-at-night is associated with increased risk of metabolic syndrome, including non-alcoholic fatty liver disease (NAFLD) in both animals and humans. Recent studies indicate that SIRT1 deacetylase plays an important role in maintenance of hepatic homeostasis by linking hepatic metabolism to circadian rhythm. Fibrolast growth factor 15 (FGF15), the mouse homologue of human FGF19, is an endocrine FGF secreted from intestines responding to increased bile acid. It is critical in suppressing bile acid synthesis and improving insulin sensitivity. Direct in vivo evidence demonstrated that FGF15 play an important role in stimulating the phases of priming and termination of liver regeneration. To investigate the molecular mechanism underlying the modulation of liver regeneration by FGF15, we compared NAD+ level and SIRT1 activity as well as mRNA expression levels of genes involved in circadian rhythm and lipid metabolism in liver tissues collected from diet-induced NAFLD and the hepatic proteome. PCB26 increased liver free fatty acids and decreased serum lipids. 8,355 hepatic proteins were identified by proteomic analysis. Protein abundance was altered by Aroclor1260 (190 proteins); PCB126 (1529 proteins); and the interaction of Aroclor1260 with PCB126 (87 proteins). TFA predicted the following alterations in transcription factor function: Aroclor1260-Hnf4α, Erry, and 5 others; PCB 126-Hnf4α, Lxrα/β, Srebp1/2 and 7 others including Nf-kb1 and CREB1; interaction of Aroclor 1260 and PCB 126-Hnf4α, Erra, and 3 others. PCB exposures differentially modulated diet-induced NAFLD and the hepatic proteome. PCB 126 altered 18.3% of all identified liver proteins. Importantly, these effects occurred 12 weeks after a single low-dose exposure.
The Role of LCN2 in Acetaminophen-Induced Acute Liver Failure

C. J. Okaro, E. D. Reed, C. J. Moses, R. Shashidharamurthy, and V. S. Bhave. Philadelphia College of Osteopathic Medicine School of Pharmacy, Suwanee, GA.

Acetaminophen (APAP) overdose is the most common cause of Acute Liver Failure (ALF) in the US. Following APAP overdose, toxicity is initiated by the conversion of APAP to its reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI), which binds covalently to mitochondrial proteins leading to mitochondrial necrosis and sterile inflammation. Lipocalin-2 (LCN2), is an acute-phase innate immune protein, upregulated during tissue injury in various organs including the liver. Recent data from our lab indicates that LCN2 KO mice are protected against ALF caused by APAP overdose compared to WT mice. This protection is not due to decreased bioactivation based initial injury, but due to differences in the progressive phase of liver injury at later time points (24-48hr). LCN2 KO mice exhibit significantly less hepatocellular damage (ALT and histopathology) and higher liver regeneration response post APAP overdose. However, the mechanism of LCN2’s involvement in ALF resulting from APAP overdose remains ambiguous and is the objective of the present study. During APAP-induced necrosis, hepatocytes release Damage Associated Molecular Patterns, of which is High Mobility Group Box 1 (HMGB1). HMGB1 can have lipopolysaccharide (LPS) like properties, playing a role based on its location in the nucleus, cytoplasm, or extracellularly. Cytoplasmic HMGB1 binding to Beclin-1 induces a favorable autophagic response in support of hepatocyte regeneration. We hypothesize that causative relationships between IL-6-HMGB1, Beclin-1, and LCN2 play a role in mediating progression of injury. Pro- and anti-inflammatory cytokine expression in WT and LCN2 KO were assessed by ELISA and immunoprecipitation, respectively, over a time course. IL-10 is not differentially expressed between the two groups negating its role in the observed protection. We observed significantly higher IL-6 expression at 0, 24, 36, 48hr in LCN2 KO mice as compared to WT. This corroborates with IL-6’s role in promoting liver regeneration and higher PCRNA in LCN2 KO. In our model observed previously. Ongoing studies investigate the extent of HMGB1 and Beclin-1 binding between LCN2 KO and WT mice as a potential mechanism for progression of injury. Findings from this project will identify a novel pathway involving LCN2 and potentially recognize targets that attenuate/prevent the progression of liver injury leading to ALF in APAP overdose cases.

Insulin Action and Steatosis Can Be Evaluated with Bioluminescent Metabolite Detection Assays

M. Bach1, M. Valley2, N. Karassina3, D. Leippe4, J. Vidugiriene5, and J. Calli6. 1Promega Corporation, Madison, WI; and 2Promega, Fitchburg, WI. Sponsor: A. Landreman.

Metabolic syndrome is a cluster of conditions - including high blood pressure, central obesity, elevated blood sugar, and high levels of triglycerides and cholesterol - that when occurring together, increase one’s risk for diabetes and cardiovascular disease. Two factors connecting these conditions are the action of insulin and the accumulation of lipids (i.e. steatosis). Insulin stimulates glucose uptake and suppresses lipolysis, and inhibits gluconeogenesis. In contrast, insulin resistance leads to increased gluconeogenesis, decreased glucose uptake, and steatosis. Although not inherently harmful, when steatosis occurs for extended periods of time (e.g. NAFLD or NASH), it can lead to chronic inflammation, cirrhosis, and potentially carcinoma. We demonstrate that core luminescent technology that couples specific metabolite dehydrogenases to the production of NAD(P)H and the generation of light can be applied in cellular models related to metabolic syndrome, reducing the need for animal studies. Data from a panel of assays including glucose uptake, glycerol detection and triglyceride detection demonstrate the relevance of the in vitro models. The glucose uptake assay can measure > 5-fold increases in cell surface glucose transporters upon stimulation of 3T3-L1 MBX adipocytes with 1 uM insulin. We observe a 4-fold inhibition of gluconeogenesis in liver microtissues by 10 nM insulin with the glucose detection assay. As measured with the glycerol detection assay, 3T3-L1 MBX adipocytes exhibit a 4-fold increase in lipolysis upon stimulation with 25 nM isoproterenol, which can be suppressed 2-fold by 150 nM insulin. Moreover, using HepG2 cells as a model in NAFLD, we observe a 5-fold increase in intracellular triglyceride upon overnight incubation with 0.3 mM BSA-bound fatty acids as measured by the triglyceride detection assay.
Hepatocyte Injury Drives Atypical Fibrinogen Cross-Linking: Potential Role of TGM2

T. J. Gray, A. Pant, K. S. Baker, L. G. Poole, A. K. Kopec, and J. P. Luyendyk. Michigan State University, East Lansing, MI.

Acetaminophen (APAP)-induced liver injury is associated with activation of the blood coagulation cascade and accumulation of the clotting protein fibrinogen in areas of hepatocellular necrosis. Prior studies have suggested that hepatocyte-associated tissue transglutaminase (TGM2) can cross-link fibrinogen independent of coagulation reactions, but the impact of APAP cytotoxicity on this process has not been investigated. We determined the role of TGM2 in hepatocyte-catalyzed fibrinogen cross-linking and tested the hypothesis that APAP-induced hepatocyte cytotoxicity increases fibrinogen cross-linking. Primary hepatocytes were isolated from wild-type mice and treated overnight with various concentrations of APAP (0-5 mM) in serum free Williams’ Medium E. APAP caused a concentration-dependent increase in hepatocyte necrosis, as determined by increased release of alanine aminotransferase into the cell culture medium. Additionally, levels of cross-linked fibrinogen protein complexes, measured by capillary western blotting, were higher in APAP-killed hepatocytes compared to untreated hepatocytes, suggesting that 1) primary mouse hepatocytes express fibrinogen in culture and 2) APAP cytotoxicity increases cell-associated fibrinogen cross-linking activity. Similar results were obtained in preliminary studies in which hepatocytes were killed in the presence of exogenous human fibrinogen (10 µg/ml); cross-linked fibrinogen levels were increased in APAP-killed hepatocytes, and exogenous fibrinogen did not alter APAP cytotoxicity. Interestingly, levels of cross-linked fibrinogen were significantly reduced in hepatocytes isolated from TGM2-/- mice compared to wild-type mice, implying that hepatocyte-associated TGM2 can cross-link fibrinogen. Overall, the results suggest that APAP-induced hepatocyte necrosis increases direct TGM2-catalyzed fibrinogen cross-linking, implying a novel mechanism whereby fibrinogen structure may change during liver injury.

Sitagliptin Exacerbates Hepatic Inflammation and Necrosis in Rats Fed High Cholesterol Diet

1Southern University and A&M College, Baton Rouge, LA; 2Pennington Biomedical Research Center, Baton Rouge, LA.

Western diets are comprised of meat, poultry and dairy products, all of which are rich in cholesterol (Cho). High Cho is associated with the development of a proinflammatory state and is a documented risk factor for atherosclerosis, nonalcoholic fatty liver disease and progression to a more severe inflammatory disease called nonalcoholic steatohepatitis. Sitagliptin, a dipeptidyl peptidase-4 inhibitor, is an oral anti-diabetic drug. Independent of its glucose lowering effects, sitagliptin confers anti-inflammatory effects. Therefore, studies were conducted to investigate the effects of sitagliptin on hepatic inflammation in rats fed a high Cho diet. Adult male Sprague Dawley rats were fed a control or high Cho diet. Rats on each diet were gavaged with either vehicle or sitagliptin (100mg/kg/d) till the end of the experiment. On day 36 the rats were euthanized, and livers were harvested for analysis of triglycerides, oxidative stress and fibrotic markers by biochemical methods and histopathological evaluation by H&E staining. Hepatic lipid accumulation was assessed by oil red O and fibrosis by picrosirius staining methods. Rats on high Cho diet developed fatty liver with increased lipid accumulation which was unaffected by sitagliptin. Cho diet slightly increased hepatic expression of inflammatory stress genes (Nos2, Lox1, Inos), and surprisingly, sitagliptin exacerbated the mRNA expression of each of these genes. The expression of liver fibrin(ogen) markers (Tgfβ, aSmα, Mmp9, Timp1, Tlr4) was also increased by sitagliptin in high Cho group. Additionally, the presence of sporadic fibrosis was confirmed in Cho-sitagliptin group. However, the inclusion of Met to the high Cho diet resulted in significant reversal of markers of hepatic oxidative stress, lipid accumulation, and fibrosis compared to the rats on high Cho diet receiving sitagliptin. Our data indicate that sitagliptin in conjunction with high Cho diet intensifies the oxidative damage resulting in NASH like symptoms. Surprisingly, the negative effects of high Cho and sitagliptin were at least partially reversed by the inclusion of high Met in the diet.

Direct Activation of Tissue Factor:Factor VIIa Procoagulant Activity by Bile Acids

D. Ivkovich, K. S. Baker, A. K. Kopec, and J. P. Luyendyk. Michigan State University, East Lansing, MI.

Tissue factor (TF) is the transmembrane receptor for the plasma coagulation factor VIIa (FVIIa), and the TF:FVIIa complex is the primary activator of the blood coagulation cascade. We posited that post-translational regulation of TF:FVIIa activity is critical for the prevention of excessive coagulation in the normal liver, where FVIIa present in plasma has unrestricted access to the TF-expressing hepatocytes. Hepatocyte-associated TF:FVIIa activates coagulation during liver disease, but the mechanisms controlling hepatocyte TF:FVIIa procoagulant activity in the liver are not known. Coagulation occurs rapidly in settings of liver damage where plasma bile acids are increased, and we found that bile acids significantly increased procoagulant activity of TF:FVIIa in cultured primary hepatocytes. However, the exact mechanism whereby bile acids increase procoagulant activity of the TF:FVIIa complex is not known. We tested the hypothesis that bile acids directly increase the procoagulant activity of the TF:FVIIa complex. Recombinant full-length human TF (10 nM) was mixed with human FVIIa (5 pM) to form the TF:FVIIa complex. Various pathologically relevant concentrations (0-500 µM) of the bile acid, sodium glycochenodeoxycholate (GCDCA) were added, and the TF:FVIIa complex activity was determined by measuring the conversion of coagulation factor X (FXa) to activated FXa using a chromogenic substrate. The TF:FVIIa complex alone had little procoagulant activity, however, the addition of GCDCA evoked a robust and concentration-dependent increase in TF:FVIIa procoagulant activity, indicating by significantly increased FXa generation. The results indicate that bile acids directly increase TF:FVIIa procoagulant activity, suggesting that bile acids may be an important trigger of TF:FVIIa procoagulant activity in the context of certain liver diseases.
Dysregulation of hepatic circadian rhythmicity is associated with the development of metabolic disorders such as non-alcoholic fatty liver disease (NAFLD). Aryl hydrocarbon receptor (AhR) activation alters the hepatic expression of several core clock regulators, however the impact on circadian-controlled hepatic metabolism and the underlying mechanisms responsible have not been elucidated. This study examines the effects of AhR activation on hepatic transcription and metabolome rhythmicity in male C57BL/6 mice orally gavaged with 30 μg/kg 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) every 4 days for 28 days. Hepatic RNA-Seq analysis detected diminished rhythmicity in 15 core clock regulators (e.g. Arntl, Clock, Nr1d1, Per1, Per2, Nfil3), involving either a ≥3.3-fold suppression in amplitude or complete loss of oscillation. Accordingly, protein levels (Arntl, Rev-Erbα, Nfil3) and genomic binding (Arntl) of select regulators were reduced and arhythmic following treatment. Chromatin immunoprecipitation (ChIP) assays demonstrated co-binding of AhR, Arntl, and Clock at E-box response elements within Per1, Per2, and Nr1d1, suggesting AhR binding may directly interfere with ARNTL-CLOCK transcriptional regulation of target genes. Consequently, the oscillating expression of 99.6% of 5,636 clock-controlled hepatic genes was abolished including genes associated with lipid metabolism, glucose/glycogen metabolism, bile acid homeostasis, heme biosynthesis, and redox homeostasis. For example, TCDD abolished the rhythmic expression of the rate-limiting enzymes in both gluconeogenesis (Pck1) and glycogenesis (Gys2), consistent with the depletion and loss of rhythmicity in hepatic glycogen levels. Examination of polar hepatic extracts by targeted mass spectrometry revealed that virtually all oscillating metabolites lost rhythmicity following treatment. Collectively, these results suggest TCDD decoupled hepatic metabolism from feeding/fasting cycles, altering metabolic efficiency and energy storage.
Most idiosyncratic drug-induced liver injury (IDILI) appears to result from an adaptive immune attack on the liver. Recent evidence suggests that the T-cell response may be facilitated by the loss of immune tolerance. In this study, we explored the hypothesis that hepatocyte-derived exosomes (HDEs) are important for maintaining normal liver immune tolerance. ExoQuick-TC™ was used to enrich exosomes from the conditioned medium of primary human hepatocytes (N=5 donors) or from a medium that was not hepatocyte exposed (mock control). THP-1 monocytes were then treated with HDEs or an equivalent volume of mock control for 24 h, followed by a 6 h stimulation with LPS. HDEs induced a significant decrease in the LPS-induced media levels of interleukin-8 (IL-8) and monocyte chemotractant-1 (MCP-1) (p<0.0001). A trend toward a decrease in tumor necrosis factor alpha (TNF-α) was also observed. Gene expression profiling performed in THP-1 cells just prior to LPS-induced stimulation identified 72 significantly differentially expressed genes in the exosome-exposed monocytes (p<0.05 with fold change ≥ 2.25), all of which were decreased compared to mock control. Pathway enrichment analysis of these genes revealed HDE-induced downregulation of the innate immune response. The greatest alteration was observed in C-C motif chemokine ligand 3 (CCL3) mRNA, with an ~6.5-fold reduction (p=0.001). MicroRNA (miRNA) profiling was performed on the HDEs collected from 4 donors to identify exosome contents that may drive immune suppression. We observed a strong concordance among predicted miRNA target genes for the 50 most abundant miRNAs in HDEs and the differentially expressed genes observed in the THP-1 cells. Two miRNAs predicted to downregulate CCL3 (miR-149-3p and miR-24-3p) were among the 50 most abundant miRNAs in the HDEs. Taken together, our data suggest that HDEs play a role in maintaining normal liver immune tolerance. Future experiments will explore the possibility that IDILI drugs promote the loss of homeostatic HDE signaling.

**1255 Gasoline-Induced Oxidative Stress in Rats**

Gasoline, having benzene as one its aromatic hydrocarbon compounds, is a ubiquitous environmental pollutant that has been implicated in cellular toxicity, via induction of oxidative stress which results in various cytopathological alterations. This calls for an urgent search for cheaper and potent natural antioxidants. A notable source of exogenous antioxidants (capable of enhancing the ameliorative role of endogenous antioxidants) is Moringa oleifera leaf. Therefore, this study was carried out to evaluate the ameliorative effects of methanolic extract of Moringa oleifera leaf (MEMOF) on gasoline-induced oxidative stress in rats using selected antioxidant parameters and liver function indices. Twenty four (24) male and female albino rats (Rattus norvegicus) of weights ranging from 150-170 g were randomly divided into four groups of six rats each: Group I rats were orally administered 100 mg/kg body weight of MEMOF; Group II rats were exposed to gasoline while Group IV rats were exposed to gasoline and orally administered 100 mg/kg body weight of MEMOF; Group III rats were exposed to gasoline while Group IV rats were exposed to gasoline and orally administered 100 mg/kg body weight of MEMOF. Exposure period of 8 hours per day was adopted for 12 weeks and the route of exposure was inhalation. After the period of administration, various liver and plasma parameters were determined. Subchronic gasoline fume exposure significantly (p<0.05) elevated plasma phenol, malondialdehyde and oxidative DNA damage product (BOH₂dG) levels in rats compared to control. These alterations were significantly reversed (p<0.05) following oral administration of MEMOF. The levels of liver antioxidant parameters (zinc, selenium, magnesium, glutathione, catalase, superoxide dismutase) which were significantly reduced (p<0.05) by gasoline exposure compared to control were significantly reversed (p<0.05) by MEMOF. The plasma activities of alanine aminotransferase, aspartate aminotransferase, gamma glutamyltransferase as well as the total bilirubin and total protein concentrations were significantly (p<0.05) elevated following exposure to gasoline compared to control; however, this was also significantly reversed (p<0.05) by MEMOF. Histopathological analysis of the liver, following exposure to gasoline, also revealed loss of normal structural architecture compared to control; however, this was ameliorated by MEMOF. These results revealed that MEMOF possesses hepatoprotective activity against gasoline-induced oxidative stress in rats; thus, it may exhibit the same activity in subjects exposed to gasoline.
Interspecies differences have limited the predictive utility of hepatic toxicity studies performed using standard rodent models. Differences in cytochrome P450 enzymes and function can lead to erroneous conclusions on the safety, or lack thereof, for human use. Therefore, it is important to develop and validate animal models to better identify drugs that may be hepatotoxic, and allow those that do not pose a risk to continue in development. The goal of this study was to evaluate a chimera mouse developed to have a humanized liver to determine if this model can demonstrate human-specific hepatotoxicity in vivo as compared to non-humanized and genetically humanized mouse models. These studies tested fluoxetine (10 mg/kg, IP), flutamide (100 mg/kg, PO) and trovafloxacin (50 mg/kg, PO), that are approved drugs with reported cases of hepatotoxicity not predicted by rodent studies. Five mice per group, using hepatic humanized TK-NOG, control TK-NOG, human CYP3A4 or CYP2D6 knock-in, and C57Bl/6 strains, for a total of 20 mice per drug, were dose for daily as 28 days. Mouse weights and survival were monitored and blood samples taken weekly to evaluate drug levels. At study end we evaluated CBC/serum chemistry, leukocyte subpopulations via flow cytometry and histopathology. Hepatic humanized mice treated with fluoxetine showed decreased survival (2/5 died before day 28) along with decreased hematocrit, and elevated total bilirubin level, ALP and ALT as compared to other groups. Trovafloxacin treated hepatic humanized mice also had early study death (4/5 died before day 28) as compared to the other mouse strains. They also showed reduced leukocyte counts and increased total bilirubin level compared to other strains. All hepatic humanized mice treated with flutamide developed severe illness at day 7 and required euthanasia while the other strains were unaffected. Flutamide treated hepatic humanized mice showed increased ALP levels compared to other strains. These results suggest that hepatic-humanized TK-NOG mice, but not other strains, developed clinical and serologic evidence of hepatotoxicity when treated with fluoxetine, trovafloxacin, or flutamide and demonstrate that hepatic-humanized mice may improve our ability to detect drug-induced liver injury and enhance pharmaceutical safety in pre-clinical and post-marketing phases of development.
Identification of Candidate Risk Factor Genes for Human Idelalisib Toxicity Using a Collaborative Cross Approach

M. Mosedale1, Y. Cai1, J. S. Eaddy2, R. W. Corty2, M. Nautiyal2, J. Therrien1, W. Valdar3, and P. B. Watkins1. 1University of North Carolina Eshelman School of Pharmacy, Research Triangle Park, NC; 2University of North Carolina School of Medicine, Chapel Hill, NC; and 3Gilead Sciences, Inc., Foster City, CA.

Idelalisib is a phosphatidylinositol 3-kinase inhibitor highly selective for the delta isomorph that has shown good efficacy in treating some hematologic malignancies. Rare, but potentially serious liver and lung toxicities were associated with idelalisib use in clinical trials. In this study, the Collaborative Cross mouse population was utilized to identify genetic factors associated with the drug response that may inform risk management strategies for idelalisib in humans. Eight (8) male mice from 50 Collaborative Cross strains were treated daily for 14 days by oral (gavage) with either vehicle (0.5 % w/v carboxymethylcellulose and 0.1% w/v Tween 80) or idelalisib at a dose selected to achieve human-relevant exposures (150 mg/kg/day). Idelalisib was well tolerated across all strains and no idelalisib-related clinical observations were observed. Strain-dependent differences in drug concentration were observed in plasma samples collected at the approximate T_max on study Days 1, 7, and 14 (p<0.001 for strain, one-way ANOVA). While no overt liver injury was observed, suggestive treatment-induced alterations in plasma total bile acids (p=0.1550) and microRNA-122 (p=0.0982 for treatment, two-way RM ANOVA) were observed and may indicate early hepatocellular stress required for immune-mediated hepatotoxicity in humans. Small but statistically significant elevations in the total cell count of terminal bronchioalveolar lavage fluid were also observed in response to idelalisib treatment (p=0.0122 for treatment, two-way RM ANOVA), which may be analogous to pneumonia observed in the clinic. Genetic mapping identified loci associated with interstrain idelalisib concentration and the other three treatment-related endpoints in Collaborative Cross mice: total bile acids, terminal plasma microRNA-122, and bronchoalveolar lavage fluid cell count, corrected for modest correlations with drug concentration (r<0.025, Pearson’s correlation). Thirteen (13) priority candidate quantitative trait genes identified in mice may now guide interrogation of risk factors for adverse drug responses associated with idelalisib in humans.

Characterization of GCDC Transport by Human Hepatic Uptake Transporters for In Vitro Testing Purposes

J. K. Zolnerckis1, B. Tóth2, V. Velky2, Z. Timár2, E. Kis2, Z. Gáborik2, and P. Krajcí2. 1SOLVO Biotechnology, Boston, MA; and 2SOLVO Biotechnology, Budapest, Hungary.

Bile acids and bile salts (BAs/BSs) contribute in several physiological processes including signaling pathways, absorption of fat, or elimination of cholesterol. Primary bile acids and their conjugates are formed in the hepatocytes, then excreted into the bile. Bile is depleted in the intestine where bacterial deoxyxilation and unconjugation occur, and the majority of the bile salt species gets reabsorbed into the blood and circulates back to the liver. Giving their detergent nature, high concentration of BAs/BSs intracellularly or in the circulation system can lead to cytoxity. Therefore, testing the effect of drug candidates with high hepatic clearance on the transport of BAs/BSs is an issue of critical importance. The most commonly used probe substrate in in vitro test systems is taurocholate (TC), although the concentration of taurine-conjugated bile salts in human is two/three-fold lower than that of glycine-conjugated species, whereas taurine conjugation is the main modification in rats. Using glycochenodeoxycholate (GCDC), one of the most relevant conjugated bile salt in human, as probe substrate in in vitro test systems might provide better prediction on the effect on enterohepatic circulation of bile salts. HEK293 cells transduced with OATP1B1 and OATP1B3, as well as NTCP expressing CHO and HEK293 cells were used in uptake assay format. Proof of concept (POC) experiments were carried out with radiolabeled TC and unlabeled GCDC, sulfated GCDC and chenodeoxycholate-sulfate (3S-CDC) at two concentrations and two timepoints. All bile salts were transported by OATP1B1 and 1B3 in a time- and concentration-dependent manner, while only TC and GCDC were picked up as substrates for NTCP. Since GCDC was efficiently transported by all transporters, full transport characterization on OATP1B1, 1B3 and NTCP was conducted with tritiated TC and GCDC as probe substrates. Michaels-Menten constants (Km) were around three-fold lower for GCDC than TC, showing higher affinity for that bile salt. Inhibitory effect of known substrates and inhibitors (atorvastatin, CCK8, diclofenac, pravastatin, telmisartan and troglitazone) on both probes was also tested. Based on the obtained data, and the higher in vivo relevance, the authors suggest replacing TC with GCDC for human in vitro test systems.

Assessing Drug-Drug Interactions Using the HEPATOPAC Model, a Long-Term In Vitro Liver Platform

O. Ireczuk1, J. Gaffney1, H. Eng2, A. Doran2, C. Black1, and R. Obach2. 1BioIVT, Medford, MA; and 2Pitzer, Groton, CT.

Accurate prediction of drug-drug interactions (DDI) using in vitro models is critical in drug development as these studies ultimately influence the design of clinical trials. Current in vitro models lack the full complement of drug metabolizing enzymes and do not reflect the biochemical mechanisms present in hepatocytes in vivo. Also, these models are short-term and cannot recapitulate the effects of long-term drug exposure such as metabolism of enzyme inhibitors or enzyme re-synthesis after inhibition. The HEPATOPAC model, a long-lived, metabolically stable model is ideally suited to address these limitations. To this end, human HEPATOPAC cultures were treated with varying concentrations of selective CYP3A4 inhibitors, ketoconazole (0.1µM-10µM) or verapamil (1µM-30µM), for varying time intervals (1.5hrs-48hrs). The results showed a concentration-dependent decrease in CYP3A4 enzyme activity. Additionally, at low micromolar concentrations, there was a trend towards increasing CYP3A4 activity over time suggesting that the enzyme was re-synthesized during that period. Moreover, MS analyses showed a time-dependent decrease in inhibitor concentration (except at the maximum test concentrations), indicating that the inhibitors were being metabolized. Further studies seek to use HEPATOPAC cultures to determine the changes in AUC and IC50 values for drug-drug interaction between midazolam (a CYP3A4 substrate) and ketoconazole or verapamil. These preliminary findings provide evidence of CYP3A4 re-synthesis and inhibitor metabolism, and hence, the value of the HEPATOPAC model as a tool for accurate in vitro assessment of drug-drug interactions.

In Vitro Evaluation of Hepatotoxicity by Amiodarone in Micropatterned Cocultured Hepatocytes (HEPATOPAC) Using Liver-Specific Biomarkers

J. K. Zolnerckis1, Z. Nerada2, R. De Wilde1, and Z. Gáborik2. 1SOLVO Biotechnology, Boston, MA; and 2SOLVO Biotechnology, Budapest, Hungary.

Drug induced liver toxicity (DILI) is a major reason for discontinuing drug development programs and identifying potential risk for DILI is therefore important. Several in vitro tests have been developed to assess hepatotoxicity risk. Models using polarized primary hepatocytes with functional drug metabolizing enzymes and transporters, such as sandwich cultured hepatocytes, synthetic liver-on-a-chip models, or in vitro cocultured hepatocytes and micropatterned cocultured hepatocytes (HEPATOPAC) are used because their in vivo-like properties are considered to be among the more physiologically relevant models. A drawback of many in vitro tools however is lab-to-lab variability. Micropatterned co-cultures (HEPATOPAC) have a tightly controlled architecture and because of this we hypothesized its lab-to-lab variability might be minimal. In addition, the model has a life-span of several weeks in culture, allowing repeat dosing of test compounds. We therefore evaluated the known hepatotoxicant amiodarone in HEPATOPAC and compared results to published data. Using albumin, urea, adenosine triphosphate (ATP) and glutathione (GSH), we found TC50 (the concentration that decreases a response by 50%) values close to published values. After single dosing, similar TC50 values were obtained on day 5 and 9 using intracellular ATP and GSH levels. After dosing every 2 days, we measured TC50 values of increasing potency over time, using albumin and urea levels in the medium. No toxicity was observed for negative control acetysalicilic acid (aspirin) at any of the conditions. In conclusion, we successfully used the HEPATOPAC toxicity assay in our lab and demonstrated low variability between our and published data, indicating the robustness of this method between labs.
3D liver spheroids made from primary human hepatocytes (PHHs) are being adapted to in vitro systems for drug discovery and development activities such as liver safety assessment and disease modeling. Characterization, validation and standardization of liver spheroid culture are some key aspects to consider in order to successfully implement these novel 3D liver model-based assays. Because of large lot-to-lot variations among PHH lots, qualifying hepatocytes for liver spheroid culture could significantly facilitate the researcher’s efforts to standardize the use of this novel 3D liver spheroid model. In this study, we have performed qualification studies for multiple lots of PHHs for liver spheroid culture using a standard protocol in Corning Ultra-Low Attachment Spheroid Microplates. Liver spheroid formation, stable morphology and viability in long term culture (up to 4 weeks) are main criteria used for these qualification work. Characterizations for liver functions such as albumin secretion, drug metabolizing enzyme activities, cytotoxicity response are shown to demonstrate the possible utilization of liver spheroids made from these spheroid-qualified PHHs for different end points. These PHHs can also be used to set up co-culture liver spheroids with non-parenchymal liver cells such as Kupffer cells to model the in vivo responses to bacterial endotoxin (lipopolysaccharides or LPS) treatment, inflammatory responses of Kupffer cells in liver spheroids are demonstrated by IL6 and TNF-a secretion by ELISA assays. By comparing PHH only and co-culture liver spheroids, we show that both in intrinsic hepatotoxicity and immune-mediated cytotoxicity from Kupffer cells are underlining the mechanism of drug induced liver injury (DILI) by trovafloxacin. We extended this comparison to a selection of known DILI and control compounds including 5 tyrosine kinase inhibitors used in targeted cancer therapy. Both short-term 3D toxicity assay with a single dose and long-term 3D toxicity assay with repeated dosing regimen were used in this study for comparison. Our results demonstrate that using spheroid-qualified PHHs and spheroids made of different liver cell compositions can help the implementation and standardization of 3D liver spheroid model while providing flexibility for researchers to conduct both toxicity screening as well as investigative and mechanistic studies for liver safety assessment.

3D liver models (in vitro) are starting to be adopted by the pharmaceutical industry as an approach to de-risk drug induced liver injury (DILI). Recent approaches have focused primarily on the use of human hepatocytes (PHH) and comparing responses in 2D versus 3D cultures to a known reference list of DILI compounds, usually utilising a single measurement of cellular ATP. Here we have further developed this approach with the addition of multiparametric confocal high content imaging (HCI) to measure a range of endpoints including glutathione (GSH) content, mitochondrial membrane potential (MMP), reactive oxygen species (ROS) formation as well as cellular ATP content. We have evaluated two 3D models either PHH with the addition of Kupffer cells and the hepatic cell line, HepaRG in a 3D spheroid format. Characterisation of cytochrome P450 activity in liver microtissues (MTs) showed higher activities in HepaRG MTs compared to a single donor PHH MTs following 21 to 28 days in culture (CYP3A4: 210pM/min/MT HepaRG, 80pM/mn/MT PHH), indicating MTs are amenable to prolonged drug exposure. 57 DILI reference compounds (39 positive, 19 negative) were dosed through each MT for 14 days (with 4 repeat doses) and confocal HCI was determined in addition to cellular ATP content. PHH/PHH co-culture DILI was investigated in HepaRG MTs when compared to the overall response in the human hepatocyte MTs. However, donor specific sensitivity was observed across three different sources of PHH. In addition prediction of DILI was increased further when a multiparametric approach was taken when compared to measurement of ATP alone. Using HCI a sensitivity of 81.6% and a specificity of 100% was measured in PHH MTs whereas a sensitivity of 86.8% was observed in HepaRG spheroids and maintained the high specificity of 100%. 3D MTs consisting of either PHH or HepaRG cells gave an increased prediction of DILI over 2D approaches. In addition the prediction of DILI is also significantly improved by the addition of multi-parametric approaches when compared to only measuring cellular ATP. MTs of both types are amenable to high throughput screening, are cost effective and as such could play an important role in mitigating DILI risk in early drug discovery for the pharmaceutical industry.

Accumulating evidence implicates aryl hydrocarbon receptor (AhR) signaling in the regulation of liver fibrosis, which is a pathological condition characterised by excessive accumulation of extracellular matrix proteins. Liver fibrosis is mediated by myofibroblast precursors called hepatic stellate cells (HSCs). Upon chronic liver injury and inflammation, quiescent HSCs become activated and synthesise collagen type I. We previously reported that exposure to the high-affinity AhR ligand 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) increases HSC activation in vitro, which raises the possibility that HSCs are directly targeted by TCDD. Recent reports indicate that chronic exposure of mice to TCDD elicits liver fibrosis with concomitant changes observed in parenchymal hepatocytes. The goal of this project was to determine how AhR signalling in HSCs and hepatocytes contributes to HSC activation during TCDD-induced liver fibrosis. Cre-Lox recombination was used to create mice with AhR-deficient hepatocytes (AhRfl/fl) or AhR-deficient HSCs (AhRfl/fl; Col1a1Cre). AhRfl/fl mice were used as controls. All mice expressed the AhR receptor. To induce liver fibrosis, female, adult mice were gavaged with TCDD (100 µg/kg) or peanut oil every four days for 92 days. In AhRfl/+/ mice but not AhRfl/fl mice, the TCDD-induced Col1a1 expression was similar to vehicle-treated mice. TCDD produced a similar effect in AhRfl/fl mice but had no effect on HSC activation in AhRfl/fl mice. Exposure to TCDD did not elicit robust hepatocyte necrosis, based on serum levels of alanine aminotransferase, but it did induce hepatic steatosis, and this effect was completely abolished in TCDD-treated AhRfl/fl mice. Finally, TCDD treatment increased inflammatory cell infiltration in the liver of all mice, regardless of AhR knockdown. We conclude that chronic TCDD exposure increases HSC activation indirectly through a mechanism that requires AhR signaling in hepatocytes. It is possible that hepatic steatosis contributes to HSC activation in TCDD-treated mice, whereas hepatocyte necrosis and hepatic inflammation do not appear to play a major role.
**1266 Elucidating Mechanisms of Intrahepatic Drug-Induced Liver Injury**

Drug-induced liver injury (DILI) continues to be a major cause of drug attrition and withdrawal from the market. While the development of bile-acid (BA) transporters (e.g., BSEP) has been implicated as a risk factor for DILI potential, not all potent BSEP inhibitors are associated with this risk. Given the complex and multifaceted nature of BA handling, other mechanisms that may be involved in intrahepatic cholestatic (IC) DILI progression such as mitochondrial injury secondary to BA accumulation in hepatocytes were investigated. To begin to study this, we assessed direct mitochondrial effects of 11 human relevant BA species using oxygen-based respiration studies in mitochondria isolated from rat liver. Similar to previous reports, we found specific hydrophobic BAs primarily inhibit mitochondrial ADP-stimulated respiration at physiologically relevant concentrations. Cholesterol oxidase activity, a suggestive for complex I inhibition, was noted in liver mitochondria from humans. We have further observed that liver mitochondria from humans have a higher sensitivity to mitochondria protein, while more hydrophilic BAs (e.g., C 4:0, GDCA, GCA, TCA) did not inhibit mitochondrial respiration appreciably (∆Ψ=500mV). However, a novel finding of this work identified the properties of unconjugated BA species (UDCA, CA, CDCA, DCA) to uncouple basal respiration versus their glycine/taurine conjugates contingent on complex I inhibition. Surprisingly, lithocholic acid (LCA) did not have any effect on mitochondrial respiration. We then assessed individual BA effects on cell-based respiration. While the trends were largely similar to those in isolated mitochondria, inhibition and not uncoupling was observed with LCA having the most prominent response. The disconnect between responses in the whole cell versus isolated system supports the complexity of primary and secondary mitochondrial toxicity effects that may ensue in an in vivo context. In conclusion, work presented here identifies a unique complex I specific mechanism for BA-mediated mitochondrial injury. These results add to the weight of evidence supporting drug-induced mitochondrial dysfunction coupled with increased accumulation of these BA species (mediated by inhibition of bile-acid transporters) increases risk for DILI. Other compensatory mechanisms and effects on nuclear transcription factors, downstream signaling, stress cell death/pathways are currently being investigated.

**1267 Effects of FGF15 on Expression of Genes Involved in Circadian Rhythm and Lipid Metabolism in Mouse Liver**

K. Bendinelli,1,2 Z. Yang,2 B. Kong,2 G. L. Guo,1 H. Zarb,1 and M. Fang.1

1Dickinson College, Carlisle, PA; 2Rutgers, The State University of New Jersey, Piscataway, NJ; and 3Ernesto Mario School of Pharmacy, Piscataway, NJ.

Non-alcoholic fatty liver disease (NAFLD) is a growing epidemic that affects 30-40% of the general population. There is accumulating evidence suggesting that hepatic cirrhotic disruption is linked to NAFLD development. Fibroblasts growth factor 15 (FGF15), the mouse homologue of human FGF19, is an endocrine FGF secreted from the intestines in response to increased bile acid. It is critical in suppressing bile acid synthesis and improving insulin sensitivity. Direct effects of FGF15 on liver mitochondria have been previously shown to play an important role in stimulating the phases of priming and termination of liver regeneration. This study explored the mechanisms in prevention of NAFLD by FGF15. Total RNA was extracted from liver tissues collected from Wild-type (WT), FGF15 transgenic (TG), and FGF15 knockout (KO, loss-of-function) mice and relative mRNA expression levels were determined using quantitative RT-PCR. Results showed that mRNA expression levels of a major circadian gene, Per2, was significantly higher, whereas the expression levels of another major circadian gene, Ntr1d1, and a major circadian regulatory gene, Bmal1, were significantly lower in liver tissues from TG mice compared to those in KO and WT mice. Meanwhile, mRNA expression levels of other lipid metabolism genes, including Cyp4a, Lcn2, and Mtp, were significantly higher in TG vs. KO or WT mice. In addition, mRNA expression levels of inflammatory genes, Il6 and Tnf-a as well as Cd36, were also affected by FGF15, although none of them were statistically significant. Collectively, these results suggest that FGF15 modulates expression of genes involved in circadian rhythm and lipid metabolism, which might contribute to its potential preventive effect on NAFLD in mice.

**1268 Development of a High-Throughput iPSC-Derived Liver-on-a-Chip for Hepatotoxicity Detection**

1Mimetas, Gaithersburg, MD; 2University of Pittsburgh Drug Discovery Institute, Pittsburgh, PA; 3Mimetas, Leiden, Netherlands; and 4FUJIFILM Cellular Dynamics Inc., Madison, WI.

Hepatic injury accounts for two-thirds of drug development failures in the pharmaceutical industry. The current regulatory-accepted models for assessing hepatotoxicity include: i) rodent models, which are expensive, low-throughput, and overall have unreliable concordance with human hepatotoxicity; ii) standard two-dimensional (2D) in vitro systems, using liver cancer cell lines and primary human hepatocytes, which have only a marginally improved predictivity. This study sought to optimize a 3D in vitro model of the human liver and predictive hepatotoxicity assays by adopting the vascularized Liver Acinus MicroPhysiology System (vLAMPS) developed by the University of Pittsburgh Drug Discovery Institute into Mimetas’ high-throughput organ-on-a-chip platform. Extracellular matrix (ECM) gels and flowing medium can be patterned into the Organoplate®, allowing for solid tissue structures to form adjacent to continuously-perfused, tubular endothelial vessels. The resulting platform contains 96 x 3D microfluidic liver sinusoid mimics, including FUJIFILM Cellular Dynamics Inc. (FCDI) induced pluripotent stem cell-derived hepatocytes (iPSC hepatocytes; iCell® Hepatocytes 2.0) and stellate cells incorporated in an ECM gel, fed by nutrient perfusion from an adjacent endothelial and Kupffer cell-lined blood vessel. Viability of the co-culture remained stable (80-95%) for up to 21 days of culture. We report long-term maintenance of metabolic activity including CY3P4A, as well as albumin and urea production (1-21 days, both up to 20 µg/day/10^6 cells). Further, we report a significant drop in the viability of APAP-treated Organoplate® cultures while 2D cultures were unaffected by the same concentration of the hepatotoxicant, including acetaminophen (APAP). The cell viability assay revealed up to an 80% reduction in the viability of APAP-treated Organoplate® cultures while 2D cultures were unaffected by the same concentration of the hepatotoxicant. These studies display the feasibility of using our iPSC-derived 3D human liver model as a high-throughput screening platform for pharmaceutical and environmental hepatotoxicity.

**1269 AhR Signaling in Hepatocytes Is Required for Maximum Myofibroblast Activation by TCDD**

G. N. Cholico1, C. Stegelmeier1, J. M. Nelson1, J. VanTreso1, K. Cornell,1 and K. A. Mitchell1.

1Boise State University, Boise, ID; and 2Brigham Young University-Idaho, Rexburg, ID.

The aryl hydrocarbon receptor (AhR) is a soluble, ligand-activated transcription factor that has been implicated in liver fibrosis. During fibrosis, chronic injury and inflammation drive the activation of myofibroblast precursors, namely hepatic stellate cells (HSCs), which produce collagen. We have previously shown that AhR activation by 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) increases HSC activation in vitro and in a mouse model of liver fibrosis elicited by chronic carbon tetrachloride (CCL4) administration. It is possible that HSCs are direct, cellular targets for TCDD/AhR signaling. However, TCDD could also increase HSC activation indirectly through AhR-dependent events in hepatocytes that exacerbate liver damage and/or inflammation. The goal of this project was to determine the cell-specific consequences of TCDD/AhR signaling on HSC activation during liver fibrosis. Cre-Lox recombination was used to generate male mice in which the AhR was removed from either hepatocytes (AhR^fl/fl) or HSCs (AhR^fl/fl). AhR^fl/fl mice were used as controls. Mice (n=8) were treated with 1.0 ml/kg CCl4 every four days for 5 weeks, and TCDD (100 µg/kg) was administered during the final week of the experiment. HSC activation was measured by hepatic expression of αSMA and Colla1. Liver damage and inflammation were assessed based on serum alanine aminotransferase (ALT) levels and histological analysis, respectively. Results indicate that TCDD treatment increased HSC activation in the liver of all CCl4-treated mice, but not in wild-type mice. Treatment with TCDD marginally improved predictivity. This study sought to optimize a 3D in vitro model of the human liver and predictive hepatotoxicity assays by adapting the vascularized Liver Acinus MicroPhysiology System (vLAMPS) developed by the University of Pittsburgh Drug Discovery Institute into Mimetas’ high-throughput organ-on-a-chip platform. Extracellular matrix (ECM) gels and flowing medium can be patterned into the Organoplate®, allowing for solid tissue structures to form adjacent to continuously-perfused, tubular endothelial vessels. The resulting platform contains 96 x 3D microfluidic liver sinusoid mimics, including FUJIFILM Cellular Dynamics Inc. (FCDI) induced pluripotent stem cell-derived hepatocytes (iPSC hepatocytes; iCell® Hepatocytes 2.0) and stellate cells incorporated in an ECM gel, fed by nutrient perfusion from an adjacent endothelial and Kupffer cell-lined blood vessel. Viability of the co-culture remained stable (80-95%) for up to 21 days of culture. We report long-term maintenance of metabolic activity including CY3P4A, as well as albumin and urea production (1-21 days, both up to 20 µg/day/10^6 cells). Further, we report a significant drop in the viability of APAP-treated Organoplate® cultures while 2D cultures were unaffected by the same concentration of the hepatotoxicant, including acetaminophen (APAP). The cell viability assay revealed up to an 80% reduction in the viability of APAP-treated Organoplate® cultures while 2D cultures were unaffected by the same concentration of the hepatotoxicant. These studies display the feasibility of using our iPSC-derived 3D human liver model as a high-throughput screening platform for pharmaceutical and environmental hepatotoxicity.
1270 Does Triclosan Affect High-Fat Diet-Induced Non-Alcoholic Fatty Liver Disease (NAFLD) in Mice?

J. P. Fyolek, X. Li, Z. Wang, K. Tilman, and J. E. Klaunig, Indiana University, Bloomington, IN.

Prior studies have suggested that the progression of NAFLD may be mitigated by the activation of constitutive androstane receptor (CAR) or peroxisome proliferator activated receptors (PPARs). The purpose of the current study was to investigate the effects of dual CAR and PPARα activator triclosan on preexisting NAFLD. Hepatic steatosis was established, as we previously reported, by administering a high-fat diet (HFD) ad libitum to male C57BL/6J mice for 16 weeks prior to chemical treatment. Controls were fed a low-fat diet (LFD). Mice were subsequently treated with vehicle or 100 mg/kg/day triclosan for another 2, 8, and 16 weeks by oral gavage. Dietary treatment continued throughout the whole study. PPARα and CAR, as measured by increased acyl-CoA oxidase (ACO) and peroxisome proliferator-activated receptor (PPAR) activity respectively, were activated by triclosan in the liver regardless of diets as expected. Expression of Cyp4a10, a target gene of PPARα, was induced concurrently by triclosan with a peak increase at 2 weeks exposure. Transcriptomic analyses showed that “PPAR signaling pathway” and “peroxisome” were significantly enriched after 8 weeks triclosan exposure. The mRNA level of CAR signature gene, Cyp2b10, was increased by triclosan treatment regardless of diet, with the highest fold-change seen at 16 weeks of exposure. The preexisting fatty liver seemed to have a protective role in triclosan induced CAR activation. Comparing to LFD-fed triclosan-treated mice, HFD-fed triclosan-treated mice had a significantly lower PROD activity across all time points studied and a trend of reduced expression of TNRFα and TNFβ versus TNRFα and TNFβ respectively. In conclusion, decreased HFD-induced elevation of serum ALT in mice, histological examination and quantification of hepatic triglycerides indicate no modulation of hepatic steatosis. Gene expression analysis showed that transcripts in both fatty acid uptake and oxidation pathways were upregulated, which may result in an overbalance of lipid metabolism. The expression of fibrosis markers such as Collα1 and Tinp1 also showed no significant change comparing triclosan-treated to vehicle controls in HFD-fed mice, although a decrease was observed. Taken together, these results demonstrate that triclosan treatment significantly activate both PPARα and CAR without impact on the hepatic steatosis.

1271 The Effect of Kupffer Cells on Hepatobiliary Transporters in Human and Rat Hepatocyte/ Kupffer Co-Culture Model

Non-parenchymal cells of the liver have a significant impact on hepatocyte activity, and it was also shown that they play in concert in the progression of hepatotoxicity. Kupffer cells (KCs), the resident macrophages of the liver are involved in response to many stresses of the liver, such as infection, toxins and ischemia. Activation of the KCs results in the secretion of stress factors, which in turn modulate the expression and function of transporters involved in the elimination of toxic endogenous compounds and xenobiotics. The aim of this study was to investigate the effect of KCs on the activity of transport proteins, which are essential in the maintenance of liver homeostasis and bile secretion. Freshly prepared primary human and rat hepatocytes were cultured in monolayers, or co-cultures with KCs in sandwich configuration. KCs were applied at a physiological (H/KC 3:1 - human; 2:1 - rat) or pathological (H/KC 3:1 - human; 2:1 - rat) ratio. All protocols were approved by the Institutional Animal Care and Use Committee and the Research Ethics Committee of the Medical Research Council in adherence to the declaration of Helsinki. Lipopolysaccharide (LPS) was used for KCs activation, and the effectivity of activation was confirmed by TNFα and IL-6 levels, which were measured by ELISA. Hepatocyte function was determined by monitoring albumin and urea secretion. The mRNA expression and transport activity of NTCP/Ntcp, BSEP/Bsep and Mrp2,3/Mrp2,3 were measured using their selective endogenous substrates taurocholic acid (TA) and bilirubin (B), respectively. LPS increased Bsep and MRP2,3/Mrp2,3 were measured using their selective endogenous substrates TAurocholic acid (TA) and bilirubin (B), respectively. LPS increased both activities in both human and rat cultures. Activated KCs decreased albumin secretion more effectively in rat than in human, though urea secretion did not change significantly. In rat cultures, both influx and efflux of TC increased in a KCs concentration dependent manner irrespective of KCs activation. In contrast, TC transport by human hepatocytes proved to be more sensitive. LPS treatment than to the amount of KCs. KCs decreased bilary transport of B in both human and rat cultures, which was accelerated by LPS. The sinusoidal efflux of B decreased just in rat co-cultures. In conclusion, the activity and expression of the transporters examined here were highly influenced by KCs. The direction and extent of alterations were markedly different in human compared to rat that calls the attention to species differences in case of liver injury. This study was supported by a GINOP-2.1.1.-15-2016-00826 grant.

1272 Biochemical Mechanisms of Orally Administered Phenobarbital in Minipig Liver

CiToxLAB, Evreux Cedex, France; CiToxLAB, Lille Skensved, Denmark; and Solvo Biotechnology, Ploboin, France.

Biochemical mechanisms of toxicity are often studied in rodents to establish a mode of action for adverse, chemical-induced effects. Phenobarbital (PB) has been shown to induce differential gene expression and CYP2B, CYP3A and UGT enzyme activities in rodent liver, resulting in increased thyroid hormone clearance and subsequent stimulation of cell proliferation in the thyroid leading to thyroid tumors after long-term exposures. This pathway has not been completely investigated in nonrodents. In this study, male Gottingen minipigs were orally administered 15 mg/kg/day PB for 6 days following by investigation of phase I and II liver enzymes (mRNA expression and enzyme activities), circulating thyroid hormone levels and differential gene expression in the liver in addition to standard toxicology evaluations. PB had no effect on body weight, hematology or clinical pathology. Treated minipigs had 42-46% increased liver weights with mild, diffuse hepatocellular hypertrophy versus the control group. PB reduced plasma concentrations of T3 (by 27% and 47%) and T4 (by 21% and 32%) vs respective controls. PB increased the expression of many phase I and II enzymes, with the most significant increase in CYP3A429 and CYP4A24, 5-fold increase in CYP1A2 and around 11-fold increase in CYP2B22 compared to the control group, with increases in mRNA expression of these genes. A 1.6-fold increase in T3-specific UGT phase I activity was observed in PB-treated animals, with a 1.6-fold increase in total UGT phase I activity. PB increased the expression of mucin 16 (MUC16) and decreased the expression of carboxylesterase 2 (CE2). Activation of the unfolded protein response (UPR) in a concentration-dependent manner was observed. The mRNA expression of these genes was upregulated in PB-treated animals, with a 1.6-fold increase in T3-specific UGT phase I activity and a 1.6-fold increase in total UGT phase I activity. PB increased the expression of mucin 16 (MUC16) and decreased the expression of carboxylesterase 2 (CE2). Activation of the unfolded protein response (UPR) in a concentration-dependent manner was observed. The mRNA expression of these genes was upregulated in PB-treated animals.

1273 A Comprehensive Landscape of the Temporal Dynamics of Cellular Stress Response Pathway Activation in Drug-Induced Liver Injury

L. Wijaya, M. Niemeijer, J. Keet, S. Le Dévédec, and B. van de Water.

Leiden Academic Centre for Drug Research, Leiden, Netherlands.

Drug-induced liver injury (DILI) is the most prevalent adversity occurring in drug development and clinical settings. Various liver toxicants cause cellular perturbations that lead to the activation of particular cellular adaptive stress response pathways. So far insight in the quantitative temporal responses of stress pathway activation remained fully unclear due to lack of adequate methods. In this study, we systematically determined the dynamics of key cellular stress response pathways in direct relation to the onset of cytotoxicity during drug exposure. We applied automated live cell high content confocal imaging of 13 different BAC-GFP HepG2 reporter cell lines representing various components of i) unfolded protein response (ATF4, XBP1, BIP and CHOP), ii) oxidative stress response (NRF2, SRXN1, HMox1), iii) DNA damage response (P53, P21, BTG2, MDM2), and iv) NF-κB signaling pathway (A20, ICAM1). For 14 different DILI compounds the concentration-dependent (from 1 until 100 Cmax) dynamics of stress response activation and cell death markers were followed for 72 h at 1-2 h time resolution. Quantitative image analysis captured the activation of stress responses at the single cell level and with distinct temporal dynamics. Interestingly, some compounds showed the partial activation of the unfolded protein response (UPR) in a concentration-dependent manner. At higher concentrations, the progressive UPR pathway ATF4/CHOP was found more prominently activated than the adaptive response XBP1/BIP. Compounds that activated specifically the ATF4/CHOP signaling branch affected significantly cell survival. Typically DILI compounds activated the oxidative stress response at early time points. On the other hand, the DNA damage response was only partially activated by some toxicants. The NF-κB signaling pathway is immediately activated after TNF-α co-exposure with the persistent expression of ICAM1 and A20. Altogether, our data suggest that the activation dynamics of stress response pathways is dependent on the DILI compound as well as predictive for the cell fate. In context of cellular adaptation and adverse cell fate, understanding the dynamics of cellular stress response pathway activation will provide an improved DILI hazard assessment at the early phase of pre-clinical drug development. This work was part of the Dutch-German ZonMW-BMBF SysBioToP project and the EU Innovative Medicine Initiative TransQST project. Grant agreement No. 116030.
**1274 In Vitro 3D Culture Systems for the Study of Human Liver Diseases**

V. Shevchenko, and D. Steen, Biopredict International, Saint Gregoire, France.

Presently, the most common culture system used to address in vitro human hepatic disorders and hepatobiliary functions is the 2D or 2D+ (collagen-matrix sandwich) monoculture systems of primary human hepatocytes (PHH). Although these models have proven to be very useful in the past, they reproduce neither the complete physiology of the human hepatocytes, nor the cellular complexity of the liver. With the aim of establishing in vitro culture models closer to the in vivo situation, we set up 3D mono- and multi-cellular spheroids, respectively composed of PHH, or PHH combined with non-parenchymal cells (NPCs). Here, we first described the process of spheroid generation and the viability of the formed spheroids. Then, we performed phenotypic and metabolic characterizations and found that 3D monocellular spheroids exhibit enhanced liver-specific functions, such as increased albumin secretion and higher metabolism of phase II substrates, compared to the same batches of PHH cultivated in 2D+. Furthermore, we performed whole transcriptome and microproteomic analysis in order to better characterize these models. Finally, we present preliminary results regarding their use as models for the study of i) human hepatic disorders, such as liver fibrosis, and ii) toxicological studies and drug testing applications, the latter targeting the hepatic stage of malaria, the deadliest parasitic liver infection. Thus, this present study provides a human microphysiological 3D system for in vitro liver disease modeling and toxicological studies as well as drug screening.

**1277 Human Liver-Chip Model for Drug Metabolism and Liver Safety Assessment**

K. Jang1, D. Conegliano1, J. Sliz2, J. Rubins1, L. Tang3, Z. Jayyosi4, W. Brian1, S. Klieber1, V. Antontsev1, J. Ronxhi1, D. Lavern1, G. A. Hamilton1, and D. Keller1.

Emulate, Boston, MA; and 4Sanofi, Bridgewater, NJ.

The pharmaceutical industry has an unmet need for predictive human models for drug metabolism and pharmacokinetics, drug-drug interactions, and drug-induced liver injury (DILI) that can better emulate human response to drugs. Current 2D liver models often fail to capture responses seen in the clinic, as the cellular microenvironment does not accurately reflect what is found in vivo. Here we applied a vascularized human Liver-Chip model that contains primary human hepatocytes, sinusoidal endothelial cells, and Kupffer cells, cultured under physiological fluid flow in a spatial configuration that recapitulates their cytoarchitecture in the liver. We demonstrated that albumin and urea are expressed and that CYP450 enzyme activity and protein expression were decreased. Induction profiles in human Liver-Chips showed improved functionality over conventional monolayer culture and were maintained in culture for >2 weeks. In the tri-culture model (with Kupffer cells) LPS stimulated secretion of TNFα in proportion to the Kupffer cell ratio, while tacrine stimulated the release of a number of cytokines in both the hepatocyte and endothelial cell channels. We tested benz bromarone, trazadone and two proprietary tool compounds, to evaluate the ability of a co-culture (hepatocytes and endothelial cells) Liver-Chip to assess DILI. The data demonstrated that the Liver-Chip provided a more sensitive response compared to conventional monolayer culture to toxicity. The hepatocyte/endothelium/human Kupffer cell co-culture system was developed to provide a proof of concept that HEPATOPAC® platform is amenable to hepatic stage of malaria, the deadliest parasitic liver infection. Thus, this present study provides a human microphysiological 3D system for in vitro liver disease modeling and toxicological studies as well as drug screening.

**1275 Multidrug Resistance-Associated Protein 4 (MRP4) Plays a Crucial Role in the Pathogenesis of Fatty Liver Disease**

M. De La Rosa1, A. C. Donepudi2, J. E. Manautou3, and S. J. Torb2.
San Joaquin Delta College, Stockton, CA; and 3University of Connecticut, Storrs, CT.

Hepatic steatosis without alcohol abuse (non-alcoholic fatty liver disease, NAFLD) is characterized by excess lipid accumulation in the liver that can impair various liver metabolic functions. Recently, our laboratory determined that genetic ablation of the efflux transporter Multi-drug resistance associated protein 4 (Mrp4) in mice increases hepatic lipid accumulation following partial hepatectomy, a model for hepatic tissue regeneration. The aim of this study was to further characterize this association between Mrp4 function and NAFLD development. To address this, we employed prolonged fasting, a model for studying hepatic lipid metabolism and NAFLD. In this study, both male and female wildtype (WT) and Mrp4 Knockout (KO) mice were either free-fed or fasted for 24 hr. Mice were then euthanized and liver, adipose tissue and plasma were collected. Lipid content in the form of triglycerides, free-fatty acids, glycerol, and cholesterol in plasma and liver samples was quantified. Hepatic lipid accumulation was also examined by Oil red-O staining of liver sections. Although no genotype- or gender-related changes in plasma lipids were detected, both male and female KO mice had greater hepatic lipid accumulation compared to WT mice. This was also confirmed by Oil red-O staining. Fed KO mice of both genders showed increases in hepatic triglycerides and free fatty acids, with no changes in cholesterol. By contrast, only fasted female KO mice had increases in hepatic free fatty acids levels, and not other lipids. Overall, this study supports the role of Mrp4 in hepatic lipid homeostasis and a genetic contributor to NAFLD and also document gender-related differences in hepatic lipid handling in the absence of Mrp4. Further studies are warranted to decipher this novel role of Mrp4 in hepatic lipid metabolism.

**1276 Demonstration of Hepatocyte-Targeted siRNA Transfection and Gene Silencing in the Micro-Patterned Hepatocyte Co-Culture System (HEPATOPAC)**

M. Yang, Q. Irrechukwu, and J. Gaffney. BiolVT, Medford, MA.

The HEPATOPAC® model, an in vitro bioengineered co-culture of primary hepatocytes and fibroblasts, has demonstrated invaluable utility for liver-based safety, metabolism, and efficacy evaluation for small molecule drug candidates, due to its close resemblance to the in vivo liver. Here, we identify a method to specifically deliver small-interfering RNAs (siRNA) into the hepatocytes in the HEPATOPAC® co-cultures, by using a commercially available, non-liposomal transfection reagent that targets hepatocytes (PromoFectin-Hepatocyte). Upon the transfection of a fluorescent control siRNA, fluorescent signal was detected mainly in the hepatocyte islands, but not in the surrounding stromal cells. When siRNA targeting a cytochrome P450 enzyme was transfected in HEPATOPAC® cultures, a time-dependent reduction in the CYP activity following transfection was observed. The results provide a proof of concept that HEPATOPAC® platform is amenable to hepatocyte-specific siRNA transfection and siRNA-mediated gene knockdown, which can be useful in elucidating the hepatocellular mechanisms in various research areas, aiding in reaction phenotyping assessment, as well as in vitro safety and efficacy studies for novel RNA therapeutics.

**1278 Effects of Phenobarbital on Minipig Liver Gene Expression**

P. Ancian1, C. Bansard1, J. Nielsen2, L. Richert1, P. Singh1, and R. Forster1.
CIToxLAB, Evreux Cedex, France; 2CIToxLAB, Lille Skensved, Denmark; and 1Kaiy-Cell, Plobsheim, France.

Phenobarbital (PB) is a widely used anti-seizure drug. Oral administration of PB in rodents results in hepaticomegaly and induction of CYP450 xenobiotic metabolizing enzymes in the liver, and long term treatment results in hepatic tumors. While PB has been extensively studied in mice and rats, little is known about the impact of PB treatment on gene expression profiles in minipig liver. The present study was aimed at analyzing the effect of repeated acute oral administration of PB on minipig liver gene expression and comparing the data to liver enzyme induction and activity in a non-rodent model. For that purpose, three male Göttingen minipigs aged 4-5 months were treated orally with vehicle or 15 mg/kg PB for 6 days. On day 7, animals were euthanized and RNA was extracted from an 80 mg section of flushed liver. Affymetrix target preparation was performed using the Affymetrix 3’-IVT Plus kit and cRNA product was hybridized to Affymetrix GeneChip® Porcine Arrays. The differentially expressed genes were filtered using an absolute fold-change threshold at 1.5 with a corrected p-value lower than 0.05. Treatment with PB was well tolerated. A total of 161 and 139 probesets were found to be significantly down and upregulated in minipig liver, respectively, following PB administration. Induction of mRNA encoding for CYPs such as CYP2A19, CYP2B22 and CYP2C42, CYP3A9 and CYP3A46 was observed with mean fold changes varying between 31.19 and 1.51. Results were broadly concordant with those of relative quantitative RT-PCR and some of the corresponding enzymatic activities. Transcripts of phase II metabolizing enzymes such as UGTs, SULTs and GSTs were also found to be significantly upregulated by PB treatment in minipig liver. Pathways and ontology classification using the DAVID software revealed that the oxidoreductase, retinol metabolism, chemical carcinogene-
Lack of Multidrug Resistance-Associated Protein 4 (Mrp4) Does Not Alter Susceptibility towards Acetaminophen Toxicity

A. C. Donepudi1, M. J. Goedken2, and J. E. Manautou1.1 University of Connecticut, Storrs, CT; and 2Rutgers, The State University of New Jersey, Piscataway, NJ.

Acetaminophen (APAP) is the most frequent cause of drug-induced liver injury in humans and a common chemical model to investigate genetic determinants of susceptibility to drug-induced liver injury (DILI). Previous studies performed in our laboratory identified the efflux transporter multidrug resistance-associated protein 4 (Mrp4) as an inducible gene in liver following toxic APAP exposure in both humans and rodents. In mice, prevention of hepatic Mrp4 induction following APAP administration increases susceptibility towards APAP hepatotoxicity. Collectively, these findings suggest that Mrp4 plays an important role in tolerance towards APAP-induced liver injury. To further study the role of Mrp4 in APAP-induced hepatotoxicity, we challenged 10-12 weeks old male wild type (WT, C57BL/6J) and Mrp4 knock out (Mrp4–/–) mice with either APAP (400 mg/kg in saline, ip), or vehicle. Following treatment, plasma and liver samples were collected at 12, 24 and 48 hr and liver injury was assessed by plasma alanine aminotransferase (ALT) activity and histopathological examination. No significant differences in plasma ALT levels or histological scores were observed between Mrp4–/– and WT mice, except at 12 hr where Mrp4–/– mice exhibited delayed death and hepatic necrosis compared to WT mice. Gene expression analysis indicates that lack of Mrp4 is associated with decreased expression of hepatic glutathione metabolism and drug metabolizing genes, such as glutamate-cysteine ligase modifier subunit (Gclm), Cyp3a11 and Mrp2 under basal conditions. These differences in gene expression were not observed in Mrp4–/– mice at any time point post APAP administration. In contrast to the gene expression data, Mrp4–/– mice had increased hepatic non-protein sulfhydryl (NPSH) content at 12 and 24 hr after APAP treatment. Although significant decreases in endpoints of liver injury were detected early after APAP treatment in Mrp4–/– mice, these changes were not sustained at later time points. In conclusion, our data indicate that lack of Mrp4 in mice does not alter susceptibility to APAP toxicity.

3D Spheroids from Nonhuman Primary Hepatocytes as an In Vitro Cell Culture Model

Currently used 2D sandwich cultures of primary hepatocytes is characterized by short longevity and lack of predictivity. Recent evidence suggests that putting primary hepatocytes in 3D hepatic spheroids offers major advantages in providing longevity and increased physiological relevance in modeling liver metabolism. Although a vast amount of data exist for human 3D spheroids, limited information is provided for animal 3D spheroids for their use in drug discovery and development. Here we show data that supports formation and use of 3D spheroids from rat (Srague-Dawley), mouse (CD-1), dog (beagle), and monkey (Cynomolgus) for drug testing. Rat (RTCP10), mouse (MSCP10), dog (DGP10) and monkey (MCP10) primary hepatocytes from Thermo Fisher Scientific were plated for spheroid qualified activity following the hepatic necrosis compared to WT mice. Gene expression analysis indicates that lack of Mrp4 is associated with decreased expression of hepatic glutathione metabolism and drug metabolizing genes, such as glutamate-cysteine ligase modifier subunit (Gclm), Cyp3a11 and Mrp2 under basal conditions. These differences in gene expression were not observed in Mrp4–/– mice at any time point post APAP administration. In contrast to the gene expression data, Mrp4–/– mice had increased hepatic non-protein sulfhydryl (NPSH) content at 12 and 24 hr after APAP treatment. Although significant decreases in endpoints of liver injury were detected early after APAP treatment in Mrp4–/– mice, these changes were not sustained at later time points. In conclusion, our data indicate that lack of Mrp4 in mice does not alter susceptibility to APAP toxicity.

CryoHepatoPearl: Ready-to-Use Cryopreserved 3D Human Liver Model

HepatoPearl is an innovative encapsulated 3D liver micro-tissue model developed by Cyprio using the CryoHepatoPearl technology. This technology was developed to overcome limitations of usual 3D culture models such as difficulties related to sphere handling and incompatibility to high-throughput screening. Viable and metabolically functional over 6 weeks, they have already been validated for drug-drug interaction studies and for the prediction of hepatotoxicity with 5 well-known compounds with different hepatotoxic potentials in acute (24 and 48h) and chronic (14 days, 3 dosing) exposures. For each compound, we observed a decrease in IC50 values with chronic conditions compared to those of acute exposure from 2 times for low concern compound (Acetaminophen) to more than 5 times for severe compound (Tolcapone). Moreover, after chronic exposure, IC50 values of low and chronically toxic compound far exceeded their non-cryopreserved counterpart. Tolcapone under it indicating its severe toxicity. Furthermore, by applying a margin of safety of 30 for the categorization of toxic potentials, we demonstrated that HepatoPearls efficiently categorized the same previously described toxic potential of these compounds. In order to avoid the problems linked to transport of fresh cells and facilitating the design of experiments for end users (in terms of timing and management), we thus developed a cryopreserved HepatoPearl model, named cryoHepatoPearls, as a ready-to-use tool for the previously mentioned assays. To do so, we directly froze the HepatoPearls after their encapsulation. After thawing, cells are still able to form spheroids in the same time range of their non-cryopreserved counterpart. Moreover, we did not observe a decrease in viability, metabolic activities and hepatic functionalities compared to non-cryopreserved HepatoPearls produced from the same batch between day 1 and 35 post thawing. We then measured cytochrome P450 basal enzymatic activity (CYP1A2, CYP2B6, and CYP3A4) and their mRNA expression inhibited by the concentration of albumin and urea secreted in the culture medium and observed that all these features are present in levels comparable to non-cryopreserved HepatoPearls. Hence, cryoHepatoPearls provide a unique storable liver 3D cellular model, metabolically and functionally equivalent to their fresh counterpart, offering an improved ease of experimental planning in pharmacokinetics, safety and toxicity studies.

Transient Vinyl Chloride Exposure Exacerbates High Fat Diet-Induced Hepatic Injury and Tumor Formation in Mice

R. D. Schnegelberger1, L. Chen2, B. Wahlang3, M. Cave4, and J. Beier1.1 University of Pittsburgh, Pittsburgh, PA; and 2University of Louisville, Louisville, KY.

Vinyl chloride (VC), a common environmental pollutant, directly causes hepatic angiosarcoma and toxicant-associated steatohepatitis at high exposure levels. The risk for developing liver disease is thought to have been largely mitigated by lowering the OSHA exposure limits. However, we have recently shown that lower exposure levels (i.e.< OSHA exposure limits), which do not directly damage the liver, enhance injury caused by a high fat diet (HFD). Although these lower exposure levels are currently considered “safe”, the long-term impact of low-concentration VC in combination with a HFD is unknown. C57Bl/6J mice were fed HFD, or a low-fat control diet (LFD) for 1 year. During the first 12 weeks of feeding, mice were also exposed to VC using an inhalation chamber at concentrations below the current OSHA limit (<1 ppm) or room air for 6 hours/day, 5 days/week. The remaining 9 months of feeding, mice were not exposed to VC. Plasma and liver samples were collected for histology and determination of liver damage. As expected, chronic HFD feeding for 1 year caused significant hepatic injury, including steatohepatitis and fibrosis; 12 weeks exposure to VC at the beginning of HFD feeding exacerbated this normal tissue damage. Specifically, the increase in indices of fibrosis (Sirius red staining, TGF-beta levels, and propyl-4-hydroxylase levels) were significantly enhanced by VC exposure. Additionally, 1 year HFD feeding induced the formation of hepatic tumors in all mice, predominantly Ki67-positive adenomas, as well as damaged altered foci. The number and severity of these lesions was enhanced by VC exposure. The increase in indices of proliferation caused by HFD (e.g., Ki67 and cyclin D1) was enhanced by VC exposure. Importantly, 40% of the mice in this group also had an increase in CD31, and endothelium-derived tumors, which were characteristic of VC-induced hepatic angiosarcomas in humans. Taken together, these data suggest that although VC causes no overt hepatic injury in LFD-fed mice, it sensitizes the liver to other stressors (e.g., HFD) resulting in enhanced tumorigenesis. Importantly, these data raise concerns about potential for overlap between fatty diets (i.e. Western diet) and exposure to VC and the health implications of this co-exposure for humans. It also emphasizes that current safety restrictions may be insufficient to account for other factors that can influence hepatotoxicity.
Non-alcoholic fatty liver disease (NAFLD) is the most prevalent type of liver disease and currently affects ~30% of the population. With progression to non-alcoholic steatohepatitis (NASH), this disease can eventually lead to liver cirrhosis and failure. To date, there are no approved drugs for NASH treatment and drug development has been impeded by the lack of predictive in vitro models reflecting the complex pathology of NASH. Here, we present a human in vitro NASH model based on 3D microtissue technology. Engineered to incorporate the primary human hepatocytes, hepatic stellate cells, Kupffer cells (KCs) and liver endothelial cells (LEC), this model includes all the liver cell types that play a crucial role in disease initiation and progression. Upon treatment with free fatty acids and LPS in diabetic medium these microtissues showed key physiological aspects of NASH. Increased lipid accumulation within the hepatocytes could be detected as well as tissue secretion of pro-inflammatory markers, such as TNF-α, IL-6, IL-8, MCP-1, MIP-1α and αvβ5. Furthermore, lipotoxic stress stimuli increased expression of pro-fibrotic markers, such as collagen type I and a-smooth muscle actin (a-SMA), a marker of activated stellate cells. Further treatment with NAS stimuli resulted in increased deposition of ECM, indicating the activation of fibrotic pathways. In summary, we present a human 3D NASH model that recapitulates key biological aspects of the NAFLD spectrum of diseases, including inflammation, steatosis and fibrosis. Compatible with high-throughput screening approaches, this model is a powerful tool for assessing efficacy of anti-NASH drugs.

Iron-catalyzed formation of reactive oxygen species (ROS) increases after APAP overdose and triggers the mitochondrial permeability transition (MPT). Previous studies show that iron translocation from lysosomes into mitochondria by MCU promotes the MPT after APAP. Mfrn2 is also a pathway for mitochondrial iron transport. Here, our aim was to compare the roles of Mfrn2 and MCU in APAP hepatotoxicity. Hepatocytes isolated from Mfrn2 knockout (KO) and wildtype (WT) mice were treated with 10 mM APAP. Mitochondrial membrane potential and cell death were visualized by confocal imaging of rhodamine 123 (Rh123) and propidium iodide (PI), respectively. Mitochondrial chelatable Fe⁺⁺ was monitored by fluorescence quenching of mitochondrially targeted mitoferrofluor (MFF). For in vivo studies, Mfrn2 KO and MUC KO mice were treated with 300 mg/kg APAP. Liver injury was assessed by serum ALT and histology. Mitochondrial polarization and cell death were assessed by intravital multiphoton microscopy of Rh123 and PI. Progressive quenching of MFF began after ~6 h in both Mfrn2 KO and WT hepatocytes, signifying increased mitochondrial chelatable Fe⁺⁺. Mitochondria then depolarized after ~11 h followed by cell death. Of mice treated with APAP, ~85% of Mfrn2 KO hepatocytes were apoptotic. MFF quenching and mitochondrial depolarization in both WT and Mfrn2 KO hepatocytes. In vivo in WT mice, APAP increased ALT (5.104 U/L) and necrosis (23%) at 6 h, which increased further to 10,254 U/L and 53% in Mfrn2 KO mice. By contrast in MUC KO mice at 24 h, ALT and necrosis decreased to 465 units/L and 12%, respectively, compared to 6015U/L and 42% in WT. Intravital microscopy confirmed mitochondrial depolarization and necrosis in pericentral hepatocytes of WT mice, which was decreased in MUC KO mice. After APAP, MUC mediates uptake of chelatable Fe⁺⁺ into mitochondria, leading to ROS formation and mitochondrial dysfunction, whereas Mfrn2 may mediate Fe⁺⁺ release and protection.

Using 3D Human Liver Microtissues to Model NASH Progression In Vitro for Drug Discovery and Safety Testing

The compound 3-(3,5-dichlorophenyl)-2,4-thiazolidinedione (DCPT) is hepatotoxic in rats and exhibits cytotoxicity in a variety of cells, including the HepG2 cell line. DCPT toxicity in vitro may be due to its breakdown into different metabolites. In order to see how the presence of cells affects the breakdown of DCPT, the compound was incubated in HBSS with HepG2 cells at a concentration of 20,000 cells/ml and with MDCK cells. Results show that when incubated in HBSS, DCPT underwent hydrolysis into S-(3,5-dichlorophenyl)aminocarboxyl)thioglycolic acid (DCTA) after 30 min and continued to breakdown into 3,5-dichlorophenylisocyanate (DPI) within an hour. The concentration of DCPT also decreased steadily over time while concentrations of DCTA and DPI increased. When incubated with cells, DCPT broke down into DCTA after 30 min, but break down to DPI was not evident until the 24-hour time point. Additionally, the concentration of DCPT after 24 hours was much less than that of DCPT incubated in HBSS alone. This could indicate that cells accelerate the breakdown of DCPT and that the breakdown into DCTA is favored over DPI, explaining its low concentration. DCPT was also incubated with Madin-Darby Canine Kidney (MDCK) cells at a concentration of 20,000 cells/ml and in HBSS. In comparison to DCPT incubated in HBSS, the amount of DCPT in solution with MDCK cells decreased at all time points, while DCTA increased after 30 and 60 min, and DPI was present in small amounts after 60 min and 24 hours. These results may indicate that the cells are accelerating the breakdown of DCPT into DCTA and DCTA into other undefined compounds based on its significant drop in concentration after 24 hours. Comparatively, MDCK and HepG2 cells showed different results when it comes to the breakdown of DCPT. With MDCK cells, DCPT levels were slightly lower at all time points than that of the HepG2 cells; however, DCTA and DPI concentrations appeared to be very different. The concentration of DCTA after 30 and 60 min was much higher and decreased to much lower levels after 24 hours with MDCK cells. DPI was also present after 60 min of incubation with MDCK cells compared to 24 hours with HepG2. Overall, these results suggest that the breakdown of DCPT varies when it was incubated with different cell lines. The relevance of these results to cytotoxicity and potential cellular uptake of the compounds requires further investigation. This research was supported by the Department of Pharmaceutical Sciences.
1287 Transcriptomic Profiling of the Inter-Individual Variability of Chemical-Induced Cellular Stress Response Activation Using a Large Panel of Primary Human Hepatocyte Donors
M. Niemeijer1, S. Huppelschoten1, A. Bazè2, C. Parmentier1, R. S. Paules2, L. Richert2, and B. van de Water1. 1Leiden University, Leiden, Netherlands; 2Kaly-Cell, Poissy, France; and 1-NEIHs/NTP, Research Triangle Park, NC.

Drug-induced liver injury (DILI) remains a major concern for the clinic and pharmaceutical drug development. Given the diversity of DILI outcomes, it is crucial to improve the prediction of DILI liability for novel chemical entities at an early stage in drug development by integrating mechanistic understanding. Many DILI markers are known to influence the activation of stress response pathways in a cellular mechanism to overcome stress. Since some patients are more prone to develop DILI, it is key to understand what the inter-individual variability is in activation of these stress responses. To shed light on the variability of DILI susceptibilities among patients, we profiled the transcriptome of a panel of 50 cryo-preserved primary human hepatocytes (PHHs) derived from different individuals using TempO-seq technology with the expanded Tox21 S1500+ gene set. To evaluate stress response activation, cells were exposed for 8 or 24 h to a broad concentration range of tunicamycin for unfolded protein response, diethyl maleate for oxidative stress response, cisplatin for DNA damage response and TNFα for NF-kB signaling activation. Transcriptomic profiles were related to LDH leakage as a measure for cytotoxicity. The variance in the concentration-dependent stress response activation among individuals could be captured. Genes mostly reflecting the divergence in stress response activation were identified. For each stress response, hepatocytes were classified for sensitivity using maximum fold change across dose response and rank of departure from pathway-related gene sets. Correlation of sensitivity for stress response activation and their background such as disease status was identified. Next, the three most sensitive or insensitive hepatocytes for unfolded protein or oxidative stress response activation were exposed to various DILI compounds. Here, the variability in sensitivity for DILI compounds among hepatocytes and their respective stress response activation and cytotoxicity was captured. In conclusion, profiling of the inter-individual variance in chemical-induced stress response activation will aid in the improved understanding of the variance in susceptibility towards DILI among patients. Supported by EU-ToxRisk project (grant agreement No 681002) and IMI MIP-DILI project (grant agreement 115336).

1288 Improved Phenotypic Relevance of Primary Mouse Hepatocyte Spheroids Supports Development of an In Vitro Collaborative Cross Platform for the Evaluation of Genetic Susceptibility Factors Associated with DILI
M. Nautiyal1, S. U. Vorrink1, M. Ingelman-Sundberg2, and M. Mosedale1. 1University of North Carolina Eshelman School of Pharmacy, Research Triangle Park, NC; and 2Karolinska Institutet, Stockholm, Sweden.

We are developing an in vitro Collaborative Cross platform to enable the rapid and cost-effective investigation of gene-by-treatment interactions associated with adverse drug response. The platform will contain primary cells isolated from the genetically diverse lines of the Collaborative Cross mouse population and cultured on multi-well plates to allow for multiple concentrations, treatment regimens, and endpoints to be assayed across replicate wells in a single experiment. Previously, we demonstrated the ability to culture primary mouse hepatocytes in 3D spheroids to support an initial focus on drug-induced liver injury (DILI). The objective of this study was to evaluate the phenotypic relevance of primary hepatocyte spheroids over time. Spheroids were generated from cryopreserved C57BL/6 mouse hepatocytes by spontaneous self-aggregation in ultra-low attachment 96-well plates. Mouse hepatocyte spheroids with well-defined parameters were observed within 5 days and morphology, ATP, and albumin levels were maintained for 2 weeks post spheroid formation. Enzyme activities for 4 major cytochromes P450 were measured on days 1, 7, and 14 post spheroid formation were comparable to that reported for primary human hepatocyte spheroids. Concentration-dependent decreases in viability were observed in response to acetaminophen treatment, and a leftward shift in the EC50 for viability was observed with increasing exposure time. Conifocal, high-content imaging demonstrated rotenone-induced effects on morphology, viability, mitochondrial function, and oxidative stress. Taken together, our results support improved phenotypic relevance of the spheroid model over time and the ability to multiplex mechanistic endpoints via cellular imaging. Furthermore, the use of 3D spheroids will decrease the number of cells required per well and as a result the number of cells (and animals) needed overall. We are now isolating and cryopreserving hepatocytes from Collaborative Cross lines and comparing C57BL/6 mouse hepatocyte spheroids to native liver and fresh hepatocytes using gene expression profiling and quantitative targeted absolute proteomics.

1290 Pharmacological Estrogens and Reduced Risk of Cognitive Deficits in the US Elderly Population
M. V. Preciados, A. Deoraj, Q. Felty, V. Narayanan, C. You, and D. Roy. Florida International University, Miami, FL.

Cognitive loss and brain health are growing public health concerns. Deficits in olfactory and cognitive functions are considered early indicators for neurodegenerative diseases such as Parkinson’s and Alzheimer’s. Epidemiological and clinical studies suggest estrogen use is associated with beneficial odds of cognitive impairment in later life, although findings have been mixed. Here, we evaluated cross-sectional estimate of cognitive and olfactory functions in past users of oral contraceptives (OC) and hormone replacement therapy (HRT) among the U.S. population 65 years of age and older using data from the National Health and Nutrition Examination Survey (NHANES). The surrogates of cognitive health in this study included the test scores based on the: 1) word learning and recall modules from the Consortium to Establish a Registry for Alzheimer’s disease (CERAD) (immediate recall and delayed recall); 2) the Animal Fluency test; and 3) the Digit Symbol Substitution test (DSST). For sensory functions, smell, phantom odor, and persistent taste in mouth over the past 12 months were included in the test scores. Chi-square test of independence was used to test the associations between the medical questions and the brain health indicators. Logistic regression was used to calculate odds ratios (ORs) and 95% confidence intervals (CIs). We found significant association of OR with 95% CI between the past OC and HRT and lowered risk of the cognitive deficits in adjusted models with suspected covariates (age, race, ethnicity, education, diabetes, alcohol use, high blood pressure, physical activity, smoking status) of cognitive functions. We did not observe a significant association for olfactory as well as taste functions as indicators of olfactory functional impairments in response to past use of OC and HRT. In summary, pharmacological use of estrogen is associated with decreased odds of cognitive impairment in the US elderly population. Prospective studies are needed to address the causal relationship between use of OC and/or HRT, and cognitive impairment, dementia and AD.
85-90% of PD cases are apparently sporadic in nature, consistent with an environmental impact on disease etiology. Epidemiological studies have further confirmed the role of environmental factors like pesticide exposure in PD development. Various genetic risk factors have been identified from genome-wide associated studies (GWAS), but available model systems have a limited ability to interrogate gene-environment crosstalk at scale. Here we propose using Drosophila as a model system to understand complex gene-environment interactions in PD. We have used our newly developed α-syn model in Drosophila, and the environmental toxicant rotenone to develop the model for studying these complex interactions. In this study, we have shown that flies expressing human α-syn specifically in neurons, showed age dependent motor deficits and neuronal loss. Further, seahorse bioassay on Drosophila brain revealed that human α-syn expression induced mitochondrial dysfunction in these flies. Further, RNA-sequencing and proteomics analysis revealed that some key lipid metabolism pathways are altered in this model system. Previous studies have shown that mitochondrial complex I inhibition alters lipid metabolism in neuronal cells. Interestingly, our study showed that exposing these flies to the environmental pesticide, rotenone, a complex I inhibitor, exaggerated behavioral deficits and reduced lifespan in human α-syn expressing flies. Moreover, α-syn induced mitochondrial dysfunction also worsened in flies exposed to rotenone. These studies indicate that an environmental factor can be a modifier of a genetic factor in PD and we can use Drosophila to investigate these complex gene-environment interactions. To further validate our model, we selected four key genes which have been implicated by GWAS in PD. Next, we systemically knocked these genes down in neurons and glia separately and exposed the flies to pesticide to identify the mechanisms of pesticide toxicity by performing behavior assays and measuring dopamine level. In summary, we have developed a model to investigate genetic modifiers of pesticide toxicity, which may provide opportunities for the identification of personalized drug targets. Forward genetic screening using this model system, coupled with multiplexing technology can identify key pathways and drug targets.

**Development of Gene-Environment Interaction Model in Drosophila for Neurodegenerative Disease: A Step towards Personalized Medicine**

S. Sarkar, A. Olsen, and M. Feany. Brigham and Women’s Hospital, Harvard Medical School, Boston, MA.

Alzheimer’s disease (AD) is a neurodegenerative disorder associated with aging and characterized by decline in cognitive function. Currently, there is no effective treatment in slowing the progression of AD. However, several studies have shown that natural compounds found in fruits and vegetables can improve memory impairment. Indole-3-carbinol (I3C) is a phytocompound present in edible cruciferous vegetables. It has been reported that I3C produces 3,3'-diindolymethane (DIM) in the acidic environment of the stomach. This study was designed to investigate the effects I3C and DIM on Aluminum Chloride (AlCl₃)-induced AD in male Wistar rats. Forty-two rats were divided into 6 groups of 7 animals each. Animals in groups 1, 2, 3 and 4 received corn oil (2mg/kg), I3C (10mg/kg), DIM (10mg/kg) and AlCl₃ (100mg/kg) for 4 weeks prior to AlCl₃ (100mg/kg) challenge for 8 weeks. Brain silver staining observations, immunohistochemistry assays (Amyloid beta 1-42 (Ab), amyloid precursor protein (APP), B-cell lymphoma 2 (Bcl-2), Bcl-2-associated X protein (BAX) and immunofluorescence assessment of A Disintegrin and metalloproteinase domain-containing protein 10 (ADAM 10) of rat brains revealed that AlCl₃ intoxication decreased α-secretase expression with elevated expression of insoluble plaque and apoptosis. However, pre-treatment with I3C and DIM prior to AlCl₃ exposure significantly reverted the ADAM 10 expression, amyloid protein and apoptosis markers in the studied regions. These results, however, require an animal model treated with I3C and DIM prior to AlCl₃ exposure. The results obtained from the study showed that I3C and DIM reversed memory loss caused by aluminum chloride in rats by attenuating synaptic impairment, apoptosis, and amyloidogenic pathways.

**Long-Term Swimming Exercise in Caenorhabditis elegans Improves Mitochondrial Health and Protects Animals from Age- and Toxicant-Induced Degeneration**

J. H. Hartman¹, K. L. Gordon¹, R. Laranjeiro², L. L. Smith², M. Driscoll², D. R. Sherwood², and J. N. Meyer¹. ¹Duke University, Durham, NC; and ²Rutgers, The State University of New Jersey, Piscataway, NJ.

Age-related chronic diseases, including neurological disease and cancer, are well-recognized to involve contributions from genetic and environmental factors. However, the role of lifestyle in the initiation and progression of chronic disease, and how it interacts with genetic and environmental factors, is far less studied. Exes of providing noted benefits in humans, including reducing risk of age-associated chronic diseases. However, molecular mechanisms underlying these protections and how those mechanisms may impact exposure risk from environmental chemicals have remained elusive, partly due to the high cost and time investment of long-term exercise intervention studies in mammals. We have developed a long-term exercise intervention in the nematode C. elegans by subjecting them to twice daily swimming during their entire reproductive adulthood (6 days). Following exercise, we assessed mitochondrial health and general physiological health in aging animals. We also exposed the animals to common mitochondrial toxicants (rotenone and arsenic). Exercise protected from age-related decline in mitochondrial morphology (p<0.05) and spare mitochondrial respiratory capacity (30% increase from exercise, p<0.05). We observed modestly increased lifespan in exercised animals (median lifespan 19 days) compared to non-exercised animals (16 days; p<0.05). Exercised animals were markedly protected against oxidative stress with increased lifespan (19 days; p<0.05) and spare mitochondrial respiratory capacity (30% in exercised animals vs. 20% in non-exercised animals). In summary, swimming exercise provides effective intervention in C. elegans against age-related mitochondrial and physiological decline and toxicant exposure. This novel long-term exercise model will allow toxicologists to take advantage of the short lifespan and genetic power of C. elegans to dissect the mechanisms that mediate exercise modulation of exposure risk.

**Induction of Autophagy in Mouse Neuroblastoma Cells by Rabies Lyssavirus Infection**

M. Hojo¹, A. Noguchi², S. Inoue³, and Y. Sugita-Konishi¹. ¹Azbu University, Sagamihara, Japan; and ²Institute of National Infectious Diseases, Tokyo, Japan.

Autophagy (ATG) is induced by the condition of extra and intracellular stress stimuli or nutrient starvation. Interestingly, ATG has the immunological function such as multiple innate and adaptive immune pathways involved in the control of inflammation, removing endogenous inflammasome agonists through effects on the secretion of immune mediators. Rabies lyssavirus (RABV) is highly neurotropic and induces the different degree of ATG during the infection according to their viral pathogenicity. In this study, the kinetics of ATG focused on the accumulation of autophagosome during the infection of RABV HEP Flury (HEP) strain to mouse neuroblastoma cells (MNA). MNA cells were propagated and used ATG induction. HEP strain propagated in MNA cells was determined its infectious titer by a focus forming unit (FFU). MNA cells were exposed to 20 FM rapamycin well as a positive control of ATG. After the day 0, 4, 6 and 24th treatment with lysis buffer, MNA cells were examined by the western blotting (WB). LC3-II signal compared to LC3-I was higher in MNA cells treated with rapamycin and infected with HEP strain than MNA cells without any treatment. LC3-II /LC3-I signal was decreased in MNA cells treated with rapamycin after 4 h, however LC3-II /LC3-I signal in MNA cells infected HEP strain was not decreased. The highest LC3-II /LC3-I signal in MNA cells treated with rapamycin was shown at 6 h and it was decreased at 24 h. On the other hand, LC3-II /LC3-I signal in MNA cells infected with HEP strain was not decreased after 6 h and kept high LC3-II /LC3-I signal after infection. RABV N protein of HEP strain was increased visibly at 24 h. As levels of endogenous LC3-II in MNA cells were correlated with an increased number of autophagosomes, the signal of ATG induction was induced by the infection of RABV HEP strain induced ATG. This suggests that the infection of HEP strain pulled the trigger of ATG signal induction during early infection and continued the induction of ATG signal. It was reported that RABV was inactivated through the suppression of ATG by mTOR-dependent autophagy signaling pathway. But kinetics and mechanism of causal interrelation between RABV and ATG was not yet proved to satisfactory extent in RABV infected cell. Therefore, we are studying further analysis immunologically and histopathologically to understand the kinetics of ATG on the accumulation of autophagosome during the infection of RABV HEP strain to mouse MNA cells.
Evaluation of Role of Pericytes in Cerebral Amyloid Angiopathy (CAA) Model of Alzheimer’s Disease (AD)

Excessive deposition of amyloid-beta (AB) plaques and neurofibrillary tangles are two salient features of AD. Among most AD patients, 75-80% of them show CAA. CAA occurs because of deposition of plaques in the microvessels, a key component of neurovascular units (NVU). These endothelial cells are surrounded by pericytes, another component of NVU. Pericytes regulate blood flow in the brain and provide support to the microvessels and eliminate toxic molecules from the brain by an efflux mechanism. In this study, we evaluated the role of pericytes in a mouse model of CAA which shows AB deposition in the vessels in addition to parenchyma. To visualize pericytes in the brain, Fluoro-Ruby (FR)-dextran, a retrograde tracer was injected bilaterally into lateral ventricles of mouse brains. In addition, CD31 immunolabeling was performed to evaluate the integrity of the endothelial cells of the brain. Fluoro Jade C labeling was also done to evaluate neurodegeneration in the brain. FR labeled pericytes were dystrophic in nature in the CAA mice compared to their wild type counterparts. The results also showed that compared to the wild type, there was a higher number of pericytes in the cortex but fewer pericytes in the hippocampus of the CAA mice. Most FJC labeled axonal degeneration was prevalent in the hippocampus with a moderate amount in the cortex. While the number of endothelial cells were increased in the CAA mice compared to wild type mice; the area fraction and intensity of the endothelial cells in the brain of the CAA mice were significantly less than that found in the wild type. These findings suggest degeneration of the pericytes and endothelial cells and ischemia of the vessels in the cortex and hippocampus resulting from deposition of AB plaque deposition in the microvasculature of the brain and CAA could also cause axonal degeneration.

Decreased NRF1 Activity Contributes to Neurogenesis Deficits in Alzheimer’s Disease (AD)

K. Bhawe, Q. Feltly, C. Yao, A. Deoraj, and D. Roy, Florida International University, Miami, FL.

AD is a heterogeneous, multifactorial disease, and a major challenge in AD research is to fully understand the multiple etiologies and age-related pro-dromal processes involved. Hippocampal atrophy and cognitive deficits in AD patients are associated with marked alterations in neurogenesis. Deposits of AD-toxins, amyloid-β42 (Aβ42) and p-tau, lead to decreased neurogenesis and synaptogenesis contributing to memory deficits and learning impediments. There is an urgent need for a direct and targeted approach to identify molecular factors associated with neuronal loss and neurogenesis deficits in AD. Adult hippocampal traits-proliferation, survival/maintenance of new-born neurons and astrocytes are controlled by a wide range of gene expression. To date, over 250 genes have been implicated in adult hippocampal neurogenesis although causal NRF1 signature genes involved remain unknown. The primary objective of this study is to identify the key NRF1 transcriptional regulatory modules controlling neurogenesis and neurodegeneration in AD patients. Since adult neurogenesis is polygenic, it likely depends on multi-target gene interactions of NRF1 regulating gene expression, protein abundance, epigenetic state, and signaling activity. We hypothesize that NRF1 gene networks specific to neuronal and astrocytic become dysregulated during AD pathogenesis. Through transcriptomic data from four independent AD studies, we found decreased NRF1 activity in AD brain compared to normal controls. This also allowed us to identify a core set of NRF1 target genes down-regulated in AD. We characterized key molecular pathways associated with these genes including ALAS1, TRIM37, WRB, POP7 and STXBP1. Using Comparative Toxigenomics Database, we found 255 unique chemical substances interacting with at least one of these genes. We then employed Bayesian machine learning to determine gene relationships in various brain regions of AD patients compared to non-AD individuals stratified by age and gender. NRF1 regulated genes that show significantly decreased expression in AD brain tissue are also regulated by estrogen and endocrine disrupting compound bisphenol A (BPA), and have distinct gene networks in brain tissue from Alzheimer’s patients. NRF1 target genes, SOX2, SOX2-OT, NR2E1, MAPT and PSEN2, are associated with Alzheimer’s. Clinical confirmation of our findings will have significant impact on our understanding of NRF1 as a valuable biomarker for AD diagnosis and prognosis and will provide strong rationale for future studies to develop NRF1 signaling based therapeutics for Alzheimer’s disease.
individuals with ND, including Alzheimer’s Disease, Parkinson’s Disease and Amyotrophic Lateral Sclerosis, similar to those reported by us in neurotoxicity studies. Autoantigens (AAg) have included neurofilaments (NF), and glial proteins (glial fibrillary acidic protein (GFAP) and myelin basic protein (MBP)), among others. To investigate the prevalence and titers of NAB against a panel of these AAg in horticulturists exposed to pesticides, 106 (45-6 years old; 73 male; 33 female) active farmers residing in the Nile Delta with varying duration (5-40 years) of agricultural activity were recruited. According to records, all participants had occupationally used multiple classes of pesticides including organophosphates, carbamates, dipyr idimido and aminophosphonates. IgG titers against axonal NF-H, GFAP and MBP were significantly more prevalent compared to IgM titers against the same antigens (p<0.0001-0.0001), in contrast to NF-L and NF-M, where IgM was more prevalent (p<0.05). Furthermore, NAB IgG titers against NF-H, GFAP and MBP were significantly higher (p<0.00001-0.0001) compared to IgM against the same AAg. For NF-L and NF-M, IgM was the higher isotype (p<0.003-0.007). Stratification by NAB score (total IgG detected of 10 measured) indicated that the high NAB group had increased titers against NF-L and NF-M, and IgM titers against NF-H, GFAP and MBP significantly differed from those with higher scores (p<0.0001-0.04). Since IgG is the class associated with development of immunological memory and acute insult, its greater prevalence against NF-H and glial proteins suggests a longer term axonal and glial involvement, and a more chronic involvement of NF-L and NF-M, as suggested by IgM prevalence. This preliminary study indicates that exposure to pesticides with known neurotoxic potential results in detectable levels of serum NAB similar to those reported in other neurotoxic exposures and ND. A follow-up and expanded study incorporating neurological exam and genomic profile is underway.

**1300 Diesel Exhaust Dysregulates Markers of Disease-Associated Microglia**

H. J. Greve 1, C. L. Muma 1, U. P. Kodavanti 1, P. R. Kodavanti 1, J. E. Royland 2, and M. L. Block 1.

An increasing amount of evidence indicates an association of traffic-related air pollution, such as diesel exhaust (DE), with Alzheimer’s disease (AD). At present, how inhaled environmental pollutants impact central nervous system (CNS) and neurodegenerative diseases remains poorly understood. In recent decades, the importance of microglia, the parenchymal myeloid cells of the CNS, to the neurodegenerative process has become increasingly clear. Currently, little is known about the mechanisms through which DE may impact the microglial phenotype associated with containing AD plaques (Disease-Associated Microglia, DAM). TREM2 (Triggering Receptor Expressed on Myeloid Cells 2) is a myeloid-cell specific membrane protein and its increased expression is necessary for microglia to obtain the DAM phenotype. Further, inactivating TREM2 mutations are associated with increased AD risk. At present, how DE might affect TREM2 is unknown. To begin to address these issues, twelve- to fourteen-week-old male Wistar Kyoto rats were exposed to DE (0, 50, 150, 500 µg/m³) by inhalation for 4 weeks (4 hours/day, 5 days/week). Frontal cortex mRNA expression was analyzed by qPCR to discern the effects of DE on pro-inflammatory and DAM markers. Tn1C expression demonstrated a step-wise increase relative to dose. However, the DAM markers CX3C chemokine receptor 1 (CX3CR1), TREM2 and lipopolysaccharide lipase (LPL) exhibited an inverted-U pattern of expression, where an increase in expression at 50 and 150 µg/m³ was observed, but the highest concentration of DE decreased expression suggesting that higher levels of DE exposure may impair the DAM response. Analysis of frontal lobe TREM2 protein by ELISA revealed that full length TREM2 protein levels were diminished at all concentrations of DE, while soluble TREM2 (sTREM2) protein demonstrated a dose-dependent decrease with DE concentration. Together, these data support that DE perturbs the DAM phenotype and in particular, decreases TREM2 protein expression. Given the role of the loss of TREM2 function in elevated AD risk and an impaired DAM phenotype, these findings provide much needed insight into the potential underlying mechanisms of how air pollution affects AD.

**1301 The Selective Group I Metabotropic Glutamate Receptor Agonist 2-Chloro-5-Hydroxyphenylglycine (CHPG) Enhances BDNF and Reverses Demyelination**

K. Saitta, L. Lercher, A. Patel, Y. Huang, W. McAuliffe, and C. Dreyfus.

Rutgers Robert Wood Johnson Medical School, Piscataway, NJ.

The demyelinating agent cuprizone (0.2%) causes a decrease in brain-derived neurotrophic factor (BDNF) and myelin proteins with an upregulation of metabotropic glutamate receptors (mGluRs) in astrocytes within the lesion site following 4-6 weeks of treatment. Similarly, patients with multiple sclerosis not only have deficits in myelin, but also have enhanced expression of mGluRs within active chronic lesions and decreases in BDNF. Therefore, an intriguing therapeutic approach for these types of demyelinating diseases may be to enhance the endogenous source of BDNF. The aim of this study was to enhance endogenous BDNF through the application of 2-chloro-5-hydroxyphenylglycine (CHPG), by using the clinically relevant approach of a peripheral injection. Cuprizone or identically processed control feed was fed to adult mice for 4 or 6 weeks prior to intraperitoneal (ip) injections of saline vehicle or CHPG (20 or 40 mg/kg). CHPG increased levels of BDNF and myelin proteins 24 hours after injection and this effect lasted up to 3 days. Myelin proteins increased without increases in CC1+ mature oligodendrocytes at 24 hours, suggesting that CHPG increases myelin protein per cell. Interestingly, CHPG did not alter BDNF, myelin protein numbers or neurons of CC1+ oligodendrocytes in control-fed mice. Furthermore, BDNF and myelin proteins remain elevated following administration of CHPG every other day for 2 weeks, suggesting that CHPG’s effects can be maintained over time. The same dosing regimen of CHPG also increases myelin thickness and the number of myelinated fibers following cuprizone as analyzed by transmission electron microscopy. To begin to elucidate the receptor responsible for CHPG’s actions and the site of action, the selective mGluR-5 antagonist 2-methyl-6-(phenylethynyl) pyridine (MPEP) was injected directly into the lesion site prior to ip injection of CHPG. While CHPG treatment increased BDNF and myelin proteins in the absence of MPEP, and aggregation of the protein alpha-synuclein leading before CHPG, suggesting both a role of mGluR-5 in mediating the actions of CHPG and that CHPG injected peripherally acts within the lesion site. Taken together, these data suggest that selectase mGluR Group 1 agonists such as CHPG may be a therapeutic approach for treating demyelinating diseases by increasing the levels of BDNF and improving myelination, possibly through astrocytic mGluR-5. **1302 Using the Transgenic Zebrafish Model to Compare Mechanisms of Action of Two Environmental Toxics with Opposite Correlations to Parkinson’s Disease Development, DEPe and CSE**

Parkinson’s Disease (PD) is the second most common neurodegenerative disease and is caused by both genetic and environmental factors. The main hallmarks of PD include loss of dopaminergic neurons in the substantia nigra, neuroinflammation, and aggregation of the protein alpha-synuclein leading to the formation of Lewy bodies. Epidemiological studies have reported a positive association between exposure to traffic-related air pollution (AP) and development of PD, but an inverse association between cigarette smoking and development of PD. We used zebras as a model organism to uncover the molecular mechanisms of action that are responsible for these opposing effects. Transgenic zebrafish embryos were treated with diesel exhaust particulate extract (DEPe) or cigarette smoke extract (CSE) to determine the effects of exposure to these toxicants on neuron health, neuroinflammation, and behavior. DEPe exposure led to a significant loss of aminegic neurons in the ZF brain and an activated microglia. CSE exposure led to a significant loss of aminegic neurons in the ZF brain and no activation of microglia. There was also significantly decreased light-cycling behavior in both DEPe and CSE treated embryos. The opposite effects of DEPe and CSE exposure on the activation of microglia may shed light on molecular mechanisms responsible for the anti-relationship of the two exposures with development of PD. Ultimately, these studies will help elucidate the mechanisms by which AP contributes to neurodegeneration in PD, and conversely, the mechanisms by which cigarette smoking is linked to lowered risk of PD development.

**1303 Pharmacological Activation of Prokineticin-2 Signaling Protects against Dopaminergic Neurodegeneration in MPTP and Mitopark Rodent Models of Parkinson’s Disease**

Ultimately, these studies will help elucidate the mechanisms by which AP contributes to neurodegeneration in PD, and conversely, the mechanisms by which cigarette smoking is linked to lowered risk of PD development.
plays a major compensatory protective function during neuronal injury. While we showed that AAV-mediated PK2 overexpression protects against MPTP-induced neurodegeneration, CNS delivery of PK2 via recombinant protein or gene transfer remains challenging. In this study, to harness the protective potential of PK2 activation, we utilized a small-molecule PK2 receptor agonist, iS2O, to pharmacologically activate PK2 signaling pathway. iS2O induced intracellular Ca\(^{2+}\) in CHO cells overexpressing PK2 receptor, suggesting that iS2O can pharmacodynamically engage the receptor PKR1. PK2 activation by iS2O also conferred significant protection against MPP\(^{+}\) neurotoxicity in N27 dopaminergic cells. Importantly, we assessed the neuroprotective property of iS2O in a subacute MPTP mouse model of PD, wherein it restored levels of dopamine, and preserved dopaminergic neuron bodies and neuron fibers in the substantia nigra of MPTP-treated mice. Next, to reduce systemic exposure to iS2O, we intranasally administered iS2O in MitoPark mouse model, a chronic, genetic model of PD that harbors selective TFAM loss-of-function mutations in DAergic neurons, leading to manifestation of Parkinsonian symptoms by age 12 wk. iS2O administration significantly improved the locomotor activity and attenuated severe nigrostriatal degeneration in MitoPark mice. Additional studies revealed that iS2O treatment decreased fluorescent apoptotic cell staining in the substantia nigra (SN), and neuroinflammatory IBA-1 expression in SN, striatum of MitoPark mice. Pharmacokinetics studies via LC/MS analysis indicated that intranasally-treated iS2O becomes rapidly bioavailable in the brain. Together, our results indicate that pharmacological modulation of PK2 signaling by the receptor agonists could be an efficient and viable option to harness the neuroprotective effects of PK2 signaling against PD neurodegeneration. R01 NS078247, R01 NS088206.

1304 Manganese Exposure Induces the Release of Exosomes Containing Misfolded α-Synuclein by Impairing Endosomal Trafficking and Protein Degradation Machinery

D. Rokad, D. Harischandra, D. Luo, V. Anantharam, A. Kanthasamy, and A. G. Kanthasamy, Iowa State University, Ames, IA.

Environmental exposure to excessive manganese (Mn) increases the risk of chronic neurological diseases, including Parkinson’s disease (PD). Aggregated α-synuclein (aSyn) is a key pathophysiological characteristic of PD. Oligomeric proteins like aSyn can be released from neurons by exosomes, facilitating the spread of misfolded proteins to neighboring cells, which can trigger a neurotoxic response. We recently discovered that Mn enhances the release of misfolded aSyn via exosomes from dopaminergic neurons, but the underlyung molecular mechanisms are unclear. To better understand the Mn-induced release of exosomal aSyn, we examined how Mn modulates endosomal protein trafficking and misfolded protein degradation. We exposed MN9D dopaminergic neuronal cells stably expressing human wild-type (WT) aSyn (MN9D-aSyn) to Mn (300 μM) for 24 h. Mn significantly suppressed expression of the key endosomal recycling protein Rab11a, both at the protein and mRNA levels, suggesting Mn downregulates endosomal recycling mechanisms, thus forcing late endosomes to mature into multivesicular bodies (MVBs). Moreover, ectopic expression of WT Rab11a significantly mitigated exosome release from iS2O-treated and Mn-exposed MN9D-aSyn cells. Aggregated aSyn expression of mutant Rab11a (S25N) increased exosome release. Intriguingly, our qRT-PCR, Western blot, and ICC analyses also revealed that Mn exposure upregulated mRNA and protein levels of Rab27a, a key endosomal protein that mediates exosome release through fusion of MVBs with the plasma membrane, suggesting Rab27a upregulation contributes to Mn-induced exosome release. Since aggregated aSyn can get degraded via the autophagic/lysosomal degradation pathway, we examined if Mn impairs this pathway to promote exosomal aSyn release. Our Western blot analysis of MN9D-aSyn cells shows Mn upregulated the expression of the autophagosomal markers LC3-II and Beclin-1, but downregulated the lysosomal marker LAMP2, suggesting an impairment of autophagosome formation following Mn exposure. Results from other key lysosome function assays, such as LysoTracker staining and Cathepsin D activity assay, confirmed Mn-induced lysosomal dysfunction. Taken together, these novel findings demonstrate that Mn compromises endosomal trafficking and lysosomal function, thereby promoting the exosomal release of misfolded aSyn. NIH grants ES026892, NS088206 and the Eugene & Linda Lloyd Endowed Chair.

1305 Development of an Electrochemiluminescence-Based Assay to Characterize Pyroptosis-Related Proteins in Plasma Obtained from Parkinson’s Disease Patients

F. L. Anderson\(^1\), A. S. Andrew\(^2\), K. M. von Herrmann\(^1\), F. P. Bispo\(^3\), A. L. Young\(^1\), S. L. Lee\(^1\), and M. C. Havrda\(^1\), Dartmouth College, Lebanon, NH, and Saint Anselm College, Manchester, NH.

Parkinson’s disease (PD) is a highly prevalent neurodegenerative disease affecting approximately 5 million people worldwide. Neuroinflammation is a widely recognized aspect of PD; however, the impact of inflammation on PD incidence and progression remains unclear. Exposure to environmental toxicants, including pesticides, heavy metals, and industrial solvents, has been implicated in PD risk, but the molecular basis by which toxicants impact PD progression is not completely characterized. Inflammases are pro-inflammatory intracellular protein complexes containing pattern recognition receptors capable of responding to sterile triggers by initiating inflammation and a subcategory of programmed cell death called pyroptosis. Our lab has previously shown that loss of NLPR3, the pattern recognition component of the NLRP3 inflammasome, in mice mitigates the development of PD symptoms resulting from exposure to the pesticide and mitochondrial toxin rotenone. More recently we observed expression of NLPR3 in the mesencephalon in late-stage PD patients. Based on the recognition that inflammasomes are activated in PD and cytosolic proteins are released during the process of pyroptosis, our lab has developed electrochemiluminescence-based immunoassays for the detection of pyroptotic proteins including NLR family pyrin domain containing 3 (NLPR3) and Gassdermin D (GSDMD). Utilizing this method, we have compared NLPR3 and GSDMD protein levels in human plasma samples collected from PD patients and age-matched controls. The detection of the downstream NLPR3 inflammasome targets, including GSDMD and IL-18, suggest that we may be able to monitor the activity of inflammasomes and evaluate pyroptotic processes in plasma. To complement these biochemical studies we have collected surveys from PD patients and controls detailing potentially inflammatory lifestyle factors, occupational exposures, and medical history information to identify environmental risk factors associated with circulating inflammasome and pyroptosis-associated proteins. Our study will allow us to correlate levels of inflammasome and pyroptotic activity with environmental exposure data to elucidate their relationship to PD diagnosis.

1306 Zebrafish Transgenic Model for Studying the Dynamics of Mitochondrial Dysfunction Induced Epigenetic Hyperacetylation: Relevance to Environmentally Linked Parkinson’s Disease

Growing evidence implicates occupational exposure to pesticides as an important risk factor for the development of Parkinson’s disease (PD). Exposure to neurotoxic pesticides induces mitochondrial dysfunction and oxidative stress, both of which are key pathological hallmarks of PD. We recently demonstrated that exposure of dopaminergic neuronal cultures to the neurotoxic pesticides rotenone, tebufenpyrad and pyridaben induced significant neurotoxicity by affecting mitochondrial structure and function. To further characterize the relationship between mitochondrial dysfunction and epigenetic dysregulation, we examined the effects of pesticide exposure on histone acetylation in cell and animal models of PD. Exposing N27 to rotenone (1 μM) and pyridaben (3 μM) time-dependently increased acetylation levels of the global histones H3/H4, including site-specific histone acetylation at H3-K23 and H4-K5. In a mitochondria-defective MitoPark mouse model of PD, we verified both global histone H3 and site-specific H3-K23 acetylation in the substantia nigra of MitoPark mice compared to age-matched controls. Importantly, we observed increased histone acetylation of both H3/H4 and H3-K23 in nigral lysates from postmortem human PD brains. To investigate the detailed molecular mechanisms of pesticide-induced histone hyperacetylation, we adopted the zebrafish model, which is increasingly being employed to study the epigenetic modifications relevant to human diseases. Transparent cristalline zebrafish mutant embryos, devoid of pigmentation, were exposed to various doses of rotenone at 24 h post-fertilization and harvested 4 days later. Immunostaining revealed that a 10-nM rotenone exposure induced a loss of TH neurons in the zebrafish larval brain. We intend to compare the histone global and site-specific acetylation profiles between our rotenone zebrafish model and mouse models of PD. Collectively, our findings show that mitochondrial dysfunction induces histone hyperacetylation in DAergic neu-
1307 Effects of Low-Dose Developmental Dieldrin Exposure on Neuroinflammation and α-Synuclein Aggregation in the Mouse Nigrostriatal Pathway

A. O. Gezer, S. E. VanOeveren, J. Kochmanski, and A. Bernstein, Michigan State University, Grand Rapids, MI.

Human and animal studies have shown that exposure to the organochlorine pesticide dieldrin is associated with increased risk of Parkinson’s disease. Although previous work demonstrated that developmental dieldrin exposure increases neuronal susceptibility to MPTP toxicity in male C57BL/6 mice, the mechanisms driving this increased susceptibility are not well characterized. Male mice developmentally exposed to dieldrin display enhanced MPTP toxicity compared to mice treated with MPTP alone, showing greater induction of glial fibrillary acidic protein (GFAP) and α-synuclein (α-syn) expression. This suggests that dieldrin-induced changes in neuroinflammation and α-syn may underlie increased neuronal susceptibility. Here, we tested the hypothesis that low-dose developmental dieldrin exposure induces changes in neuroinflammatory markers and α-syn, thereby increasing vulnerability of the nigrostriatal pathway to dopaminergic toxicity. Starting at 8 weeks old, male C57BL/6 mice were exposed to 0.3 mg/kg dieldrin by feeding every 3 days, continuing through adult maturing, gestation, and lactation. At 12 weeks of age, male and female pups from independent litters were sacrificed, and striatum and substantia nigra were dissected. To determine whether sex-specific changes in neuroinflammation and α-synuclein underlie male-specific enhanced vulnerability, both sexes were included in analyses. We assessed markers of neuroinflammation via target-ordered expression assays to test if developmental exposure to dieldrin led to induction of neuroinflammatory pathways in the striatum and substantia nigra. In addition, we analyzed α-syn aggregation by western blot in non-denaturing and non-reducing conditions to test whether exposure leads to changes in α-syn species. We identified changes in both systems, demonstrating that developmental dieldrin exposure produces “sub-toxic” changes in these pathways that produce a phenotype of increased vulnerability. In a parallel study, we identified sex-specific DNA methylation changes in genes related to the development and maintenance of the nigrostriatal pathway. Taken together, these data suggest that developmental dieldrin exposure leads to persistent changes in phenotype that may contribute to the development of Parkinson’s disease.

1308 Nanotherapy for Parkinson’s Disease: Nicotine-Nanoceria Prevents Neuronal Damage and Reverses Electrophysiological Function in Primary Human Dopaminergic Neurons

The pathophysiology of dopaminergic (DA) loss in Parkinson’s disease (PD) is still unclear. Lack of effective therapies maybe due to limitations in our understanding of the molecular and cellular events leading to degeneration of the nigrostriatal DA system. Here, we report that a combination of Nicotine and NanoCeria presents an outstanding case of prevention of PD progression, in a 1-methyl-4-phenylpyridinium (MPP+) induced in vitro model of PD in primary human dopaminergic neurons. A co-treatment of Nicotine and NanoCeria significantly inhibited MPP+ induced inhibition of parkin expression and prevented the aggregation of α-synuclein suggesting a regulation of protein degradation pathway. More importantly, in a functional electrophysiological analysis using Multi-Electrode Array, we report for the first time that this therapeutic combination of Nicotine and NanoCeria was not only able to prevent MPP+ induced loss of neuronal function but also was able to significantly reverse it towards normal. Our data might suggest an efficacious role of Nicotine-NanoCeria combination for the prevention of neuronal loss and restoration of neuronal function during PD progression. Additional in vivo work will be required to validate these significant findings.

1309 Function of lncRNA NR_030777 in Affecting Cell Proliferation and Apoptosis by Regulating Zfp326/Cpne5 in Nerve Cell Damage Induced by Paraquat

H. Yang, Q. Lin, N. Chen, Z. Luo, J. Li, F. Zheng, Q. Zhang, S. Wu, and H. Li. 1Fujian Medical University, Fuzhou, China; and 2University of Louisville, Louisville, KY.

Parkinson’s disease (PD) is a common age-related degenerative disease of the central nervous system. It is generally believed that PD is caused mainly by environmental and genetic factors. Previous studies have shown that paraquat (PQ) may be one of the environmental factors leading to PD, but its specific mechanism remains to be further elucidated. lncRNAs generally refer to non-coding RNA transcripts longer than 200 nucleotides and researches have shown that lncRNA plays irreplaceable roles in neurodegenerative diseases. However, the exact roles and mechanisms of lncRNAs remain unclear. In this study, we identified IncRNAs related to PD caused by PQ and clarified the biological functions and regulatory mechanisms of a specific lncRNA in nerve cell damage induced by PQ. We found changes in lncRNA expression profile of mouse substantia nigra (SN) induced by PQ using microarrays, and six of them validated by qRT-PCR and two by FISH. Bioinformatics analysis was applied to predict the functions of IncRNAs and predict the targeted genes. Among the differently expressed IncRNAs, the dysregulation of NR_030777 which is highly homologous with its gene symbol Zfp326 drew our attention. We observed that the changes of Cpn5 expression through CNC prediction and mRNA microarrays was related to the high expression of NR_030777. So we reasonably supposed that NR_030777/Zfp326/Cpne5 pathway plays a crucial part in nerve cell damage induced by PQ. In vitro, Parkinson’s disease virus infected cells used to knock down or overexpress NR_030777 expression in order to explore the regulatory mechanism and biological functions of NR_030777 in cell damage caused by PQ. We found that NR_030777 regulated the expression and stability of Zfp326 and Cpne5, and thereby regulated cell proliferation and apoptosis induced by PQ. In addition, we further discovered that by scavenging ROS by N-acetyl-cysteine (NAC), NR_030777 expression was suppressed. In summary, NR_030777 plays a protective role against neurotoxicity of PQ by regulating the expression of Zfp326/Cpne5. Our study first reveals the novel role of NR_030777 in PQ-induced nerve cell damage and provide a potential method to prevent and treat neurodegenerative diseases caused by common environmental neurotoxins such as PQ.

1310 Neurobehavioral and Neurochemical Effects of Acute to Subchronic PhIP Exposure

R. M. Foguth, and J. R. Cannon. Purdue University, West Lafayette, IN.

Heterocyclic amines (HCAs) occur in a variety of foods, especially in the crust of charred meats. HCAs have been widely investigated as mutagens, though our published data suggest that HCAs are selectively neurotoxic to dopamine neurons, with potential relevance to Parkinson’s disease (PD). 2-Amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) is the most abundant HCA in cooked meat. Of the major primary metabolites, N-Oh-PhIP selectively affects dopamine neurons. Rodents are far less efficient than humans in metabolizing PhIP to N-Oh-PhIP due to differences in CYP1A2. Thus, we wished to test the contribution of CYP1A2 to PhIP-induced neurotoxicity using humanized mice. Here, we hypothesized that PhIP treatment in mice would lead to neurobehavioral deficits and selective dopamine neurotoxicity and that humanized mice would be more sensitive. C57BL/6 mice were exposed to acute (100 or 200mg/kg bodyweight; single dose; 8-hour exposure; males and females; n = 4-5/group) or subchronic (75mg/kg; 3x/week for 16 weeks; males; 200mg/kg bodyweight; single dose; 8-hour exposure; males and females; n = 4-5/group) PhIP. Doses and time-points were chosen from the cancer bioassay literature and our studies. Behavior was assessed through rearing and pole tests in subacute exposure groups. Brains were collected for neurotransmitter and histological analyses. Acute PhIP exposure significantly decreased striatal dopamine turnover in mice humanized for CYP1A1/2 vs. wild-type controls and wild-type exposed, indicating heightened sensitivity. Subchronic exposure significantly decreased motor function as evidenced by decreased rearing and increased pole test descent time, with behavioral changes detectable beginning after 11 weeks of treatment. Subchronic PhIP-treated mice showed significantly increased striatal dopamine levels, with no significant changes in other neurotransmitters. Turnover changes were not detected, suggesting the effect is acute. There were no detectable changes in striatal dopamine terminal density or oxidative damage markers in either sex, suggesting a lack of overt neuropathology. In conclusion, our studies in mice support findings in other model systems showing that PhIP selectively targets dopaminergic neurotransmission and that PhIP metabolism may have a critical role in neurotoxicity. Future studies will add male and female mice exposed from subacute to chronic time-points to determine potential relevance to human PD.
Environmental toxiants that cause mitochondrial dysfunction, such as the organic pesticide rotenone, and the common herbicide paraquat, are associated with elevated Parkinson’s disease (PD) risk. A heavily used industrial solvent, trichloroethylene (TCE), also causes mitochondrial toxicity, and is a ubiquitous environmental contaminant. Occupational TCE exposure is linked to the development of PD (odds ratio (OR): 6.1; 95% CI). Similarly, high doses (900-1,000 mg/kg) of TCE administration to rodents results in dopaminergic neurodegeneration. New data from our lab indicates that rotenone, paraquat, and TCE interact with PD susceptibility genes, notably, causing the activation of the protein LRRK2 (leucine-rich repeat kinase 2) in wildtype human embryonic kidney (HEK) cells, which could be blocked by a selective LRRK2 inhibitor (GNE-7915). As LRRK2 is the most commonly inherited mutation associated with familial PD, this evidence suggests that a gene-environment interaction exists between LRRK2 and common environmental mitochondrial toxicants.

Aberrant LRRK2 activation leads to pleiotropic cellular dysfunction, such as disruption of vesicular trafficking and autophagy, accumulation of phosphorylated alpha-synuclein, and neuroinflammation; all of which are mechanisms hypothesized to precede dopaminergic neuron degeneration in PD. As TCE is a widespread environmental contaminant, we postulated that relatively low levels of TCE exposure in aged rats may induce LRRK2 activation in dopaminergic neurons and increase risk of a Parkinsonian phenotype. Using aged Lewis rats (12 mo) we administered 200 mg/kg TCE (oral gavage) or vehicle (olive oil) daily for 6-weeks. Animals receiving TCE displayed a moderate loss of dopaminergic neurons within the substantia nigra, which correlated with a significant increase in LRRK2 kinase activity in surviving cells. In addition, we observed marked deficits in endolysosomal trafficking and function, concomitant with accumulation of toxic forms of alpha-synuclein (phospho-Serine129) within dopaminergic neurons. Together, these data suggest that LRRK2 activation by environmental TCE may be a novel gene-environment interaction, resulting in early pathological changes within susceptible individuals to increase PD risk.

The etiology of neurodegenerative diseases such as Parkinson’s (PD) and Alzheimer’s disease is unknown but likely linked to combinatorial interactions between genetic risk factors, environmental stressors including viruses, and environmental neurotoxins. Our understanding of the environmental links to PD and related neurodegenerative disorders remains extremely limited, emphasizing the need for better animal models in which to test interactions between environmental toxins and genetic backgrounds. Current animal models emphasizing the need for better animal models in which to test interactions between environmental toxins and genetic backgrounds. Current animal models focusing on the use of neurotoxins and transgenic mice may show loss of neurons but often lack other key hallmarks of these diseases, such as neuroanatomical specificity, progressive neuronal loss, glial activation and protein aggregation. Notably, certain neurotropic mosquito-borne alphaviruses, such as Western equine encephalitis virus (WEEV), can target the midbrain, or vago, or vehicle (olive oil) daily for 6-weeks. Animals receiving TCE displayed a moderate loss of dopaminergic neurons within the substantia nigra, which correlated with a significant increase in LRRK2 kinase activity in surviving cells. In addition, we observed marked deficits in endolysosomal trafficking and function, concomitant with accumulation of toxic forms of alpha-synuclein (phospho-Serine129) within dopaminergic neurons. Together, these data suggest that LRRK2 activation by environmental TCE may be a novel gene-environment interaction, resulting in early pathological changes within susceptible individuals to increase PD risk.

The pathology of neurodegenerative diseases such as Parkinson’s (PD) and Alzheimer’s disease is unknown but likely linked to combinatorial interactions between genetic risk factors, environmental stressors including viruses, and environmental neurotoxins. Our understanding of the environmental links to PD and related neurodegenerative disorders remains extremely limited, emphasizing the need for better animal models in which to test interactions between environmental toxins and genetic backgrounds. Current animal models focusing on the use of neurotoxins and transgenic mice may show loss of neurons but often lack other key hallmarks of these diseases, such as neuroanatomical specificity, progressive neuronal loss, glial activation and protein aggregation. Notably, certain neurotropic mosquito-borne alphaviruses, such as Western equine encephalitis virus (WEEV), can target the midbrain, or vago, or vehicle (olive oil) daily for 6-weeks. Animals receiving TCE displayed a moderate loss of dopaminergic neurons within the substantia nigra, which correlated with a significant increase in LRRK2 kinase activity in surviving cells. In addition, we observed marked deficits in endolysosomal trafficking and function, concomitant with accumulation of toxic forms of alpha-synuclein (phospho-Serine129) within dopaminergic neurons. Together, these data suggest that LRRK2 activation by environmental TCE may be a novel gene-environment interaction, resulting in early pathological changes within susceptible individuals to increase PD risk.
Evidence indicates that complex gene-environment interactions underlie the incidence and progression of Parkinson’s disease (PD). Neuroinflammation, characterized as a well-characterized feature of PD, is widely believed to exacerbate the neurodegenerative process. Environmental toxicants associated with PD, such as pesticides and heavy metals, can cause cellular damage and stress potentially triggering an inflammatory response. Inflammasomes are intracellular protein complexes that contain pattern recognition receptors capable of initiating and propagating inflammation in response to toxicants, pathogens, and non-pathogenic cellular damage and stress. Our laboratory has characterized the NLRP3 inflammasome in toxicant-based animal models and PD patients. Long-term intragastric exposure to the PD-associated pesticide and mitochondrial toxin rotenone results in Nlrp3-dependent systemic and neurologic inflammation and Nlrp3 mice are protected from rotenone-induced nigral cell loss. Similarly, in MPTP treated animals, we observe increased sparing of nigral neurons in Nlrp3 homozygous mice with a dramatic reduction in nigral microgliosis. In PD patients, histologic studies revealed elevated NLRP3 expression in mesencephalic tissues. Analysis of exome sequencing data for genetic variation of NLRP3 in PD identified the rs7525979 variant associated with a significantly reduced risk of developing PD. We subsequently characterized this polymorphism and found that the rs7525979 variant caused a severe disruption of the NLRP3 protein lifecycle likely resulting in inflammasome inactivation. Further characterization of how inflammasomes may function in PD is a high priority because most PD cases are sporadic, supporting the widely-held belief that environmental exposure is a major factor in disease initiation and progression. Inflammasomes may represent a common mechanism that helps to explain the strong association between exposure and PD by mechanistically linking environmental toxicant-driven cellular stress with neuroinflammation and ultimately cell death.

Using Human Cells Based High-Throughput Neuronal-Schwann Cells Culture System

L. McCoy, A. D. Sharma, E. Jacobs, J. Curley, and M. J. Moore. AxoSim Inc., New Orleans, LA; and Tulane University, New Orleans, LA.

Currently, high-throughput screens (HTS) for chemotherapy-induced peripheral neuropathy are lacking, because in vitro systems fail to reliably mimic the side effects of chemotherapeutics, the physiological function of the cells. HTS based on neurons alone lacks the physiological complexity of the nervous system, as it does not account for the contribution of glial cells in neuropathy. To overcome this, we have characterized a novel human cells-based coculture system comprising of iPSCs-derived sensory neurons (hSNs) and primary human Schwann cells (hSCs). HTS platforms, such as high content imaging systems (HCS) and multielectrode arrays (MEA) can provide more relevant biological information than standard biochemical assays. We first compared a range of densities and ratios of hSNs to hSCs to reveal that a 4:1 ratio induced the fastest electrical maturity in terms of firing rate using the MEA system. A coculture of 30,000 hSNs to 7,500 hSCs became electrically active on day 6, while hSNs alone required densities of 70,000 neurons to become electrically active on day 6. MEA experiments showed the benefits of the coculture system in terms of faster, more consistent electrical maturation as well as a reduced number of hSNs resulting in reduced cost of screening. Furthermore, we used the same 4:1 ratio for evaluating dose responses using HCS system for two chemotherapeutic drugs, Paclitaxel and Oxaliplatin. Automated high-throughput neurite outgrowth and cell count analysis showed that the cocultures were less sensitive to drugs compared to monocytes in terms of overall neurite length, number of branches, number of processes, and total number of cells. Paclitaxel showed a toxic response only with hSCs in the coculture as opposed to monocytes. While Oxaliplatin did not show differences in neurite outgrowth parameters between mono- and cocultures, viability of neurons was still found to be different. The IC50 and LD50 concentrations were found to be significantly different between cocultures and monocytes across all parameters. These differences in sensitivity show the importance of the presence of glia along with neurons in high-throughput assays to capture biological complexity. In summary, both the MEA and HCS experiments demonstrated that a high-throughput neuronal-glial coculture system can be a more effective tool for assessing the safety of potential therapeutics results.

Expression of Drug-Metabolizing Enzymes in Cochlea: Implications for Ototoxicity of Analgesics

S. Kennon-McGill, M. Clemens, and M. McGill. University of Arkansas for Medical Sciences, Little Rock, AR.

Acetaminophen (APAP) and non-steroidal anti-inflammatory drugs (NSAIDs) are the most popular drugs in the US, but can cause hearing loss. Epidemiological studies indicate that chronic use of APAP and NSAIDs over the course of years increases risk of hearing damage. Additionally, numerous reports of rapidly progressive hearing loss in patients taking APAP/opioid combinations have been published. Importantly, though, little is known about the mechanisms of ototoxicity of these drugs. In other tissues, the toxicity of APAP and some NSAIDs is dependent on drug metabolizing enzymes (DMEs) and transporters. In particular, cytochrome P450 (Cyp) enzymes catalyze formation of toxic reactive intermediates, while UDP-glucuronosyltransferases (UGTs), sulfotransferases (Sults), and transporters promote drug clearance. However, expression of DMEs and transporters in cochlea has never been systematically studied. We created a PCR panel to compare expression of major isoforms of these enzymes in mice between cochlea and liver, an organ with high expression of DMEs. The panel includes 11 Cyps, 8 UGTs, 3 Sults, and 8 transporters. The specific DMEs and transporters were chosen because they account for metabolism of more than 70% of all clinically-relevant drugs. Data from PCR was confirmed by enzyme kinetics. Expression of Cyp was low in the cochlea compared to liver, with the exceptions of Cyp1a1, Cyp1b1, Cyp2c65, and Cyp2c66, which had similar levels of expression. All UGTs and Sults were also lower in cochlea than in liver, except for UGT1a3 and Sult2a1. Interestingly, expression of most transporters was low, with two major exceptions: Abcc2/8bcrp expression was similar between cochlea and liver, while expression of Mdr1/P-gp, which is thought to be highly expressed in cochlea, was barely expressed in other tissues. On the other hand, Bcrp expression was significantly higher in cochlea compared to liver, while expression of Mdr1/P-gp, which is thought to be highly expressed in liver and poorly expressed in neuronal tissue, was 3-fold greater in cochlea.

Organophosphorus nerve agents exert their peripheral and central toxicity by deactivating acetylcholinesterase (AChE), leading to an accumulation of acetylcholine (ACh) in the synaptic cleft. Prolonged residency of ACh can overstimulate nicotinic acetylcholine receptors (nAChRs) in diaphragm muscle, resulting in respiratory failure. The oxime pyridine-2-aldoximochloride (2-PAM) has historically been used to re-activate AChE following nerve agent exposure. A second oxime, 1,1’-methylenebis(4-(hydroxyimino)methyl)pyridinium (MMB4), is currently under development as a more potent and more promiscuous replacement for 2-PAM. However, preclinical animal studies have demonstrated that MMB4 has an exacerbated toxicity in rabbits at doses exceeding 200 mg/kg MMB4. One possible mechanism for MMB4 toxicity is via antagonism of nAChR due to its molecular similarity to ACh. Patch-clamp electrophysiology was used to compare agonist-evoked currents in the presence of MMB4 or 2-PAM on recombinant human α1 and α7 nAChRs, as well as α1 nAChR in dissociated mouse flexor digitorum brevis (FDB) muscle fibers. Preliminary data suggest that both oximes antagonize human and mouse α1 and α7 nAChRs, with 2-PAM acting as a more potent inhibitor in all cases. We anticipate that these studies will contribute to our understanding of oxime toxicity at neuromuscular junctions and define important safety considerations when screening future nerve agent antidotes.
Changes of CaMKII/CREB Signaling in NAc during the Acquisition, Extinction, and Reinstatement Phase of the Nicotine-Induced Conditioned Place Preference in Rats

H. Chen. China National Tobacco Quality Supervision and Test Center, Zhengzhou, China. Sponsor: S. Jia

The Ca2+-calmodulin-dependent protein kinase II(CaMKII) and cAMP response element binding protein(CREB) are involved in nicotine reward and withdrawal. In the current study, we investigated the roles of CaMKII/CREB signaling in the nucleus accumbens(NAc) in the three phases (acquisition, extinction, and reinstatement) of the nicotine-induced conditioned place preference(CPP). CPP was induced by the subcutaneous injection of nicotine(0.5mg/kg) at seven dosing periods, and 4 d saline training extinguished CPP. CPP was reinstated by the injection of nicotine(0.2mg/kg) after three dosing periods. During the acquisition phase of CPP, the levels of CaMKII and pCaMKII were significantly decreased. However, these changes disappeared in the extinction phase, indicating the levels of CaMKII and pCaMKII return to normal. The level of CREB was significantly decreased in the extinction phase. There were no significant differences in the reinstatement phase of CPP. The results show that CaMKII/CREB signaling in the NAc may play critical roles in nicotine addiction and withdrawal.

Exposure to Bisphenol A Impairs Mitochondrial Function and Alters the Activity of Antioxidant Enzymes in Human Neuroblastoma Cells

The potential human health risk of Bisphenol A (BPA) is considered a major public health concern. Exposure to even a low dose of BPA has been linked to diverse negative pathological, cellular, and molecular effects. Neurodegeneration has increasingly been associated with mitochondrial dysfunction and inhibition of the electron transport chain. Neurons require high levels of energy in order to operate. Therefore, either exceedingly high demand for ATP or diminished production of ATP can affect normal neuronal function and the level of brain stress encountered during the development of neurodegeneration. In addition, the production of ATP in these neurons may be reduced due to mitochondrial dysfunction. Mitochondrial membrane potential is an important parameter of mitochondrial function used as an indicator of cell health. To address the cellular and molecular mechanisms that might underlie BPA-induced brain damage, we extended our previous studies of BPA-induced neural toxicity by further investigating the mitochondrial dysfunction and antioxidant enzymes activity in this process. Human neuroblastoma SH-SY5Y cells were exposed to BPA at a concentration range of 0.01 to 50 µM for up to 24h. Cell viability, mitochondrial membrane potential, and the activity of antioxidant enzymes (glutathione reductase, glutathione peroxidase, and catalase) were evaluated. Exposure to BPA for 3h resulted in a significant decrease of mitochondrial membrane potential similar to CCCP, the mitochondrial uncoupler positive contrast, no effect was observed on the activity of catalase after exposure to BPA. The activity of glutathione reductase and glutathione peroxidase was significantly reduced at concentrations of 10µM and 50µM BPA. In contrast, no effect was observed on the activity of catalase after exposure to BPA. These results suggest that loss of mitochondrial membrane potential, depletion of the cellular levels of ATP, and alteration of the capacity of antioxidant enzymes may play a contributory role of BPA toxicity and that BPA adversely results in neurodegeneration. The findings of this study confirm that increases in BPA concentration reduce ATP levels in neurons inducing an energy crisis that drastically interferes with the neurons’ ability to mount effective defenses against the toxic action of BPA. Supported by Title III.

Ethanol Increases Manganese-Induced Spatial Learning and Memory Deficits via Oxidative/Nitrosative Stress Induced p53 Dependent/Independent Hippocampal Apoptosis

K. Nkpaa1,2, B. Amadi2, M. Wewu2, and E. Farombi1. 1Federal Ministry of Environment, Port Harcourt, Nigeria; 2University of Port Harcourt, Port Harcourt, Nigeria; and 3University of Ibadan, Ibadan, Nigeria.

The diet is a major route of manganese (Mn) exposure for humans. The diet is a major route of manganese (Mn) exposure for humans. Evidence of histopathology was used as the standard for CNS toxicity diagnosis, with special staining applied in some cases for improved detection. Additional in-life endpoints included functional observational battery (FOB) and MRI imaging. In general, these neurotoxicants exhibited a steep dose response curve and variability in CNS toxicity response and mortality. Although most studies produced expected CNS injuries by the standard of histopathology, some gave rise to more complicated results, in which severe mortality was observed without visible histopathological findings in the CNS. In the latter cases, FOB often provided sufficient sentinel signals in a dose-response manner even in the absence of general clinical signs. On the other hand, MRI imaging with certain algorithms provided a noninvasive approach to assessing the neuronal and axonal injuries correlating with histomorphological changes. With this presentation, we will discuss the challenges and pitfalls in animal model development and potential ways to optimize the process, compare findings in FOB and MRI imaging with histopathology in relation to different treatments, and discuss the utility of the integrated endpoints in potential preclinical CNS toxicity screening.
concentrations of 400 μM, did not produce seizures. In 14 DIV rat cortical neurons or 14 DIV rat hippocampal neurons. In the 14 DIV GlutaNeuron/Astrocyte co-culture, however, there was a robust response at 31.6 μM, with decreasing intensities at lower concentrations in a dose response manner. At 31.6 μM, pilocarpine caused up to 2-fold decreases in firing rates, 3-fold increases in percent isolated spikes (spikes occurring outside of bursts) and S to 10-fold increases in median/mean ISI and median ISI (indicators of burst structure deterioration) in the 14 DIV GlutaNeuron/Astrocyte co-culture. In subsequent experiments, we restated pilocarpine in the rat cortical neurons and hippocampal neurons at 21 DIV, which produced a much more robust response. The changes in the rat cortical neurons included 2-fold decreases in the number of spikes in bursts and 2-fold decreases in the median ISI, both responses indicating a deterioration in burst organization. We also observed a breakdown in network synchrony. This pattern was consistent with the iPSC neuron response observed at 14 DIV. Alternatively, the 21 DIV rat hippocampal neurons responded with an increase in regularity characterized by changes in endpoints such as 3-fold increases in the number of spikes in bursts, 3-fold increases in burst duration and 2-fold decreases in the MAD burst spike number, which indicates an increase spike train regularity. When changes in muscarinic receptor expression over time were measured, expression changes in maturing cells were the cause of the significant differences. In conclusion, we have identified different neuronal cell types is important for determining whether a model is correct for identifying liabilities associated with specific receptors.

1324 Role of Microglial Activation and Neuroinflammation in Neurotoxicity of Acrylamide, an Environmental Soft Electrophile

C. Zong 1, R. Hasegawa 1, M. Urushitani 1, T. Sakurai 2, O. Ishako 1, and G. Ichihara 1
Tokyo University of Science, Noda, Japan; 2Shiga University of Medical Science, Otsu, Japan; and 1University of Tokyo, Tokyo, Japan.

Acrylamide (ACR) is widely used in the production of polymers or gels and is also formed when carbohydrate-rich foods are cooked at high temperature. Neurotoxicity of ACR has been reported in humans and experimental animals, while the underlying mechanism remains elusive. The present study aims to investigate the role of microglial activation and neuroinflammation in the neurotoxicity induced by ACR exposure. First, male Wistar rats were exposed to ACR by gavage at 0, 0.2, 2, or 20 mg/kg BW, 7 d/week for 5 weeks. At the end of the exposure, rats were decapitated and the cerebral cortex was dissected out. Expression of inflammatory, neurotoxic, and microglial markers in the cerebral cortex were examined by real-time quantitative reverse transcription (qRT-)PCR, Western blot or immunohistochemistry. Secondly, BV2 microglial cells were treated with ACR at different dose (0, 5, 50, or 500 μM), for different time duration (0-36 h). MTS assay was performed to evaluate effects of ACR on cell viability. Expression of inflammation-related genes was examined by real-time qRT-PCR. In vivo studies showed that 5-week ACR exposure at 20 mg/kg BW upregulated mRNA levels of cytokines IL-1β and IL-6 in rat cerebral cortex; and ACR exposure at 2 mg/kg BW significantly upregulated IL-18 level. In vitro studies showed that 5-week ACR exposure at 20 mg/kg BW upregulated mRNA levels of cytokines IL-1β and IL-6 in rat cerebral cortex; and ACR exposure at 2 mg/kg BW significantly upregulated IL-18 level. Western blot showed that IL-1β was increased after exposure to ACR at 0.2 and 2 mg/kg BW, and IL-18 was increased by exposure to ACR at 20 mg/kg BW. ACR exposure at 2 mg/kg BW upregulated mRNA level of microglial markers CD11b and CD40. Immunohistochemistry showed that exposure to ACR at 2 or 20 mg/kg BW increased CD11b/c positive microglial area and/or length of processes, suggesting microglial activation after ACR exposure. The NLRP3 inflammasome-related genes, including NLRP3, Caspase 1 and ASC, which regulate production of IL-1β and IL-18, were upregulated by ACR exposure at 2 mg/kg BW. In vitro studies showed that BV2 cell viability measured by MTS assay was decreased by exposure to ACR only at 2000 μM or above. ACR exposure increased mRNA levels of cytokine IL-1β and IL-18 in BV2 cells in a time- and dose-dependent manner. Expression of iNOS, which is an inflammatory marker, was significantly upregulated by ACR exposure. The above in vivo and in vitro results suggest that ACR exposure induces neuroinflammation, including microglial activation and upregulation of cytokine expressions.

1325 Development of a Neurotoxicity Assay That Is Tuned to Detect Mitochondrial Toxicants

J. Delp, M. Funke, and M. Leis, University of Konstanz, Konstanz, Germany.

Mitochondrial toxicity is one of the major reasons for drug withdrawals. In particular, many neurotoxicants affect energy metabolism. Both animal models and cell-based test methods often fail to predict mitochondrial effects and neurotoxicity independent of neuronal activity. Thus, there is a need for improved sensitivity in this area. LUHMES cells are conditionally immortalized human neuronal precursors that can be quickly differentiated to fully mature dopaminergic neurons. They have been routinely used for the NeurTox assay to screen and characterize neurotoxicants. Using this test method, cells have been exposed here to a panel of 30 test chemicals for 24 h. Data (cell viability and overall neurite area) were acquired, after live cell staining, by high content imaging microscopy coupled to a fully automated data processing pipeline. In parallel, metabolic data, such as ATP content, central carbon metabolite levels, mitochondrial oxygen consumption and lactate production were monitored. Experiments were run in medium, containing either 18 mM glucose or 18 mM galactose as main carbohydrate source. Mitochondrial toxicity was predicted by the ratio of the EC25 values (for neurite outgrowth) in glucose medium (cells little dependent on mitochondria) vs. galactose medium (cells highly dependent on mitochondria). The panel of chemicals contained at least 5 inhibitors for each mitochondrial respiratory chain (MRC) complex, and also chemicals not affecting mitochondrial respiration. We found that inhibitors of MRC complexes I, II, IV and V were detected more sensitively in galactose medium, and their EC25 ratio (glucose/galactose) was >2. Uncouplers, complex II inhibitors and non-mitochondrial toxicants had EC25 ratios close to 1. Therefore, the modified NeurTox assay represents a novel and more sensitive method to detect neurotoxicants. Moreover, it pinpoints chemicals that inhibit various functions of the MRC (except for complex II).

1326 TSPO Gene Dosages Decrease Nox2 Subunit Gene Expression in Microglia: Implications for Regulation of ROS in the CNS

V. Nunes de Paiva, D. J. Azzam, and T. R. Guilarte, Florida International University, Miami, FL

Translocator protein 18 kDa (TSPO) is a biomarker of neuroinflammation and brain injury that has been extensively used in preclinical and clinical studies. TSPO is expressed in glial cells, specifically microglia and astrocytes, and levels increase rapidly following CNS insult. Similar to TSPO, NADPH Oxidase (Nox2) is a protein that is highly expressed in microglia and it is a major source of ROS production in the CNS. Previous studies from our laboratory have shown a direct protein-protein interaction between TSPO and NOX2 in primary microglia. We have proposed that the functional significance of this novel interaction may be to modulate reactive oxygen species (ROS) production in microglia with important implications to brain inflammation and neurodegeneration. In this study, we used global TSPO knockout (KO) mice to examine the relationship between TSPO and NOX2. Mice heterozygous for TSPO were obtained from Helmholtz Zentrum Munich (GMC), Germany as part of the International Mouse Phenotyping Consortium (IMPC) and INFRAFRONTIER /European Mouse Mutant Archive (EMMA). We used these animals to generate TSPO-wildtype (WT), -heterozygous (HET), and - knockout (KO) primary microglia and examined TSPO and Nox2 subunit gene expression. Quantitative real-time reverse transcriptase PCR (qRT-PCR) was used to assess mRNA expression for Tspo and the Nox2 subunits gp91phox, p22phox, p40phox, p47phox, and Rac1. We also measured Vdac mRNA expression as a mitochondrial marker since TSPO is highly expressed in mitochondria and heme-oxidase 1 (HO-1) which has anti-oxidative properties. As expected, we found a TSPO gene dosage effect on mitophagy in Nox2 subunits gp91phox, p22phox, and p40phox. Expression of gp91phox, p22phox, and p40phox were significantly decreased in a TSPO gene dose-dependent manner with no effect on p47phox, p47phox, and Rac1. No significant effect of TSPO gene dosage was found on Vdac or Ho-1 mRNA expression. Future studies will examine the effect of TSPO gene dosage on other subunit protein expression and NOX2 enzymatic activity. These novel findings strongly suggest that TSPO specifically regulates the transcription of key NOX2 subunit genes with significant implications for the modulation of ROS production and neuroinflammation in the CNS. NIEHS grant number ES007062-19 to TRG.

1327 Effects of New Psychoactive Substances on Neuronal Activity in Vitro Measured Using Microelectrode Arrays (MEAs) in Rat Primary Cortical Neurons and Enzymatic and Prolonged Exposure and Washout

A. Zwartsen 1, L. Hondebrink 1, and R. Westerink 1, 1Institute for Risk Assessment Sciences (IRAS), Utrecht, Netherlands; and 2Dutch Poisons Information Center (DPIC), Utrecht, Netherlands.

The use and number of new psychoactive substances (NPS) is increasing even though pharmacological and toxicological knowledge is limited. Most data on mechanisms of action is acquired by studying specific targets, like monoaminergic transporters and receptors, after or during acute exposure. While information on acute effects is useful to determine potency and possible structure-activity relationships, exposure scenarios that more closely resemble human exposure may further increase health risk assessment. Therefore, we
determined the effect of 11 illicit drugs and NPS on neuronal activity using different durations of exposure (30 min and 4 h). Rat primary cortical cultures were grown on microelectrode arrays (MEAs) and exposed to amphetamine-type stimulants, cathinones, hallucinogenic phenethylamines, pergazines or cocaine. Reversibility of effects was determined after a washout period of 19 h, i.e. 24 h after the start of exposure. During acute exposure, all drugs decreased concentration-dependently inhibited neuronal activity. Prolonged exposure did not further increase inhibition of neuronal activity compared to acute exposure. After 19 h washout, effects of methamphetamine, cocaine, methylene and BZP on neuronal activity were fully reversible. For all other compounds, a right-shift in potency was seen indicating (partial) recovery following washout. Moreover, neuronal networks exposed to MAPM and MDMA at concentrations relevant for human exposure did not show a full recovery of neuronal activity. Interestingly, neuronal activity increased following washout of human-relevant concentrations of methylene. Recovery measurements can have an added value in hazard characterization of emerging NPS by identifying substances that may not be the most potent inhibitors of neuronal activity following acute exposure, but may be more harmful following prolonged exposure and washout due to poorly reversible effects.

2,4,6-Tribromophenol Differentially Regulates ABC Transporters In Vivo and Ex Vivo in Rat Brain Microvessels

2,4,6-Tribromophenol (TBP, CAS No. 118-79-6) is a brominated chemical used in the production of flame retardant epoxy resins and as a wood preservative. TBP is found in marine environments, where it is incorporated in shellfish that may be consumed by predatory fish. It is most commonly detected as a byproduct during food processing and water treatment. TBP is a bio-active and bio-concentrated endocrine disruptor that interferes with estrogen and thyroid hormone signaling. Estrogen and thyroid hormones regulate important barrier functions, including the blood-brain barrier. The blood-brain barrier is a selectively permeable barrier composed of microvilli of endothelial cells that are anchored by tight-junctions and express ATP Binding Cassette (ABC) transporters that actively remove toxic endobiotics and xenobiotics from the brain. In this study, we examined the effect of TBP exposure on the transport activity of three well-characterized ABC efflux transporters: P-glycoprotein (P-gp, ABCB1), Breast Cancer Resistance Protein (BCRP, ABCG2), and Multidrug Resistance-associated Protein 2 (MRP2, ABCC2). We measured TBP-dependent changes in transport activity in freshly isolated rat brain microvessels (adult male Sprague-Dawley rats) using a confocal microscopy-based assay to measure the steady-state luminal accumulation of a transporter-specific fluorescent substrate after oral administration in vivo or direct application to ex vivo preparations. We found TBP exposure resulted in a time- (1-4h) and dose- (1-1000 nM) dependent decrease in P-gp and BCRP transport activity ex vivo, and a dose- (0.4-10 µmol/kg, 4h) dependent increase in vivo. We saw no change in MRP2 transport activity under identical conditions, indicating selectivity and capillary integrity. Our work is meaningful because changes in transporter activity in the blood-brain barrier can impact immunopathogenesis and increase CNS exposure to potentially toxic endobiotics and xenobiotics from the brain. This research was supported in part by the Intramural Research Program of NIH/NIC (Project ZIA BC 011476).

Developing Highly Accurate Computational Models for Neuronal Targets

The ability to mechanistically predict whether compounds will or will not target important protein receptor(s) is a major goal of toxicology. Thus, we sought to build such models for major neuronal targets. We mined public data sources (ToxCast, CHEMBL, BindingDB and ZINC), together with the scientific literature for compounds that did or did not interact with the nicotinic and muscarinic acetylcholine receptors, acetylcholinesterase, the GABA-A and B receptors as well as the serotonin and glycine cys-loop receptors. We developed machine-learning algorithms in KNIME using structural fingerprints and two-dimensional identification of common structural motifs (scaffolds) to screen compounds for interaction with these receptors. For targets with a sufficient number of active compounds, the fingerprint and scaffold-based prediction models were able to predict a positive outcome with high sensitivity (>80%). Exquisite sensitivity (98.4-100%) and balanced accuracy (82.6-100%) statistics were observed for data-rich targets such as the cholinergic system. The high sensitivity of these models correlated with high negative prediction values (84.7-99.8%), underscoring the confidence with which novel compounds can be aligned with these neuronal targets. By iteratively building our models with 1-90% of the compiled data, we show that <20% of data are needed to yield >75% balanced accuracy, suggesting that these models will not change for the foreseeable future. In conclusion, we demonstrate the feasibility of using computerized workflows to mine public data and develop accurate positive and negative prediction models for important neuronal targets. Due to their implementation within KNIME, these models can be used to rapidly screen in vivo datasets and provide mechanistic insights into the modes of action for substances of interest.

High Fat Diet Consumption Results in Bioenergetic Crisis and Oligodendrocyte Loss in the Spinal Cord in a NAD-Dependent Fashion

Metabolic syndrome is a prevalent co-morbidity in both spinal cord injury and multiple sclerosis patients, so a better understanding of how a high fat diet (HFD) contributes to oligodendrocyte loss has the potential to highlight new therapeutic targets. Mice consuming a HFD for 12 weeks had a significant loss of oligodendrocyte lineage cells in the dorsal column of the spinal cord and corpus callus of the brain as revealed by immunohistochemistry. Moreover, impaired spinal cord mitochondrial function was observed in chronic HFD-fed mice by decreased oxygen consumption rates (OCR), significant depletion of mitochondrial (ATP) cycle intermediates and changes in genes and proteins related to mitochondrial biogenesis and quality control processes. In oligodendrocyte progenitors, increased mitochondrial fragmentation and a reduced OCR were observed when exposed to saturated fat such as palmitic acid. Astrocytes, however, significantly increased OCR following exposure to palmitic acid and increased expression of pro-inflammation markers. In HFD-induced oligodendrocyte lineage cell loss includes an impairment of NAD+-mediated mitochondrial dynamics and bioenergetics. Importantly, we show that pharmacological inhibition of a NAD+-degrading enzyme, CD38, with 78c can overcome the dysmyelinating effects of lyssolecithin and palmitic acid in ex vivo cerebellar brain slice cultures. Together, these findings suggest that changes in the spinal cord in response to consumption of a HFD creates an environment less conducive to neural repair processes in neurological disorders by impairing mitochondria function and thus oligodendrocyte survival.

Oral Administration of Citronellal for Eight Weeks Does Not Produce Large Changes in Peripheral Nerve Function or Somatosensory Evoked Potentials

G. L. Jung,1 K. L. McDaniel,1 A. R. Smith,2 and D. W. Herr1, US EPA, Durham, NC, and 2ORISE, Durham, NC.

Citronellal is a monoterpenic oil that has been reported to have anti-nociceptive properties in mice when given alone to produce the amplitude of compound action potentials in the sciatic nerve of an ex vivo frog preparation. These findings suggest that citronellal has the potential to alter peripheral nerve function. The physico-chemical properties of citronellal indicate it has the potential to react with cellular proteins through imine formation. We treated adult male Long-Evans rats with an oral gavage of 0 (corn oil vehicle), 9.5, 11.6, or 16.8 mg/kg/day citronellal for 8 weeks. Behavioral observations (gait, open field activity, arousal, foot splay, grip strength, rearing) were made each week during treatment. Nerve excitability testing was performed using recordings from the tail nerves (motor and mixed) and sciatic (motor) nerve during the 6th week. Compound nerve action potentials (CNAP) and nerve conduction velocity (NCV; tail nerves), and somatosensory evoked potentials (SEPs) were recorded over the cortex and cerebellum during the 8th week of treatment. Treatment with citronellal did not alter the animal’s weight gain over the 8 weeks. No changes were observed for gait, open field activity, arousal, hindlimb foot splay, or rearing. There was evidence of decreased motor strength, but the results were not dose- or time-related. Nerve excitability testing of tail motor nerves did not indicate changes in nerve function. However, nerve excitability testing of the sciatic nerve suggested increased thresholds following a hyperpolarizing pulse, possibly due to greater membrane hyperpolarization associated with decreased K⁺ conductance. No changes in tail mixed nerve SEPs were indicated. No changes in tail CNAPs, NCV, or SEPs from the cortex or cerebellum were indicated. Our data
suggest that treatment with citronellal (over this dose range and duration) did not result in large changes in peripheral nerve, motor, or somatosensory function. These results do not preclude anti-nociceptive properties after acute treatments. This is an abstract of a proposed presentation and does not necessarily reflect US EPA policy.

1332 Propranolol as a Novel Treatment for Gulf War Illness in a Preclinical Mouse Model
L. T. Michalovicz1, K. A. Kelly1, D. B. Miller1, K. Sullivan2, and J. P. O’Callaghan1, 1NIOSH, Morgantown, WV; and 2Boston University School of Public Health, Boston, MA.

Gulf War Illness (GWI) is a multi-symptom, neuro-immune-based disorder that presents with features similar to sickness behavior. Unfortunately, current treatments for GWI tend to focus on managing symptoms as opposed to addressing the underlying cause of the illness. Using a preclinical mouse model, we have found that GWI is associated with an exacerbated neuroinflammatory response to immune challenge, like lipopolysaccharide (LPS) exposure, and the activation of microglia. Interestingly, β-adrenergic antagonism has been found to inhibit microglial activation and its associated release of inflammatory cytokines. Here, we tested the therapeutic potential of the beta-blocker propranolol in our established mouse model of GWI. In this model, mice are exposed to the stress hormone corticosterone (CORT; 200 mg/L) in the drinking water for 7 days followed by a single injection of diisopropyl fluorophosphate (DFP; 4 mg/kg, i.p.) to model the “in theater” conditions of high physiological stress and potential nerve agent exposure. This is then followed by periodic administration of CORT for 7 days every other week to a total of 5 weeks with a systemic LPS challenge (0.5 mg/kg, s.c.) on the final day. Propranolol (20 mg/kg, i.p.) was given during or outside of CORT exposure. Mice were sacrificed 6 hours after LPS challenge and brain cytokine mRNA expression was evaluated by qPCR. We found that propranolol significantly reduced the neuroinflammation instigated by the GWI exposure model when given during CORT exposure. In particular, treatment reduced cytokine expression in the GWI exposure group to levels comparable to CORT-LPS, which models a normal response to inflammatory challenge. These initial studies indicate the potential for propranolol to treat the underlying neuroinflammation associated with GWI and to return veterans to a healthy neuroimmune functional state. Disclaimer: The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention.

1333 Functional Characterization of Neural Network Activity in Human iPSC-Derived Neuron/Glial Co-Cultures

The increasing amount of chemicals with human exposure, and the accumulating evidence for inter-species differences regarding adverse effects on the CNS, call for scalable in vitro neurotoxicity screening tools using human cells. Generating neuronal cells through differentiation from induced pluripotent stem cells (iPSCs) carries a great potential to overcome the inaccessibility of human primary tissue and accelerate cell-based assays. In combination with multi-electrode array (MEA) readouts, neural activity in response to chemical compounds can be quantified allowing neurotoxicity screening. However, the assessment of neuroactive effects in human-derived cell-based assays remains challenging due to cell type variability and poorly defined baseline physiology. Here, we describe a new screening platform using highly functional neural cultures with defined cell ratios consisting of excitatory and inhibitory neurons that were separately generated by direct conversion from human iPSCs (NeuCyte SynFire®16), as well as primary human astroglial cells. The reduced complexity of this iPSC-derived co-culture system, compared to primary rodent cultures, enables a detailed molecular and functional characterization to define its applicability domain and develop screening assays. Therefore, we conducted comprehensive transcriptome profiling at different maturation time points of the co-cultures and tested altered neuronal firing, bursting and synchrony metrics in response to a set of 15 agonistic and 15 antagonistic tool compounds targeting neuronal signaling (e.g. GABA, AMPAR, NMDAR, ACHR, D1/2R, and 5-HTR) on MEAs. We then correlated dose-dependent responses with expression patterns at the different co-culture time points to determine sensitivity, specific neuroactivity profiles and potential assay windows for interference with these pathways. Furthermore, we confirmed specific responses by patch clamping of matched neuronal/glial co-cultures. This unique physiological characterization of NeuCyte’s human iPSC-derived neuron/glial co-cultures as baseline and reference for multiple neurotoxicity testing applications.

1334 Nanomolar Tetramethylpyrrole Alters Ca2+ Dynamics in Cortical Neuronal Networks by Selective Modification of Rydnome Receptors and Micromolar is Neurotoxic Due to SERCA Pump Inhibition
J. N. Pessah1, J. Zheng2, W. Feng3, S. Antonbus3, S. McKinnie4, and B. Moore5. 1University of California Davis, Davis, CA; and 2University of California San Diego, San Diego, CA.

Naturally synthesized marine organohalogenes (MOH) and their anthropogenic homologs produced as disinfection byproducts (DBP) are an emerging environmental health concern because several have been identified to exhibit potent biological activities in model systems, including cytotoxicity, genotoxicity, carcinogenicity and developmental toxicity. The molecular mechanisms underlying toxicity are poorly understood. Recently we discovered that several specific MOH and DBP measured in environmental and biological samples, including halopyrroles, halobipyrroles, haloindoles, and hydroxylated polybrominated diphenylethers directly modify rydnone receptors and SERCA pump activity, two key proteins anchored within sarcoplasmic/endoplasmic reticulum (SR/ER) that work in physiological opposition to tightly regulate net ER/SR Ca2+ dynamics and thereby shape meaningful Ca2+-dependent cellular processes. Using intact HEK293 cells null for rydnone receptors (RyrRs) expression and those that stably express Ryr1, we demonstrate that tetramethylpyrrole (TDP) selectively sensitizes Ryr1 channels to caffeine-triggered Ca2+ release only in Ryr1-expressing cells, TBP at higher concentrations also depletes of SR/ER Ca2+ stores in both null and Ryr1 expressing cells commensurate with its lower potency to inhibitory SERCA in biochemical assays. Exposure of primary neuronal/glial co-cultures derived from newborn mice shows that TBP inhibits the frequency and amplitude of spontaneous Ca2+ oscillations (IC50 = 246 and 426nM, respectively), whereas >1µM produces a sustained rise in cytoplasmic Ca2+. Subchronic (24HR) exposure to TBP caused loss of neuronal/gial viability using the MTT assay (EC50 =12.4µM). These results show that nM TBP selectively targets Ryr-mediated Ca2+ dynamics in a manner that has been shown to affect neurodevelopment, whereas low-µM exposures cause overt neurotoxicity, likely mediated by the combination of Ryr activation and SERCA inhibition. Supported by NIH grants ES030318 and ES014901.

1335 Tetramethylphenol A Alters ABC Transport at the Blood-Brain Barrier

Tetramethylphenol A (TTPA, CAS No. 79-94-7) is a brominated flame retardant (BFR) used in 90% of epoxy coated circuit boards. Exposures to TTPA can disrupt mitogen-activated protein kinase (MAPK), estrogen, thyroid and peroxisome proliferator-activated receptor (PPAR) signaling pathways. Since these pathways also regulate transporters of the CNS barriers, we sought to determine the effect of TTPA on the expression and activity of three major ABC efflux transporters of the blood-brain barrier (BBB). Using a confocal based assay, we measured the ex vivo and in vivo effects of TTPA on P-glycoprotein (P-gp), Breast Cancer Resistance Protein (BCRP), and Multi-Drug Resistance Protein 2 (MRP2) transport activity in rat brain capillaries. We found TTPA (1-1000 nM) had no significant effect on MRP2 transport in either sex. However, low concentrations of TTPA (1-100 nM) significantly decreased BCRP transport activity in both sexes. Additionally, TTPA exposures (1-100 nM), elicited a sex-dependent response in P-gp transport: increasing transport in males and decreasing transport in females. All TTPA exposures in transport were measured within a TTPA dose and time of 1-1000 nM and 1-6 hours respectively. Inhibitors of either transcription or translation abolished the TTPA dependent increases in male P-gp transport. Western blot and immunofluorescent assays confirmed the TTPA dependent P-gp expression increases in males and decreases in females. Inhibition of PPAR-y by GW9662 abolished the TTPA dependent increases in males but not the decreases in females. However, the TTPA decreases in female P-gp transport were blocked by the ER antagonist, ICI. This work indicates that environmentally relevant concentrations of TTPA (1-100 nM) alter ABC transporter function at the blood-brain barrier. Moreover, changes in BBB permeability alters brain homeostasis, modifies CNS drug delivery and increases brain exposure to harmful xenobiotic toxicants. This work was supported by the Intramural Research Program at NCI/NIEHS, ZIA BC 011476.
1336  Neurotoxic Effects of Erythrophleum ivorense in Experimental Animal Model

Erythrophleum ivorense (EI) is a common plant in tropical Africa. The stem bark of this plant is employed as an ordeal brew and causes a display of psychological symptoms, altered personality and several behavioral effects though the mechanism is yet to be understood. Sixty male Wistar rats were divided into five groups (A-E) of twelve rats each. Group A, control received distilled water. The test groups (B-E) were administered 10, 20, 30 and 40 mg/kg ethanol extract of EI in a single oral dose for 28 days. Cognition (Morris water maze, forced swim and tail suspension tests) and motor function (wire grip and inverted wire mesh grid grip tests) assessments were done. The brains were harvested and stained with Haematoxylin and Eosin (H&E), cresyl violet and immunohistochemistry was done using anti-Glial Fibrillary Acidic Protein (Z0334) (GFAP), anticalbin- din (D-28k), ionized calcium binding adapter molecule 1 (019-19741) (Iba-1) and Myelin Basic Protein (ab65988) (MBP) antibodies. At all tested doses, EI ivorense significantly (p<0.05) increased escape latency in the Morris water maze compared to control. A dose-related increase in duration of immobility was observed in the forced swim and tail suspension tests. There was also significant reduction in hanging latency in the wire grip and inverted wire mesh grid grip test. Depletion of cells in the Purkinje layer, CA1 and CA4 of the cerebellum and hippocampus was observed with H&E and cresyl violet. Immuno-staining revealed astrocystic activation in the cerebellum, loss of dendritic spines and arborization, microglial activation in the cerebrum, neuronal loss in CA3 and CA4 of the hippocampus, and demyelination in the cerebel- lum, corpus striatum and the dentate gyrus of the hippocampus. The ethanol extract of the stem bark of EI caused a dose-dependent deficit in learning, memory and motor coordination with evidences of depression in rats. It is concluded that the plant is neurotoxic and is able to induce several neurobehavio- ral changes in rats. Therefore, the use of this plant as ordeal poison should be reconsidered.

1337  Investigation of Protein Adduct Formation as Mechanism of Neurotoxicity in Rats Exposed to 1-Bromopropane

Following the frameworks of predictive toxicology, a recent US EPA report lists chemicals predicted to cause neurotoxicity based on the Hard Soft Acid Base (HSAB) Theory. Acrylamide, a soft electrophile which results in cumula- tive neurotoxicity through protein adduct formation, fits this theory based on experi- mental data. 1-bromopropane, a solvent widely used in adhesives, aerosols, and cleaning of metals and electronics, is predicted to behave similarly based on HSAB parameters (hardness, softness, electrophilicity). Due to widespread use, there is an increasing number of reported cases of neuropa- thy in workers exposed to 1-bromopropane; however, the mechanism driving the toxicity is not understood. We hypothesized that rats exposed to 1-bromo- propane would exhibit similar neuropathies compared to acrylamide, as a result of protein adduct formation in brain synaptosomes. To address this, we exposed rats orally to acrylamide (20 mg/kg) or 1-bromopropane (800 mg/ kg) via gavage. Gait was analyzed weekly or biweekly until a sufficient level of gait abnormality was achieved. Once euthanized, half of the rat brain was preserved to examine histological changes, while the other half was dissected for proteomic (synaptosomes) and gene expression analysis. Throughout the study, we observed decreased weight gain in chemical-exposed animals. Rats exposed to acrylamide began to show symptoms between weeks 4-5, while the neurotoxicity from 1-bromopropane did not present until 10-12 weeks. Unexpectedly, the symptoms of neurotoxicity were distinct between the two groups with acrylamide-exposed rats exhibiting foot splay, altered balance, and an inability to stand, while the 1-bromopropane rats exhibited an inability to right the hind legs and shuffling of hind feet. These contrasting symp- toms coincided with histological differences and diversity in protein adduct profiles generated by TMT proteomics. This study demonstrates the utility of chemical properties in predicting the mechanisms and toxicity of chemicals, as a way to better prioritize and regulate chemicals in the future.

1338  Dioxin induces Accumulation of Neurofilament Light Protein in Neurons: AHR-Mediated Transcriptional Upregulation through Enhancement of ERK1/2 MAPK Pathway
Y. Chen, L. Xu, S. Zhang, and B. Zhao. Research Center for Eco-Environmental Sciences, CAS, Beijing, China.

It is known that exposure to and bioaccumulation of dioxins produce a wide variety of toxic and health effects, such as tumor promotion, teratogenicity, endocrine disruption and tissue- and organ-specific toxicities. The study of mechanisms of dioxins’ neurotoxicity is a hot area in the past years since signific- ant deficits in cognitive functioning have been reported in humans exposed to dioxins and dioxin-like compounds. Studies demonstrated that dioxin produced its neurotoxicities by disrupting neuronal differentiation and the function of neuro-transmission systems. In our studies, we found novel mech- anisms whereby dioxin may produce its biological or toxicological effects by decreasing neuronal AchE activity through a transcriptional down-reg- ulation mechanism via the AHR-dependent signaling pathway. Meanwhile, dioxin was also found to exert the disturbance on neuronal differentiation by up-regulating the expression of neurofilaments, the main component of neurites, also regarded as the biomarker for both neuronal differentiation and neurodegeneration. Furthermore, AHR mediates the transcriptional regula- tion of filament L through enhancement of the ERK1/2 MAPK pathway, which suggests a crosstalk between the two pathways in neurons.

1339  Proteomic Analysis Links Proteasome Inhibitors Induced Peripheral Neuropathy to Mitochondrial Toxicity in a Human Neuronal Cell Model
A. Jannuzzi1, G. Sari1, A. Yilmaz2, M. Federova1, B. Karademir1, and B. Aşpertunga1. 1Istanbul University, Istanbul, Turkey; and 2Universität Leipzig, Leipzig, Germany.

Bortezomib (BTZ) is a boronic acid based and a reversible proteasome in- hibitor, whereas carfilzomib (CFZ) is an epoxymycin derivate and irreversible proteasome inhibitor. Both have been used successfully to treat haema- tological malignancies. However, neuropathic manifestations are dose limit- ing for BTZ as many other chemotherapeutic agents. CFZ is associated with lower incidence of neuropathy than BTZ by as yet unknown mechanisms. The aim of this study is investigating the effects of BTZ and CFZ on human neu- rons derived from human neural precursor cells for a better understanding of molecular mechanisms that cause different neurotoxic profiles. βIII-tubulin expression was validated by confocal microscopy to ensure neuronal differen- tiation. Neurotoxic effects of BTZ and CFZ on human neurons were anal- ysed by a proteomic approach using nano-HPLC/nano-ESI-LTQ-Orbitrap MS/ MS. Quantitative data from significant protein alterations were analysed by Pathway Studio Software v.11.4 to determine possible functional interactions. According to the results of the study, proteins regulating the mitochondrion organization and biogenesis, mitochondrion membrane permeability and respiratory chain, heat shock response, selective autophagy showed signifi- cant changes. Proteasome inhibition was measured by fluorometric assay and both drugs caused significant inhibition of proteasomal activity. BTZ caused mitochondrial membrane potential decrease where CFZ did not cause any change by flow cytometry. Mitochondrial mass per cell assessed by staining with Mitotracker Green FM and flow cytometry, showed significant reduction with BTZ treatment. LysoTracker Red and MitoTracker Green colocalisation under confocal microscopy showed that mitophagy was upregulated with BTZ treatments. BTZ caused higher upregulations in the protein levels of heat shock response (HSP) HSP 32, HSP 60, HSP 70, HSP 90 and autophagy receptor protein p62 than CFZ. According to our study results, the higher neurotoxic pro- file of BTZ may be related to more severe mitochondrial toxicity, heat shock response and selective autophagy in neurons. This study supported by TUBITAK, Grant Number: 216S838.

1340  3D Neurone-on-a-Chip Model Effectively Screens Neurotoxic Compounds
H. Nguyen1, L. Kramer1, K. Pollard2, J. Curley1, and M. J. Moore2. 1AxxoSim Inc., New Orleans, LA; and 2Tulane University, New Orleans, LA.

Organ-on-a-chip devices that mimic in vivo physiology have the potential to identify chemical and drug toxicities in earlier preclinical stages of develop- ment while relying less heavily on animal models. We have developed a nerve-on-a-chip construct to culture animal and human neural tissue in a dual hydrogel system that promotes axon growth analogous to mature nerve
anatomy. Here we culture rat sensory dorsal root ganglia (DRG) in the
construct to demonstrate its potential as a preclinical assay for screening impli-
cations of nerve dysfunction by measuring electrical signals in tissue exposed to
4 chemical drugs known to cause peripheral neuropathy. The dual hydrogel construct consists of a cell-impermeable polyethylene glycol (PEG)
outer layer and a growth-permissive inner gel layer that permits bundled nerve-like growth. DRG tissue from E15 rat pups was inserted into the inner
gel and cultured for 4 weeks until mature. The constructs were exposed to Bortezomib, Oxaliplatin, Paclitaxel, or Vincristine, all common chemothera-
peutics for various cancers, at doses ranging from 0.1 to 1.0 μM. After 7 days of treatment, compound action potentials (CAP) were measured by electric-
ally stimulating the capsaicin-sensitive Aδ fibers. All nerve cultures had a 500 mg/kg group in the

DMAB body. We collected nerve conduction velocity (NCV) and the peak amplitude (AMP), which are two electrophysiological clinical metrics indica-
tives of healthy or diseased populations. A trend was observed towards de-
creased NCV and AMP in a dose-dependent manner across all drugs. At high
drug concentrations, NCV and AMP measurements were typically lower than Control by 10-60%. Fluorescent microscopy revealed that the robust growth of
axons remained intact following drug exposure. Only in the high doses there was a visible loss of axon density. Maintained cell viability in low doses was
confirmed with CCK-8 and LDH viability assays. Dose-response curves of evoked
neurons displayed that significant functional pathologies occur before
important changes in cell viability as measured in the CCK-8 assay. This indi-
cates that functional, clinically-relevant measurements represent a more sensi-
tive metric. Our data suggests electrophysiology recordings collected from our
nerve-on-a-chip platform can closely track subtle pathologic changes in nerve function, demonstrating the feasibility of using this in vitro nerve-on-a-
chip model as a preclinical screen for peripheral neuropathy.

1341 The Metabolomic Profile of Monoaminergic Neuronal Perturbation in Caenorhabditis elegans

V. Kalia1, J. Bradner1, M. Chen2, D. Walker2, D. Jones3, and G. Miller1. 
1Columbia University, New York, NY; 2Emory University, Atlanta, GA; and 3Icahn School of Medicine at Mount Sinai, New York, NY.

Neurodegeneration is a complex phenomenon that has environmental, ge-
etic, and aging risk factors. MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropy-
ridine) is known to induce Parkinsonism in humans and animal models. Its active metabolite MPP+ (1-methyl-4-phenylpyridinium), is a complex I inhibi-
tor that weakly binds to the mitochondrial carrier of mono-
aminergic neurons, the vesicular monoamine transporter 2 (VMAT2; SLC18A2)
transports monoamines into vesicles, where they reside until release into the
synapse, protected from cytoplasmic degradation. VMAT2 can also sequester
MPP+, preventing it from exerting its toxicity on the mitochondria. Altered
expression of VMAT2 has been associated with susceptibility to MPP+ and
Parkinson’s disease, as observed in both animal and human studies. To mea-
sure holistic changes in biochemical responses from genetic mutations and
chemical exposures in C. elegans, we have developed a high-resolution me-
tabolomics framework using a Thermo QExactive LC Orbitrap that leverages the
sensitivity of high-resolution mass spectrometers and the unparalleled genetic
tracability of the nematode model. In studies using both a mutant strain lacking the VMAT2 orthologue cat-1 and the potent neurotoxicant
MPP+, we detected changes in features suggestive of altered monoamine
metabolism. Differentially expressed metabolic features were evaluated using metabolic pathway enrichment analysis, which detected altered fatty acid β-oxidation,
which is known to be regulated by the monoamine serotonin in C. ele-
gans. In wildtype L4 worms exposed to 1 μM MPP+ for 4 hours, we detected
changes in tryptophan metabolism and altered levels of 5-hydroxyindole ac-
eate, the primary metabolite of serotonin, suggesting additional changes in
serotonin pathways. Wildtype worms in the first larval stage exposed to 2μM
MPP+ for 4 hours show an increase in neuronal blebbing (p < 0.0001) compared to controls. Using fluorescent markers of neuronal integrity and
metabolomics, we can identify genetic and environmental contributors to
neurodegeneration and compare metabolomic profiles to elucidate underly-
ing biochemical pathways of neurodegeneration.

1342 14-Day Dermal Toxicity Study in B6C3F1/N Mice and HSD:Sprague-Dawley Rats Exposed to Dimethylamine Borane (DMAB)

A. Watson1, S. Thakur1, M. Behl1, M. Vallant1, K. Elsas2, B. Sparrow2, and D. Gormolec1. 1NIEHS/NTP, Research Triangle Park, NC; and 2Battelle, Columbus, OH.

Dimethylamine borane (DMAB) is a reducing agent used in the manufacturing
of electronics and other industrial processes. DMAB is a known irritant to
the eyes, skin, and respiratory tract, and one incident involving occupational

...exposure provides some evidence to suggest that DMAB may be a neurotox-
icant. Given the limited toxicity data available and the potential for occupa-
tional exposure, DMAB was nominated to the National Toxicology Program to
evaluate potential systemic and neurotoxic effects following dermal ex-
posure. In this study, male and female B6C3F1/N mice and Harlan Sprague
Dawley (HSD) rats (n=5/sex/species) were exposed to vehicle (95% ethanol), 15.6, 62.5, 125, 250, or 500 (B6C3F1/N female only) mg DMAB/kg body weight via dermal administration for 14 days.

Animals were assessed for clinical signs of toxicity, histopathological
lesions, and alterations in neurobehavioral function (fore- and hindlimb
grip compression strength and footspan distance). All male mice survived to
study completion and treatment-related effects were limited to clinical observa-
tions of nasal and/or ocular discharge in all males at doses ≥ 125 mg/kg and in
two females administered 250 mg/kg DMAB. Plasma concentrations of DMAB,
dimethylamine (DMA), and N-nitrosodimethylamine (NDMA), however, were
not detected above the limit of quantitation in males at 6 hours (0 and 125 mg/kg B6C3F1/N; 0 and 62.5 mg/kg HSD) or in males and females from all dose
groups 24 hours following the last application. Overall, these data sug-
gest that DMAB is overtly toxic to female B6C3F1/N mice at levels ≥ 250 mg/
kg, and B6C3F1/N mice are more sensitive to dermal exposure to DMAB than
the HSD rat. While this preliminary study provides evidence to suggest that
DMAB may be neurotoxic in B6C3F1/N mice, additional studies are needed to
fully characterize the neurotoxic potential of DMAB in mice.

1343 Chronic, Low-Level Oral Exposure to Marine Toxin, Domoic Acid, Alters Whole Brain Morphometry in Nonhuman Primates

Domoic acid (DA) is an excitatory neurotoxin produced by marine algae and
responsible for Amnesiac Shellfish Poisoning in humans. Current regulatory
limits (approximately 0.075-0.1 mg/kg/day) protect against acute toxicity, but
recent studies suggested chronic ingestion of DA resulted in neurotoxicity near the current human regulatory limit are related to structural and chemical
changes in the brain.
results show that 4-OH PCB 52 is more toxic than PCB 52 to N27 cells - a dopaminergic cell line. Our work intends to understand how PCB 52 and its metabolites modulate the dopaminergic system. This includes analyzing dopamine metabolism in cell culture and rat brain tissue. We have also performed preliminary studies on detecting reactive oxygen species. Furthermore, we will analyze changes in gene expression to explore alterations in dopamine cell trafficking. PCB 52 and 4-OH PCB 52 have previously shown toxicity in neurogenic cell lines. However, not much is known about how these compounds alter and modulate the dopaminergic system. Future studies will employ neuroprotective strategies.

### 1345 Dietary Strategies Affect Marine Algal Toxic Levels in Subsistence Harvested Alaskan Pinnipeds

A. Hendrix1, K. A. Lefebvre2, L. Quakenbush3, R. Stimmelmayr4, A. Bryan5, G. Sheffield6, P. Kendrick7, E. Frame7, D. J. Marcinek8, and T. Burbacher1
1University of Washington, Seattle, WA; 2NOAA Northwest Fisheries Science Center, Seattle, WA; 3Alaska Department of Fish and Game Arctic Marine Mammal Program, Fairbanks, AK; 4North Slope Borough Department of Wildlife Management, Barrow, AK; 5University of Alaska Fairbanks Alaska Sea Grant Marine Advisory Program, Nome, AK; 6University of Washington Medical School, Seattle, WA; and 7King County Department of Natural Resources and Parks, Seattle, WA.

Domoic acid (DA) and saxitoxin (STX) are marine algal-produced toxins that elicit acute neurotoxic symptoms in mammals following ingestion. Trophic transfer of both toxins allows for their spread through marine food webs. Cases of acute DA and STX toxicity are termed Amnesiac Shellfish Poisoning and Paralytic Shellfish Poisoning respectively, as the primary vector of human exposure is contaminated shellfish. Knowledge of these toxicoses has led to the implementation and enforcement of seafood safety regulatory limits for both DA and STX in shellfish (20 and 0.8 ppm, respectively). However, human exposure to algal toxins can occur through additional vectors. Native communities in Alaska conduct annual subsistence harvests of marine mammals that are a part of complex marine food webs. As DA and STX prevalence in Alaskan Arctic food webs has not been extensively quantified, such harvests are of interest both with regard to potential human toxic exposure and to marine mammal health. We tested 856 samples collected from the gastrointestinal tracts of pinniped subsistence harvest in Alaska between 2003 and 2016. Samples were analyzed for DA and STX presence using commercially available Enzyme-linked Immunosorbent Assay (ELISA) kits. Toxin prevalence was found to be highest in bearded seals and walruses and lowest in ribbon seals. Maximum DA and STX concentrations followed similar trends. Additionally, few samples were found to have toxin concentrations above the seafood safety limits for acute toxicity. Dietary strategy is suggested as one explanation for interspecies variations in toxin level, though the clarity of this relationship is complicated by features of the opportunistic dataset as well as oceanographic, seasonal, and physiological factors.

### 1346 Behavioral and Histological Evidence of a Neuroimmune Basis for Gulf War Illness

K. Kelly1, L. Michalovich2, C. Fornal3, D. Miller1, J. O’Callaghan1, and S. Lasley4
1CDC-NIOSH, Morgantown, WV; and 2University of Illinois, Peoria, IL.

Chronic exposure to the gluccorticoid, corticosterone (CORT), at levels associated with high physiological stress, has been shown to prime the neuroimmune response to neurotoxic exposures and systemic inflammation, significantly increasing the expression of proinflammatory cytokines/chemokines following exposure. Gulf War Illness (GWI) is a multi-symptom, neuroimmune-based disorder that presents with features characteristic of persistent sickness behavior. Using a preclinical mouse model of GWI, we have found that chronic exposure to the stress hormone corticosterone (CORT; 200-400 mg/L) in the drinking water for 7 days exacerbated the initial neuroinflammatory response to the sarin surrogate diisopropylfluorophosphate (DFP; 4 mg/kg, i.p.). A more recent study using this exposure protocol has found that CORT+DFP exposed animals exhibit cognitive impairment in the Novel Object Recognition Test with decreased discrimination of the novel versus familiar object. However, this acute exposure model is more representative of the veterans’ time in theater, and those suffering with GWI are nearly 30 years removed from their tours of duty. Thus, a more extended duration animal model is necessary. Our model of GWI at 5 weeks after the initial CORT+DFP event, constituting periodic administration of CORT for 7 days every other week and a subsequent systemic immune challenge with the bacterial mimic lipopolysaccharide (LPS; 0.25-0.50 mg/kg, s.c.) mimics the long-term illness and ‘flare up’ of symptoms as is reported in GWI. This longer CORT regimen produced signs of decreased cognition in the Novel Object Location Test, signified by CORT+DFP+LPS animals less able to distinguish the displaced versus familiar object. This paradigm reveals a further exacerbation of neuroinflammatory markers and emergence of activated microglia in key brain areas including hippocampus and cortex that affects behavior for at least 12 days after the last LPS dose. Together, these data provide additional support that GWI is a chronic, stressor-primed, neuroinflammatory condition with adverse long-term neurobiological and behavioral outcomes. Disclaimer: The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention.

### 1347 Comparison of Acute Effects of Neurotoxic Compounds on Network Activity in Human and Rodent Neural Cultures

L. Saavedra1,2, K. Wallace1, T. Freudenrich1, M. Mall1, W. R. Bundy1, J. Davila2,2, T. C. Sudhoff1, T. J. Shafer1, M. Wernig1, and D. Haag2,3
1Neurobyte, Sunnyvale, CA; 2Stanford University School of Medicine, Stanford, CA; and 3US EPA/NHEERL, Research Triangle Park, NC.

Assessment of neuroactive effects of chemicals in cell-based assays remains challenging as complex functional tissue is required for biologically relevant readouts. Recent in vitro models using rodent primary neural cultures grown on multimicroelectrode arrays (MEAs) allow quantitative measurements of neural network activity and have been demonstrated to be suitable for neurotoxicity screening. However, robust systems for testing effects on network function in human neural networks are still lacking. The increasing number of differentiation protocols for generating neurons from induced pluripotent stem cells (iPSCs) holds great potential to overcome the unavailability of human primary tissue and expedite human cell-based assays. Yet, the variability in neuronal activity, prolonged ontogeny and rather immature stage of most neuronal cells derived by standard differentiation techniques greatly limit their utility for screening neurotoxic effects on neuronal networks. Here, we used excitatory and inhibitory neurons that were separately generated by direct conversion from human iPSCs together with primary human astroglial cells to establish high-fidelity microBrain models. 3D-grown neuron/glia co-cultures showed pronounced neuronal activity and robust formation of synchronized network activity on MEAs, albeit with noticeable delay vs primary rat cortical cultures. We further investigated the effects of neurotoxic test compounds, including 4 GABA receptor antagonists, an organotin, and 4 pyrethroid insecticides, as well as 3 negative control compounds on network activity (in these human neuron/glia co-cultures). Importantly, we observed largely corresponding dose-dependent alterations in firing, burst and synchrony metrics of neuronal network activity in iPSC-derived human neuron/glia and rat primary cortical cultures. These results demonstrate the utility of this direct-differentiated human model for neurotoxicity screening using MEAs.

### 1348 Validation of High-Throughput 3D microBrain Model to Predict Drug-Induced Neurotoxicity across a Diverse Set of Pharmaceuticals

Drug-induced central nervous system (CNS) toxicity is a top three cause of safety-related attrition across the pharmaceutical industry. Undesired side-effect on CNS in human account for 10% of all drugs withdrawn from sale during the periods 1960-1999. A main reason for the high failure rate is that the concordance rate is low between human adverse drug reaction (ADR) and identification in preclinical toxicity studies. The development of predictive CNS toxicity assays is needed to help pharmaceutical companies design and optimize safer therapies. Over a dozen different IPS-derived microBrain and miniBrain models have been published in recent years, but their ability to predict CNS toxicity in patients is as of yet unproven. To evaluate the predictive capabilities of one of these models, we validated an IPS-derived microBrain model using 84 structurally diverse pharmaceuticals, a combination of US FDA-approved drugs and clinical drug candidates with varying levels of seizurogenic and neurodegenerative liability. Seven endpoints were analyzed using Ca oscillations and cellular ATP levels after a single and repeated exposure treatment, respectively. The microBrain in vitro IC50 for each endpoint were rooted into clinical used therapeutic exposure (fCmax) as classifiers (ICmax/IC50) to predict clinical drug-induced seizures and neurodegeneration. We used logistic regression with clinical reported CNS toxicity as binary response variable and combined each endpoint as independent variables (ICmax/IC50) to calculate probability for CNS toxicity. After refining these endpoint cutoffs on separate training and test sets, we find that in total...
the human microBrain gave us a specificity 93.33% and sensitivity 53.49%. Importantly, this high throughput model has very low false positive rate in the prediction of seizures, convulsions and neurodegeneration. This assay has the potential to be used as a predictive assay during early drug discovery phase for neurotoxic hazard identification. It can be incorporate readily into the pharmaceutical toxicological screening paradigm, aiding the early identification of compounds that eventually may fail due to CNS toxicity.

1349 Anatomical Features of Brain Slices That May Be a Source of Variability When Measuring the Effect a Compound Has on Synaptic Plasticity

Examining field potentials evoked from acutely prepared slices of rodent brain tissue (particularly from the hippocampal area) offers an excellent means for preliminary screening of neurotoxicity. Whereas many studies using this approach will measure effects on basal synaptic transmission alone, studying synaptic plasticity, as well, can provide additional important information on a compound’s neurotoxicity. Of the various forms of synaptic plasticity available for study, long-term potentiation (LTP) has received significant attention, given its presumed role as a critical cellular mechanism underlying learning and memory. However, variation in LTP expression and magnitude is often seen across studies, and may serve to discourage some from using the measure in their work. Notably, some of the variability may arise (at least, in part) because many studies using LTP ignore: 1) the possibility that tissue harvested from the two poles of the hippocampus (i.e., septal and temporal) may not respond uniformly; and 2) the precise site of response recording, given that not all synapses within a brain region are homogenous. Hence, using slices prepared from the hippocampal region of adult-electrode array recording system, we investigated the difference in LTP induced by electrical stimulation (tetanus, 2 x 100 Hz) as a function of both distance between the cell body layer and the recording site (100, 200, 300, 400 µm away, within the CA1 sub-field), and the pole from which the slices were harvested (septal, or temporal). Preliminary results show that LTP expression is different among the four recording points and between poles. Specifically, tetanus-induced the greatest magnitude of LTP expression at points that were 100 µm from the soma; furthermore, potentiation in temporal slices was found to be the greatest. In addition, slices from the temporal pole took longer to reach peak post-tetanus potentiation relative to slices from the septal pole. Our observations reveal that LTP expression within hippocampal slices can be affected both by the distance of the recording site from the soma and where along the longitudinal axis the slice was found. As a result, we have demonstrated the need to consider both the relative recording position and the anatomical pole of origin when measuring LTP in acute hippocampal slices.

1350 An Engineered 3D Peripheral Human “Nerve-on-a-Chip”: A Novel Assessment for Neurotoxicity In Vitro

A. D. Sharma1, L. McCoy1, E. Jacobs1, H. Ngyuen1, J. Curley1, and M. J. Moore2. 1AxoSim Inc., New Orleans, LA; and 2Tulane University, New Orleans, LA.

The development of human iPSC-derived neurons has greatly expanded the predictive potential of 2D preclinical assays. Additionally, these iPSC-derived neurons are more accessible than neural stem cells for tissue engineering and screening purposes. Concurrently, the use of engineered microphysiological systems (MPSs), Organs-on-Chips, and 3D organoids have seen tremendous growth as a preclinical drug screening tool because they are more biometric than 2D assays. Especially when trying to model the complexity of the human nervous system, 3D engineered cultures provide marked advantages by recapitulating cell-cell interactions. However, a limited focus has been given to MPSs that mimic peripheral nerves (PNs) even though peripheral neuropathy is implicated in numerous disease states and is a common and significant side effect of many therapies. In this study, we fabricated a novel in vitro human-iPSC based 3D nerve that supports axon growth analogous to PN anatomy. This in vitro nerve can provide clinically relevant metrics such as nerve conduction velocity (NCV) and histological ultrastructure. These read-outs represent the gold-standard in preclinical testing and, previously, were only obtainable through in vivo experimentation. Using low adhesion microplates, self-assembling spheroids comprised of either iPSC-derived human nerves alone or co-cultures with primary human Schwann cells and iPSC-derived human nerves were fabricated. Over 4 weeks, the nerves were grown in a 3D environment to reach maximum lengths of 5 mm, with diameters varying from 0.015% to 0.001%. Interestingly, two AFFF did not affect cellular viability at any concentration, whereas many studies using this approach will measure effects on basal synaptic transmission alone, studying synaptic plasticity, as well, can provide additional important information on a compound’s neurotoxicity. Of the various forms of synaptic plasticity available for study, long-term potentiation (LTP) has received significant attention, given its presumed role as a critical cellular mechanism underlying learning and memory. However, variation in LTP expression and magnitude is often seen across studies, and may serve to discourage some from using the measure in their work. Notably, some of the variability may arise (at least, in part) because many studies using LTP ignore: 1) the possibility that tissue harvested from the two poles of the hippocampus (i.e., septal and temporal) may not respond uniformly; and 2) the precise site of response recording, given that not all synapses within a brain region are homogenous. Hence, using slices prepared from the hippocampal region of adult-electrode array recording system, we investigated the difference in LTP induced by electrical stimulation (tetanus, 2 x 100 Hz) as a function of both distance between the cell body layer and the recording site (100, 200, 300, 400 µm away, within the CA1 sub-field), and the pole from which the slices were harvested (septal, or temporal). Preliminary results show that LTP expression is different among the four recording points and between poles. Specifically, tetanus-induced the greatest magnitude of LTP expression at points that were 100 µm from the soma; furthermore, potentiation in temporal slices was found to be the greatest. In addition, slices from the temporal pole took longer to reach peak post-tetanus potentiation relative to slices from the septal pole. Our observations reveal that LTP expression within hippocampal slices can be affected both by the distance of the recording site from the soma and where along the longitudinal axis the slice was found. As a result, we have demonstrated the need to consider both the relative recording position and the anatomical pole of origin when measuring LTP in acute hippocampal slices.

1351 Effects of 10 New Generation PFAS–Containing Aqueous Film Forming Foams (AFFF) on Human Liver Cell Viability

K. A. Mauge-Lewis1, and S. Fenton1. 1NIEHS, Research Triangle Park, NC; and 2NIEHS/NTP, Research Triangle Park, NC.

Per- and polyfluoroalkyl substances (PFAS) are man-made chemicals characterized by their carbon-fluorine bonds, and resistance to heat, water, and oil. PFAS have been used in hundreds of industrial applications and consumer products, including aqueous film forming foams (AFFF), and as such have contaminated human food and water sources. The purpose of this study was to evaluate the cytotoxicity of 10 AFFFs, thought to be in current use in 2018, in a human hepatocyte/cholangiocyte cell line (HepaRG). In previous work, we have demonstrated that AFFF are particularly sensitive to many adverse effects of PFAS, so confluent HepaRG cells were exposed to the AFFF by blinded allocation for 72 hours at a concentration range of 0.001% to 2% in media. CellTiter-Glo luminescence assay detected substantial declines in cellular viability at concentrations between 0.25% and 0.5%, and total cell death at concentrations of 1% and 2% for several AFFF. Three AFFF produced significant cell death at concentrations as low as 0.01%, with an EC50 as low as 0.015%. Interestingly, two AFFF did not affect cellular viability at any concentration tested. However, noticeable dose-dependent morphological changes were evident in the cell cultures that were exposed to one of those two AFFF. Accumulation of lipid droplets were seen in hepatocytes, specifically. Unsupervised high-resolution mass spectrometry analysis of the AFFF detected no 8-carbon PFAS, but numerous 6-carbon PFAS were present, many of which were similar in mass. Further studies will identify hepatocyte accumulations, and the active fraction of the AFFF. The AFFF with the highest EC50 and least biological toxicities will be prioritized for testing in vivo, in hopes of identifying AFFF with little/no toxicities.

1351a Different Human-Induced Pluripotent Stem Cell Models for In Vitro Neurotoxicity Assessment

A. Tukker, F. Wijnolts, R. van Kleef, and R. Westerink. Utrecht University, Utrecht, Netherlands.

Neurotoxicity testing largely relies on time consuming and ethically debated animal experiments that are neither amenable for high-throughput screening nor fully predictive for human risk. Nowadays, there is an increasing availability of human induced pluripotent stem cells (hiPSC) from varying donors differentiated in different neuronal cell types such as glutamatergic, GABAergic and dopaminergic neurons as well as astrocytes. Such hiPSC models can circumvent interspecies translation and thus hold great promise for replacing the current gold standard of (rodent) primary cultures and future neurotoxicity testing. The present study therefore aims at investigating the usability of different (commercially available) hiPSC-derived neuronal models for in vitro neurotoxicity screening. We cultured different hiPSC-derived neuronal models with different ratios of GABAergic and glutamatergic neurons in the presence of astrocytes. Using immunofluorescent stainings, we confirm the mixed neuronal nature of these hiPSC-derived neuronal co-cultures. Furthermore, using multiwell micro-electrode arrays (mwMEA), we demonstrate that these hiPSC-derived co-cultures can develop spontaneous neuronal network activity and (network) bursting behavior. As a proof of concept for neurotoxicity testing, we exposed our cultures to the seizurogenic compounds picrotoxin (PTX), 4-aminopyridine (4-AP) and strychnine. Our data indicate that spontaneous neuronal activity and (network) bursting are concentration-dependently modulated by these compounds. While further characterization and validation is required to facilitate the acceptance of these physiologically-relevant hiPSC-derived neuronal co-cultures for neurotoxicity testing, our data indicate that these models represent the cellular heterogeneity of the in vivo brain, develop spontaneous activity and are amenable for in vitro neurotoxicity and seizure liability testing. This work was funded by NCI3Rs (project number 50308-37216), ZonMW (project number 11407201) and the Faculty of Veterinary Medicine (Utrecht University, Utrecht, The Netherlands).
1352 iPSC Derived Human 3D Brain Model to Study Developmental Neurotoxicity Adverse Outcome Pathways (DNT AOP)

D. Pamies, C. Nunes, D. Tavel, and M. Zurich Fontanellaz. University of Lausanne, Lausanne, Switzerland.

A variety of molecular and cellular processes is known to be crucial to proper development and function of the central nervous systems (CNS), making this stage one of the most sensitive exposure windows for chemical insult. Current regulatory test strategies are high cost and long. Moreover, systematic testing of DNT is not a standard requirement in chemical legislation safety assessment. In consequence, there is a critical lack of knowledge when it comes to toxicity of drugs and other xenobiotic chemicals on the developing brain. This together with the increase of developmental disorders such as autism and hyperactivity syndromes have increase the awareness that we could be facing a silent pandemic. An AOP represents the existing knowledge concerning the causal links between the molecular initiating event and the cascade of key events (KE) that lead to a specific adverse outcome of regulatory concern. Adverse outcome pathways (AOPs) are expected to guide identification of experimental testing and non-testing approaches to support regulatory decision-making referring also to developmental neurotoxicity evaluation. Recently an AOP13 has been endorsed by OECD, describing how inhibition of glutamatergic spine growth is associated with hyperactivity in humans and zebrafish. Our goal is to determine how AhR activation alters zebrafish brain development and function due to impaired expression of the transcriptional changes that lead to developmental defects. Epidemiology concerns the causal links between the molecular initiating event and the environment relevant compounds with various anticipated MoAs. We found that exposure-induced behavioral alterations were reproducible and dependent on concentration and time. Comparative and quantitative analyses of the obtained locomotor patterns revealed that behavioral effects were not restricted to compounds primarily known to target the nervous system. A clear distinction of MoAs based on locomotor patterns was not possible for most compounds. Furthermore, chemicals with an anticipated same MoA did not necessarily provoke similar behavioral phenotypes. Finally, we determined an increased sensitivity (≥10-fold) compared to observed mortality in the LMR assay for 5 of 8 neuroactive chemicals as opposed to non-neuroactive compounds. This study (Leuthold et al.) is currently under review in ES&T.

1354 Can Environmentally Relevant Neuroactive Chemicals Specifically Be Detected with the Locomotor Response Test in Zebrafish Embryos?

D. Leuthold, N. Klüver, R. Altenburger, and W. Busch. Helmholtz Centre for Environmental Research-UFZ, Leipzig, Germany.

Chemicals considered as neuroactive (such as certain pesticides, pharmaceuticals and industrial chemicals) are among the largest groups of bioactive substances recently detected in European rivers. However, the determination of nervous system-specific effects has been limited using in vitro tests or conventional endpoints including lethality. Thus, neurobehavioral tests using in vivo models (e.g. zebrafish embryo) have been proposed as complementary approaches. To investigate the specificity and sensitivity of a light-dark transition locomotor response (LMR) test in 4 to 5 days post fertilization zebrafish with respect to different modes of action (MoAs), we analyzed a set of 18 environmentally relevant compounds with various anticipated MoAs. We found that exposure-induced behavioral alterations were reproducible and dependent on concentration and time. Comparative and quantitative analyses of the obtained locomotor patterns revealed that behavioral effects were not restricted to compounds primarily known to target the nervous system. A clear distinction of MoAs based on locomotor patterns was not possible for most compounds. Furthermore, chemicals with an anticipated same MoA did not necessarily provoke similar behavioral phenotypes. Finally, we determined an increased sensitivity (≥10-fold) compared to observed mortality in the LMR assay for 5 of 8 neuroactive chemicals as opposed to non-neuroactive compounds. This study (Leuthold et al.) is currently under review in ES&T.

1355 Evaluating the Developmental Toxicity of Halogenated Pyrroles in Zebrafish

B. Yaghoubi, I. N. Pessah, and P. J. Lein. University of California Davis, Davis, CA.

Halogenated pyrroles, or halopyrroles, are one of the largest classes of halogenated alkanoids. Anthropogenic halopyrroles are increasingly detected in wastewater and drinking water. While they are currently an unregulated class of disinfection by-products, halopyrroles are generating public health concern due to their persistence in the environment, and recent findings indicating that these compounds are cytotoxic and interfere with development in worms. We recently demonstrated that anthropogenic halopyrroles dysregulate calcium dynamics in microsomes isolated from rabbit fast-twitch skeletal muscle by sensitizing ryanodine receptors (RyRs). Because of the importance of calcium signaling in vertebrate development, these observations raise the question of whether halopyrroles interfere with development in vertebrates. To address this question, teratogenic effects and photomotor response were assessed in developing wild-type (Tropical 5D) zebrafish (Danio rerio) exposed to varying concentrations (0.03 μM to 30 μM) of three different halopyrroles: tetrabromopyrrole, 2,3-dibromomaleimide, and 2,3-dibromo-N-methylmaleimide. Zebrafish embryos were dechorionated and exposed via static waterborne exposure to halopyrroles beginning at 6 h post-fertilization through 5 days post-fertilization (dpf). Zebrafish were observed daily for gross teratological malformations and mortality. Behavioral tests were conducted at 4 and 5 dpf using the Noldus automated tracking system to assess effects of the compounds on an apical endpoint of developmental neurotoxicity. Tetram bromopyrrole and 2,3-dibromo-N-methylmaleimide were embryonic lethal at 1 μM and 30 μM, respectively, while 2,3-dibromo-N-methylmaleimide was not lethal at any concentration tested. Developmental malformations were only observed in fish exposed to tetram bromopyrrole at 0.3 μM to 1 μM. Photomotor response was significantly altered only by 2,3-dibromo-N-methylmaleimide which decreased swimming during dark phase in a non-monotonic concentration-response related manner. Given the potential for human exposure to anthropogenic halopyrroles, these observations suggest that further evaluation of the developmental neurotoxicity of this class of compounds in vertebrate species is warranted. Supported by the NIEHS (R01 ES014901, PBL & INP).

2019 SOT Annual Meeting
1356 Identifying Neurophysiological Signatures of Neurotoxic Action Using Classification Models

S. Davila-Montero,1 T. Shafer,1 K. Wallace,2 B. Lynch,1 and A. Mason1.
1Michigan State University, East Lansing, MI; and 2US EPA/ORISE, Research Triangle Park, NC.

Exposure to environmental chemicals during nervous system development can result in developmental neurotoxicity (DNT). In vitro microelectrode array (MEA) recordings of the ontogeny of neural network function following chemical exposure can be used to screen chemicals for DNT hazard. These recordings capture temporal and spatial aspects of action potential activity, which are described by a set of network parameters. To date, ~250 compounds have been tested in this assay, but with the same molecular initiating event (MIE) have similar effects on network parameters that have not been explored. This could lead to identification of “fingerprints” for DNT compounds that provide information useful for determining the MIEs for unknown compounds. Here, effects of 45 previously tested compounds with varying modes of action were studied by comparing neural network recordings of 16 voltage-gated sodium channel modulators, 11 GABA agonists and antagonists, and 18 acetylcholinesterase inhibitors. These data were used to investigate the relationship between neural network recording parameters and the mode of action of the compounds. This approach could lead to a better understanding of the mechanisms underlying DNT and the ability to identify compounds with similar modes of action.

1358 Zebrafish Larvae Require Specific Strains of Bacteria to Allow for Control-Like Neurobehavioral Development

1Meredith College, Raleigh, NC; 2US EPA/ORISE, Research Triangle Park, NC; 3US EPA/OR, Cincinnati, OH; and 4US EPA/OR, Research Triangle Park, NC.

There is an increasing appreciation of the relationship between gut microbiota and neurodevelopmental function. We previously showed that axenic (microbe-free) zebrafish are hyperactive at 10 days post fertilization (dpf) relative to colonized zebrafish. Interestingly, while exposure to heat-killed bacteria or microbe-associated molecular patterns failed to block hyperactivity in axenic larvae, colonization of axenic zebrafish with Vibrio cholerae produced locomotor activity similar to colonized controls. These data suggest that there is a developmental requirement for microbial colonization to modulate host behavior. To address this hypothesis, nineteen bacterial isolates were obtained from 10 dpf conventionally colonized zebrafish. 16S rRNA gene sequencing identified five unique gram-negative isolates: Acinetobacter, Vibrio, Comamonas, Comamonadaceae, and Aeromonas. Monoclonization of axenic embryos at 1 dpf with 100 cells/mL of Acinetobacter, Comamonas, or Comamonadaceae resulted in behavioral profiles that partially blocked axenic-related hyperactivity. In comparison, axenic embryos monoclonalized at 1 dpf with Vibrio, Comamonas, or Aeromonas also blocked hyperactivity. These data suggest that specific bacterial taxa are sufficient for control-like neurobehavioral development while colonization with other strains of bacteria may influence motor behavior. These findings raise the possibility that environmental chemicals may disrupt neurobehavioral development by selecting for specific classes of host-associated microbes. This abstract does not represent US EPA policy.

1357 Thyroid Toxics and Neurodevelopment: Molecular Initiating Event May Be an Important Consideration

M. E. Gilbert,1 K. L. O’Shaughnessy,1 I. Hassan,1 S. E. Thomas,2 J. L. Ford,1 C. R. Wood1, A. R. Smith,2, and W. O. Oshiro1.1 US EPA, Research Triangle Park, NC; and 2ORISE, Research Triangle Park, NC.

Developmental neurotoxicity is a primary concern for thyroid disrupting chemicals (TDCs). Many environmental TDCs include antimicrobials, pesticides, flame retardants, and perfluorinated compounds. These TDCs reduce circulating levels of thyroid hormones (THs) by direct and/or overlapping mechanisms, many of which are not well characterized. It is unclear if these chemicals also reduce THs in the brain and cause neurodevelopmental deficits. This study investigated the potential developmental neurotoxicity of 14 of these chemicals, and demonstrated a decrease in THs in the brain but not circulating THs. Pregnant rats were dosed with a single high dose of triclosan (300mg/kg/day) or gavage or vehicle control once daily from gestational day 6 (GD6) to postnatal day 21 (PN21). Results show that triclosan did not induce changes in litter size or pup body weight. No effects were seen on liver weight or body-weight ratios in dams or pups, but liver metabolism genes were increased in expression. Serum total and free T4 were reduced in the dam (GD20 and PN21) and pup (PN0, PN2, PN6, PN14) to varying degrees; however, thyroid stimulating hormone (TSH) was unchanged. In the neonatal brain, no gene expression changes associated with TH dysfunction were detected, and there was no evidence of a TH-dependent phenotype (hypothyrotoxia). Neither were behavioral tests of learning and memory (trace fear conditioning) or sensory motor function (prepulse inhibition) impaired in adult offspring. These data suggest that despite reductions in serum T4 in dams and offspring, according to these metrics, the developing brain does not appear to be adversely affected. Further study regarding the relationship between THs in the brain and more sensitive measures of neurodevelopmental impairment are needed to more fully characterize the risk of chemicals like triclosan and others with similar mode(s) of action. Disclaimer: This work does not reflect EPA policy.

1359 Cytotoxicity of Quantum Dots on Human Neural Progenitor Cells Are Influenced by Their Surface Chemistry and the Sex Origin of Cells

D. M. Leme1,2, Y. J. Suh1, S. Hong2, T. Workman2, M. Smith2, W. C. Griffith2, and E. M. Faustman1.1 Federal University of Paraná (UFPR), Curitiba, Brazil; and 2University of Washington, Seattle, WA.

Quantum dots (QDs) are highly promising nanomaterials for clinical imaging/diagnosis due to their advantageous optical properties. They are a diverse class of nanostructures, varying in their composition (core, surface chemistry) and design (shape, shell thickness). However, safety is the major barrier in translating QDs to clinical uses. Brain development is an extremely intricate process, and its disruption may have severe and long-lasting consequences on brain structure/function. Brain function can be differentially affected by chemicals due to sex-specific regulatory mechanisms of brain development. We evaluated the cytotoxicity potential (LDH assay) of two CdSe/ZnS QDs with different surface chemistries (carboxyl functional group - ITK1, polyethylene glycol (PEG) without reactive functional group - Qtracker1), on proliferating and differentiating human neural progenitor cells (hNPCs). Sex-specific cytotoxicity of QDs was evaluated by the use of hNPC lines derived from males (NSC-H14) and females (hNPC1). Cadmium chloride (Cd) was tested under the same conditions in order to determine if the cytotoxicity mechanism of QDs is related to ion release. Exposures (days in vitro 1, 24 hours) to ITK1 at five different doses (2.5-40 nm) demonstrated a significant dose-dependent decrease in viability of both cell lines (NSC-H14, hNPC1) during the proliferation stage. Moreover, NSC-H14 (male) were more susceptible to the cytotoxicity of ITK1 than hNPC1 (female). Qtracker and Cd, at the same dose range as ITK1, did not induce cytotoxicity either in the proliferation and differentiation stages of either hNPC line. Our results show that surface coating defines the cytotoxicity of QDs on hNPCs and suggests that PEGylation can be a strategy for the safe use of QDs on clinical settings. In addition, our data supported the novel use of hNPCs from male and female origin as an in vitro model for examining sex-specific impacts of chemicals on brain development. This project is supported by US EPA (RD 83573801, RD 83541001) and the NIEHS (SP01ES009601, SP03ES00703, T32ES015453). The views expressed in this paper are those of the authors and do not necessarily reflect the views of the US EPA.
**1360 Neurodevelopmental Effects of a Non-Dioxin-Like Polychlorinated Biphenyl (PCB153)**

Polychlorinated biphenyls (PCBs) are persistent legacy contaminants that bioconcentrate in fish and other predators. Fish are a major dietary source of exposure for humans. One of the most abundant PCBs found in aquatic biota and in human maternal plasma and amniotic fluid is the planar, non-dioxin like PCB153, yet its biological activity is not well understood. There is increasing evidence that PCB153 targets the nervous system and may be responsible for developmental delays following exposures in early development. In this study, we used the zebrafish larvae to investigate the effects of PCB153 on the neural circuitry during development. We tested behavioral effects in PCB treated fish by assessing the larval escape response, and several other behaviors such as locomotion and preference for light or dark. Our results show that PCB153 dramatically increased the latency and maximum head turning angle in the escape response in 6-day old larvae. The escape response is driven by a neuronal circuit involving detection of the signal in auditory hair cells and other sensory neurons, and transmission to the Mauthner cells and other reticulospinal neurons. By using immunohistochemistry and electrical stimulation, which bypasses the sensory system and directly activates the Mauthner neurons, our data indicate that these neurons are present and functional. PCB153 is likely disrupting the function of the neural circuit in the hindbrain between the sensory ganglia and the Mauthner cells leading to increased latency and turning angle. Mutations in the axon guidance receptor (dcc) as well as a transporter regulating glutamate levels in synaptic regions (slc1a2b) phenotype the observed increased turning angle. Whether pathways involved in these genes are affected by PCB153 is not known. Targeted transcriptomics of brain from PCB153 exposed larvae compared to brain from control larvae is under way. The zebrafish model provides insight into both the ecological relevance of rapid escape from predators, and the human health relevance of proper neuronal development. This study will advance our understanding on the mechanism of action of an ubiquitous environmental contaminant. NIH 5P42ES007381 - The Boston University Superfund Research Program.

**1362 The Role of ATP13A1 in the Developing Brain: Effects on Locomotor Activity and Motor Function**

Y. Sene, R. Conaway, I. Rivera, A. Parton, L. Massie, P. J. Schultheis, and P. Curran. Northern Kentucky University, Highland Heights, KY.

ATP13A1 and ATP13A2 are P-type transport ATPases. ATP13A2 mutations result in a rare form of Parkinson’s disease and increased susceptibility to manganese exposure. ATP13A1 plays an important role in the normal functioning of the endoplasmic reticulum and is widely expressed during brain development. A previous human study identified a mutation in ATP13A1 correlated with a higher risk of ADHD. We are using a mouse model to understand the normal role of the gene and to determine the effects on motor function and behavior. Knockout Atp13a1(-/-) mice die before birth; therefore, we were only able to test heterozygous Atp13a1(+/-) and wild type Atp13a1(+/-) mice in our neurobehavioral test battery. Results from two tests are reported here. We found a significant gene x sex interaction for total activity in the open field locomotor activity test and during multiple intervals of the 60 min. test. Heterozygous female Atp13a1(+/-) mice had significantly higher activity than wild type females. However, heterozygous male Atp13a1(+/-) mice had significantly lower activity levels compared with wild type males (P < 0.05). We found a significant gene x sex interaction on two days of testing and a significant effect of sex on two days of testing. Heterozygous Atp13a1(+/-) females had longer latencies to fall on Days 1 and 3 compared with all other groups (P < 0.05). There was also a main effect of sex with females out-performing males on Days 1 and 5 of testing (P < 0.05). Overall, all mice showed evidence of motor learning over the five days of testing. This indicates normal motor function in both wild type and heterozygous mice.

**1363 A Lack of Changes in the Transcriptomic Response in the Hippocampus or Amygdala after Developmental Exposure to Mild Variable Stress**

Early developmental exposure to stress has been reported to influence learning and memory mechanisms. Changes in the gene expression of brain-derived neurotrophic factor (Bdnf), Ca2+/calmodulin-dependent protein kinase II alpha (Camk2a), and cyclic adenosine monophosphate (cAMP) response element binding (Creb1) have been associated with learning in rodent models. We utilized perinatal exposure to a variable stress paradigm to examine changes in learning and expression of these gene targets after trace fear conditioning. Pregnant Long Evans rats were exposed to an unpredictable series of mild stressful events, which had previously been shown to increase maternal corticosterone levels. These nonchemical factors were presented daily from gestational day (GD) 13 through GD 21 with a postnatal group that also included maternal separation. Starting at postnatal day 97, male and female adult offspring were trained with a trace fear conditioning (TFC) protocol whereby rats were exposed to a compound cue (light and tone) followed by 30 seconds (trace period) and a mild foot shock (1mA, 0.5 seconds). Five paired training sessions occurred on the training day. Hippocampus and amygdala were removed and flash frozen at 3 or 6 hours after TFC. All treatment groups displayed learning during context testing. Quantitative RT-PCR data generated from hippocampus or amygdala showed a lack of significant change in the expression of Bdnf, Camk2a, or Creb1 at either time point, or for either sex, regardless of stress exposure. This lack of change may indicate that these genes are influenced at different time points than when these tissues were collected, or that other gene targets could be responding to this learning task for these rats. On-going research will examine a wider range of RNA targets using RNAseq in adult rats that have completed TFC compared to controls that have not undergone testing, to isolate RNA targets that are influenced by TFC. Additional work will examine treatment-related changes in the offspring of dams concurrently exposed to manganese and variable prenatal stress, including transcriptional changes in the hippocampus and amygdala of adult rats after learning the TFC task. This abstract does not necessarily reflect US EPA policy.
1364 Early-Life Lead Exposure Increases µ-Opioid Receptor Levels in the Juvenile Rat Brain: Implications for Opioid Addiction

Opioids and cocaine are two of the main drugs of abuse that contribute to death by overdose. In the United States, from 2015–2016, overdose deaths from these drugs increased by 21%. Opioid-related overdoses accounted for 66% of the cases and cocaine overdose increased by 52% (Seth et al, 2018). The juvenile period is a time in which humans are particularly driven to seek rewards and to engage in drug-seeking and risk-taking behaviors. In the brain, activation of µ-opioid receptors is directly involved in these behaviors and µ-opioid receptor play an important role in opioid use disorders. Previously, we have shown that chronic early life exposure to lead (CELE) sensitizes animals to cocaine an effect mediated by an increase in D1-dopamine receptors. In this study, we examine the effect of CELE on µ-opioid receptor levels in the brain of juvenile rats. Our CELLE protocol has been extensively described over the last 25 years. This exposure paradigm results in blood lead levels in juvenile animals (28 days of age) as follows: control males: 1.71 ± 0.07 ug/dL (n=54); lead-exposed males: 19.9 ± 0.49 ug/dL (n=61); control females: 1.78 ug/dL (n=40); lead-exposed females: 24.4 ± 1.1 (n=39). To examine µ-opioid receptor levels in the brains of juvenile animals, we used quantitative autoradiography with the specific µ-opioid receptor agonist ligand [3H]-D-Ala2-MePhe4-Gly-ol2 enkephalin. Analysis of [3H]-D-Ala2-MePhe4-Gly-ol2 enkephalin specific binding to µ-opioid receptor was performed in the basolateral amygdala, hypothalamus, midthalamus, stria medullaris of the thalamus, lateral posterior thalamus, nucleus accumbens, prefrontal nucleus, and dorso-lateral geniculate nucleus of male and female rats. Statistical analysis indicates that lead-exposed male and female rats had significant increased levels of µ-opioid receptor than controls except in the hypothalamus of males and stria medullaris of the thalamus in females. Our results indicate that CELLE increases brain µ-opioid receptor levels in lead-exposed rats and this may be a risk factor for drug-seeking and risk-taking behaviors in juveniles. NIEHS grant Number E006189-24 to TRG.

1365 Altered Sterol Homeostasis during Neurodevelopment, In Vivo and In Vitro, Is a Common Target for Benzalkonium Chloride Disinfectants

Lipids are critical for neurodevelopment; thus, disruption of lipid homeostasis by environmental chemicals is expected to have detrimental effects on this process. We have demonstrated that the benzalkonium chlorides (BACs), a class of commonly used disinfectants, alter cholesterol biosynthesis and lipid homeostasis in neuronal cells, in a manner dependent on the alkyl chain length. However, the ability of BACs to reach the neonate brain and alter sterol and lipid homeostasis during neurodevelopment has not been characterized. Moreover, the impact of BACs on neurodevelopment has not been fully elucidated, although increased incidences of neural tube defects following in utero exposures has been observed. Therefore, we hypothesize that BACs would affect neurodevelopmental processes by altering sterol and lipid homeostasis. Damas were fed BACs of different alkyl chain lengths (C12 and C16) at 120 mg/kg/day via diet for one-week prior to mating and throughout gestation. BAC exposure led to an increase in sterol and lipid homeostasis was assessed using targeted and untargeted mass spectrometry methods and RNA sequencing. BACs were found in the neonate brain at low nM concentrations, which resulted in decreased total sterol levels and altered lipidome. BAC C12 treatment resulted in the differential expression of 507 genes, whereas BAC C16 altered the expression of 139 genes. Cholesterol biosynthetic genes were significantly upregulated, which is consistent with the inhibition of cholesterol biosynthesis by BACs. Changes to genes in lipid metabolism were also consistent with identified lipidomic changes i.e. significant decreases in levels of triglycerides and diglycerides. To examine effects of BACs on neurodevelopment, neural precursor cells were isolated from the mouse brain at embryonic day 14.5, cultured to neurospheres, and treated with either BAC at 10-100 nM. Neurosphere diameter was reduced to approximately 50% of the control, which was attributed to a loss of proliferative cells (Ki67+/DAPI+) rather than a decrease in proliferation (EdU+/Ki67+). Inhibition of cholesterol synthesis was also observed in treated neurospheres. Overall, the effects of BACs on sterol and lipid homeostasis and neurosphere proliferation support our hypothesis and prompt further investigation into the developmental neurotoxicity of BACs.

1366 The Placenta as a Potential Target of Neuroendocrine Disruption: A Comparison of Brominated and Organophosphate Flame Retardants

K. D. Rock, B. Horman, A. L. Phillips, M. Ruis, H. M. Stapleton, and H. B. Patisaul. 1 North Carolina State University, Raleigh, NC; and 2 Duke University, Durham, NC.

Chemical flame retardants (FRs) are commonly applied to consumer products including foam-based furniture and infant products, textiles, and electronics. Widespread human exposure and accumulating evidence of endocrine dis-
rption have raised concerns regarding the possible toxicity of these chemicals, particularly on the developing brain. Throughout gestation, the placenta is a critical coordinator of fetal growth and development, including neuro-development. We have shown in rats and humans that FRs accumulate in placental tissue; in some cases, to a greater degree in male-associated placentas than female-associated placentas. Given the important role the placenta plays in fetal programming, disruption of placental function may be a critical but underappreciated mechanism by which FRs induce changes, including sex-specific changes, in brain and behavior. Here we compare the gene expression profiles of male and female-associated placentas collected from Wistar rat dams gestationally exposed to one of three different FR mixtures. One consisted of a mixture of polybrominated diphenyl ethers (PBDEs), an important class of FRs that, although largely phased out, are strongly associated with behavioral and cognitive impairments in humans. The other two FR mixtures contained more recently introduced brominated and organophosphate ester (OPE) compounds. Using a combination of transcriptomic approaches, we identified several putative pathways and/or putative FR targets that were altered by FRs, including endocrine, inflammatory and neurotransmitter signaling pathways. Some of these mRNA expression changes were sex-specific, with upregulation of genes like Esr1 and Ar present in female-associated placentas and Tdo2 and Htr2a in male-associated placentas. Future work will continue to probe the hypothesis that sex-specific alterations in placental function could be a mechanism by which exposure to FRs alters neural developmental behavior and outcome.

1370 Perfluorooctane Sulfonate (PFOS) Exacerbates Microglial Responses to Brain Injury in Exposed Zebrafish Embryos
S. E. Martin, and J. Plavicki. Brown University, Providence, RI.
Per- and Polyfluoroalkyl Substances (PFAS) are a class of manufactured organic compounds commonly found in repellent or stain-resistant products, food packaging, and clothing, and are also additives in some cleaning agents, detergents, and cosmetics. Due to their high structural stability, these ubiquitous global toxicants do not readily degrade and, consequently, are environmentally persistent and highly bioaccumulative. Perfluorooctane sulfonate (PFOS), a prevalent PFAS congener, is immuno- and neurotoxic in both developmental and adult contexts. However, it is not known whether PFOS exposure affects the development and function of microglia, the resident immune population in the brain. Microglia play an active role in neuronal pruning and clearance during development, are required for synaptic remodeling, and are primary responders to CNS insults such as pathogen invasion or injury. In the present study, we examined microglia migratory behavior and function in response to minor injury via puncture to the right hemisphere of the telencephalon in 3-day-old zebrafish raised in either 0.1% DMSO or 32μM PFOS. As a developmentally rapid and transparent model, transgenic zebrafish allow for real-time in vivo analysis of fluorescently-labeled cellular activity. Using transgenic fish with fluorescently-labeled macrophages, which includes microglia, we demonstrate that embryos raised in water containing 32μM PFOS have similar numbers of brain macrophages, though exhibit a significantly heightened inflammatory response to injury, as evidenced by an expanded inflammatory field surrounding as well as an increased macrophage recruitment. Additionally, macrophages in PFOS-exposed embryos had prolonged residency at the site of injury. This suggests both a sustained release of inflammatory mediators, such as cytokines, by neurons and cells in the surrounding microenvironment, an intensified adverse reaction to minor injury, or both. Our findings present an opportunity for brain macrophages to recover after clearance of damaged tissue. Together, these data reveal an amplified and persistent response by microglia to brain injury with PFOS exposure and support current evidence that PFOS is neurotoxic, as prolonged neuroinflammation is known to contribute to neurotoxicity and drive neurodegeneration.

1371 Neuroactive Compound Alter Neural Network Formation Measured in Micro electrode Arrays with Potencies Lower Than Median Toxcast Potencies
T. Shafer1, J. Brown1, B. Lynch1, S. Davila-Montero2, K. Paul-Friedman2, and K. Wallace1. 1US EPA/NHEERL, Research Triangle Park, NC; and 2Michigan State University, East Lansing, MI.
Thousands of chemicals with human exposure potential have not been evaluated for developmental neurotoxicity (DNT) due to resource limitations. This has driven efforts to develop efficient screening approaches to identify and prioritize compounds with the potential to cause DNT. One promising approach is assessment of chemical effects on neural network formation (NFA) using cultures grown on microelectrode arrays (MEAs). In a current study, 137 unique compounds were evaluated for their ability to disrupt formation of cortical networks grown on MEAs. Chemical exposure was initiated 2 hr following cell plating and continued for 12 days in vitro (DIV). Network activity was recorded on DIV 5, 7, 9 and 12, with cell viability assessed at DIV 12. Of the 137 unique compounds tested, 53 did not alter the connectivity of any network parameter. The remaining 84 compounds affected at least one parameter of network development, with 46 showing selective effects defined by ≥3x more potent EC50 values for effects on network formation vs viability. Assay results were highly reproducible; results with nine compounds tested twice as biological replicates were qualitatively 100% concordant. Tipping points, i.e., biological threshold concentrations that reflect effects on multiple NFA parameters, were determined for 61 compounds, and tended to be similar to or lower than the minimum EC50 (typically within less than 1 log10EC50). To characterize the value added by the NFA MEA to available high-throughput screening assay data, EC50 values for effects on network parameter were compared to the range of EC50 values observed in ToxCast assays. Generally, the NFA EC50 values for neurotoxic (and potentially developmentally neurotoxic) compounds were less than the interquartile range for ToxCast assay EC50 values for the same compounds, whereas compounds lacking evidence for neurotoxicity had EC50 similar to the median EC50 values in other ToxCast assays. These results indicate that NFA screening may identify the nervous system as a sensitive endpoint compared to other ToxCast assays, and demonstrate that data from the NFA could be used to screen and prioritize compounds for additional testing. Disclaimer: This abstract does not reflect policy of the US EPA.

1372 Maternal Exposure to Organophosphate Flame-Retardants and Anxiety-Like Behavior
Endocrine disrupting compounds (EDCs) are compounds found in our environment that interrupt typical endocrine function. A particular group of EDCs are flame-retardants due to their interaction with steroid and nuclear receptors in vitro investigations. Humans are consistently exposed to flame-retardants daily as they are used in everyday items such as plastics, clothing, toys, and electronics. In the past, polybrominated diphenyl ethers have been used; however, since 2004, they have been replaced with organophosphate flame-retardants (OPFR) as the major flame-retardant chemical. The effects of maternal or developmental exposure to OPFR on behavior are currently underexplored. Yet, one such maternal exposure study in rodent models utilizing a commercial flame-retardant mixture containing OPFR reported significant differences in open arm entries on the elevated plus maze (EPM) in females (Pataisal et al., 2013, J Biochem Mol Toxicol). Here we evaluate anxiety-like behavior in the open field test (OFT), as well as, the EPM in male and
female offspring that were maternally exposed to OPFR or oil controls. Males that were maternally-exposed to OPFRs had significantly reduced time of exploration in the center zone of the OFT, a marker of anxiogenic-like behavior, relative to their same-sex controls t(28) = 2.128, p = .042. No significant differences were found in center zone exploration time in maternally-exposed OPFR females relative to their oil controls (t(25) = -1.018, p = .319. Interestingly, experimental females displayed anxiety-like behavior as evidenced by a decreased number of entries in the corners of the OFT, t(25) = 3.556, p = .002. In contrast, we saw no effect in experimental males on number of corner entries t(29) = - .443, p = .661. We also assessed behavior in the EPM. Similar to outcomes in the OFT, maternally-exposed OPFR males had significantly reduced percent time in the open arms compared to same-sex controls (t(28) = 2.096, p = .045. However, we did not see an effect in females on this measure t(25) = .579, p = .567. Our research illustrates that there are sex-dependent effects of OPFR exposure on exploratory behaviors in a mouse model as was previously found in a rat model. Future studies will evaluate other behavioral measures such as the Light/Dark box, social interactions, the effects of high-fat diets, and the receptor-mediated mechanisms underlying the sex differences.

### 1373 Integration of Genomic and Metabolomic Data Streams in an In Vitro Neuronal Development Model

C. A. Marable1, S. Hester1, W. M. Henderson2, B. N. Chorley1, K. A. Wallace1, T. M. Freudenrich1, and T. J. Shafer1. 1US EPA/NHEERL, Research Triangle Park, NC, and 2US EPA, Athens, GA.

A microelectrode array-based assay (MEA) has been developed in rat primary cortical cultures for screening and prioritization of chemical effects on neural network formation. In this study, pathway-based transcriptomic and metabolomic methods were utilized to complement this assay and identify molecular events involved in adverse outcomes associated to neural network disruption. Gene expression and metabolomic alterations were determined after exposure to two DNA synthesis inhibitors (Cytosine Arabinoside and 5-Fluorouracil), two voltage-gated sodium channel (VGSC) modulators (Deltamethrin and Cypermethrin), a dopamine receptor antagonist (Haloperidol) and a glutamate receptor antagonist (Domoic Acid). Doses (0.1-3μM) were selected based on critical concentrations at which the neural networks switched from recovery to non-recovery trajectories based on the MEA results. Global transcriptomic response for the DNA synthesis inhibitors repressed gene response, consistent with robust impacts on DNA synthesis, while the dopamine receptor antagonist showed a dose-dependent increase in gene expression. By contrast, exposure to VGSC modulators and the glutamate receptor agonist tended to increase gene expression. Regardless of chemical class, "Axonal Guidance Signaling" was a significantly altered transcriptomic pathway identified for all chemicals excluding Haloperidol, highlighting a shared disruption in neural development. Metabolomic analysis indicated twelve altered metabolites common to all tested chemicals related to neuronal, developmental, and psychological disease. Further, "Activation of mRNA charging" was the most significantly perturbed metabolomic pathway with all chemicals, indicating an impact on a general translational response in rat cortical neurones. Overall, our combined findings across MEA, transcriptomic, and metabolomic responses consistently reinforce each other, suggesting that the molecular endpoints may serve as a complement to the functional MEA assay. Importantly, these results provide data to build an adverse outcome pathway network based on neural development disruption. This abstract does not necessarily reflect US EPA policy.

### 1374 Adolescents’ Methymercury: Effects on Sustained Attention and Retention and Interactions with d-Amphetamine

D. Kendricks, and M. C. Newland. Auburn University, Auburn, AL.

Some recent studies of human exposure have shown that exposure to methylmercury (MeHg) may result in attention deficits, but an experimental model of this has not been produced. Prolonged effects of adolescent exposure to MeHg on sustained attention and short-term retention were examined by exposing adolescent male Long-Evans rats to 0, 0.5, or 5 ppm MeHg throughout adolescence and testing them in adulthood, on a two-choice visual signal detection task. Rats were trained to respond on one lever in the presence of a 0.3” signal (hit) or an alternative lever in its absence (correct rejection). Stimuli were presented randomly within a 0.3-74 second window. To examine retention, the response lever was made available after a random delay of 0.3-29.3 seconds. Acute effects of d-amphetamine were also examined in order to determine the sensitivity of MeHg exposed animals to dopamine modulation. Animals exposed to 0.5 ppm MeHg had lower overall accuracy, and this was attributed to a selective decrease in the hit rate. Amphetamine reduced overall accuracy across post-stimulus delays by decreasing the hit rate, especially at long delays. This occurred in all exposure groups. Further, amphetamine decreased correct rejections (increasing false-alarms) for animals exposed to the low dose of MeHg. These findings suggest that MeHg alters attention and retention and these effects are sensitive to modulation by dopamine agonists. Interestingly, previous reports of a nonlinear dose-effect curve that has previously been reported, in which the 0.5 ppm exposure group is more sensitive than the 5 ppm group, was replicated here.

### 1375 Autism Spectrum Disorders (ASD) and Cerebral Palsy (CP) as Neurodevelopmental Disorders in Children in Ibadan, Nigeria: Pb and Se in Focus

A. O. Akinade1, I. O. Omotosho1, I. A. Lagunju1, and M. A. Yakubu1. 1University of Ibadan, Ibadan, Nigeria; and 2Texas Southern University, Houston, TX.

The level of exposure to toxic metals is on the increase worldwide. Recent studies have shown that some of the toxic metals are associated with neurological diseases and affect essential elements and micronutrients absorption. Autism spectrum disorders (ASDs) and cerebral palsy (CP) are neurodevelopmental disorders that affect millions of children worldwide and diminish quality of life. Toxic element like Pb have been shown to affect essential element and micronutrient absorption and their interaction have been shown to have toxic effect. This study was conducted to investigate the levels of toxic metal (Pb) and micronutrients (Se) and their roles in aetiologypathogenesis of ASD and CP in Ibadan, Nigeria. 8 children with ASD and 8 CP and 16 age-sex matched neurotypical children as controls were recruited for this study. All diagnoses were made by the pediatric neurologist. Plasma levels of Pb, and Se were analyzed using ICP-MS method. Ethical clearance was obtained from UCH/UI ethical review committee. Results were analyzed using Students t-test. The analysis of the questionnaire revealed that the gender difference was not significant in the children (p=0.579). The children's mean Se level was significantly lower in ASD than in CP (14.45±4.29) compared to controls (32.51±9.71) and control subjects (58.26±11.69). Moreover, chemical concentration in neurotypical children showed Pb level in ASD (7.92±1.30) and CP (10.38±1.45) compared to control (6.83±0.72) while Se level was significantly reduced in subjects (0.37±0.05; 0.30±0.02) compared to control (0.57±0.02). The central nervous system is prone to the deleterious effect of Pb: thus its effect is more pronounced in children where it interferes with the normal brain development. On the other hand, Se has a neuroprotective effect due to its antioxidant and anti-inflammatory properties. The important redox properties of Se may have been compromised by the reduced Se level observed in ASD and CP children in this study may contribute to the pathophysiology of these neurodevelopmental disorders. It may be concluded that the burden of lead and reduced Se status in these participants contributed to the consequences of the disorders.

### 1376 Assessment of Neurotoxic Potential of 90 Blinded Compounds Using Zebrafish Embryos

C. Quevedo1, M. Behl1, K. Ryan1, R. S. Paul51, A. Alday1, A. Muriana1, and A. Alzuadul1. 1Biobide, San Sebastian, Spain; and 2NIHES, Research Triangle Park, NC.

Developmental toxicity and neurotoxicity of 90 blinded compounds containing known neurotoxicants (DNT/NT) and compounds with undetermined neurotoxic potential (e.g. flame retardants, bisphenol A analogs) were assessed using zebrafish embryos. To evaluate developmental toxicity, chemicals were tested at 5 to 8 concentrations and a teratogenic index (TI) was then calculated (log dose ratio = TICM (median effect concentration) and TELC (lethal effect concentration) on morphological alterations). For neurotoxicity evaluation, embryos were treated at 3 dpf (days post fertilization) with 5 doses, with the lowest concentration where morphological effects appeared selected as the highest concentration, and after 48 hours of exposure, locomotor activity was analyzed as indicative of neurotoxicity. Larvae from the developmental toxicity assay were analyzed for internal compound concentrations to determine the real concentration at which toxic effects were induced. Moreover, chemical concentration in the medium was also determined. After compound unblinding, within the 38 DNT/NT compounds, 26 (68.4%) were detected as active in zebrafish embryos, 54% of the active chemicals being neurotoxic and the other 46% toxic. The remaining 12 compounds did not induce any toxicity. However, the bioavailability data showed that in 11 out of the 12 cases the internal concentration did not reach 10 μM because of the limited uptake, instability or precipitation. In addition, 33 out of 45 (76.7%) of compounds with unknown DNT/NT were the most neurotoxic and 31 of these were toxic as well. This study demonstrates the utility of zebrafish embryos as a prioritization method to identify novel compounds with neurotoxic potential.
**1377 Social Behavioral Effects in Prairie Voles Perinatally Exposed to Firemaster 550**

S. A. Gillera, B. Horman, W. Marielli, R. Grinceviciute, and H. Patsiala.1 North Carolina State University, Raleigh, NC; and University of Texas at El Paso, El Paso, TX.

The prairie vole (Microtus ochoaegaster) is a uniquely valuable model organism used to study complex social behavior. This species readily form social bonds and spontaneously display social monogamy, bi-parental care, and partner preference; behaviors not seen more traditional laboratory rodent models such as rats or mice. Our studies demonstrate the utility of the prairie vole for investigating the impact of chemical exposures on social behavior. Healthy social interactions and the ability to form stable social attachments are important for mental health and impairments are common characteristics of some mental health disorders. The incidence of neurodevelopmental disorders in children is rapidly rising raising speculation that developmental exposure to environmental contaminants may be contributory. Firemaster 550 (FM550) is one of the most prevalent flame retardant (FR) mixtures used in foam-based furniture and baby products. We and others have published evidence of developmental neurotoxicity and sex-specific effects of FM550 on anxiety-like and exploratory behaviors in rats and zebrafish suggesting impacts on social behavior. To test this hypothesis, we investigated the impact of perinatal FM550 exposure on a range of social behaviors in prairie voles. Dams were exposed to 0, 500, 1000, or 2000 μg of FM500 via subcutaneous injections throughout gestation, and pups were directly exposed to the same dose beginning the day after birth until weaning at three weeks of age. Tasks performed on the offspring of both sexes were open field, novel social, social preference, social recognition, novel object recognition, and partner preference. Effects were dose responsive and sex specific, with females more affected than males. Behavioral effects included elevated anxiety, decreased social interaction, decreased exploratory motivation, and altered social preference for novel versus partner animals. Future studies will probe the possible mechanisms by which these effects arise. These data support the hypothesis that developmental FR exposure impacts the social brain and demonstrate the value of the prairie vole for assessing chemical effects on sociality and attachment.

**1378 Sex-Specific Effects of Polychlorinated Biphenyls (PCBs) on Hippocampal Dendritic Arborization in Weanling Mice**

Early-life exposures to environmental chemical contaminants are associated with increased risk of neurodevelopmental disorders (NDDs). PCBs are environmental contaminants that are resistant to degradation and globally distributed with high potential for human exposure. We previously identified elevated levels of specific PCB congeners in the serum of pregnant women enrolled in the MARBLES study, all of whom are at increased risk of having a child with a NDD. We hypothesized that developmental exposure to a PCB mixture that proportionally mimics the 12 most prevalent PCB congeners in the MARBLES maternal serum would alter neuronal maturation in the hippocampus via modulation of dendritic arborization. Wild type mouse dams were exposed daily to vehicle (peanut oil) or the MARBLES PCB mix (0.1, 1.0, or 6.0 mg/kg) in peanut butter beginning 2 weeks prior to mating and continuing throughout gestation and lactation. Offspring weaned at postnatal day (PND) 21 were euthanized at PND 28 to collect brains for Golgi staining. The basal dendrites of Golgi-impregnated CA1 pyramidal neurons were visualized on a confocal microscope and traced using Neurolucida software for Sholl and morphometric analyses. There was an overall significant effect of PCB exposure on dendritic complexity, the total number of dendrites, and mean dendritic length, with a trending effect on the number of dendritic tips. Significant sex by dose interactions were observed for cell body area, total number of nodes, and total number of dendritic tips, indicating the effects of developmental PCB exposure may be sex-specific. Dendritic effects exhibited non-monotonic dose-response relationships: in female offspring increased mean dendritic length and tips per dendrite observed only in the 0.1 mg/kg dose group, whereas in male offspring, decreased total dendrite number, nodes, tips per dendrite, and cell body area were observed in the 1.0 mg/kg dose group. These data indicate that developmental PCB exposure causes sex-specific changes in neuronal maturation in the hippocampus. These findings underscore the need for further investigation to identify the biological reasons for the differential vulnerability of the female vs. male brain in PCB developmental neurotoxicity. Supported by NIHS (RO1 ES014901; K99 ES029537 KPK; T32 ES007059 SS; P01 ES011269 PLJ).

**1379 Assessing the Developmental Toxicity and Developmental Neurotoxicity of 26 Organophosphorus Pesticides Using a Zebrafish (Danio rerio) Larval Assay**

The US Environmental Protection Agency is evaluating methods to screen and prioritize organophosphorus (OP) pesticides for developmental toxicity and developmental neurotoxicity (DNT). One of those methods uses larval zebrafish. Developmental toxicity in zebrafish embryos/larvae is defined as lethality, non-hatching, or dysmorphology (e.g. curved body axis, edema, non-inflation of swim bladder). DNT is defined as behavioral alterations in the light/dark locomotor assay, in which the locomotor response to light stimuli under tandem light and dark conditions in a 96-well plate is quantified using a video tracking system on 6 day post fertilization zebrafish larvae. Twenty-six OP pesticides were tested for their developmental toxicity and DNT potential by exposing zebrafish embryos/larvae to the pesticide at several concentrations (≤ 100 μM nominal concentration) during the first 5 days of development (daily renewal of chemical), followed by 24 hours of depuration. Behavioral testing was conducted at six days after fertilization followed by a visual assessment of the larvae for lethality, hatching status, and dysmorphology. Behavior was only analyzed for normal animals. Five of the pesticides produced no effect in either assay: Chlorothoxyx, Dimethoate, Fosthiazate, Methamidophos, and Trichlorfon. Slightly more than half (14/26) of the OP pesticides were developmentally toxic, and half (13/26) were neurodevelopmentally toxic to the developing zebrafish. Six of the OP pesticides (Profenofos, Acephate, Coumaphos, Diclofop, Ethoprop, and Terbufos) showed significant specificity for DNT in that they were neurodevelopmentally toxic to the zebrafish larvae at doses ≥ 3 orders of magnitude below the doses that elicited death of larvae. This suggests that some of these OP pesticides could affect brain development in zebrafish at concentrations below toxic levels for embryos. This abstract may not necessarily reflect official Agency policy.

**1380 Behavioral Consequences of Retinoid Disruption during Embryonic Development in the Zebrafish**

Z. R. Holloway1, A. B. Hawkey1, C. L. Dean1, A. Akhiesh1, T. Shoval1, S. Kullman1, and E. D. Levin1. Duke University Medical Center, Durham, NC, and North Carolina School of Math and Science, Durham, NC.

A variety of environmental contaminants are known to cause neurobehavioral toxicity after developmental exposure(s), although more work is needed to understand the relevant adverse outcome pathways. Our previous work with the zebrafish model has shown that excess vitamin A (retinol) or exposure to valproic acid (VPA) which disrupts retinoidic acid (RA), alters behavioral function in larval zebrafish and into adulthood. This suggests that RA signaling may be a key adverse outcome pathway. Recent screening of Tox21 compounds has revealed a number of chemicals which may transactivate the retinoic acid receptor, including select pesticides (see below). Further work is needed to link their putative retinoid activity to adverse behavioral outcomes. The present study measured the behavioral effects of embryonic exposure to these compounds in larval and adult fish. Zebrafish embryos were exposed to vehicle (DMSO), chlorothalonil (CTN, 10-100μM), imazalil (IML, 0.1-1μM), endosulfan-I (ESF, 0.1-1nM) or buprofezin (BPF, 0.3-5μM) from 5-120 hours post-fertilization (hpf). Doses fell below the threshold for overt toxicity. Larval motility was assessed at 144hpf. Adult testing took place at 5-7 months. Each of the selected compounds significantly altered larval motility. The high doses of BPF and IML reduced motility under both light and dark conditions, while the lowest dose of IML increased motility regardless of lighting condition. The highest dose of CTN reduced motility in the dark, as did the lowest dose. The highest dose of ESF enhanced motility in the dark. Preliminary data from adult fish suggest alterations in affective functions in adulthood. CTN, ESF and IML appear to disrupt the dive response in the novel tank test, while BPF appears to enhance this response. As more fish and behavioral assays are added to this toolkit, the possible outcome pathways are expanded. The long-term consequences of these exposures may be clarified. Supported by the Duke Superfund Research Center (ES010356).
Due to their ubiquitous use, there is major concern regarding the use of flame retardants, specifically organophosphate flame retardants (OPFR) and their actions as endocrine disrupting chemicals (EDC). OPFR concentrations are detectable in urine samples and breast milk from pregnant and nursing women. The effects that maternal exposure of OPFR have on offspring metabolism is unknown. This study will provide evidence to the impact of OPFR on hypothalamic and liver gene expression in the neonate of a wild-type mouse. Breeding pairs were established using virgin females and assigned to either oil or an OPFR mixture (triphenyl phosphate, tricresyl phosphate, and tris(1,3-dichloro-2-propyl)) at 1 mg/kg each from gestational day 7 to postnatal day 14. Total litter weight was taken at birth (day 0) and basal hypothalamic and liver tissue was collected from one female and one male along with individual body weights. On postnatal day 14, the same tissue was collected from a second female and male pup from each litter along with individual body weight. RNA was extracted and processed for measurement of hypothalamic and liver genes using quantitative real-time PCR. In the hypothalamus, we found age-dependent effects for Pomc, Npy, Agpp, Cart, Esr1, Esr2, Kiss1, Lepr, Insr, Ghsr, Pparg, Bdnf, Pdyn, and Tac2 and effect of OPFR exposure on Esr1, Pparq, and Tac2 with interactions of OPFR, age, or sex in Tac2, Pdyn, Bdnf, Pparq, Kiss1, Esr1, and Cart. Specifically, OPFR exposure increased Bdnf, Pdyn, Tac, Esr1, and Pparq and decreased Kiss1 expression in females on Day 14 with no effects in males. We are currently examining liver gene expression from the same neonates focusing on genes involved in glucose, fatty acid, and triglyceride homeostasis and nuclear receptors. Collectively, these data suggest that maternal OPFR exposure has age- and sex-dependent effects of neonatal gene expression. Supported by R25ES020721 and R21ES027119.

1338 Behavioral Impairments of Infant and Adult Mice Exposed to 2,3,7,8-Tetramethyl-benzofuran In Utero and via Lactation

E. Kimura1, N. Uramaru1, G. Suzuki1, and F. Maekawa1. 1National Institute for Environmental Studies, Ibaraki, Japan; 2Japan Society for the Promotion of Science, Tokyo, Japan; and 3Nihon Pharmaceutical University, Saitama, Japan.

In utero and lactational exposure to environmental chemicals has been reported to induce behavioral abnormalities and cognitive function impairment in humans and laboratory animals. We have previously shown that maternal exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin, the most toxic congener in the group of chlorinated dioxins and furans, congeners, induced activation of aryl hydrocarbon receptor (AhR), a ligand-activated transcription factor, in various tissues, including liver and brain tissues, and led to atypical ultrasonic vocalization (USV) in infant mouse offspring. Polybrominated dibenzofurans (PBDFs) have been detected as impurities in brominated flame retardants; however, little is known about the effects of perinatal PBDF exposure on brain function. Therefore, we assessed whether PBDF exposure affects infant and adult behavior by analyzing mouse offspring born to dams treated with 2,3,7,8-tetrachlorodibenzo-furan (TCDD) by gavage at 0.9 or 45 μg/kg b.w. on gestational day 12.5 (hereafter referred to as control, L-TCDF, and H-TCDF groups, respectively). On postnatal day (PND) 1, the mRNA and protein expression levels of Cyp1a1, an AhR target gene, in the liver were markedly increased in the L-TCDF and H-TCDF groups, in a dose-dependent manner, indicating that AhR activation occurs at these exposure doses. Next, USVs emitted by infant offspring on PNDs 3-9 were recorded for 1 min in a sound-attenuated chamber. Total USV duration was significantly reduced in the H-TCDF group compared to that in the control and L-TCDF groups, indicating lower adaptivity to novel environments. These results show behavioral impairment in infant and adult stages induced by perinatal TCDD exposure, and suggest USV and adaptivity as useful endpoints to assess the developmental neurotoxicity of chemicals.
Genetic Differences in Neurological Development in Mice Exposed to Benzo[a]pyrene Exposure during Late Gestation and Lactation

A. Parton, Y. Sene, G. Rivera, C. Baldwin, L. Massie, and C. P. Curran. Northern Kentucky University, Highland Heights, KY.

Traffic-related air pollution (TRAP) is a mixture of chemicals with the predominant forms being polycyclic aromatic hydrocarbons (PAHs) (US EPA 2017). Although the effects of TRAP on lung function and heart health are well known, there is emerging evidence that TRAP and PAHs also harm the developing brain. Genetic variation can increase an individual’s resistance or vulnerability to environmental exposures. Based on previous work indicating that Cyp1a1(-/-) knockout mice were more susceptible to fetal loss and DNA adducts following maternal exposure to the PAH benzo[a]pyrene, we extended our findings to look at neurobehavioral outcomes. Pregnant mice with the Cyp1a1(+/-), Cyp1a1(+/s) or Cyp1a1(-/-) genotypes were treated with 10mg/kg BaP in corn oil-soaked food from gestational day 10 (GD10) through weaning at postnatal day 25 (P25). Offspring were tested for surface righting reflex at P5, P7 and P10 and in the negative geotaxis test at P7, P10 and P14 to assess neurological development in the neonatal period. We found no significant differences based on treatment or genotype in the surface righting reflex test at P5, P7 or P10, however, there was a significant main effect of treatment at P7. BaP-exposed mice were significantly faster than corn-oil-treated controls (P < 0.05). In the negative geotaxis test, there was a significant main effect of genotype at P7 with wild type Cyp1a1(+/-) mice having the longest latencies to turn compared with heterozygous and homozygous knockout mice. At P10, there was a significant gene × treatment interaction (P < 0.001). BaP-exposed heterozygous mice took significantly longer to turn compared with corn-oil-treated mice and BaP-exposed wild type and knockout mice. There were no significant differences at P14. In summary, these findings suggest there is a gene-dose effect for negative geotaxis but no delay in development of the surface righting reflex. Instead, the shorter latencies in BaP-exposed mice are suggestive of a hyperactive phenotype.

Developmental Exposure to Polychlorinated Biphenyls (PCBs) Induces Increased Nerve Density and Inflammation in the Bladder and Voiding Changes in Young Adult Mice

K. P. Keil1,2, S. Sethi1, D. E. Bjorling2, and P. J. Lein1. 1University of California Davis, Davis, CA; and 2University of Wisconsin-Madison, Madison, WI.

Lower urinary tract symptoms (LUTS) affect people of all ages. Bladder inflammation is a common feature, yet underlying mechanisms driving the onset and progression of LUTS are poorly defined. Developmental exposure to environmental neurotoxins is implicated in the pathogenesis of many neurodevelopmental diseases, but whether they increase individual LUTS risk remains unknown. We tested the hypothesis that developmental exposure to polychlorinated biphenyls (PCBs) increases bladder inflammation, nerve density and contributes to abnormal voiding in young adult mice. Wild type mice were exposed through gestation and lactation to 0, 0.1, 1 or 6 mg/kg/d PCB mix via the maternal diet. The PCB mix proportionally mimics the 12 most prevalent PCB congeners in serum of women at increased risk of having a male child with a neurodevelopmental disorder. Bladder tissue for immunohistochemistry, bladder metrics and spontaneous void spot assays were collected from postnatal day 28-31 mice. Effects of PCBs on bladder were sex-and dose-dependent. Compared to vehicle controls, PCBs (0.1 mg/kg/d) increased CD45-positive immune cells in the bladder in both sexes. PCBs (1 mg/kg/d) also altered immune cell localization by increasing CD45-positive cells within bladder epithelium in male mice. Inflammation can lead to nerve hyperplasia, therefore we examined abundance of beta tubulin-positive nerve fibers adjacent to epithelium. This was increased by PCBs (6 mg/kg/d) in males, and this effect was greater in males vs. females. PCBs also altered bladder metrics and voiding. PCBs (6 mg/kg/d) increased bladder volume, and PCBs (1 and 6 mg/kg/d) decreased the number of urine spots sized 0-0.1cm in male mice. Urine creatinine and protein were unaltered, but urine ATP was increased from postnatal day 28-31 mice. Effects of PCBs on bladder were sex- and chemistry, bladder metrics and spontaneous void spot assays were collected at weaning at postnatal day 25 (P25). Offspring were tested for surface righting reflex at P5, P7 and P10 and in the negative geotaxis test at P7, P10 and P14 to assess neurological development in the neonatal period. We found no significant differences based on treatment or genotype in the surface righting reflex test at P5, P7 or P10, however, there was a significant main effect of treatment at P7. BaP-exposed mice were significantly faster than corn-oil-treated controls (P < 0.05). In the negative geotaxis test, there was a significant main effect of genotype at P7 with wild type Cyp1a1(+/-) mice having the longest latencies to turn compared with heterozygous and homozygous knockout mice. At P10, there was a significant gene × treatment interaction (P < 0.001). BaP-exposed heterozygous mice took significantly longer to turn compared with corn-oil-treated mice and BaP-exposed wild type and knockout mice. There were no significant differences at P14. In summary, these findings suggest there is a gene-dose effect for negative geotaxis but no delay in development of the surface righting reflex. Instead, the shorter latencies in BaP-exposed mice are suggestive of a hyperactive phenotype.

Methylmercury is a potent neurotoxicant, however the mechanisms involved in its neurotoxicity are not elucidated. We recently found that the expression of TNF-α (tumor necrosis factor-α), an inflammatory cytokine, was specifically induced in the brains of mice, which administered with methylmercury causes neuronal damage. Thus, elucidation of the mechanisms involved in the induction of TNF-α expression could be a clue to reveal the mechanisms related to methylmercury-induced neurotoxicity. This study aimed to identify the responsible cells that involved in the induction of TNF-α expression by methylmercury in mouse brain and to approach the mechanisms. Increase of TNF-α mRNA level was observed in mice cerebrum cortex and cerebellum 7 days after the subcutaneous injection of methylmercury (25 mg/kg). We performed in situ hybridization using the brains and found that TNF-α expressing cells were observed in the cerebrum cortex and cerebellum. Next, immunostaining was performed using antibodies against GFAP or Iba1, which are marker proteins for astrocytes or microglia respectively. As a result, TNF-α expressing cells are positive for Iba1 staining but negative for GFAP staining. This indicates microglia are mainly involved in the induction of TNF-α expression by methylmercury in mouse brain. We next investigated the effect of methylmercury on TNF-α expression using primary mouse microglia. Exposure of the cells to methylmercury increased TNF-α mRNA level in a dose- and time-dependent manner. This increase was abolished by pretreatment with transcription inhibitor. These results suggest that methylmercury induces TNF-α expression in microglia via the activation of some transcription factors. It has been reported that transcription factor NF-kB and AP-1 are mainly involved in the induction of TNF-α expression in microglia. Exposure of the cells to methylmercury resulted in the phosphorylation of p65 and c-Jun, which are subunits of NF-kB and AP-1. However, transfection of the siRNA for c-Jun did not affect induction of TNF-α expression by methylmercury, while the siRNA for p65 partially suppressed the induction. Our result indicates that NF-kB is a transcription factor that partly involved in the induction of TNF-α expression by methylmercury in microglia.

Manganese is an essential metal that becomes neurotoxic at elevated levels. Yet, mechanisms by which manganese homeostasis is regulated in the brain are unclear. Loss-of-function mutations in SLC30A10, which codes for a cell-surface localized manganese efflux transporter expressed in the brain and liver, induce familial manganese neurotoxicity in humans, suggesting the major route of manganese excretion, manganese levels in the brain and blood under basal conditions. Further, while transport into bile is thought to be a major route of manganese excretion by methylmercury in mouse brain; we next investigated the effect of methylmercury on TNF-α expression using primary mouse microglia. Exposure of the cells to methylmercury increased TNF-α mRNA level in a dose- and time-dependent manner. This increase was abolished by pretreatment with transcription inhibitor. These results suggest that methylmercury induces TNF-α expression in microglia via the activation of some transcription factors. It has been reported that transcription factor NF-kB and AP-1 are mainly involved in the induction of TNF-α expression in microglia. Exposure of the cells to methylmercury resulted in the phosphorylation of p65 and c-Jun, which are subunits of NF-kB and AP-1. However, transfection of the siRNA for c-Jun did not affect induction of TNF-α expression by methylmercury, while the siRNA for p65 partially suppressed the induction. Our result indicates that NF-kB is a transcription factor that partly involved in the induction of TNF-α expression by methylmercury in microglia.

Activity of SLC30A10 in the Digestive and Nervous Systems Regulates Brain Manganese under Basal and Neurotoxic Conditions Respectively

Exposure of the cells to methylmercury resulted in the phosphorylation of p65 and c-Jun, which are subunits of NF-kB and AP-1. However, transfection of the siRNA for c-Jun did not affect induction of TNF-α expression by methylmercury, while the siRNA for p65 partially suppressed the induction. Our result indicates that NF-kB is a transcription factor that partly involved in the induction of TNF-α expression by methylmercury in microglia.
1390 SLC30A10 Mutation Involved in Parkinsonism Results in Manganese Accumulation within Nano-Vesicles of the Golgi Apparatus Revealed by Synchrotron X-Ray Fluorescence Imaging

SLC30A10 is a cell surface protein involved in the efflux of Mn and protects the cell against Mn toxicity. Disease causing mutations block the efflux activity of SLC30A10, resulting in Mn accumulation. Determining the intracellular localization of Mn when disease-causing SLC30A10 mutants are expressed is essential to elucidate the mechanisms of Mn neurotoxicity. Here, using cryogenic nano-imaging (<50 nm resolution) indicated that Mn was trapped in single vesicles within the Golgi apparatus. Our results confirm the role of SLC30A10 in Mn efflux and the accumulation of Mn in cells expressing the disease causing SLC30A10-A105-107 mutation. Moreover, we identified sub-organellar Golgi nano-vesicles as the main compartment of Mn accumulation in SLC30A10 mutants suggesting interactions with the vesicular trafficking machinery as a cause of the disease.

Manganese (Mn) is an essential metal that can be neurotoxic when elevated exposure occurs leading to parkinsonian-like syndromes. Mutations in the SLC30A10 gene have been identified in new forms of familial parkinsonism. SLC30A10 is a cell surface protein involved in the efflux of Mn and protects the cell against Mn toxicity. Disease causing mutations block the efflux activity of SLC30A10, resulting in Mn accumulation. Determining the intracellular localization of Mn when disease-causing SLC30A10 mutants are expressed is essential to elucidate the mechanisms of Mn neurotoxicity. Here, using cryogenic nano-imaging (<50 nm resolution) indicated that Mn was trapped in single vesicles within the Golgi apparatus. Our results confirm the role of SLC30A10 in Mn efflux and the accumulation of Mn in cells expressing the disease causing SLC30A10-A105-107 mutation. Moreover, we identified sub-organellar Golgi nano-vesicles as the main compartment of Mn accumulation in SLC30A10 mutants suggesting interactions with the vesicular trafficking machinery as a cause of the disease.

1391 LRRK2 Kinase Activity Is Involved in Manganese-Induced Oxidative Stress, Inflammation, and Apoptosis in Microglia

Chronic exposure to excess manganese (Mn) induces a Parkinson’s disease (PD)-like neurological disorder referred to as manganism, however, the molecular mechanisms underlying Mn-induced neurotoxicity are not fully understood. The leucine-rich repeat kinase 2 (LRRK2) and its genetic mutations have been associated with the pathogenesis of familial and sporadic PD. LRRK2 is a multi-domain protein including GTPase and kinase domains. Several environmental toxicants such as rotenone have been reported to enhance LRRK2 kinase activity, indicating that environmental toxicants interact with LRRK2, contributing to LRRK2-induced PD pathogenesis. In the present study, we investigated if Mn increases LRRK2 kinase activity, contributing to Mn-induced toxicity in HMC3 microglia and RAW264.7 cells. We also tested if SLC30A10 mutations in single vesicles within the Golgi apparatus. Our results confirm the role of SLC30A10 in Mn efflux and the accumulation of Mn in cells expressing the disease causing SLC30A10-A105-107 mutation. Moreover, we identified sub-organellar Golgi nano-vesicles as the main compartment of Mn accumulation in SLC30A10 mutants suggesting interactions with the vesicular trafficking machinery as a cause of the disease.

1392 Urinary Cadmium and Cognitive Function

F. Scinicariello.

Gradual cognitive decline, usually affecting memory, is the hallmark feature of dementia and Alzheimer’s disease. Cadmium (Cd) is a widespread industrial and environmental pollutant, with tobacco and food being the primary sources. Cd has a long biological half-life (15-30 years in humans) mainly due to its low rate of excretion from the body and urinary excretion of Cd is assumed to mirror chronic exposure to Cd. To examine the association between urinary cadmium and cognitive functions. Multivariate linear regression were used to analyze the association of urinary cadmium with cognitive function in adults 60 and older, participants in the National Health and Nutrition Examination Survey cycles 2011–2012 and 2013–2014. Multiple cognitive domains were assessed: 1) verbal episodic memory assessed by the Consortium to Establish a Registry for Alzheimer’s Disease (CERAD) Word List Learning Test, the CERAD Word List recall Test, and the CERAD Saving Score; 2) semantic fluency, executive functions assessed by the Animal Fluency test; and 3) attention and executive function assessed by the digit symbol substitution test (DSS). The analyses were performed with urinary natural log-transformed Cd expressed as µg/g of urinary creatinine (InUCd) stratified by age group (60 - 69 years, and 70 years and older) with age years as continuous co-variate. Result: Decreased cognitive function domains were independently associated with increased InUCd in adults 70 and older, whereas the decrease in the age group 60 - 69 years was not statistically significant. For each InUCd there was a decrease in the verbal episodic memory tests CERAD-word list, recall (β = -0.70; 95% CI: -1.02, -0.38); CERAD-Delayed recall (β = -0.60; 95% CI: -1.21, -0.07); and CERAD-saving score (β = -0.85; 95% CI: -1.17, -0.35). For each InUCd there was a decrease in the animal fluency test (β = -1.20; 95% CI: -2.13, -0.26) and in the DSS (β = -1.20; 95% CI: -2.13, -0.26). This is the first study reporting an association of urinary cadmium, which is an indicator of cumulative body burden levels with poorer cognitive functioning in elderly aged 70 years and over using a nationally representative sample. Disclaimer: The findings and conclusions in this presentation have not been formally disseminated by CDC/ATSDR and should not be construed to represent any agency determination or policy.

1393 Sex-Dependent Effect of Arsenic on Hippocampal Neuronal Apoptosis and Cognitive Impairment in Rats: Involvement of BMP and BDNF Signaling

Recent studies report a sex-dependent effect of arsenic on cognitive performances; however, the sex-dependent effect of arsenic on hippocampal neurons and learning-memory functions remain elusive. Therefore, in the present study, we were interested in identifying the effect of arsenic on hippocampal neurons of male and female rats. Here, we identified that arsenic exposure induced greater hippocampal neuronal apoptosis, marked by caspase-3 activation and Terminal deoxynucleotidyl transferase dUTP nick-end labeling, within the male rat brain compared to female. Correlating these observations with cognitive performances indicated a more severe reduction in transfer latency time and learning-memory ability for passive avoidance and Y-Maze tests respectively in arsenic-exposed male compared to female rats. Supportively, we noticed that noggin or recombinant BDNF supplementation reduced the arsenic-induced hippocampal neuronal apoptosis and cognitive loss, and here we further identified that arsenic caused a greater increase in BMP2/Smad and decreased BDNF/TkRk signaling as responsible for arsenic-induced hippocampal neuronal apoptosis and cognitive loss, and here we further identified that arsenic caused a greater increase in BMP2, BMP2P and p-Smad levels and decrease in BDNF and p-TkRk levels in arsenic-exposed male compared to female rats. 47 tadpoles were exposed stage III to IV to arsenic and then sacrificed at the age of 37 days. We noticed that noggin or recombinant BDNF supplementation reduced the arsenic-mediated loss in transfer latency time and learning-memory ability for passive avoidance and Y-Maze tests respectively in both the sexes. Overall, our study suggests that men may be more prone to arsenic-induced loss in cognitive performance and via increased BMP2/Smad and decreased BDNF/TkRk-dependent hippocampal neuronal apoptosis.

1394 Lead (Pb) Exposure Induces Biphasic Changes in Brain Development and Disrupts Thyroid Hormone Physiology in the Developing Tadpole Brain

Lead (Pb) poisoning during early development is associated with behavioral deficits, including low IQ. The specific neural mechanisms by which Pb causes these effects is still not fully understood. To address this issue, experiments assessed the effects of Pb on cellular and molecular mechanisms of brain development in Xenopus laevis tadpoles. We exposed stage III to IV tadpoles to Pb baths ranging from 10 ppb to 10,000 ppb and sacrificed them at various time points post-onset of treatment. Within the first few days of treatment,

1. Cadmium, a neurotoxic environmental compound, produces cognitive disorders, although the mechanism remains unknown. Cadmium induces a more pronounced cell death on cholinergic neurons from basal forebrain (BF), mediated, in part, by increase in Aβ and phosphorylated Tau protein levels, which may explain cadmium effects on learning and memory processes. Cadmium downregulates the expression of heat shock proteins (HSPs) HSP 90, HSP70 and HSP27, and of HSF1, the master regulator of the HSP pathway. This downregulation of HSP expression is observed in BF neurons from our laboratory using non-human primates in which we found dysfunctional but an intact nigrostriatal dopaminergic system suggesting that the neuropathology of chronic Mn exposure is different than that observed in PD. Ongoing studies aim to further characterize the behavioral effects and neuropathology of elevated Mn in SLC39A14-KO male and female mice.

1398 Identification of Accessible Cysteine Residues in Neuronal-Derived Sepiapterin Reductase as Targets of Methyl Mercury

S. Yang, Y. Jan, V. Mishin, D. Heck, J. Richardson, and J. Laskin

1. Rutgers University School of Public Health, Picartoway, NJ; 2. Ernest Mario School of Pharmacy, Picartoway, NJ; 3. New York Medical College, Valhalla, NY; and 4. Florida International University, Miami, FL.

Methylmercury (MeHg) is an important environmental contaminant known to cause neurotoxicity. Our laboratories have examined the mechanism of action of MeHg using SK-N-MC cells, a cell line derived from a human brain neuroepithelium. In SK-N-MC cells, MeHg binds to sulfhydryl containing proteins, treatment of the cells with buthionine sulfoximine (BSO) a gamma-glutamylcysteine synthetase inhibitor which reduces levels of cellular glutathione (GSH), enhanced MeHg protein binding, BSO also enhanced MeHg cytotoxicity in the cells (LC50 = 3.1 µM and 3.8 µM in the presence of BSO, respectively). We identified sepiapterin reductase (SPR) as target for MeHg. SPR is an NADPH-dependent enzyme that catalyzes the reduction of sepiapterin to dihydrobiopterin (BH2), a precursor for tetrahydrobiopterin (BH4), a cofactor critical for enzymes mediating the biosynthesis of neurotransmitters. SPR also mediates redox cycling, catalyzing one electron reduction of reductase active chemicals including quinones; rapid reaction of these radicals with molecular oxygen generates reactive oxygen species. Using a recombinant human enzyme, MeHg was found to inhibit both the reduction of sepiapterin and quinone redox cycling (IC50 = 4.2 and 5.1 µM, respectively). Cysteine readily suppressed inhibition of SPR enzyme activities indicated that MeHg reacts with accessible thiols in the enzyme forming reversible thiol mercuration.

1397 Cadmium Alters Heat Shock Protein Pathways in SN56 Cholinergic Neurons, Leading to aβ and Phosphorylated Tau Protein Generation and Cell Death

Cadmium, a neurotoxic environmental compound, produces cognitive disorders, although the mechanism remains unknown. Cadmium induces a more pronounced cell death on cholinergic neurons from basal forebrain (BF), mediated, in part, by increase in Aβ and phosphorylated Tau protein levels, which may explain cadmium effects on learning and memory processes. Cadmium downregulates the expression of heat shock proteins (HSPs) HSP 90, HSP70 and HSP27, and of HSF1, the master regulator of the HSP pathway. This downregulation of HSP expression is observed in BF neurons from our laboratory using non-human primates in which we found dysfunctional but an intact nigrostriatal dopaminergic system suggesting that the neuropathology of chronic Mn exposure is different than that observed in PD. Ongoing studies aim to further characterize the behavioral effects and neuropathology of elevated Mn in SLC39A14-KO male and female mice.

1395 Refining In Vitro Models in Neurotoxicology: Comparing Biological Responses in a Neuronal Cell-Type after Manganese Nanoparticle Exposure

S. H. Pradhan, H. Lulan, and C. M. Sayes, Baylor University, Waco, TX.

Manganese (Mn) is an industry-used agent. At levels of overexposure, Mn has been implicated in neurodegenerative complications such as the manifestation or exacerbation of Parkinson-like or Parkinsonian symptoms, i.e. tremor production and gait difficulties. Mn influx is localized in the basal ganglia and is associated with neuronal death of dopaminergic cells in this region. Biological Mn acts as a deoxidizing and desulfurizing agent, creating two biochemical mechanisms for which apoptosis of dopaminergic cells can occur. In the deoxidization pathway, Mn acts as a reducing agent and has implications related to the production of reactive oxygen species and sustained cellular oxidative stress, which often induces apoptosis. In the desulfurization pathway, the high affinity of Mn to bind with sulfur perturbs the normal function of amino acids, such as a cysteine and methionine, inducing apoptosis. In addition, Mn acts as an inhibitor of the enzymes involved in the desulfurization pathway, which interferes with the cerebral spinal fluid. Ongoing in vivo imaging experiments are assessing the effects of Pb on developing dendritic arbors. Collectively, these results reveal new information about how Pb exerts toxic effects on brain development and suggests that Pb-related toxicity may be mediated at least in part by compromised TH physiology in the developing brain.

1396 SLC39A14 Knockout Mice: A Genetic Model to Understand Manganese-Induced Neurotoxicology

Chronic exposure to high levels of manganese (Mn) results in a debilitating form of parkinsonism with dystonia and cognitive function deficits in humans and non-human primates. SLC39A14 is now recognized as a Mn influx transporter. Homozygous loss of function genetic mutations in humans result in behavioral manifestations of parkinsonism with dystonia that is not responsive to typical treatment of idiopathic Parkinson’s disease (IPD). The use of the SLC39A14 knock-out (KO) mouse model provides us with a powerful tool to study and describe the neuropathogenesis of chronic Mn exposure along the lifespan. Preliminary characterization of the locomotor behavior of SLC39A14-KO male and female mice show impairment in locomotor behavior as adults relative to age-matched wildtype (WT). Preliminary analysis of striatal dopamine concentrations using HPLC with electrochemical detection indicates no apparent differences between SLC39A14-KO and WT male mice dopamine levels. Similarly, there was no apparent differences in tyrosine hydroxylase immunostaining in the striatum in SLC39A14-KO versus WT adult male mice. Blood Mn concentrations in the SLC39A14-KO adult male mice (941 ± 8.45 µg/L, n=5) were on average nearly 40 times those of WT mice (24.63 ± 5.39 µg/L; n=6) confirming the accumulation of Mn in the blood (p<0.0001). These preliminary results indicate that SLC39A14-KO mice with high blood Mn concentrations express significant locomotor impairment as adults in the apparent absence of a change in dopamine concentrations and tyrosine hydroxylase levels in the striatum. Our preliminary findings suggest that the locomotor deficits resulting from the accumulation of Mn in the SLC39A14-KO male mice are not associated with the loss of nigrostriatal dopaminergic terminals in the striatum. These studies are consistent with previous results from our laboratory using non-human primates in which we found dysfunctional but an intact nigrostriatal dopaminergic system suggesting that the neuropathology of chronic Mn exposure is different than that observed in PD. Ongoing studies aim to further characterize the behavioral effects and neuropathology of elevated Mn in SLC39A14-KO male and female mice.
trast, two additional cysteines in SPR (Cys133 and Cys234) were not modified by MeHg and these amino acids are structural elements of the enzyme and likely inaccessible to MeHg. Taken together our data demonstrate that accessible 3 cysteine residues in SPR are important targets for MeHg. By inhibiting SPR, neurotransmitter biosynthesis is suppressed, a process that can result in MeHg-induced neurotoxicity. Supported by NIH grants AR055073, NS108956, NS079249 and ES005022.

1399 Neurotoxicity of Metal Mixtures Containing Cadmium, Lead, and Manganese in the Nematode Caenorhabditis elegans

B. Tang, K. Xue, P. Williams, J. Wang, and L. Tang. University of Georgia, Athens, GA.

Heavy metals are a class of persistent environmental toxicants and harmful to animals and human health. Cadmium (Cd) and lead (Pb) are two of the most common toxic heavy metals that have been linked with cancers and malfunction of nervous system, while contamination of manganese (Mn) is usually coexisted with Cd and Pb in environmental and occupational settings. Studies are regularly conducted to examine the toxic effects of individual metals, however, potential health and toxic effects of the mixture containing two or more heavy metals are largely unknown. In this study, we investigated toxic effects of single Cd, Pb and Mn as well as their binary and ternary mixtures in the nematode Caenorhabditis (C.) elegans. The toxic outcomes, including effects on growth, reproduction and feeding behavior, were measured using high-throughput platform analysis (COAPS Biosort). The transgenic strain BY250 (Pdat-1::GFP) that expresses GFP in dopaminergic neurons was used to further explore the neurodegenerative effects induced by single metals or their mixtures. The combination index (CI) for mixtures effect was calculated using isobolograms methods. Following exposure to single metals and mixtures (combination concentration at 0 to 4 times of EC50 of each single metal), we found significant toxic effects on growth, reproduction, and feeding behavior in C. elegans. For single metals, the toxicity order for growth, reproduction and feeding was similar, Pb>Cd>Mn. For metal mixtures, the Mn+Cd induced a less-than-additive (antagonistic) effect in C. elegans whereas the mixture of Cd+Pb, Pb+Mn, and Cd+Pb+Mn induced a more-than-additive (synergistic) effect. About 65% of worms exposed to mixture of Cd+Mn exhibited dopaminergic neurodegenerative toxic lesions, and such neurotoxic effects were found in 85%, 70% and 75% of worms exposed to mixture of Cd+Pb, Mn+Pb and Cd+Pb+Mn, respectively. These results showed combinatory toxic and neurodegenerative effects of heavy metal mixtures, with Cd, Pb, and Mn and future studies will be focused on characterization of dose-response patterns and identification of potential molecular mechanisms in C. elegans model.

1400 Methylmercury In Vivo Preferentially Stimulates Spontaneous GABAergic Synaptic Transmission in Brainstem Hypoglossal Motorneurons (MNs) of Mouse

Y. Yuan, J. M. Bailey, J. B. Spitsbergen, and W. D. Atchison. Michigan State University, East Lansing, MI.

Amyotrophic lateral sclerosis (ALS) is a progressive, degenerative, and fatal neurological disorder characterized by decreased skeletal muscle function due to loss of upper and/or lower motor neurons (MNs). The exact cause of ALS remains elusive. Gene-environment interactions likely contribute to the etiology of ALS. We previously showed that chronic exposure of mice overexpressing the human superoxide dismutase 1 (hSOD1) gene mutation (hSOD1<sup>10</sup>); G93A) mouse model for ALS, to methylmercury (MeHg), accelerates the onset of ALS-like phenotype in hSOD1 mice. We also showed that in vivo MeHg exposure preferentially potentiates AMPA-mediated currents, while simultaneously reducing GABA-mediated currents in brainstem hypoglossal MNs from G93A mice. In those studies, both AMPA- and GABA-mediated currents were evoked by direct applications of AMPA and GABA onto the postsynaptic hypoglossal MNs. Thus, the MeHg-induced effects on these currents appear to be a postsynaptic mechanism of MeHg actions. To test if in vivo MeHg exposure also acts presynaptically to affect synaptic function, we examined changes in spontaneous glutamatergic and GABAergic synaptic transmission in hypoglossal MNs in brainstem slices prepared from G93A, hSOD1<sup>10</sup>; G93A mice and WT mice following in vivo exposure to MeHg for defined time periods. Daily exposure of mice to 3 ppm MeHg via drinking water began at postnatal day 28 (PND28). At PND47, 64 and 84, fresh brainstem slices were prepared and spontaneous excitatory or inhibitory postsynaptic currents (eSPSCs or iSPSCs) were examined using whole cell recording techniques. Untreated littermates were sacrificed at the same time points to serve as control. MeHg exposure appeared to potentiate spontaneous release of GABA expressed as an increase in iSPSC frequency but had no significant effect on eSPSCs in hypoglossal MNs. Examination of the action potential firing pattern also revealed no significant difference between control and MeHg-treated mice. Thus, consistent with our previous in vitro studies, chronic in vivo treatment with MeHg appears to preferentially affect GABAergic systems. Supported by NIH grants ES024064.

1401 Huntingtin and Cadmium Induce Striatal Neurotoxicity and Neurodegeneration via Altered Metal Transport and Protein Kinase C Dependent Oxidative Stress and Apoptosis Signaling Mechanisms

M. G. Thomas, J. A. Jiménez, M. McVilin, M. A. Saito, and G. F. Kwakye. 1Oberlin College, Oberlin, OH; and 2Woods Hole Oceanographic Institution, Woods Hole, MA.

Huntington’s disease (HD) is functionally linked to environmental factors including cigarette use and dyshomeostasis in the levels of metals. Interestingly, one of the most abundant heavy metals in cigarettes is cadmium (Cd), which also accumulates in the striatum and causes neurotoxicity upon exposure. Thus, we hypothesized that heterozygous huntingtin (HTT), responsible for the majority of cases of HD in patients, in combination with Cd exposure would cause neurotoxicity and neurodegeneration via increased intracellular accumulation of Cd and activation of oxidative stress signaling mechanisms in a mouse striatal cell line model of HD. We report that heterozygous HTT striatal cells are significantly more susceptible to Cd-induced cytotoxicity as compared to wild-type HTT cells upon exposure for 48 h. The heterozygous HTT and Cd-induced cytotoxicity led to a NADPH oxidase (NOX) mediated oxidative stress that was attenuated by exogenous antioxidants and a NOX inhibitor, apocynin. Heterozygous HTT coupled with Cd exposure caused increased expression of protein kinase C ζ (PKCζ) and other key oxidative stress proteins levels, enhanced the activation of caspase-9 and caspase-3 mediated apoptosis, and blocked the overexpression of extracellular signal-regulated kinase (ERK). We observed significantly greater intracellular accumulation of Cd and reduced expression of divalent metal transporter 1 (DMT1) protein in the heterozygous HTT striatal cells upon Cd exposure. Treatment with zinc, manganese, and iron as well as exogenous antioxidants significantly attenuated the Cd-induced cytotoxicity. Collectively, these results demonstrate that heterozygous HTT exhibits greater neurotoxic properties when coupled with Cd exposure to cause cell death via caspase mediated apoptosis, altered metal transport, and modulation of ERK and PKCζ dependent oxidative signaling mechanisms.

1402 Role of Internal Calcium Pools during Acute Methylmercury-Mediated Increase in Internal Calcium Concentration in C57BL6J Mouse Spinal Cord Slices

N. Rivera, M. Rios-Cabanillas, and W. Atchison. Michigan State University, East Lansing, MI.

Methylmercury (MeHg) is an environmental organic contaminant of current concern. In isolated motor neurons in culture, a key contributor to MeHg neurotoxicity is dysregulation of intracellular calcium (Ca<sup>2+</sup>), homeostasis and subsequent hyperexcitability. The MeHg-mediated increase in Ca<sup>2+</sup> concentration (Ca<sup>2+</sup><sub>calc</sub>) occurs in two kinetically distinct phases. Phase 1 is due to Ca<sup>2+</sup> release from the cytosolic Ca<sup>2+</sup> pools: mitochondria and smooth endoplasmic reticulum (SER). Phase 2 corresponds to Ca<sup>2+</sup> entry into the cell across the plasma membrane. The relative contributions that the mitochondria and SER have to MeHg-induced increases in motor neuron (Ca<sup>2+</sup>), have not yet been reported. The aim of this project is to elucidate the role of Ca<sup>2+</sup> pools to elevations of Ca<sup>2+</sup> following an acute 20μM MeHg exposure. Adult C57BL6J mice spinal lumbar slices were exposed for 15min to MeHg through continuous superfusion. To record Ca<sup>2+</sup> changes in motor neurons we used Fluo4-AM, a fluorescent Ca<sup>2+</sup> indicator. Data were collected at 15min and 1hr-post MeHg, alone or in the presence of cyanobyl cyanide m-chlorophenyl hydrazone (CCK), and thapsigargin (THP), which uncouple mitochondrial oxidative phosphorylation, and block Ca<sup>2+</sup> uptake through the endoplasmic reticulum Ca<sup>2+</sup>-ATPase (SERCA), respectively. CCK causes release of mitochondrial Ca<sup>2+</sup> by depolarizing the mitochondrial inner membrane potential. We hypothesize that these agents will increase MeHg-mediated Ca<sup>2+</sup> increase, compared to MeHg treatment alone, especially during Phase 1, which depends on Ca<sup>2+</sup> stores. MeHg alone significantly increased Fluo4 fluorescence from baseline at both 15min MeHg (50%) and 1hr-post MeHg exposure (56%). MeHg+THP+CCK treatment significantly increased fluorescence from baseline at 1min (68%) followed by a significant decrease at 1hr-post MeHg (76%). MeHg+THP+CCK treatment significantly decreased Ca<sup>2+</sup> fluorescence at 1hr-post MeHg.
1403 Early Postnatal Manganese Exposure Causes Lasting Changes in Prefrontal Cortex Catecholaminergic Systems Accompanied by Arousal Dysregulation and Heightened Behavioral Reactivity

T. Conley, S. Beaudin, S. Ladey, C. Forna, B. Strupp, W. Uribe, T. Kahn, and D. Smith. 1University of California Santa Cruz, Santa Cruz, CA; 2University of Illinois College of Medicine, Peoria, IL; and 3Cornell University, Ithaca, NY.

Recent animal studies from our group have shown that developmental postnatal Mn exposure causes lasting deficits in selective attention, impulse control, and arousal regulation, recapitulating analogous findings from epidemiological studies in children. Given the critical role that the prefrontal cortex (PFC) catecholaminergic systems play in regulating these functions, we determined the effect of early postnatal Mn exposure (0, 25, or 50 mg Mn/kg/day orally PND 1-21 or lifelong) on evoked neurotransmitter release in the PFC, dentritic spine density on pyramidal PFC neurons, PFC catecholaminergic system protein levels, and behavioral reactivity in the open field (OF; 5 days). Postnatal Mn exposure caused increased OF activity in each of the 5 daily sessions, but only over the first 5 min of each session, indicating deficits in arousal regulation and heightened behavioral reactivity. Mn also reduced the evoked release of norepinephrine (NE) in the PFC, and caused lasting changes in the levels of multiple DA/NE synaptic proteins. These changes included decreased tyrosine hydroxylase, DA and NE transporters, and D1 receptor protein levels, along with increased D2 receptor levels. However, PFC alpha-2A adrenergic receptor levels and dentritic spine density on pyramidal neurons were unchanged by Mn. In light of the possibility of mitochondrial neuroinflammation in altering PFC catecholaminergic systems, we assessed gial fibrillary acidic protein (GFAP), complement C3, and S100A10 protein levels as markers of reactive astrocyes expressing A1 pro-inflammatory (C3) or A2 anti-inflammatory (S100A10) phenotypes. Results show that Mn caused a lasting increase in A2 astrocytes (based on GFAP colocalization analyses), which may contribute to Pb-induced amyloid plaques in brain. The implication on Aβ accumulations in the brain and blood vessel endothelium following Pb exposure. Quantifying fluorescent signals revealed the hypothesis that Pb exposure altered RAGE’s expression and function in the CP, contributing to Pb-induced amyloidal aggregation. Freshly dissected CP, adopting perivascular and intravascular structures using custom in-house developed software. Data showed that Pb exposure increased permeability surface area product (PS), indicating that Pb disrupted the mouse blood-brain barrier system. It is agreed with our hypothesis that Pb exposure at toxic levels would directly damage the brain and induce dementia by allowing blood contents to escape into the brain parenchyma. The implication on Aβ accumulations in the brain and blood vessel affected by various doses of Pb is currently under investigation. Supported by NIH/NIEHS R01 ES027078.

1404 Autophagy: An Early Pathogenic Target of Manganese but a Therapeutic Target of Drp1 Inhibition

C. Sportelli, R. Z. Fan, M. P. Helley, T. R. Guilarte, and K. Tieu. 1Florida International University and Plymouth University (UK), Miami, FL; and 3Florida International University, Miami, FL.

The precise mechanism of manganese (Mn) inducing parkinsonism is not known. At relatively high concentrations, however, this heavy metal has been well reported to induce mitochondrial dysfunction and more recently, mitochondrial fission and autophagic impairment. Given the complex relationship between mitochondria and autophagy, it is not fully understood whether mitochondrial dysfunction precedes impaired autophagy or vice versa. Furthermore, it is not clear if these impairments are the cause or consequence of cytoxicity. To this end, we first performed dose-response studies to establish the LC50 values for multiple cell lines after 24h of Mn treatment: The human M17 dopaminergic neuronal cells (21.7 ± 4.4 μM), the N27 rat dopaminergic neuronal cells (266 ± 7.2 μM) and HeLa cells (32.3 ± 8.7 μM). Next, we deter- mined the effect of Mn on autophagy flux using the autophagy reporter HeLa cells stably overexpressing mRFP-GFP-LC3. Mn, at 62.5 μM, severely impaired autophagy flux. In M17 and N27 neuronal cells, autophagy was also blocked by 125 μM Mn as evidenced by a statistically significant increase in LC3 III and P62 puncta. Using transgenic mice with the same autophagy reporter system as our stable HeLa cells, we injected Mn (50mg/kg, s.c) every 3 days (0, 3, 6) for 3 doses, killed on day 7 and then quantified for autophagosomes and autolysosomes in the brain. Consistent with the in vitro data, Mn treatment significantly impaired autophagy flux in these animals. Interestingly, genetically knocking down dynamin related protein 1 (Drp1), which is commonly known as a mitochondrial fission protein, significantly attenuated autophagy blockade induced by Mn in all of our 3 cell types. To investigate the possibility that Mn impaired autophagy via mitochondrial dysfunction, we assessed autophagy using the Seahorse XFe96 Extracellular Flux Analyzer. mitochondrial membrane potential and mitochondrial morphology in the Mn-treated cell models as described above. None of these mitochondrial parameters were altered. In summary, our results indicate that Mn is capable of blocking autophagy at an environmentally relevant concentration that does not induce mitochondrial dysfunction and cytotoxicity in both neuronal and non-neuronal cells. The discovery that the pathogenic and protective mech- anisms of Mn and Drp1 inhibition, respectively, intersect at the autophagic pathway is novel and suggestive of a therapeutic target.

1405 Pb-Induced Neurotoxicology of the Brain Barrier System: New Implications

H. Gu, P. Territo, S. Persohn, A. Bedwell, Z. Chen, W. Zheng, and Y. Du. 1Indiana University School of Medicine, Indianapolis, IN; and 2Purdue University, West Lafayette, IN.

Lead (Pb) is an environmental factor has been suspected of contributing to the dementia including Alzheimer’s disease (AD). Our previous study has shown that Pb exposure at the subtoxic dose increased brain levels of beta-amyloid (Aβ) and amyloid plaques, a pathological hallmark for AD, in APP transgenic mice possibly by inhibiting Aβ clearance in the blood-CSF barrier (BCB). However, it remains unclear how toxic levels of Pb affect Aβ clearance in the blood-brain barrier system. This study was designed to investi- gate whether chronic exposure of toxic Pb affected the permeability of the blood-brain barrier system by using the Dynamic contrast-enhanced CT (DCE-CT) method. To test Pb toxicity in mice, 10 Tg-SwDi mice were orally treated with Pb-acetate at 100 mg/kg (equivalent to Pb at 54 mg/kg) for 4 weeks. After 2-week treatments, 20% of mice died and 60% lost more than 20% of their initial weight. Thus, for the DCE-CT study, 20 Tg-SwDi mice were administrated with Pb-acetate or the equivalent amount of Na-acetate for 1 week from the DET-CT was performed on a Phillips Brilliance CT scanner. The images were acquired at 1201sec, 50ksec, and 1010sec acquisitions were acquired. At the 5sec frame, each subject was infused with 0.2ml of Isovone-370 at 3ml/min, followed by a saline flush. Images were registered across subjects and time. Whole brain regions were segmented using Analyze 12.0 (AnalyzeDirect). To perform morphological modeling, custom written software was designed based on dif- ference images between baseline and peak enhancement. To extract kinetic parameters such as tissue blood perfusion and permeability-surface area, a voxel-wise tracer kinetic modeling was performed and mapped to anatomical structures using custom in-house developed software. Data showed that Pb exposure increased permeability surface area product (PS), indicating that Pb disrupted the mouse blood-brain barrier system. It is agreed with our hypo- thesis that Pb exposure at toxic levels would directly damage the brain and induce dementia by allowing blood contents to escape into the brain paren- chyma. The implication on Aβ accumulations in the brain and blood vessel affected by various doses of Pb is currently under investigation. Supported by NIH/NIEHS R01 ES027078.
increased 10.6% and 107% in respected dose groups at 8 weeks. Quantification of Aβ by ELISA displayed a trend of increased Aβ levels in the CSF, albeit not statistically significant as compared to controls. Taken together, our results suggest that RAGE plays a notable role in mobilizing Aβ between two distinct fluid compartments, i.e., the CSF and blood. Pb exposure, either in vitro or in vivo, appears to stimulate RAGE intracellular trafficking. The implication of these findings on Aβ accumulation in the CSF is currently under investigation. Supported by NIH/NIEHS R01 ES027078.

1407 Whole-Brain Approaches for Investigating Iron Accumulation R2* Show No Excess from Occupational Exposure to Welding Fumes

J. L. Davis, D. A. Edmondson, and U. Dydk, Purdue University, West Lafayette, IN.

Iron (Fe) is commonly found in elevated quantities in the human brain affected by neurodegenerative diseases. While it is unknown how Fe plays in the etiologies of these diseases, welders inhale large quantities of metal particulates in welding fume, including iron (Fe) and manganese (Mn). Mn is a neurotoxin that has been shown to accumulate in the brains of welding fume exposed workers by increasing the magnetic resonance imaging (MRI) R1 contrast. R1 and R2* are MRI parameters that are proportional to Mn and Fe accumulation, respectively. Measurements of Mn in the brain could be confounded by accumulated Fe, mostly altering R2* contrast, but also R1 contrast to some degree. Therefore, monitoring human Fe amount using human quantitative imaging in welders is of consequential interest. While some groups, including our own, have reported increased R2* levels in region-of-interest (ROI) based analyses, such findings were inconsistent and targeted few brain regions. To enable an unbiased whole-brain analysis of Fe accumulation in the brain using MRI, 47 welders and 38 controls were recruited from a local manufacturer. Whole-brain R2* maps were coregistered with T1-weighted structural images using SPM12 and then segmented into 192 different brain regions using Freesurfer. R2* in these segmented ROIs within the brain (e.g. white matter tracts and basal ganglia nuclei) were separately averaged and compared between welders and controls. Student’s t-tests showed no statistically significant differences between controls and welders. Therefore, a more comprehensive analysis using machine learning was used to determine if any patterns using all 192 regions could discriminate between controls and welders. Principle component analysis (PCA) was performed on five different statistics of R2* distributions in each ROI: mean, median, skew, 90th percentile, and maximum value. For example, PCA performed on R2* mean showed that only 32 principle components (PCs) were required to explain 90% of variation in mean within all 192 ROIs. A support vector machine (SVM) with a linear kernel was employed using these 32 PCs but could not distinguish between welders or controls better than chance. Similar results were found for the other four statistics. These null results suggest that R2*, and thus brain Fe accumulation, cannot distinguish welders from controls. This provides some evidence that measures of Mn accumulation shown in previous work in the same cohort is only caused by elevated Mn brain levels and not confounded by elevated iron levels.

1408 LRP-1 Expressions and Distribution across BBB and BCB Following Subchronic Lead Exposure

L. Xia, X. Shen, and W. Zheng, Purdue University, West Lafayette, IN.

Lead (Pb) exposure has been shown to facilitate amyloid plaque formation in transgenic AD mouse models. Transport of β-amyloid peptide (Aβ) between the blood and brain parenchyma is regulated by the receptor for advanced glycation end products (RAGE) for Aβ influx and the low-density lipoprotein receptor-related protein-1 (LRP1) for Aβ eflux in the blood-brain barrier (BBB); however, how these transporters may operate in the blood-CSF barrier (BCB) in the choroid plexus (CP) is unclear. The purpose of this study was to determine whether subchronic Pb exposure affected the expression and subcellular location of LRP1 in the BBB and BCB. Sprague-Dawley rats received oral gavage of 0, 14 (low), or 27 (high) mg Pb/kg, 5x/wk for 4 or 8 weeks. At the end of exposure, brain tissues were dissected, and a “capsular depletion” method was employed to separate cerebral capillary fraction from brain parenchyma. Western blot analysis of capsular and parenchymal frac-
tions demonstrated that LRP1 expression in the hippocampal parenchyma, following low- and high-dose Pb exposure, increased by 34% and 106% of the control, respectively (p<0.05). In the capillary of hippocampus, LRP1 in low- and high-dose groups reduced by 6% and 5% of the control, respectively, although this decreased LRP1 expression did not reach the statistical significance. Confocal imaging studies of the choroid plexus showed that the green fluorescent signals representing LRP1 were relatively evenly distributed throughout cytoplasm in all groups including control, low-dose, and high-
dose groups following 4-week Pb exposure. After 8-week gavage with Pb, the translocation of LRP1 was visibly observed in the choroidal epithelial cells, the LRP1 fluorescent signals moved to the cytosol above the nucleus, which were clinging to the apical membrane. The signal intensities in both low- and high-dose groups were visibly increased as compared with controls. Further quantitation of LRP1 expression in the choroid plexus is currently in progress. Taken together, these results suggest that in vitro Pb exposure does not alter the expression of LRP1 in brain parenchyma, but not in the BBB; Pb exposure also causes the intracellular trafficking of LRP1 in the BCB. The implication of these observations remains unknown. Since LRP1 participates in Ab efflux, the significance of Pb interaction with LRP1 deserves further investigation. Supported by NIH/NIEHS R01 ES027078.

1409 Transcription Factor REST/NRSF Is a Positive Regulator of Tyrosine Hydroxylase and Protects Dopaminergic Neurons against Manganese-Induced Neurotoxicity

E. Pajarillo, J. Kim1, A. Rizor1, J. Johnson1, M. Aschner2, and E. Lee1.
1Florida A&M University, Tallahassee, FL; and 2Albert Einstein School of Medicine, New York, NY.

RE1-silencing transcription factor/neuron-restrictive silencer factor (REST/ NRSF) is a transcriptional factor which is originally discovered to silence neuronal genes in non-neuronal cells. Recent emerging evidence reveals that REST induces neuroprotection against Alzheimer’s disease (AD) and Parkinson’s disease (PD) by silencing human growth hormone (GH) transgene in neuronal cells. However, the effects of REST on manganese (Mn)-induced neurotoxicity have not been tested. In the present study, we investigated if REST can protect Mn-induced neurotoxicity in dopaminergic neurons. Our findings reveal that overexpression of REST attenuated Mn-induced oxidative stress by using CM-H2DCFDA as an indicator for reactive oxygen species (ROS), as well as Mn-induced impairment of mitochondrial membrane potential in mouse catecholaminergic/dopaminergic (CAD) neuronal cells. REST also attenuated Mn-induced TNF-α production by qPCR and ELISA in CAD neurons. REST inhibited Mn-induced levels of proapoptotic proteins Bax and Daxx, while it reversed Mn-decreased antiapoptotic proteins, Bcl-2 and Bcl-xL. Flow cytometry data also showed that REST attenuated Mn-induced apoptotic in CAD neurons by Annexin V/PI staining. Intriguingly, REST, which is known to be a repressor of many genes, served as a positive transcription factor of tyrosine hydroxylase (TH), a dopaminergic neuronal marker, by its binding to RE1/NRSE consensus sites in the TH promoter, and increasing TH promoter activity, mRNA and protein levels in CAD as well as LÜHMES cells (human dopaminergic neuronal cells). REST thus reversed Mn-induced repression of TH promoter activity, mRNA and protein levels in dopaminergic neurons. Taken together, our findings indicate that REST can be a potential molecular target to treat Mn-induced neurotoxicity as well as other neurological disorders associated with dopaminergic neurodegeneration such as PD.

1410 Manganese Exposure Induces Misregulation of Tyrosine Hydroxylase and Dopamine Receptor D2 Protein Expression in Differentiated SH-SY5Y Cells: Implications for an Epigenetic Mechanism of Mn Neurotoxicity

N. Santiago, A. Rios, S. Howard, D. McDonald, and D. Smith, University of California Santa Cruz, Santa Cruz, CA.

Epidemiological studies have reported associations between elevated manganese (Mn) exposure during late gestation and early childhood and the development of inattention, impulsivity, hyperactivity, and fine-motor impairments. We developed a rodent model of developmental Mn exposure that recapitulates these behavioral impairments, and found they were accompanied by life-long catecholaminergic system alterations in the prefrontal cortex. Here we sought to develop a neuronal cell model of Mn exposure that demonstrates several of those key findings, including decreased tyrosine hydroxylase (TH) and increased dopamine receptor D2 (D2) protein levels, to elucidate the molecular mechanism(s) underlying developmental Mn neurotoxicity. We hypothesize that Mn induces mis-regulation of TH and D2 gene expression via an epigenetic mechanism. To test this, SH-SY5Y neuroblastoma cells were exposed to 0, 100, or 300 μM Mn for 8 days while undergoing retinoic acid and TPA-induced catecholaminergic differentiation. Cell differentiation into a neuronal phenotype was verified via cell morphology and increased synaptophysin expression. The Mn exposure regimen did not cause overt cytotoxicity, based on MITT assay and trypan blue cell counts. TH and D2 protein and gene transcript levels were determined using quantitative immuno- fluorescence microscopy and qPCR, respectively, while DNMT enzyme
activity and protein levels were determined using a kinetic enzyme assay and immunofluorescence microscopy, respectively. TH and D2 promoter methylation state is being determined by bisulfite sequencing. Mn exposure decreased TH and increased D2 protein levels, consistent with results from our animal model. We expect reduced DNMT enzyme activity and altered TH and D2 gene transcripts and methylation status to corroborate our observed protein level changes (analysis ongoing). Understanding whether Mn causes lasting changes in expression levels of catecholaminergic system proteins via an epigenetic mechanism will fill an important knowledge gap on the mechanisms of developmental Mn neurotoxicity. These findings will also elucidate how Mn causes the behavioral impairments in animal models and children, and potentially provide molecular targets to develop preventative therapies.

**1411 Role of Akt/AMPKa-Regulated Autophagy Pathway in Arsenic-Induced Neurotoxic Injuries**

J. Lin, Y. Chiu1, K. Lee2, C. Su1, C. Lin, W. Wu1, S. Liu3, C. Huang1, and Y. Chen.1.1 China Medical University, Taichung, Taiwan; 2Buddhist Tzu Chi Medical Foundation, Taichung, Taiwan; 3Changhua Christian Hospital, Changhua, Taiwan; 4Department of Public Health, Taipei, Taiwan; 5National Taiwan University, Taipei, Taiwan.

Inorganic arsenic (iAs) is a common toxic heavy metal and carcinogenic factor and is easily detected in pressurized groundwater veins, environmental pollutants and industrial waste. Recently, epidemiological studies have suggested a possible relationship between iAs exposure and neurodegenerative disease risk level changes. However, inorganic arsenic (iAs) exposure has been demonstrated to cause neuro-pathological effect in neuronal cell remain unclear. In this study, the results show that iAs exposure reduces the level of cell viability and apoptotic events (such as caspase 3, caspase 7, PARP) and upregulated Akt and AMPKα phosphorylation as well as autophasosome formation (acidic vesicular organelles, AVOs) and autophagy (such as atg 5, atg 12, atg 10). Inhibition of activation of Akt by LY294002 and AMPKα by compound c potentiated iAs-induced apoptosis and alleviated iAs-induced autophagy. Taken together, these results suggest that iAs-induced neurotoxicity is reduced through an activation of Akt/AMPKα-regulated pathway pathway.

**1412 Lead (Pb) Exposure Induces Dopaminergic Neurotoxicity in Caenorhabditis elegans**

A. Akinyemi, and M. Aschner. Albert Einstein College of Medicine, Bronx, NY.

Oxidative stress is linked to many pathological conditions including the loss of dopaminergic neurons in Parkinson’s disease. Lead (Pb) is a ubiquitous pollutant and studies have shown that Pb cause dopaminergic dysfunction, however, the mechanism remains unexplored. Hence, this study sought to investigate the effect of Pb exposure on dopaminergic neurodegeneration and function as well as the expression level of some dopaminergic signalling and oxidative stress genes in Caenorhabditis elegans. Pb treatment result in gradual loss of dopaminergic cell morphology and structure in worms expressing green fluorescent protein (GFP) under a DAergic cell specific promoter. HPLC analysis revealed a significant decrease in dopamine content in worms treated with Pb when compared with control. In addition, the expression levels of dat-1, sod-1, gst-4 and skn-1 genes were altered in Pb treatment. In summary, our results revealed that Pb exposure induces dopaminergic dysfunction in C. elegans. This action could be attributed to oxidative stress-induced degeneration as initiated by Pb treatment.

**1413 Role of Internal Calcium Pools during Acute Methylmercury-Induced Cell Death in the C57BL6J Mouse**

A. Aldaz1, and W. Atchison2. 1St. Mary’s University, San Antonio, TX; and 2Michigan State University, East Lansing, MI.

Methylmercury (MeHg) is an environmental neurotoxicant of contemporary concern that causes a cascade of cellular effects leading to cell death. MeHg targets a-motor neurons (oMNs) located in the lumbar region of the spinal cord and eMNs responsible for skeletal movement; their degeneration is a key feature of amyotrophic lateral sclerosis. MeHg-induced cell death results from uncontrolled increase in internal calcium concentration ([Ca\(^{2+}\)]. The initial effect is release of Ca\(^{2+}\) from internal organelles (mitochondria and smooth endoplasmic reticulum (SER)) followed by extracellular Ca\(^{2+}\) entry. Our purpose was to elucidate the immediate and delayed contribution that mitochondria and SER provide during MeHg-induced cell death. This was being performed using lumbar spinal cord slices isolated from C57BL6J mice, and calcine-AM, a fluorophore that label viable cells green. Cell viability was determined following a 15min [20μM] MeHg exposure in the presence and absence of chemicals that modulate internal Ca\(^{2+}\) pools: Carbonyl cyanide m-chlorophenyl hydrzone (CCCP) and thapsigargin. CCCP depolarizes the inner mitochondrial membrane increasing cytosolic Ca\(^{2+}\). Thapsigargin blocks the SER Ca\(^{2+}\)-ATPase (SERCA), preventing uptake of cytosolic Ca\(^{2+}\). We hypothesized that CCCP + thapsigargin treatment would increase [Ca\(^{2+}\)], increasing further incidence of MeHg-induced cell death. MeHg alone significantly decreases viability from baseline at 3hrs post-MeHg by 0.65 relative change. Internal Ca\(^{2+}\) stores contribute to MeHg-induced cell death since the MeHg + CCCP + thapsigargin shows a significant viability loss by 0.52 relative change from MeHg control group. This project sheds light on the role of Ca\(^{2+}\)-organelles to MeHg-induced neuronal death. This research is important because it sheds light on the role of Ca\(^{2+}\)-containing organelles, mitochondria and SER, to MeHg-induced motor neuronal death.

**1414 Neurotoxicity of Low-Concentration Chronic Metal Exposures to Motor Neurons In Vitro**

Amyotrophic lateral sclerosis (ALS) is the most common adult-onset paralytic disorder characterized by the degeneration of motor neurons (MNs). ALS is mainly a sporadic disease but about 10% of patients have a familial history. Most mutations linked to ALS present a variable penetrance and a wide range of age at onset and disease progression, indicating there is more to the disease than merely a genetic component. Environmental factors implicated in ALS are still elusive, but exposure to chronic-low-level metal toxicity has been proposed to contribute to ALS and other neurodegenerative diseases. However, little is currently known about the vulnerability of MNs to long-term and low-level metal exposures. To begin addressing this gap in knowledge, we evaluated the cytotoxicity of manganese (Mn), selenium (Se), lead (Pb), and arsenic (As) on MNs from primary spinal cord cultures. To better model chronic low-level exposures, we exposed the spinal cord cultures for a period of 7 days to metal concentrations ranging from 0.25μM-100μM. Exposure started at day in vitro (DIV) 1, cultures were fixed at DIV 8, then immunostained for the neuronal marker SMI32-immunopositivity and a healthy cell morphology. Our results show that for a 7-day-exposure period the order of potency for the tested metals is: As > Se > Mn > Pb. The lethal concentration of each metal required to kill 50% (LC\(_{50}\)) of the MN cell population is 1, 2, 25, and 70μM respectively. This is the first time that cytotoxicity of each of these metals has been evaluated in a 7-day-exposure paradigm and in an ALS-relevant cell type, such as primary MNs. Currently, we are evaluating the cytotoxicity of the same set of metals in MNs that carry a genetic mutation (G928S in the TDP-43 gene) associated with ALS. By comparing the LC\(_{50}\) obtained in WT versus TDP-43 mutant MNs, we hope to bring insights into potential differences in MN susceptibility to metal toxicity based on gene-environment interaction. Our next step will be to chronically expose WT and TDP-43 mutant mice to metal candidates to provide information on the potential of metal exposure to contribute to the pathology of ALS. Identifying environmental modifiers to ALS is pivotal for the development of treatments and prevention strategies.

**1415 Cytotoxicity of Copper (II) Octanoate on Mouse Hippocampal Astrocytes**

A. Shohatee, and L. D. Trombetta. St. John’s University, Queens, NY.

Copper, an essential trace element, is crucial for various biological processes and mechanisms associated with maintaining homeostasis within an organism. In addition, copper has been utilized as a constituent of various pesticides. Copper (II) octanoate, a copper carboxylic acid complex utilized agriculturally for its fungicidal properties, is applied to a wide range of crops and is suitable for use in certified organic production. Due to limited toxicological data, the objective of this study was to investigate the potential toxicity of copper (II) octanoate in vitro. Astrocytes, in conjunction with pericytes and endothelial cells, comprise the blood-brain-barrier and thus one of the first cells within the nervous system to encounter xenobiotics. Previous studies have also demonstrated the capability of astrocytes to regulate copper homeostasis in the brain. Mouse hippocampal astrocytes were isolated from C57BL6J mice and characterized by ELISA for glial fibrillary acidic protein (GFAP). Copper (II) octanoate was synthesized and characterized by mass spectroscopy and elemental analysis. Astrocytes were treated with 100-1000 μM of copper (II) octanoate for 24 Cell viability was assessed and the LC\(_{50}\) was...
1416 Taurine Improved Motor Coordination in Wistar Rats Co-administered with Chlorpyrifos and Lead Acetate

M. Akande1, S. Ambali2, J. Ayo3, C. Orjei4, and R. Edeh1.1 University of Abuja, Abuja, Nigeria; 2University of Ilorin, Ilorin, Nigeria; and 4Ahmadu Bello University, Zaria, Nigeria.

Living organisms are constantly exposed to complex mixtures of toxicants. Chlorpyrifos (O,O-diethyl-3,5,6-trichloro-2-pyridyl-phosphorothionate) is an extensively used broad spectrum organophosphate insecticide. Lead (Pb) is a ubiquitous and pernicious heavy metal. Taurine (C2H7NO3S) is a potent antioxidant and neuroprotective conditionally essential amino acid. The aim of the study was to evaluate the effect of taurine on motor coordination in male Wistar rats co-administered with chlorpyrifos and lead acetate. In this study, fifty male Wistar rats were assigned into 5 groups of ten animals each as follows: D5 group (distilled water), SY group (soya oil, 1 ml/kg), TU group (taurine, 50 mg/kg), CP+LA group (chlorpyrifos, 4.25 mg/kg, 1/20 LD50; lead-acetate, 233.25 mg/kg, 1/20 LD50; and TU+CP+LA group (taurine+chlorpyrifos+lead acetate). The treatments were administered to the rats once daily by oral gavage for 16 weeks. The motor coordination was assessed on week 15 with the use of a beam walk-performance task. Additionally, the brain malondialdehyde concentration and activities of brain antioxidant enzymes (catalase, superoxide dismutase and glutathione peroxidase) were assessed following the termination of the study. There was a significant increase (p < 0.01) in the widths of slip off the beam of the rats in the CP+LA group compared to those in the TU+CP+LA group. Moreover, the brain malondialdehyde concentration was increased, while the activities of brain antioxidant enzymes were reduced in the CP+LA group compared to the TU+CP+LA group. However, there were improvements in the motor coordination and activities of brain antioxidant enzymes, as well as attenuation of brain malondialdehyde concentration in the groups treated with taurine. It is surmised that taurine improved the motor coordination of the rats through its antioxidant properties.

1417 Toxicologic Evaluation of SABA-10 (X-7590-15)

M. Baumer1, O. Mendez1, W. Droegge2, and T. Osimitz1.1 Eurofins Product Safety Labs, Dayton, NY; and 2Science Strategies LLC, Charlotteville, VA.

Seeds of Sabadilla, Schoencaulon officinale Grey (Liliaceae) have been used as an insecticide since pre-historic times in Mesoamerica. The insecticidal activity of sabadilla arise from the alkaloid fraction of the seed (3-6%) generally referred to as sabadilla or veratrums alkaloids. Among the alkaloid fraction, two lipophilic alkaloids veratridine and cevadine have the highest reported insecticidal potency. The toxicity of SABA-10 (formulation consisting of 10% two lipophilic alkaloids veratridine and cevadine) was determined as 350 μM. Studies have shown copper-containing compounds to activate the transcription factor Nrf2, a regulator for various antioxidant and detoxification pathways. Fluorescence microscopy of astocytes treated with 350 μM indicated an increase of Nrf2 translocation into the nucleus from the cytosol as compared to untreated cells. This suggests that the toxicity of copper (II) octanoate may be associated with the generation of oxidative stress and the subsequent induction of Nrf2 mediated pathways.

1418 Differential Effects of Organophosphate Insecticides and Their Metabolites on Neuronal Network Activity and Function Assessed in Primary Rat Cortical Cultures Using Microelectrode Array (MEA) Recordings

H. Heusinkveld1,2,3, and R. Westerink1.1 Institute for Risk Assessment Sciences, Utrecht, Netherlands; and 2National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands.

Organophosphate (OP) insecticides like chlorpyrifos (CPF) and diazinon (Dz) are widely used in agriculture and household applications. Human exposure occurs mainly in occupational settings as well as via the food chain. Neurotoxicity of OP insecticides is (primarily) exerted via irreversible inhibition of acetylcholine esterase (AChE), leading to neuronal overstimulation and malfunction, and with the -oxon metabolites being more potent than the parent compound. Recently, OP insecticides have been demonstrated to inhibit calcium influx at levels that do not induce inhibition of AChE. Therefore, this study aimed to assess the effects of two widely used OP insecticides and their -oxon metabolites on intracellular calcium homeostasis as well as development and function of spontaneously active neuronal networks in rat primary cortical cultures. Effects of acute exposure to Dz and CPF and their -oxon metabolites on calcium homeostasis were assessed using single-cell imaging of the Ca2+-sensitive dye Fura-2. Considering the pivotal role of intracellular calcium homeostasis in development and function of neuronal networks, effects on spontaneous neuronal activity were assessed using micro-electrode arrays (MEAs) following acute (30min-48h) and chronic (up to DIV 21) exposure. Acute exposure to both the OPs and the metabolites induces a concentration-dependent inhibition of depolarization-evoked calcium influx. Similar chronic exposure revealed a preferential effect for Dz as compared to CPF and their -oxon metabolites. A concentration-dependent inhibition of spontaneous electrical activity. However, chronic developmental exposure results in a concentration-dependent increase of network activity for Dz, whereas CPF affects network activity only at high (>10μM) concentrations. Importantly, for all observed effects, the parent compound showed more pronounced effects. These effects occurred at concentrations below effect concentrations for AChE inhibition, the combined results indicate that non-AChE related mechanisms may play a role in the neurotoxicity of OP insecticides.

1419 Molecular Mechanisms for the Antidepressant Effects of Ketamine in a Rat Model of Gulf War Illness

J. Zhu1, M. Kronfol1, M. Abuhelbigouj2, N. Rashid1, J. Harris1, E. Hawkins1, R. Blair1, J. McClay1, K. Phillips2, and L. S. Deshpande1. 1Virginia Commonwealth University, Richmond, VA; and 2Virginia Tech, Blacksburg, VA.

Chronic exposure to organophosphate pesticides and nerve gas is thought to underlie Gulf War Illness (GWI) which afflicts ~1 103 of the First Gulf War Veterans. Among other symptoms, GWI is chiefly characterized by therapy-resistant depression. There is strong pre-clinical and anecdotal evidence that Ketamine (KET), an NMDA receptor antagonist, produces a rapid onset and sustained antidepressant effect. This is attractive since existing antidepressants show a delay of therapeutic onset. Here, we investigated antidepressant effect of KET in a rat model of GWI. Male Sprague-Dawley rats (3-m) were exposed to DFP (0.5 mg/kg s.c., 5-d) and 6-m later assessed using the Forced Swim Test (FST). DFP exposed rats exhibited a significantly higher immobility time compared to age-matched control rats. DFP rats treated with KET produced a dose-dependent decrease in immobility time when tested at 1-h. A low, sub-anesthetic KET dose (10 mg/kg, i.p.) produced maximal reduction. The neurotoxicity of OP insecticides and their metabolites on neuronal network activity was assessed using micro-electrode array (MEA) recordings. The studies show that inhibition of the NMDAR-Ca2+ pathway plays a role in the rapid onset antidepressant effects of KET while the sustained effect was calcium-dependent in neuronal networks. The studies showed that at a low, sub-anesthetic dose KET produced maximal reduction.
antidepressant actions involves upregulation of BDNF signaling. Our studies support evidence that KET therapy could provide an important alternative for GWI depression.

1420 Selective Behavioral Deficits Months Following Exposure to Gulf War Illness Chemicals in a Mouse Model: Modulation by the Immunological Therapeutic LNFPIII

J. M. Carpenter, A. N. Diaz, R. L. Dockman, D. A. Ham, J. J. Wagner, and N. M. Filippov, University of Georgia, Athens, GA.

Approximately 30% of veterans from the 1990-1991 Gulf War (GW) suffer from Gulf War Illness (GWI), a complex illness with a number of immunological and neurological symptoms including systemic inflammation. The precise etiology of GWI remains undetermined, but overexposures to GW-related chemicals, including carboxylesterases (CarbEs) and butyrylcholinesterase (BChE), are implicated in it. Currently, there are no effective treatment options for GWI. Here, an established GWI mouse model (10 days of PB/PM exposure) was used to explore (1) the long-term behavioral effects of deployment-related GW chemicals exposure and (2) the ability of a novel immunological treatment, LNFPIII, to modulate the behavioral effects of GWI when given months after the end of initial GW chemicals exposure. A battery of behavioral tests, used for assessment of memory, mood, and motor function in rodents were performed. From the data analyzed to date, motor/sensorimotor function appears to be most affected by GWI as evident by increased steps to complete Gait Test (GT), increased contact and bromide time (PB), and the pesticide permethrin (PM), are implicated in it. Currently, there are no effective treatment options for GWI. Here, an established GWI mouse model (10 days of PB/PM exposure) was used to explore (1) the long-term behavioral effects of deployment-related GW chemicals exposure and (2) the ability of a novel immunological treatment, LNFPIII, to modulate the behavioral effects of GWI when given months after the end of initial GW chemicals exposure.

1421 Butyrylcholinesterase Inhibition and Its Effects on Ghrelin-Induced Food Intake

K. Hester1, K. Maclay2, J. Liu2, and C. Pope1,1 Oklahoma State University, Stillwater, OK; and 2Charles River Laboratories, Reno, NV.

Organophosphorus pesticides (OPs) elicit acute toxicity by inhibiting acetylcholinesterase. However, they also bind and inhibit additional hydrolases including carboxylesterases (CarbEs) and butyrylcholinesterase (BChE). Recent studies demonstrated that BChE can inactivate the peptide hormone ghrelin to its des-acyl form via des-acytylation. Ghrelin is a peripherally-produced hormone which acts on the central growth hormone secretagogue receptor (GHSR) to orchestrate orexigenic effects. We hypothesized that exposure to a BChE-selective cholinesterase inhibitor (tetraisopropyl pyrophosphoramide, iso-OMPA) would increase the orexigenic effects of acyl-ghrelin by blocking its des-acytation, in the absence of any cholinergic toxicity. Male, Long-Evans rats (150-175 g) were divided into four treatment groups: veh/veh, iso-OMPA/veh, veh/ghrelin, and iso-OMPA/ghrelin (n=7-8/group). Chow and sucrose consumption (using a two-plate choice paradigm; 5% sucrose vs water) were monitored using daily 3-hour sessions for nine days to determine baseline consumption. On day 10, animals were either given vehicle (saline) or iso-OMPA (25 mg/kg, sc; 2 ml/kg). Twenty four hours later they were given either vehicle (saline) or ghrelin (0.2 mg/kg, ip; 1 ml/kg) and 3-hour consumption was measured as before beginning immediately after ghrelin administration. Tissues (plasma, hypothalamus and liver) were then collected for biochemical assays. Iso-OMPA elicited extensive BChE inhibition in plasma (86%), but lesser inhibition in liver (45%) and hypothalamus (58%). Ghrelin-treated rats consumed more chow compared to baseline. Iso-OMPA had no apparent influence on ghrelin-stimulated intake. No differences in sucrose consumption were noted among the four treatment groups. These results suggest that BChE inhibition may not alter the orexigenic effects of ghrelin in rats. The lack of effect of iso-OMPA on chow intake may be due to a number of reasons including insufficient BChE inhibition in liver or other tissues, or the known role of other hydrolases in acyl-ghrelin metabolism. Future studies may evaluate higher doses of iso-OMPA or alternative des-acyl ghrelin inactivation mechanisms. Supported by the OSU Interdisciplinary Toxicology Program (KHI) and Howard Hughes Medical Institute (KM).

1422 Chronic Low-Dose Diazinon Exposure of Rats during Gestation Causes Long-Term Neurobehavioral Effects Lasting into Adulthood

E. D. Levin, E. Pippen, H. White, J. Kim, B. Kenou, A. Hawkey, and Z. Holloway. Duke University Medical Center, Durham, NC.

Diazinon, a widely used organophosphate pesticide, can with pulsatile exposure during development cause long-term neurobehavioural impairment. The current study investigated persisting effects of chronic low-level infusion of 0, 0.5 and 1.0 mg/kg/day of diazinon throughout gestation via osmotic minipumps (N=10-11 litters per condition). One male and one female offspring from each litter was assessed with a battery of behavioral tests that started at four weeks of age and continued into adulthood. Litter was used as the unit of variance for the analysis of variance test of significance, with sex as a within litter factor. Chronic diazinon exposure from pre-mating until the postnatal period caused a significance of hyperactivity as assessed in the Ankle-8 apparatus. Dose comparisons detected significant (p<0.05) locomotor hyperactivity in both the 0.5 and 1.0 mg/kg/day diazinon dose groups. Diazinon exposure also caused a significant impairment in novel object recognition. This higher diazinon dose (1 mg/kg) caused a significant impairment in the novel object recognition task when the male and female offspring were tested during adolescence. A significant (p<0.05) impairment in preference for the novel object was seen with diazinon. The 1 mg/kg diazinon dose (p<0.05) showed significantly less preference for the novel object than controls during the first five minutes of the novel object recognition test. This effect on cognitive function did not appear to be the result from a generalized dysfunction as the rats were not found to differ from controls on tests of emotional function. This study is continuing with additional cohorts to determine the reliability of the effect. These behavioral tests and companion neurochemical assessment will be used to guide future tests of drug treatment to alleviate the persistent behavioral impairment due to prenatal exposure to diazinon. Supported by the Duke University Superfund Research Center (ES010356).

1423 Microglia-Specific Knockout of NF-kappaB/IKK2 Protects against Neurotoxic Injury from Exposure to Rotenone

S. Rocha, C. Bantle, and B. Tjalens, Colorado State University, Fort Collins, CO.

A number of environmental pesticides have been implicated as risk factors for Parkinson’s disease (PD) due their capacity to damage dopaminergic neurons. Rotenone is a naturally occurring insecticide that potently inhibits mitochondrial complex I, leading to neurochemical and neuropathological deficits that closely resemble those in idiopathic PD, including loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc), decreased dopamine levels and aggregation of alpha-synuclein. Although rotenone exposure causes activation of microglia and astrocytes that is associated with the progression of neuronal injury, whether neuroinflammation precedes the majority of injury to dopaminergic neurons is not known. Neuroinflammatory activation of microglia and astrocytes is highly regulated through the transcription factor, nuclear factor-kappaB (NF-κB). We therefore postulated that gene ablation of IKK2 in microglia would be neuroprotective against rotenone by preventing inflammatory injury to dopamine neurons. We therefore generated microglia-specific KO mice for IKK2 by crossing Cx3cr1-Cre mice with iK2-flox mice and exposed homozygous progeny (or iK2flox genotype controls) to 2.5 mg/Kg/day rotenone for 14 days. IKK2 KO mice had dramatically decreased expression of IKK2 in microglia and did not show induction of the NLRP3 inflammasome following exposure to the Toll Receptor 4 (TLR4) agonist, lipopolysaccharide (LPS). Wildtype mice exposed to rotenone showed loss of tyrosine hydroxylase-positive dopamine neurons in the SNpc, as well as pronounced activation of microglia and astrocytes, that was prevented in microglia-specific IKK2 KO mice. Rotenone-induced locomotor deficits were also largely reversed in IKK2 KO mice. These data demonstrate that inflammatory activation of microglia following rotenone exposure is critical to both activation of astrocytes and to neurotoxic injury to dopaminergic neurons.
1424 Adult Exposure to the Pesticide Chlorpyrifos Causes Short-Term Behavioral Effects in the Zebrafish

A. B. Hawkey, C. Dean, B. Bajaj, J. Zhang, and E. D. Levin. Duke University, Durham, NC.

Organophosphate pesticides (OP), such as chlorpyrifos (CPF), were introduced as alternatives to organochlorine pesticides such as DDT, which was banned due to toxicity and environmental hazards in the early 1970s. Since then, many American farm workers have been chronically exposed to OP throughout their adult lives. Recent evidence suggests that farm workers chronically exposed to pesticides as young adults face greater risk for adverse cognitive effects and neurodegenerative diseases as they age. Our lab has recently observed that chronic adult exposure to CPF can produce short and long term effects on behavior in the zebrafish, including increased anxiety-like behaviors. The aim of the present study is to demonstrate whether adult exposure to CPF carries similar risks. Naive adult zebrafish (6-8 months of age) were separated into tanks of 10 mixed-sex fish and exposed to CPF concentrations of 0.3, 1 or 3 µM in 0.001% DMSO or to the vehicle alone over the course of two weeks. These doses were selected to fall below the threshold for overt toxicity. This relatively brief exposure models the consequences of chronic CPF exposure during a short period in early-mid adulthood, rather than over a lifetime. Following a 1 week recovery period, the fish were assessed in a behavioral test battery with assays for anxiety-related behavior, sensorimotor response and habitation, social interaction, predator avoidance. Fish were tested again at 14-months of age to assess the persistence of these effects and/or the emergence of aging-related deficits. The relatively brief exposure time of two weeks was shown to dose-dependently impact multiple behavioral outcomes 1-week after exposure, although these effects were not persistent into late adulthood. The highest dose of CPF reduced anxiety-like responding in the novel tank test at 1-week post-exposure and enhanced social approach behaviors in the shoaling test (p<0.05). Similar trends in the middle dose group approached significance (0.05<p<0.06). The low dose of CPF did not produce these effects, but rather impaired the habituation of acoustic startle in the tail test (p<0.05). These data show that adult exposure to CPF-induced neurotoxicity, although the brief exposure used here did not produce effects which persisted into late adulthood. Further testing with longer exposure periods will be necessary. Supported by the Virtual Consortium for Translational/Transdisciplinary Environmental Research (ViCTER) project (R01ES024428-0351).

1425 Inhibition of ER Stress Attenuates Deltamethrin-Induced Hippocampal Neuroinflammation in Mice

M. Hom1, M. Nair1, P. Khoooblall1, P. Alamir1, A. Belkadi1, J. R. Richardson2,3, and M. M. Hossain1,4.1 Northeast Ohio Medical University, Rootstown, OH; 2Florida International University, Miami, FL; 3Northeast Ohio Medical University, Rootstown, OH; and 4Florida International University, Miami, FL.

Emerging evidence indicates that endoplasmic reticulum (ER) stress and neuroinflammation contribute to the pathogenesis of neurodegeneration and cognitive dysfunction. Previously, we reported that exposure to pyrethroid insecticide deltamethrin causes hippocampal ER stress, apoptosis, reduction of neurotrophins, and learning deficits in adult mice. Recently, we found that deltamethrin exposure also increases the markers of neuroinflammation. Here, we investigated the potential mechanistic link between ER stress and neuroinflammation following exposure to deltamethrin. We found that single oral exposure to very low dose of deltamethrin (1 mg/kg) caused neuroinflammation as mice exhibited with microglial activation and increased protein levels of TNFα, gp91phox, and iNOS in the hippocampus. These changes were accompanied by induction of ER stress as the protein levels of CHOP and GRP-78 were significantly increased in the hippocampus following exposure to deltamethrin. To determine whether induction of ER stress triggers the inflammatory response, mice were treated with two microperitoneal (i.p.) injections of 1 mg/kg salubrinal (an ER stress inhibitor) 24 h and 30 min before the administration of deltamethrin. Inhibition of ER stress with salubrinal prevented deltamethrin-induced TNFα, gp91phox, and iNOS activation. For further confirmation of these results, we performed an additional experiment with microperitoneal cell line (BV2). We found that salubrinal inhibited ER stress and significantly attenuated the levels of TNFα, gp91phox, and iNOS in BV2 cells. Collectively, these results demonstrate that exposure to deltamethrin leads to ER stress mediated neuroinflammation, which may subsequently contribute to neurodegeneration and neuronal dysfunction in mice. Supported in part by 1R01ES027481-01A1 and NEOMED SURF program.

1426 DDT Increases Neuroinflammation and Microglial Activation: Role of Microglial Sodium Channels

A. Eid, I. Mhatre, and J. R. Richardson. Florida International University, Miami, FL.

Alzheimer’s disease (AD) is the most common neurodegenerative disease, characterized by the presence of amyloid beta (Aβ) plaques, neurofibrillary tangles and chronic inflammation. Less than 5% of all AD cases are purely genetic in etiology, suggesting that the environment likely plays a role in the etiology of AD. We have previously reported that serum levels of dichlorodiphenyldichloroethylene (DDE), the metabolite of the pesticide dichlorodiphenyltrichloroethane (DDT), were significantly higher in AD patients compared to age-matched controls. Further, we also found increases in the amyloid pathway, specifically for increased mRNA and protein levels of the amyloid precursor protein (APP) and protein levels of Aβ in wild-type and transgenic mice. As Aβ is associated with neuroinflammation, we investigated the effect of DDT on neuroinflammation in mice and primary microglia. Mice exposed to DDT (3 mg/kg every 3 days) from 9-12 months of age demonstrated significantly increased levels of IL-1β mRNA in the cortex, and increased protein levels of TNFα in cortex, hippocampus and serum. Exposure of primary mouse microglia (PMG) to varying doses of DDT (0.5, 1.0 and 5.0 µM) elicited a ~4-5-fold increase in mRNA levels of IL-1β and TNFα respectively, with similar increases in mRNA levels of IL-6, Nos2 and Tnfα. In addition, we measured ~2-4-fold higher levels of Nos2 and TNFα protein by immunocytocchemistry. Mechanistically, the increase in cytoplasmic mRNA was blocked by the sodium channel antagonist tetrodotoxin (TTX), demonstrating the requirement of DDT interaction with sodium channels. These data indicate that DDT increases neuroinflammation that may be the result of direct actions of DDT on microglia, providing a novel pathway by which DDT exposure may contribute to AD risk. Supported in part by NIH R01ES026057.

1427 Characterization of Organophosphorous Pesticides on Acetylcholinesterase Inhibition Using In Vitro Assays with Xenobiotic Metabolic Capability

S. Li1, J. Zhao1, R. Huang1, M. F. Santillo1, K. A. Houck4, and M. Xia1. 1NIH/NCATS, Bethesda, MD; 2NIH, Bethesda, MD; 3US FDA, Laurel, MD; and 4US EPA/NCC, Research Triangle Park, NC.

Acetylcholinesterase (AChE) inhibition can have significant impacts on human health. A large number of environmental chemicals such as synthesized drug candidates, food additives, and industrial chemicals have not been tested for AChE inhibition activity. Moreover, some chemicals may need to be metabolically activated to show inhibitory effects. In our study, we have developed and characterized a high-throughput screening method with metabolic capability for identifying AChE inhibitors. An enzyme-based high-throughput assay was developed in the current study by using recombinant human AChE combined with human or rat liver microsomes. AChE activity was measured by two methods, one with colorometric and the other with fluorescent readouts. The enzymatic assay with human microsomes (n = 72) showed good performance with coefficient of variation (CV), signal to background ratio (S/B) and z’ factor of 2.03 ± 0.05, 3.29 ± 0.01 and 0.85 ± 0.02, respectively. The assays with microsomes were characterized by testing a group of well-known AChE inhibitors including parent compounds and their metabolites. Many organophosphorous pesticides (OPs), such as chlorpyrifos, tebuquinifos and chlorothoxyfos, only showed inhibitory effects on AChE in the presence of microsomes, showing that these OPs need to be metabolically activated to inhibit AChE. The sensitivities of the assays +/− microsomes ranged from 58% to 85% depending on the assay format and species of microsomes. These results demonstrate that the enzyme-based assays with or without liver microsomes provide a promising tool for the profiling of AChE inhibitors and to study the metabolism of OPs. Disclaimer: This abstract does not reflect US EPA, US FDA, and NIH policies.

1428 Parkinson’s Disease–Relevant Gene Mutations Render C. elegans More Vulnerable to Mancozeb Fungicide Exposure and Mitochondrial Hyperpolarization

A. Ignacz1, N. Eisel2, K. Rivenbark1, and V. A. Fitsanakis3. 1King University, Bristol, TN; and 2Northeast Ohio Medical University, Rootstown, OH.

Mancozeb is one of the most widely-used fungicides in the world. The active ingredient, manganese/zinc ethylene-bis-dithiocarbamate (Mn/Zn EBDC), has been linked to neurodegenerative diseases, such Parkinson’s disease (PD). The
vast majority of PD cases, however, are hypothesized to result from gene-environment interactions, not C. elegans strains: wild type (N2), a human LRRK2 G2019S mutant, and a strain with a park2 (pdr-1) deletion (VC1024). Each strain was treated with various concentrations of Mn/Zn EBDC (3.7 or 37 μM) for three consecutive days, with a proportion of the population assessed for lethality and mitochondrial function after each day. Following day 1 treatment, two-way ANOVA of tetrathymidinodamine ethyl ether (TMBE) accumulation indicated that only the presence of the treatment (DF=2, F = 33.98, ***p < 0.0001) contributed to the observed data variation. Post-hoc analysis showed that both mutant worm strains had statistically significantly less TMBE accumulation (**p < 0.01) than wild type worms. By the day 2, both the treatment (DF=2, F = 10.17, **p = 0.0024) and mutation (DF=2, F = 5.34, **p < 0.006), but not an interaction (DF=4, F = 2.43, p = 0.052), accounted for the variance. Contrary to day 1 data, however, WLZ3 (LRRK G2019S) worms showed a statistically significant increase in TMBE accumulation compared to N2 worms (**p < 0.001). This mutation effect was greatest in worms treated with 37 μM Mn/Zn EBDC. By day 3, the mutation alone accounted for the data variance (DF=2, F = 38.65, ***p < 0.0001). While TMBE accumulation levels for WLZ3 worms was similar to N2 worms, post-hoc analysis showed that WL1024 (pdr-1) worms had a statistically significant increase in TMBE (*****p < 0.001) at all treatment concentrations. To determine if the mitochondrial hyperpolarization suggested by augmented TMBE fluorescence adversely affected mitochondrial function, ATP levels were measured in WLZ3 worms. Results indicated statistically significantly increased ATP in day 1, but not other days, in worms treated with either concentration of Mn/Zn EBDC (**p<0.01). These results suggest that cells may compensate for the increased proton gradient by producing additional ATP. Taken together, these data support the hypothesis that subacute mancozeb exposure at levels below those used by agricultural workers leads to mitochondrial dysfunction, a characteristic of PD, and that this dysregulation may be more pronounced in C. elegans with PD-relevant mutations.

1429 Behavioral and Electrophysiological Effects of Early-Life Exposure to the Pyrethroid Insecticide Deltamethrin

Epidemiological data showed a correlation between pyrethroid metabolites in urine and increased risk of ADHD diagnosis in children. In rats, exposure to a commonly used insecticide deltamethrin (DM) is thought to play a critical role in neuropsychiatric disorders like ADHD, anxiety, and depression. The Nav 1.6 channel, critical in synaptic transmission, is abundant in the MSNs. Here, we investigate MSNs dysfunction due to developmental DM exposure and aberrations in a battery of behavioral assays. For our early-life exposure model, pregnant female B6 mice were exposed to 3.0 mg/kg of DM throughout pregnancy and lactation. Then, male mice litter-mates from post-natal day ~30 were used for subsequent experiments. We employed whole-cell patch-clamp electrophysiology in coronal brain slices to monitor changes in NAC MSNs firing due to developmental DM exposure. A decrease in the total number of action potentials and instantaneous firing frequency was observed (n=7-12, p<0.05). We are utilizing the same early-life exposure model to conduct a battery of behavioral assays measuring changes in anxiety and depressive like behaviors.

1430 Dithiocarbamate Fungicide Mancozeb Disrupts the Pituitary-Thyroid Axis and Cell Proliferation in Rat Hippocampus

M. Akhtar, and L. Trombeta. St. John’s University, Bellerose, NY.

Mancozeb is extensively used world-wide as a pesticide with millions of pounds applied annually in the United States alone to control plant diseases in the field and during storage. The presence of Mancozeb and its metabolite ethyleneurethane (ETU) in the environment can lead to ingestion, inhalation and/or transdermal absorption. Mancozeb is known to inhibit the enzyme thyroid peroxidase. Based on data obtained from both adult and fetal rats, adult onset hypothyroidism in humans is associated with cognitive dysfunction and depressed mood. Thyroid hormones are essential for the development of the mammalian nervous system. Hypothyroidism may lead to the reduction of newly generated neurons and altered differentiation in immature neurons of the dentate gyrus of the hippocampus. This study elucidated the thyroid disrupting potential of Mancozeb and its effects on the modulation of cell proliferation in the hippocampus of rats. Long-Evans rats were exposed to 0, 50, 100, or 150 mg/kg body weight of Mancozeb for 28 days. All animals received intraperitoneal injections of mitotic marker 5-bromo-2-deoxyuridine (BrdU, 50 mg/kg) twice daily on the last 5 days of Mancozeb exposure and were euthanized 24 hours after the last BrdU injection. At the end of exposure, total serum thyroxine (T4) levels were measured. Whole brains were isolated and cryopreserved for sectioning. Mancozeb exposure significantly decreased total T4 serum levels in a dose-dependent manner. Thyroid hormone disruption was reflected in a significant increase in serum levels of thyroid stimulation hormone (TSH) in rats exposed to Mancozeb, indicating a normal negative feedback response of the hypothalamic-pituitary-thyroid (HPT) axis due to low serum T4 levels. The effect of the hypothryoid status on cell proliferation in the hippocampus was assessed using the mitotic marker BrdU used to label dividing cells. A decrease in the number of BrdU-positive cells in the hilar region of dentate gyrus was observed in response to Mancozeb-induced hypothyroidism when compared to the control group. These results indicate that Mancozeb-induced reduction in thyroid hormone disrupts cell proliferation in the hippocampus, which warrants future investigation to address the functional significance.

1431 Antimycobacterial Screening and Safety Evaluation of Tithonia rotundifolia (Asteraceae), an Alien Invasive Plant Species in Southern Africa

Tuberculosis remains a global threat and one of the leading causes of mortality. The emergence of Multidrug-Resistant (MDR) and Extensively-Drug Resistant (XDR) tuberculosis has become a major challenge, especially in Africa. Considering this, the use of medicinal plants as a source of treatment is advocated. Tithonia rotundifolia, a known invasive plant with negative impacts in southern Africa, was screened against non-pathogenic Mycobacterium aurum, M. fortuitum, M. smegmatis and pathogenic M. bovis and M. tuberculosis H37Rv. Antimycobacterial activity of aceton, dichloromethane and hot water extracts of the weed plant was determined using a serial microdilution assay. Cytotoxicity test of the extracts against African Vero monkey kidney, human colon Caco-2 and human liver C3A cells was carried out using the tetrazolium-based colorimetric assay while genotoxicity test was conducted against Salmonella strains TA98 and TA100 using the Ames test. The tested extracts inhibited growth of pathogenic and non-pathogenic Mycobacterium strains, but better activity was displayed against the non-pathogenic strains M. aurum, M. fortuitum and M. smegmatis with minimum inhibitory concentration values ranging between 0.04 and 0.08 mg/ml. No toxicity of the extracts was recorded against the cells tested with the Vero cells showing LC50 values between 0.78 and 0.96 mg/ml and selectivity index (SI) value (LC50/MIC) ranging from 1.05 to 24.05. LC50 values for Caco-2 cells were between 0.198 and 0.32 mg/ml with SI values ranging from 1.01 to 5.83 and LC50 for C3A cells between 0.67 and 0.88 mg/ml and SI value ranging from 2.34 to 18.32. No genotoxic effects were displayed against the Salmonella strains TA98 and TA100. Identification of possible compounds responsible for the observed activity is ongoing. The results from this study serve as a lead for further investigation of this plant for the possible development of effective antimycobacterial treatments.

1432 Effects of Non-Gaseous Oxygen Therapeutic Drug on Five Human Cancer Cell Lines

S. Miller, F. Zhang, and E. Bruce. Baylor University, Waco, TX.

According to the National Cancer Institute, in 2018, an estimated 1,733,350 new cases of cancer will be diagnosed in the United States and 609,640 people will die from the disease. Given that cancer cells thrive in hypoxic environments, introducing oxygen into the cancerous environment through oxygen therapy may be vital to the patient, as supplying oxygen to the cells may starve them of the fuel they need to survive. Traditional oxygen therapy is most commonly known as Hyperbaric Oxygen Therapy (HBOT). This method starves them of the fuel they need to survive. Traditional oxygen therapy may be vital to the patient, as supplying oxygen to the cells may allow them to thrive and grow. Newer forms of oxygen therapy such as Hyperbaric Oxygen Therapy (HBOT) have been used to treat certain conditions, but their effectiveness remains uncertain. According to the National Cancer Institute, in 2018, an estimated 1,733,350 new cases of cancer will be diagnosed in the United States and 609,640 people will die from the disease. Evaluation of drug-induced gastrointestinal effects is an important aspect in early drug development for some drug classes. Tools for the in vitro assessment of target cells as well as for investigations of potential mechanisms of toxicity affecting the gastric mucosa are not widely available. We sought to develop additional in vitro methods that may potentially identify affected cells in the stomach mucosa therefore leading to enhanced understanding of the mechanism of the drug toxicity. Attention is paid to establish primary cultures of parietal cells isolated from dog stomach were not successful due to poor viability following a density gradient isolation procedure (Percol). Follow-on experiments utilized an innovative approach derived from dog stomach precision-cut tissue slice methodology. Stomach mucosa was dissected free from the submucosa and slices of the isolated mucosa were prepared using a tissue slicer and cultured in Williams E media. Effects of variables such as the thickness of the slices, incubation duration of the tissue slices, and the role of components of the culture media were evaluated. Stomach slices were harvested at 0 (baseline), 24 and 48 hours after the slicing. Cellular morphology and viability of the cells in the slice were evaluated using histopathology. Results indicated that maximum viability of stomach slices is the highest at baseline, followed by 24 hours of incubation. The stomach slice after 48 hours of incubation showed significant necrosis and could not be used for the study. The addition of 10% FBS into the culture media did not improve the viability of the tissue slice. In situ hybridization to identify the H+/K+ ATPase a subunit of the proton pump allowed specific identification of parietal cells. Our preliminary results indicate that the stomach slice culture technique combined with H&E and in situ hybridization provides a useful model system to monitor changes induced by experimental compounds affecting the cell types of the stomach in vitro for studies up to 24 hours in length.

**1434 High-Throughput Assessment of Cardiotoxicity Using Bioreactor Produced hiPSC-Derived Cardiomyocytes**

F. Famili, A. Reijerkerk, G. Luerman, T. Wai Lam, P. van Loenen, M. Bras, S. Honarenejad, Y. Jiang, H. Rutjes, S. Braam, and A. Reijerkerk

1Ncaridia, Leiden, Netherlands; 2Ncaridia, Germantown Pike, PA; and 3Pivot Park Screening Centre, Oss, Netherlands. Sponsor: G. Luerman, Safety Pharmacology Society

Off-target cardiotoxicity effects are the most common cause of delay in approval or even withdrawal of newly developed drugs. The application of human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) in safety pharmacology has opened unique opportunities for studying cardiac pharmacology in a platform and prediction model which is comparable with high-throughput approaches. Importantly, the technology has the potential to improve preclinical testing of drug candidates, and to reduce the time and cost of bringing new drugs to market. Calcium ions play a critical role in the electrophysiology of cardiomyocytes and regulate cardiac contraction. Primary human induced pluripotent stem cell-derived cardiomyocytes (Pluricyte® Cardiomyocytes), which recapitulate a human cardiomyocyte’s contractile and electrophysiological profile, we developed a Ca2+-flux assay to evaluate cardiotoxicity of drugs. To enable robust and scalable production of our cells for HTS applications, we have implemented a bioprocessing pipeline comprising staged -the-art bioreactor technologies. The Ca2+-flux assay was developed on a fully automated platform using FLIPR® Tetra kinetic plate reader in combination with FLIPR® calcium 6 assay kit (Molecular Devices). Pluricyte® Cardiomyocytes culturing steps in 384-well plate including plate coating, cell seeding and medium refreshment were performed in a fully automated manner using Fluent® workstation (Tecan). Using this assay, which was validated for average peak amplitude, beat frequency and peak spacing, we evaluated multiparametric effects of a set of 288 test compounds. The effects of compounds were compared to relevant negative (Nifedipine) and positive inotropic (Bayk 8644) and chronotropic (Isoprenaline) controls. The assay was validated using 32 replicates of each control per 384-well plate, revealing a robust assay window (> 2) at high reproducibility (%CV < 20). Altogether, our results confirm that the validated calcium flux assay is ready for high throughput screening to assess cardiotoxicity of compounds during the early phase of drug discovery. Phenotypic screening based on human models does not only reduce the number of late stage compound failures, it also allows continuation of projects that otherwise would fail. These state-of-the-art technologies hold great promise to get better drugs to patients faster.

**1435 Simultaneous Measurement of Contraction, Voltage and Calcium in hiPSC-CMs for the Detection of Inotropic Effects under Blinded Conditions**

1Ncaridia, Leiden, Netherlands; 2Leiden University Medical Center, Leiden, Netherlands; 3GlaxoSmitKline, Hertfordshire, United Kingdom; 4GlaxoSmithKline, Leiden, United Kingdom; and 5University of Nottingham, Nottingham, United Kingdom. Sponsor: T. de Korte, Safety Pharmacology Society

Novel in vitro models based on human-induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) provide an unprecedented opportunity for next generation cardiac safety assessment and drug efficacy screenings. While current safety approaches are mainly focused on electrophysiological assessments, the ability to identify effects on contractility remains challenging. Within the CRACK-IT InPulse Challenge, we aim to generate a physiologically-relevant contractility platform using hiPSC-CMs. Here, we present one of the platforms being evaluated within CRACK-IT and aim to simultaneously measure contraction, voltage and calcium in hiPSC-CMs to evaluate inotropic effects of compounds under blinded conditions. 7 out of the 10 test compounds were correctly classified as negative or positive inotropes or “no effect” compounds. Epinephrine, a non-selective adrenergic agonist, induced an increase in calcium peak amplitude, a decrease in calcium transient time to peak and a decrease in contraction time (positive inotropic effect). Forskolin, an adenylyl cyclase stimulator, showed positive inotropic (increase in contraction and calcium peak amplitude), chronotropic and lusitropic (decrease in relaxation time) effects. Negative inotropes showed decreases in calcium and contraction peak amplitudes. Verapamil also showed negative lusitropic and inotropic effects and altered electrophysiology. The calcium sensitizers/PDE3 inhibitors (levosimendan, pipomobendan) were classified incorrectly. The ability to simultaneously quantify multiple dynamic parameters in hiPSC-CMs provided crucial insights into electrophysiological and contractile drug responses. The assay was capable of detecting inotropic effects of compounds with various MoA. PDE3 inhibitors were not identified by the assay. This suggests that approaches to further advance hiPSC-CM culturing conditions or improving maturation are needed to further improve the predictive value of hiPSC-CMs in drug testing.

**1436 Assessment of Drug-Induced Liver Injury (DILI) Using 3D Human Liver Microtissues**

M. Kijanska, S. Messner, E. Thoma, P. Guye, and R. Kostadinova

InSphero AG, Schlieren, Switzerland.

Preclinical safety assessment is an essential step in drug development and drug-induced liver injury (DILI) constitutes a major hurdle for the progression of drug candidates to clinical studies. Thus, it’s critical to have predictive and scalable in vitro model systems for evaluating hepatic drug safety. Based on our proprietary technology, we developed human 3D liver microtissues (hLiMTs) as a highly predictive and scalable model system for drug safety assessment. Composed of primary human hepatocytes, and non-parenchymal cells (Kupffer and liver endothelial cells), hLiMTs display key physiological features and can be cultured up to four weeks for the assessment of long-term drug toxicity. A validation experiment analyzing 110 marketed drugs revealed that 3D hLiMTs exhibited a more than 2-fold increased sensitivity for detection of DILI compounds compared to 2D primary hepatocytes. Moreover, our system is compatible with the whole range of endpoints from classical biochemical assays, such as LDH leakage, albumin secretion, cell viability, omics (e.g., genomics, transcriptomics, lipidomics, etc.) and translational readouts such as AST. Thus, 3D hLiMT enable robust and predictive compound screening in a high throughput format to assess complex and mechanistic toxicity challenges. The 3D hLiMT model is available in 96-well and 384-well plates and may also be used in a plug-and-play organ-on-a-chip and a Microphysiological Platform System (Body on a Chip) to enable robust and predictive compound screening at a high throughput and scale as well as to assess complex, specific investigative toxicity challenges. In summary, we present that 3D hLiMT is a promising powerful alternative to 2D in vitro cell models and animal models that may be applied in preclinical safety evaluation of novel drug candidates, thus representing a valuable tool for pharmaceutical research.
A Novel 68-Gene Biomarker Signature to Identify Respiratory Irritation/Toxicity Induced by Inhaled Compounds Using Machine-Learning Assisted Classifications Based on Transcriptomic Data from Calu-3 Cells

An integrative discovery toxicology strategy, in which potential drug safety concerns are identified and mitigated early during drug discovery, is a key determinant of success for the development of novel innovative drugs. This requires the application of an arsenal of in vitro assays that predict clinical safety and provide mechanistic understanding of drug-induced toxicity. Novel therapeutically active agents for treatment of respiratory diseases, including asthma and chronic obstructive pulmonary disease, are often delivered by inhalation directly to the diseased tissue, which enables direct access to diseased tissue and low systemic exposure to minimize adverse effects in secondary organs. Therefore, there is a need to establish in vitro assays to screen for respiratory tract toxicity that can be employed during early stages of drug discovery. Since we have previously successfully established transcriptomic biomarkers for skin sensitization and respiratory sensitization, we explored the possibility to develop an in vitro assay for assessment of respiratory irritation/toxicity based on genomic biomarkers in chemically exposed cell cultures, with subsequent machine-learning assisted classifications. The lung-associated epithelial Calu-3 cells were exposed to a reference panel consisting of 18 compounds with a well characterized respiratory safety profile and whole genome expression data was obtained using microarray technology from biologically triplicated samples. Using a combination of analysis of variance and data-driven feature selection methods, a biomarker signature composed of 68 differentially regulated genes was established. The predictive functionality of the proposed biomarkers was verified using a leave-K-out Support Vector Machine (SVM) cross-validation exercise, establishing the predictive accuracy to 94%: 6 of 7 irritants and 11 of 11 non-irritants were correctly classified. In summary, we have established a novel 68-gene transcriptomic biomarker signature in a simple cell system, which can be employed to provide an early indication of respiratory irritancy/toxicity of inhaled drug candidates.

Controlled Conditions Reduce Critical Edge Effect in 96-Well Plates

The Edge Effect causes a substantial loss of usable assay space in pharmaceutical drug discovery assays conducted with 96-well culture plates. While mechanisms for reducing evaporation in edge wells have been employed to reduce variability in cell density, we have preliminary data suggesting that differences in temperature in edge wells while cells are settling may be a major contributing factor. Here we extend those results with careful temperature studies during and after cell plating processes with the premise that maintaining the temperature of all parts of the cell environment including plates, reservoirs, and tips, as well as the liquids at a constant 37 degrees C during cell plating will reduce edge effects. Our null hypothesis is that the Edge Effect cannot be reduced by comprehensive temperature control. We used the Xvivo System to control the environment, including the cell processing chamber floor, to a constant 37 degrees C during cell plating and cell settling, comparing results there to those obtained plating in a room temperature laminar flow hood. In both settings, we used a FLIR ONE thermal imaging camera to record movies of temperature changes in 96-well plates as well as the pipetting reservoir during and after routine cell plating. We used the HoloMonitor M4 microscope to record time lapse images of cells settling in the wells. We also used standard cell density assays to assess variability in plated adherent A549 human lung carcinoma cells. We found that plating cells under controlled, constant temperature conditions did eliminate swings in well temperatures during cell plating and cell settling that were produced by plating cells in uncontrolled room air conditions. Constant conditions also reduced variability in edge well cell density, disproving the null hypothesis. We concluded that constant conditions for cell plating and cell settling could reduce Edge Effect and, by allowing usage of all wells, have a tremendous impact upon the time and resources devoted to all cell-based toxicity assay processes.

A Novel 68-Gene Biomarker Signature to Identify Respiratory Irritation/Toxicity Induced by Inhaled Compounds Using Machine-Learning Assisted Classifications Based on Transcriptomic Data from Calu-3 Cells

K. Makita-Suzuki1, C. Kakinuma1, Y. Sakata1, T. Yamakawa1, A. Inomata1, and T. Hara1. 1FUJIFILM Corporation, Kanagawa, Japan; and 2FUJIFILM Corporation, Kanagawa, Japan. Sponsor: A. Inomata, Japanese Society of Toxicology

Background: Liposomal drugs have been recently approved that attenuate adverse effects and/or improve the efficacy of active pharmaceutical ingredients (APIs), such as Doxil (liposomal doxorubicin) and CPX-351 (liposomal formulation of cytarabine and daunorubicin). However, possible pathological responses due to the physicochemical properties of these liposomal formulations remain unknown. In the present study, we examined pathological changes in canine liver and gall bladder following injection of Doxil or empty liposome (a liposomal formulation without an API). Method: A single dose of Doxil or empty liposome was administered intravenously to eight-month-old beagle males (N=4/group), and gross necropsy was conducted at 24 hours post-injection. The liver and gall bladder were then examined histopathologically. Result and Discussion: Reddish foci were observed in the liver (sub-adventitia of gall bladder) and gall bladder (serosa from body to bottom) at necropsy in 2 of 4 males per treatment group. In histopathology, there were perivascular hemorrhage around the central/sublobular vein or Glisson’s sheath, dilated lymphatic vessels around the central vein in the liver, and hemorrhage in the adventitia of the gall bladder. Decreased cytoplasmic granules in mast cells beneath the endothelium of the hepatic vein were also noted. No differences were observed in the incidence and severity of the hemorrhagic changes between the two groups, suggesting that physicochemical properties of the liposomal formulations rather than the API caused these changes. These were considered as acute changes, because they occurred within 24 hours post-injection accompanying with little cellular infiltration. Based on these findings, we speculated physiological active substances released from mast cells contributed to the pathogenesis of hemorrhagic changes, and these changes may not occur in other experimental animals, which do not have subendothelial mast cells in the hepatic vein.

Toxicopathologic and Pathologic Evaluation of Cytochromes P450 Inhibition by 1-Aminobenzotriazole following Repeated Oral Administration in Wistar Rats

1-Aminobenzotriazole (1-ABT) is a pan-specific, mechanism-based inhibitor of cytochrome P450 enzymes, often used as co-treatment to investigate the metabolism-dependent toxicity of drugs and chemicals. To assess the confounding effects of 1-Aminobenzotriazole (ABT) in such kind of mechanistic studies, a repeated dose toxicity study with ABT following 7 days oral administration at 0, 25, 50 and 100 mg/kg/day was performed in Wistar rats (5 rats/sex/group). The parameters of standard general toxicity study viz. clinical signs, body weight, feed consumption, hematology, clinical chemistry, organ pathology, organ weight and histopathology was evaluated in this study. The 1-Aminobenzotriazole was tolerated up to the highest tested dose of 100 mg/kg/day. Neither clinical signs nor any mortality was observed at any dose tested. Slight increase in body weight gain was noted in ABT treated females. There was no significant change in food consumption throughout the study. Increased reticulocyte count and decreased triglycerides, BUN, A/G ratio and plasma potassium levels were noted in ABT treated animals. Increases in liver, kidneys, adrenals, and thyroid weights were noted in ABT treated animals. Microscopic findings included follicular cell hypertrophy in thyroid, hyper trophy in adrenal glands (zona fasciculata), basophilic cell hypertrophy in pituitary, and endometrial hyperplasia in uterus at all dose levels and hepato-cellular hypertrophy was noted at 100 mg/kg/day only. Based on this study it is concluded that 1-Aminobenzotriazole is tolerable up to 100 mg/kg/day with some changes in clinical pathology, organ weight and histopathology; these changes should be considered during the assessment of any mechanistic study with ABT.
Small Molecule Inhibitor of BRG1/SMARC4-ATPase (SWI/SNF Complex) in Phenotypic-Induced Gastrointestinal Toxicity with Possible Progenitor Cell Modulations in Athymic Mice

Members of the ATP-dependent SWI/SNF chromatin remodeling complexes are among the most frequently mutated genes in human tumors and their dysregulation plays critical role in carcinogenesis. Recent studies have shown a synthetic lethal relationship between BRM/SMARC2 and BRG1/SMARC4 in which BRG1-deficient cancer cells depend on BRM for proliferation. This discovery steered great interest in pursuing the therapeutic targeting of BRM for the treatment of BRG1-mutant/different cancers. We have discovered Compound-X, a dual small molecule inhibitor of BRM and BRG1 ATPase, as a candidate anti-cancer drug. Therapeutic potential of the Compound-X showed significant engagement through KRT80 messenger modulation and tumor growth inhibition in athymic mice. However, efficacy (decreased in implanted tumor xenograft sizes) was only observed at the dose associated with body weight loss, triggering study termination. Microscopic evaluation results revealed the poor condition of athymic mice from the study were due to the changes in the gastrointestinal (GI) tracts. In the intestines, there were altered villus architectures characterized by villus fusion/clumping with loss of discrete crypt structures. The intestinal epithelial cells were composed of relatively immature cells represented by increased cytoplasmic basophilia and large nuclei as well as decreased goblet cell populations. In the large intestine, there were ulcerations as well. Immunohistochemistry investigation results showed there was decreased Olfm4 (stem marker) expression in the ileum without expression change in proliferation index marker Ki67. Similar histopathological and Olfm4 expression changes are reported with intestinal tissue specific BRG1 Knock-Out mice. While we cannot completely rule out scaffold related off-target effects, these findings potentially inform concerns on off-target toxicity associated with dual BRM/BRG1 small molecule inhibition.

Cardiotoxicity Assessment of Triclosan in Human Stem Cell-Derived Cardiomyocytes

G. Du, W. Hu, C. L, Y. Xia, and X. Wang, Nanjing Medical University, Nanjing, China.

Triclosan (TCS), as a broad-spectrum antibacterial agent, is frequently detected in the environment and humans. There is increasing evidence TCS can transport across the placenta and affect fetal heart development via maternal exposure. Herein, human embryonic stem cells (hESCs) based cardiac differentiation model was used to determine the cardiotoxicity of TCS. hESCs were subjected to a 21 days' differentiation protocol with TCS or control treatment. Cell morphology, spontaneous beating rates of cardiomyocytes (CMs), cardiac differentiation rates were recorded. Then gene transcriptome and genome-wide DNA methylation analysis were performed. TCS greatly inhibited CMs generation and the spontaneous beating rates of CMs. Differentially expressed genes (DEGs), including 917 up-regulated and 1246 down-regulated DEGs, were identified by RNA-seq. The GO analysis revealed that these DEGs were mainly involved in aberrant cardiac development pathways. DNA methylation status was also altered by TCS exposure. 424 hypo and 779 hyper differentially methylated regions (DMRs) were identified. Several heart development transcription factors and other cardiac marker binding sites were enriched in DMRs, including GATA family members. Further combining the DNA methylation and gene expression profiles, we found a group of down-regulated cardiac development genes exhibited hypermethylated sites. In conclusion, our findings suggest exposure to TCS stimulated a reprogramming of the DNA methylation in the hESCs-derived CMs, thereby orchestrating changes in gene expressions consistent with CMs development defects. In addition, hESCs-derived CMs model enables quantitative screening of the potential cardiotoxicity of environmental chemicals in a short-term experiment.

Possible Window of Susceptibility-Dependent Effects of Tretinoin on Human Cardiomyocyte Differentiation

E. J. Tokar, and X. Wu, NIHES/NTP, Durham, NC.

Retinoic acid is essential throughout a person’s lifetime, but it is critical during pregnancy. Tretinoin, also known as all-trans-retinoic acid (ATRA), is a naturally occurring derivative of vitamin A (retinol). It regulates cell proliferation and differentiation and can be used to treat acne and photodamaged skin. Tretinoin is also used in the treatment of acute promyelocytic leukemia (APL). However, during embryonic development, the effects of tretinoin at the cellular level could lead to teratogenic effects on the central nervous system and on heart development. Embryonic stem cells (ESCs) offer an excellent opportunity for studying the mechanisms of developmental toxicity. To explore the potential adverse effects of tretinoin on cardiomyocyte formation, we used an ESC line containing an Nkx2-5 reporter to model mesoderm differentiation and cardiac induction. Using an 8-day differentiation protocol, we examined the effects of tretinoin during different potential windows of susceptibility on cardiomyocyte differentiation. Tretinoin (EC50 = 0.001 μM; Cmax value 0.12 μM) suppressed expressed cardiac induction and cardiac differentiation. Across a range of concentrations (0.01 - 10 μM), cardiomyocyte differentiation was dramatically inhibited when the ESCs were exposed to tretinoin during the mesodermal induction stage (Days 0 to 2) of the differentiation protocol. However, when the ESCs were exposed only during the cardiomyocyte induction stage (Days 2 - 4 only), tretinoin had little to no effect on the differentiation of the ESCs to cardiomyocytes. Mesoderm-associated transcription factors, Musp1 and Mlx1, showed a transient up-regulation, while the transcription factors and mesoderm markers Hand1, Sna2, Hoxp, and cardiac-specific genes Nkx2-5, Gata4, Troponin T, and α-Actinin were all significantly suppressed during early tretinoin exposure (Days 0 - 2 only) compared with exposures during the later cardiomyocyte induction stage (Days 2 - 4 only). Together, these results suggest a specific window of susceptibility to tretinoin during cardiomyocyte differentiation, which could result in cardiac-related malformations initiated during pregnancy. Additional work is being conducted to further elucidate mechanisms involved in these aberrant effects, and to determine a possible NOEL of tretinoin on cardiomyocyte differentiation.

Comparative Analysis of Human iPSC-Derived Cardiomyocytes in Diversity and Disease Modeling

D. Majewski, J. Liu, S. Lor, T. Feaster, S. Hilcove, and E. Jones. FUJIFILM Cellular Dynamics, Madison, WI. Sponsor: K. Kolaja

Human cell types differentiated from induced pluripotent stem cells (hiPSCs) provide a unique access to human cellular material for safety and toxicity screening. Here, we present data demonstrating the utility of hiPSC-derived cardiomyocytes (hiPSC-CMs) in safety assessment and disease modeling. We include a comparative assessment of the human safety profile of CTRCD compounds doxorubicin (type I) and sunitinib (type II) across hiPSC-CMs derived from 6 healthy donors (DIV 14) at three concentrations [0.1, 1.0, and 10 μM]. Clinically type I CTRCD may be associated with cellular death, structural changes, and permanent damage while type II CTRCD may be associated with cellular dysfunction, no structural changes, and reversible damage. Here, we identify both type I and type II CTRCD using a selected in vitro cohort of hiPSC-CMs. These data further provide additional insight into sensitivities to cancer therapeutics across different donors. In addition, we elucidate basic functional characterization and pharmacological response for several hiPSC-CM disease models including hypertrophic cardiomyopathy MYH7 (R403Q), LMNA-related dilated cardiomyopathy LMNA (L35P), and brugada syndrome type 3 CACNA1C (G490R) each with its respective isogenic control at DIV 14. We further identify the functional consequences of each mutation and demonstrate that each model recapitulates classical hallmarks of the disease. These data illustrate how hiPSC-CMs provide an excellent model system for assessing compound effects across multiple donors and disease models. Taken together, these examples should help to create new avenues for safety liability assessment and toxicology studies, as well as serve as a template for future opportunities in disease modeling with hiPSC-CMs.

Mechanisms of Cadmium and Arsenic-Induced Aberrant Differentiation of Human Embryonic Stem Cells to Cardiomyocytes during Heart Development

X. Wu, A. Luz, G. Hu, and E. Tokar, NIHES/NTP, Durham, NC.

Cadmium (Cd) and arsenic (As) are widespread environmental contaminants. Human exposure to Cd and As occurs mainly through ingestion of contaminated food or water. Cd and As exposure are associated with cardiovascular diseases, and maternal exposure to Cd and As are significant risk factors for congenital heart disease (CHD). However, the mechanisms of Cd and As on developmental cardiotoxicity are not well-defined. Embryonic stem cells (ESCs) offer an excellent opportunity for studying the mechanisms of developmental toxicity. 2D aggregates of ESCs, called embryoid bodies (EBs), can recapitulate events involved in early embryogenesis such as germ layer formation. Here, we found that a 7-day exposure to a human-relevant, non-cyto-
toxic dose (0.6 μM; 100 ppb) of Cd inhibited differentiation of EBs to ectoderm and mesoderm via suppression of Wnt/β-catenin signaling pathways, which play critical roles in early embryonic development. We also found As suppressed key regulators involved in Wnt/β-catenin signaling pathways at a non-cytotoxic dose (0.5 μM; 35 ppb). Human atrial and ventricular cardiomyocytes derive from mesoderm populations. NTRK-2-5 is a transcription factor that plays key roles throughout heart development and formation, and mutations can lead to atrial and ventricular defects. To explore potential adverse effects of Cd and As on cardiomyocyte formation we used a 2D ESC line containing an NTRK-2-5 reporter to model mesoderm differentiation and cardiac induction. Using an 8-day differentiation protocol, Cd (0.15 μM; 27 ppb) and As (0.05 μM; 6.5 ppb) suppressed cardiomyocyte differentiation. Mesoderm-associated transcription factors MESP1, MIXL1, EOMES, and GSC showed a transient upregulation, while the transcription factors and mesoderm markers HAND1, SNAI2, HOPX, and cardiac-specific genes NTRK-2-5, GATA4, Troponin T, and α-Actinin were all suppressed when treated with Cd. In conclusion, low concentration Cd suppressed mesoderm formation through Wnt/β-catenin signaling pathways and thus inhibited downstream cardiomyocyte differentiation and cardiac induction. As inhibited cardiomyocyte differentiation specifically through key genes in Wnt/β-catenin signaling pathways. These studies provide valuable insights into the cellular events and molecular mechanisms associated with Cd and As-induced CHD.

**1446 Gene-Environment Interaction of DDT/ DDE and APOE on the Amyloid Pathway in Induced Human Neurons**

A. D. Morris, A. Eid, J. R. Richardson, and R. P. Hart. Rutgers, The State University of New Jersey, Piscataway, NJ; and Florida International University, Miami, FL.

The E4 allele of the Apolipoprotein E (APOE) gene contributes the greatest single genetic risk for late-onset Alzheimer Disease (LOAD), but it is also affected by factors including age and environmental exposure. The pesticide dichlorodiphenyltrichloroethane (DDT) has been identified as a risk factor for LOAD due to its persistent bioaccumulation and elevated serum levels of the DDE metabolite, dichlorodiphenyltrichloroethylene (DDE) of AD patients, even after it was banned in the U.S. over forty years ago. Further, we observed that there were significant interactions between serum DDE levels, APOE genotype and cognitive dysfunction, with APOE ε4 genotype and higher DDE levels being associated with worsened cognitive function. Mechanistically, our previous experiments found significant increases in amyloid precursor protein (APP) levels in differentiated SH-SY5Y cells and primary mouse hippocampal neurons after DDT/DDE exposure. To confirm this observation in a human neuron model, we prepared induced neurons (iNs) by reprogramming induced pluripotent stem cells (iPSC) with NGN2. To test the hypothesized interaction of DDT/DDE exposure with APOE genotype, we used two isogenic iPSC lines, one with APOE ε3/ε4 and one engineered to carry inactivating frameshift mutations in both alleles (APOE-null). Preliminary results show that 24 hr treatment of heterozygous ε3/ε4 iNs with 1 μM DDT or DDE exhibited increased expression of APP in neurons, as measured immunocytochemically. Furthermore, we observed a synergistic interaction of DDE and APOE genotype, since APP expression was uniformly reduced in the APOE-null neurons and there was no evidence of an induction of APP by DDT or DDE. Results suggest that DDT/DDE acts in conjunction with APOE, altering the expression of APP, potentially increasing neurotoxic Aβ and contributing to the development of AD.

**1447 High-Throughput Toxicity Screening of iPSC-Derived Neurons on Synthetic Hydrogels**

J. Evans, G. Kaushik, E. Torr, V. Harms, W. T. Daly, and W. L. Murphy. University of Wisconsin-Madison, Madison, WI.

The developing central nervous system is often more susceptible to damage than the adult one, especially through exposure to neurotoxicants. Of the over 80,000 chemicals currently available, only 200 have undergone developmental neurotoxicity (DNT) testing according to established guidelines. The use of animal models in predicting neurotoxicity (NT) is costly, time consuming, and results often fail to translate to human physiology. Other culture scaffolds such as Matrigel introduce concerns regarding variability between batches, providing the need to develop a synthetic substrate for in vitro modelling of NT using human cell models. In this study, we evaluated neurite outgrowth as a potential screen to determine the effects of compounds on the developing nervous system. To model neurogenesis in vitro, we cultured human iPSC-derived neurons on poly(ethylene glycol) hydrogels functionali zed with CRGDS and IKVAV peptide sequences in a poly-L-lysine coated 384-well plate. After culturing the neurons for 3 days on hydrogels, we treated them with neurotoxicants at 0.1, 0.4, 1.6, 6.25, 25, and 100 μM concentrations. Multiple DMSO controls were included in each plate. Neuronal retraction due to exposure to compounds was studied over the course of 5 days. Networks were characterized and validated with neuron-specific cytoskeletal protein (βIII Tubulin, MAP-2) markers. Our results showed significant neurite regression in response to the drug thalidomide at high concentrations. Additionally, neuronal network analysis found a decreasing trend in total network area as concentrations increased. Our high-throughput screening avoids the concerns surrounding the use of animal-derived substrates while capturing the physiologically-relevant process of neuronal network formation in the development of the nervous system.

**1448 Classification of Drug-Induced Seizure-Like Activities in Cultured Human iPSC-Derived Neurons**

Human induced pluripotent stem cell-derived neurons are promising for use in toxicity evaluations in nonclinical studies. One of the major adverse events affecting the central nervous system observed during clinical trials is convulsions. Micro-electrode array (MEA) systems have recently attracted attention for use in evaluating the convulsion potential of a drug because they non-invasively measure the electrophysiological activity of neural networks at multiple sites in a high-throughput manner. MEA subteam of Neurotoxicity (NeuTox) Committee in Health and Environmental Science Institute (HESI) initiated the NeuTox Micro-Electrode Array (MEA) Subteam initiated pilot study using MEA for the prediction of seizure liability of drugs. Human iPSC-derived cortical neurons were cultured on 24-wells MEA plate for extracellular recording using Presto. Twelve compounds (pentylentetrazole, picrotoxin, 4-aminoypyridine, linopirdine, amoxapine, styrchicine, plicarpine, amoxicillin, chlorpromazine, enoxacin, phenytoin and acetaminophen) were tested at 5 concentrations for each compound. Using spontaneous firings data to drug administration, we identified the parameter sets that can separate the responses between convulsive drugs and negative control, and the responses among the several convulsiung drugs, differentiating with different principal component analysis and clustering methods. These analysis method will be effective for detecting convulsive response and predicting mechanism of action of convulsive drugs.

**1449 TRP Channel Responses in Human iPSC-Derived Sensory Neurons Using MEA System**

Functional evaluation assays using human induced pluripotent stem cell (hiPSC)-derived sensory neurons are expected to predict the pain-related toxicity of drugs and the pharmacological effects. However, evaluation assays in hiPSC-derived sensory neurons has not been established, and transient receptor potential (TRP) channel responses to pain-related molecules are also not known. In this study, we aimed to evaluate the TRP channel responses against pain-related molecules including anticancer drugs in cultured hiPSC-derived sensory neurons using high-throughput multi-electrode array (MEA) system. Human iPSC-derived sensory neurons were cultured on MEA chips (Presto), and the electrophysiological responses against capsaicin, menthol, allyl isothiocyanate (AITC), anticancer drug vincristine and oxaliplatin were measured by the MEA system. We firstly confirmed the expression of typical sensory neuron marker Nav1.7, TRPV1, TRPM8, and TRPA1 using immunostaining in culture hiPSC-derived sensory neurons at 8 weeks culture. Evoked responses against capsaicin, menthol, and AITC administration were detected using MEA system. To confirm the responses depending on each TRP channel, we examined the responses in presence of each channel antagonist. As the responses almost disappeared in presence of each channel blocker, these responses were confirmed to be TRP channel specific responses. The evoked responses against anticancer drug vincristine and oxaliplatin administration were also detected. Next, we examined whether the increase of cold sensitivities occur in presence of anticancer drug oxaliplatin in vitro hiPSC-derived sensory neurons. The responses against AITC were increased in presence oxaliplatin and in a concentration-dependent manner. In summary, we have succeeded in detecting the electrophysiological pain responses against capsaicin, menthol, allyl isothiocyanate (AITC), anticancer drug vincristine and oxaliplatin in hiPSC-derived sensory neurons using MEA system. We found that the increase of cold sensitivities in vivo phenomenon was also detected in vitro hiPSC-derived sensory neurons. MEA measurements using hiPSC-derived sensory neurons are useful to pain evaluation assay in human peripheral nervous system.
Cigarette smoking is associated with several types of cancers including hematological malignancies and a relationship between smoking and the risk for myeloproliferative neoplasms (MPN) has been shown. The mechanisms of smoke induced impairment of the hematopoietic system is thought to occur via the chronic inflammatory and pro-oxidant state linked to cigarette use. We hypothesize that cigarette smoke induces a pro-oxidant and pro-inflammatory state in the bone marrow leading functional changes in hematopoietic cells. Aqueous cigarette smoke extract (CSE) was prepared by drawing the mainstream smoke from 1 cigarette by continuous negative pressure into 10ml of buffer to produce 100% CSE. Murine bone marrow cells (BMcs) and human peripheral blood mononuclear cells (PBMCs) were isolated using standard methods and treated with CSE for 24 hrs with or without N acetylcytysteine (NAC). Colony formation in methylcellulose and cell viability by Annexin V and propidium iodide staining were determined in exposed cells. Reactive oxygen species (ROS) was determined using theDCF fluorescent dye on cells exposed for one hour. BMcs treated with CSE showed a dose dependent increase in ROS which was reduced on co-incubation with NAC. Cell viability was also decreased in CSE treated cells compared to controls. There was a profound decrease in the number of progenitor cell colonies formed by bone marrow cells exposed to CSE which was rescued by co-incubation with 100μM NAC. PBMCs from both normal and MPN subjects also exhibited reduced colony formation in response to CSE which was inhibited by incubation with NAC. We observed that CSE has an in vitro inhibitory effect on hematopoiesis accompanied by an increased redox status and cytotoxicity. Future studies will examine the cytotoxic responses and signaling cascade of BMcs and PBMCs in response to smoke extract and the effects of E-cigarette smoke condensate.

In order to investigate the mechanism of busulfan-induced chronic hematotoxicity, busulfan was intraperitoneally administered to female C57Bl6/JNcSic (CD45.2) mice (3 times/week, total 10 times, 10 ml/kg) at 0.5, 4.5, or 8 mg/kg. Hematological examination was conducted 1, 2, 3, and 4 months after the completion of dosing and bone marrow analysis by flow cytometry was performed 1 and 4 months after dosing. Moreover, a competitive bone marrow transplantation was conducted to evaluate the stem-cell and multipotent differentiation of hematopoietic stem cells (HSC) using C57BL/6 mice congenic for the Ly5 locus (CD45.1 mice) and lineage negative, c-kit positive, and Sca-1 positive cells (LSK) collected from CD45.2 mice 4 months after dosing. Furthermore, gene expression analysis was conducted in HSC and LSK at 4 months post-dose. In hematology, continuous decreases in red blood cells (RBC) and platelets (PLT) were observed at 4.5 and 8 mg/kg during the study period. In flow cytometric analysis of the bone marrow, decreases in HSC, multipotent progenitors (MPP) 3 and 4, megakaryocyte progenitors (Pre-MegE and MKP), and erythroid progenitors were observed at 4.5 or 8 mg/kg even at 4 months post-dose. Cell cycle analysis showed that quiescent cells in CD34 negative LSK decreased at 4.5 and 8 mg/kg 4 months after dosing. In bone marrow transplantation, chimerism of myeloid cells, B cells, and T cells in peripheral blood were lower than those in the corresponding control from 1 to 4 months after the transplantation. Moreover, chimerism of HSC, granulocyte-macrophage progenitors, megakaryocyte-erythroid progenitors, and common lymphoid progenitors in the bone marrow also decreased even at 4 months post-transplantation. Gene expression analysis revealed that cell cycle was activated and stem cell function and differentiation potential into erythroid lineage and megakaryocytes were inhibited in HSC or LSK. In conclusion, busulfan induced impaired self-renewal and multipotency of HSC, followed by decreased megakaryocyte progenitors and erythroid progenitors resulting in continuous decreases in RBC and PLT in mice.
Cell heterogeneity is a feature of cancer cell populations. Total cell population behaviour in response to a particular environment may not be replicated in a specific group of cells or sub-population. Determining which sub-population, if any, displays a specific biological response, and whether the plasticity of a group of cells within the population could be influenced by the environment is important for understanding biological response. To investigate this, the gastric cancer cell line SNU1, was treated with benzo[a]pyrene (BaP), a potent IARC Group 1 human carcinogen, to induce phenotypic response including DNA damage, confirmed by micronucleus assay. In addition to established BaP-AhR-associated genes (CYPs) (i.e. CYP1a1, CYP1b1, AhR, AHRR, ARNT), key genes commonly associated with epithelial to mesenchymal transition (i.e. SNAIL-1) and cell stemness (i.e. Oct3/4, Nanog and Sox2) were also temporally induced by BaP (10^{-7} M to 10^{-5} M). We suspected that certain sub-populations within the SNU1 total population were influencing biological function. Therefore, flow cytometry was used to observe the expression of cell surface marker of two BaP-treated sub-populations, CD24 and CD166. Each sorted population of CD24+CD166+ and CD24+CD166− shows different regulation of genes associated with stemness and BaP-induced phenotypic change. CNTNB1, a target gene of Wnt/β-catenin, was upregulated in the unsorted SNU-1 population, down-regulated in the sorted population of CD24+CD166+ population (BaP 10^{-7} M to 10^{-6} M) and remained unchanged in the sorted population of CD24+CD166−. Moreover, the induced expression of AhR-related and stemness genes found in the sorted CD24+ population, potentially indicates that this is the most probable candidate contributing to the plasticity of SNU-1. The co-existence and interaction of sub-populations within the SNU-1 cell culture plays a significant role in cell plasticity and in sustaining key signalling pathway responses and maintaining relative stemness of SNU-1 when it is exposed to BaP. Thus, our data suggest that in order to understand cell population physiology in response to perturbation of the environment, it is necessary to consider cell heterogeneity and that the relative plasticity of gastric cancer cells could be a contributing factor in BaP-induced gastric carcinogenicity.

Mercury (Hg) is considered by the World Health Organization (WHO) as one of the top priority chemicals that affect human and ecologic health worldwide. Although WHO recommends a constant concentration ratio (250:1) of hair-to-blood Hg for assessing mercury exposure, the mechanisms underlying variability in that ratio remain to be elucidated. The objective: to identify key determinants of the hair-to-blood ratio of total mercury in US women. The data were obtained from 1306 women aged 18-49 years, each of whom provided valid measurements of blood and hair Hg, in the National Health and Nutrition Examination Survey 1999–2000. The impact on the hair-to-blood ratio of factors, such as age, race, body mass index, socioeconomic status, seafood consumption, liver function (assessed by serum levels of alanine aminotransferase and aspartate aminotransferase), hair treatment, and smoking, were examined by linear regression analysis. Logarithmic transformations were applied when necessary. Although hair Hg level is well correlated with blood Hg concentration (Spearman correlation = 0.71, p < 0.05), there is a great deal of variability in the hair-to-blood Hg ratio in the study population (mean = 282; median [interquartile range] = 215 [129-330]). Of the physiological and sociodemographic parameters investigated, race is the leading factor followed by smoking in determining the hair-blood Hg ratio that while African-American women had the lowest estimated ratio, women in “All Other Races (including Asians)” have the highest hair-blood Hg ratio. Moreover, the hair-blood Hg ratio is approximately 13% higher among current and former smokers than their counterparts after covariate adjustment. On the other hand, the hair-blood Hg ratio among subjects with impaired liver function is 16% lower (p=0.08) than in subjects with normal liver enzymes. While this study generally supports the WHO recommendation of using a hair-to-blood Hg ratio of 250 for Hg assessment, one may need to consider contributing factors to the variation in the ratio. Further research (e.g., toxicokinetic modeling) would be informative to confirm our findings. A better understanding of the key determinants in the relation between levels of Hg in hair and blood could further improve mercury exposure assessment.
Intraperitoneal arsenic (iAs), a common drinking water and food contaminant, is associated with a variety of diseases including cancers, cardiovascular disease, and metabolic disorders. Although the mechanisms underlying iAs-associated illness remain poorly characterized, a growing body of literature raises the possibility that microRNAs (miRNAs), post-transcriptional gene suppressors, may serve as mediators and/or early biomarkers of the adverse effects of iAs exposure. To characterize the circulating miRNA profiles of individuals chronically exposed to iAs, samples of plasma were collected from 109 healthy residents of the Zimapán and Laguna regions in Mexico who were exposed to iAs in drinking water. These plasma samples were analyzed for small RNAs using high-throughput sequencing, and for iAs and its monomethylated (MAs), and dimethylated (DMAs) metabolites. Associations between plasma levels of arsenic species and miRNAs were evaluated. Six circulating miRNAs (miR-423-5p, -142-5p, -423-5p +1, -320c-1, -320c-2, and -454-5p), two of which have been previously reported as candidate biomarkers of cardiovascular disease and diabetes (miRs-423-5p, -454-5p), were found to be significantly associated with plasma MAs. No miRNAs were associated with plasma iAs or DMAs after correction for multiple testing. These miRNAs may represent mechanistic links between iAs exposure and disease or serve as biomarkers of disease risks associated with this exposure.

Circulating miRNAs as Potential Biomarkers of Arsenic Exposure

Development of Circulating Exosome-Based Biomarkers for Manganese Neurotoxicity in Human Serum and Plasma Using RT-QuIC Assay and Exosomal RNA-sequencing Analysis

S. Manne1, N. Kondru1, H. Jin1, E. Lee1, M. Lewis1, V. Anantharam1, X. Huang1, A. Kanthasamy1, and A. Kanthasamy1. Iowa State University, Ames, IA; and 2Pennsylvania State University-Milton S. Hershey Medical Center, Hershey, PA.

Chronic exposure to Mn is known to cause neurological, Parkinsonian-like symptoms in exposed individuals by affecting the extrapyramidal motor control system. Occupationally exposed individuals like welders are at high risk due to constant exposure to Mn-rich welding fumes. Recently, we demonstrated that Mn interacts with a-synuclein and promotes its aggregation in cell culture and animal models of Mn neurotoxicity. No blood-based biomarkers are available for Mn poisoning in humans except for expensive imaging techniques, like brain MRI. In the present study, we developed a rapid, sensitive quantification method that detects a-synuclein aggregation by a real-time quaking-induced conversion (RT-QuIC) assay in Mn-exposed individuals. First, we generated a high-quality recombinant human wild-type a-synuclein protein as a substrate for this assay. Next, we optimized RT-QuIC assay conditions to further quantify a-synuclein-seeded aggregation in vitro models of a-synucleinopathies. Moreover, we determined the diagnostic utility of the a-synuclein RT-QuIC assay using exosomes isolated from a blinded cohort of serum and plasma samples from a population exposed to welding fumes and age-matched controls. We could differentiate welders from controls with >95% sensitivity and specificity with the RT-QuIC assay, suggesting that exosomal a-synuclein aggregates may serve as a circulating biomarker for Mn neurotoxicity. Furthermore, next-generation sequencing of serum exosomes showed changes in several small RNAs, such as miRNAs, piRNAs, and trRNAs that may potentially contribute to Mn neurotoxicity and thus could also evolve as potential biomarkers. Collectively, our findings demonstrate the use of a sensitive, high-throughput RT-QuIC assay for discovering a-synuclein-based biomarkers and identify potential exosome-associated small RNA biomarkers. The Noonan Syndrome - A Further Update

Electronic cigarette use has increased exponentially in the past decade, especially among young adults, with little knowledge about its long-term health effects. The objective of this study was to determine if urinary biomarkers of harm are elevated in electronic cigarette users and if elevation correlates with increased concentrations of metals. This was a cross-sectional study of biomarkers of harm in urine from 53 human participants separated as non-smokers (n=20), electronic cigarette users (n=20), or cigarette smokers (n=13). Ages ranged from 19-75 years with an equal number of males and females. All participants in each group were gender and age matched. Urine samples were collected from a previous study. The inclusion criteria for electronic cigarette users or cigarette smokers required exclusive and habitual use of either electronic cigarettes or conventional cigarettes for a minimum of 6 months, abstinence from smoking any other substance for at least 6 months, and no known health issues. Biomarkers of oxidative harm (8-isoprostane, 8-OHdG) and metal exposure (metallothionein), as well as metal concentrations were measured in the urine of non-smokers, conventional cigarette smokers, and electronic cigarette users. The lipid peroxidation biomarker, 8-isoprostane, showed a significant increase in electronic cigarette users (750.8 ± 433 pg/mg) vs non-smokers (411.2 ± 287.4 pg/mg). The biomarker of DNA oxidation, 8-OHdG, was significantly elevated in electronic cigarette users (442.8 ± 300.7 ng/mg) vs non-smokers (221.6 ± 157.8 ng/mg). Metallothionein, a biomarker of metal and reactive oxygen species (ROS) exposure, was significantly elevated in the electronic cigarette group (3761 ± 3932 pg/mg) compared to the non-smokers (1129 ± 1294 pg/mg). All three biomarkers in the electronic cigarette users were similar and not lower than cigarette smokers. Linear correlation plots showed correlations between cotinine and total metals, metallothionein and total metals, and total metals and oxidative DNA damage in the electronic cigarette users. The results of this study are the first to show a significant elevation in biomarkers of harm correlated with elevated metals in the urine of electronic cigarette users.

A Whole Blood Gene Expression-Based Diagnostic Test Prototype for Determining Smoking Status

C. Pousin1, F. Martin1, J. Binder1, M. C. Peitsch1, J. Hoeng1, M. Abedi1, F. Flores1, B. Terbrueggen1, and N. V. Ivanov1. 1Philip Morris International, Neuchâtel, Switzerland; and 2DxTerity Diagnostics Inc., Rancho Dominguez, CA.

Smoking is a major risk factor for the development of diseases. A new generation of smoke-free products for adult smokers have been designed to significantly reduce the formation of toxicants in the aerosol, potentially resulting in reduced exposure to toxicants. To assess whether this reduced exposure translates into beneficial molecular changes, it is essential to identify reliable molecular biomarkers, easily measurable in human subjects, that can discriminate between smokers (S) and non-smokers. The DxDirect technology platform (DxTerity Diagnostics Inc.) enables measurement of 25 genes from isolated RNA or a stabilized fingerstick blood sample. The DxDirect chemical ligation reaction generates uniquely sized ligation products corresponding to each mRNA, which, following polymerase chain reaction amplification, are quantified using a Thermo Fisher ABI 3500Dx CE instrument. For each mRNA target, two chemically reactive exon-exon junction-spanning probes were manufactured and tested. A linear discriminant analysis predictor algorithm was developed from known isolated RNA training samples, and the final prototype multiplex test was evaluated blindly or not using RNA and blood samples from independent cohort studies. Using various human whole blood transcriptomic data and computational approaches, we identified a robust core signature, including genes such as AHR, CDKN1C, LRRN3, PID1, GPR15, and SASH1, that differentiates S from non-smokers. Using DxDirect technology, a subset of 25 genes were multiplexed in an assay to develop a gene expression-based diagnostic test prototype that discriminates S from non-smokers. Initial testing of the prototype shows a significant separation between S and non-smokers (NS) with both RNA and blood sample types. RNA samples from former smokers (FS) were classified between S and FS, however, with scores closer to those computed for NS. In conclusion, we have developed a gene expression-based diagnostic test prototype that demonstrated the capacity to determine smoking status in human subjects from RNA and blood drop. Further evaluations will determine the impact of potential confounders on the performance of the diagnostic test.
**1462** Relationship between Neurobehavioral Changes and Drug Concentrations in CSF in Cynomolgus Monkeys

Cerebrospinal fluid (CSF) has been used for research of biomarkers and development of new drugs for the central nervous system (CNS); however, there are few reports on the relationship between behavioral changes and drug concentrations in CSF. We have developed a new method for serial sampling of CSF from conscious cynomolgus monkeys. The purpose of this study is to evaluate the relationship between neurobehavioral changes and drug concentrations in CSF from cynomolgus monkeys. Nine male cynomolgus monkeys with a catheter for CSF sampling previously implanted into the cisterna magna through the spinal subarachnoid space were divided into 3 groups: control (0.5% methylcellulose aqueous solution) and diazepam 6 and 30 mg/kg (n=3, orally). Functional observational battery (FOB) observation and sampling of both plasma and CSF were conducted pre-dose and at 0.5 (sampling only), 1, 2, 4, and 24 h post-dose. Diazepam concentrations in CSF and plasma were determined using LC-MS/MS. Results Animals administered diazepam at 6 mg/kg showed decreased locomotor activity, ataxic gate, flaccidity, hypothermia, and sedation 1 h post-dose and these changes were continued until 8 h post-dose. The plasma level reached the peak 1 h post-dose and decreased thereafter (plasma range: 8.55 to 390.8 ng/mL). The level in CSF showed similar changes but lower than in plasma (CSF range: 0.64 to 15.43 ng/mL). At 30 mg/kg, neurobehavioral changes and drug concentrations in plasma and CSF were almost similar to those at 6 mg/kg; however, 1 animal showed somnolence at 2, 4, and 6 h post-dose, and drug concentrations in CSF at these time points were higher (2 h: 11.32 ng/mL; 4 h: 36.98 ng/mL; 8 h: 25.89 ng/mL) than those in other animals. At 24 h post-dose, abnormal behavior including flaccidity nearly disappeared at 6 mg/kg, and drug concentrations in plasma and CSF were low (plasma: 1.13 to 13.43 ng/mL; CSF: 0.13 to 0.88 ng/mL). At 30 mg/kg, decreased locomotor activity, flaccidity, and ataxic gate remained in all animals, and drug concentrations were higher than those at 6 mg/kg (plasma: 55.95 to 309.6 ng/mL; CSF: 2.52 to 9.87 ng/mL). Drug concentrations in CSF could reflect neurobehavioral changes induced by diazepam, and sequential sampling of CSF from cynomolgus monkeys could be useful for CNS research.

**1463** Proteomic and Metabolomic Profiling Identify Plasma Biomarkers for Exposure to Ultra-Low Levels of Carfentanil

E. Dhummkant1, G. Rizzo2, P. Feasey1, P. Machi1, B. Tran1, D. Carmany1, P. Demond1, E. McBride1, M. Maughan1, J. Sekowski1, and T. Gráros2.

1RDECOM—Chemical and Biological Center, Aberdeen Proving Grounds, MD; 2Exect Inc., Springfield, VA.

Despite the epidemic of opioid abuse, there are few validated assays capable of rapidly detecting these compounds. Carfentanil, in particular, is nearly undetectable at physiologically relevant concentrations. Therefore, we developed a systems biology approach to discover host-based markers that were specifically upregulated upon exposure in a rabbit model. Rabbits were exposed to 0.18 mg/ml of carfentanil via nose-only chamber. Blood was taken from each animal (N=6) pre-exposure, immediately post-exposure, +6 hrs, 1 day (D), 2D, 3D, 6D, 7D, 8D, 9D, and 13D. The blood was spun down to separate the plasma and CSF. Untargeted proteomics and metabolomics analysis of both plasma and CSF were conducted pre-dose and at 0.5 (sampling only), 1, 2, 4, and 24 h post-dose. The sites of glycosylation were determined as asparagine-35 (minor),134 and asparagine-135 residues were evaluated. The N-glycosylated asparagine sites of which two consensus (asparagine-37 and 134) and one non-consensus (asparagine-135) residues were evaluated. The N-glycosylated asparagine residues were converted to aspartic acid by the action of the PNGase F, which resulted in an increase in molecular mass of 0.984 Da per glycosylation site. The sites of glycosylation were determined as aspirgine-35 (minor),134 and 135 by use of trypsin digestion coupled with analysis of the resulting peptides by nano-UHPLC/HRMS. The approach is now being applied to the analysis of plasma HMGB1 from control healthy subjects and mesothelioma patients. Supported by P42ES027720 and P30ES013508.

**1464** Benzop(a)pyrene (BaP) Increases LINE-1 mRNA Export in Lung Epithelial Cell Exosomes

Although the link between cigarette smoking and lung cancer has been well-established, the causal mechanisms are still being defined and novel biomarkers are needed to improve lung cancer screening. We hypothesize that Long Interspersed Nuclear Element 1 (LINE-1) levels in lung epithelial cell exosomes may serve both as a mechanisms-based biomarker of smoking-related carcinogenesis. Exosomes are secreted membrane-bound vesicles that can regulate gene expression in recipient cells via paracrine mechanisms. LINE-1 is a DNA retroelement that can ‘copy and paste’ itself and other DNAs into different loci via a reverse transcriptase-mediated mechanism. This genomic element is epigenetically silenced in healthy cells and activated by harmful environmental exposures, such as tobacco smoke. LINE-1 activation initiates oncogenic phenotypes and is also a hallmark feature of cancer cells. In studies reported here, we challenged lung epithelial cells for 48 hours with different concentrations of benzo(a)pyrene (BaP), a cigarette smoke carcinogen that induces LINE-1. Both cells and exosomes were harvested and LINE-1 DNA and mRNA levels were quantified by qPCR. BaP increased cellular LINE-1 levels 2.5 fold with induction profiles that were mirrored in exosomes. LINE-1 mRNA levels in each cell released between 100-400 copies of LINE-1 DNA into exosomes, but no significant BaP-related trends were observed. Together, these results support the hypothesis that the LINE-1 status in lung epithelium can be inferred by examining lung epithelial cell exosomes, and suggest the eventual use of exosomal LINE-1 content as a biomarker of environmentally-related disease. Furthermore, the exosome-mediated transport of LINE-1 mRNA into neighboring cells may provide a vehicle for exposed cells to induce oncogenic phenotypes in healthy cells.
1466 BaP Exposure Increases LINE-1 ORF1 Protein Export in Lung Epithelial Cell Exosomes
A. M. Cavalcante, E. C. Bowers, and K. S. Ramos, University of Arizona, Tucson, AZ.

Exosomes are vesicles of endocytic origin that can induce physiological changes in recipient cells. At such, exosomes may have an undefined role in mediating the effects of chemical exposures in tissues that significantly influence health outcomes. There is compelling evidence connecting cigarette smoking and lung cancer; however, the mechanisms and novel biomarkers are still being defined. We hypothesize that Long Interspersed Nuclear Element 1 (LINE-1) proteins inside lung epithelial cell exosomes serve as a biomarker and mediator of smoking-induced lung cancer. We report here findings that can replicate and insert itself into different loci through reverse transcription. LINE-1 is epigenetically silenced in healthy cells and activated by harmful environmental exposures such as tobacco smoke. Furthermore, LINE-1 activation stimulates oncogenic phenotypes in lung epithelial cells. To investigate this hypothesis, we treated lung epithelial cells with different concentrations of benzo(a)pyrene (BaP), a cigarette smoke carcinogen known to induce LINE-1, and quantified levels of LINE-1 protein (ORF1) in cells and exosomes by Western blotting. We found that BaP increased ORF1 levels up to 2.3-fold in treated cells compared to vehicle controls. We discovered that ORF1 protein was secreted into extracellular media. These findings support the hypothesis that LINE-1 protein levels in exosomes serve as a biomarker of environmental exposures associated with lung cancer.

1467 Nephrotoxic Biomarkers in Gentamicin-Induced Acute Kidney Injury for Hazard Identification
S. Lee1, S. Hwang1, N. Tham1, J. Bang1, B. Jeon1, H. Lee1, G. Woo2, H. Kang1, Y. Kim1, and H. Ku1.1 Toxicological Evaluation Laboratory, Animal and Plant Quarantine Agency, Gimcheon, Korea, Republic of; 2Semyung University, Jucheon, Korea, Republic of; and 1Animal Pathodiagnostic Laboratory, Animal and Plant Quarantine Agency, Gimcheon, Korea, Republic of. Sponsor: Y. Chung

Bioliquid-based microRNAs (miRNAs) have been explored as biomarkers for predicting toxicity of chemicals. Here, we evaluated that miRNA biomarkers could be employed as nephrotoxic endpoints in vivo acute kidney injury models. For this, the SD rats were subcutaneously administered daily with gentamicin sulfate (single dose of 400 or 600 mg/kg, and repeated doses of 200 or 600 mg/kg per day) for 7 days. Acute kidney injury was confirmed by typical endpoints (the elevation of blood urea nitrogen, serum creatinine and urinary kidney injury molecule-1, or the presence of histopathological lesion). About 50 genes were selected as literature-based candidate miRNA biomarkers by reviewing previous studies. Among these genes, miR-378a-3p was significantly upregulated in serum and urine of rats administered to repeated doses of gentamicin sulfate (600mg/kg). In addition, miR-26b-5p, miR-34a-5p, miR-320-5p and miR-345-3p were increased with more than 3-fold changes in rat urine of same treatment groups. These findings suggested that miRNA biomarkers may be useful as additional endpoints for predicting nephrotoxic potential of chemicals.

1468 Assessment of Welding Fume Exposure on Telomere Length and Regulation in Peripheral Blood Mononuclear Cells and Lung Tissue in Rats

Telomeres are DNA fragments at the ends of chromosomes that protect genetic information during cell proliferation. Telomeres control cell DNA damage response (DDR) and DNA repair activity during cell division by regulating ATM and ATR kinases. Protection of telomeres 1 (POT1) protein specifically binds the 3’ overhang of the telomere and plays a key role in chromosomal end protection and telomere length regulation. In this study, we examined POT1 mRNA expression and telomere length and regulation by shelterin complex proteins in peripheral blood mononuclear cells (PBMCs) and non-lung whole lung tissue in male Sprague-Dawley rats following exposure, by intratracheal instillation, to 2 mg/rat of manual metal arc-stainless steel welding fume (WF) particulate or saline (vehicle control). PBMCs and lung tissue were harvested at 30 days after exposure. For 48 hours with different metals (41% Fe, 28% Cr, 17% Mn, 3% Ni) with a mean count diameter of 600 nm. The PBMCs recovered from WF-exposed animals had increased telomere length as analyzed by fluorescent in situ hybridization (FISH), flow cytometry, and qPCR compared to controls. Altered expression of shelterin regulatory proteins, tripeptide-peptidase 1 (TPP1) and TERF1-interacting nuclear factor 2 (TIN2), was observed in PBMCs and lung tissues. Additionally, increased telomere length in lung tissue as analyzed by qPCR was observed in the WF group compared to control. However, qPCR analysis showed that POT1 expression levels in the lung tissue of the WF group relative to those in the control group (T/N ratio) was significantly lower, leading to the activation of ATR expression that was not observed in PBMCs. These results indicate that exposure to WF down-regulated lung POT1 which in turn activated ATR-dependent DNA damage signaling and telomere elongation in the lungs, as well as activation of telomerase-independent pathway, an alternative mechanism leading to telomere elongation in PBMCs.

1469 miRNA Profile Assessment of Urine Exosomes from Boric Acid Treated Rats as Potential Biomarkers for Testicular Toxicity
R. W. Ball1, B. R. Gould2, and J. Wise1. 1REACH Borates Consortium, Brussels, Belgium; and 2QIAGEN Inc., Germantown, MD.

The objective of this study is to identify miRNAs in urine specific to boric acid (BA) related reproductive effects in rats. Urine samples were evaluated to identify differentially expressed testis-specific miRNAs in BA treated rats using next-generation sequencing (NGS). Boric acid was administered to male Sprague Dawley rats via oral gavage at a dose level of 500 mg BA/kg bw/day for 28 days, a dose level known to produce fertility effects in male rats with minimal overt signs of toxicity. At the end of 28-days urine was collected over 24 hours. Urine samples were shipped to QIAGEN Genomic Services for exosome isolation and miRNA isolation. Histopathology was conducted on testes and epididymis of BA treated rats. Tenex BA treatment-related effects, 6 test substrate-related findings included lower epididymis weights, smaller epididymides, and microscopic findings of cellular debris and decreased spermatid cellularity in the epididymis and tubular degeneration/apoptosis and atypical residual bodies in the testes. Tubular degeneration/apoptosis in the test substance-treated group was characterized by vacuolar degeneration of spermatocytes and spermatids. Urine exosomes and miRNA were isolated with QIAseq 52 Spike-ins through exoRNeasy. miRNA sequencing was performed using an Illumina NextSeq 500. The miRNA library preparation was completed using the QIAseq miRNA Library Kit. Several miRNAs were identified in rat urine as potential biomarkers for BA related effects on male reproductive system: miR-34c-5p, miR-449a-5p and miR-122-5p were decreased in BA treated rats compared to untreated controls. These miRNAs have also been identified to be decreased in humans with sertoli cell related spermatogenic failure. BA has been shown to affect Sertoli Cells in the testes of rats. Additionally, let-7p (decreased), miR-141-3p (increased) and miR21-5p (increased) were differentially expressed in BA treated rats. These miRNAs have been identified as potential biomarkers for human male non-obstructive azospermia. Also, miR-27b-3p levels decreased in BA treated rats shown to be associated with asthenozoospermia in humans. These results provide the basis for the potential application of miRNAs as biomarkers for BA related testicular toxicity and highlight the value of urine exosome miRNA NGS as a discovery tool.

1470 Transient Alanine Aminotransferase Increases following Acetaminophen Treatment in Rats
W. B. Matthews1, A. Regev1, R. J. Church3, P. B. Watkins4, M. Avigan4, D. L. Mendrick1, J. J. Greenhaw1, and Q. Shi1. 1US FDA/NCTR, Jefferson, AR; 2Eli Lilly and Company, Indianapolis, IN; 3Institute for Drug Safety Sciences, Research Triangle Park, NC; and 4US FDA/CDER, Silver Spring, MD.

A persistent concern in pharmaceutical development is the appropriate response to serum alanine aminotransferase (ALT) increases seen in patients during clinical trials. While ALT increases can portend serious liver injury, it is also well known that for certain drugs, such increases in clinical settings reverse with continued treatment, with no further evidence of liver injury. This well-documented phenomenon is often referred to as adaptation. A means to distinguish those ALT increases that will resolve from those that do not is needed. We report here a pilot animal model of BTALT increases. Sprague-Dawley rats were given daily oral doses of 1.0, 1.5 and 2.0 g/kg acetaminophen (APAP) and sacrificed after 8 days of treatment. Tail bleeds were conducted at days 1, 3, 6 and 7 of treatment. ALT increases were seen at day 3 in APAP treated rats. Strikingly, 1) these increases were not seen in all treated animals and the extent varied greatly from animal to animal, 2) all ALT increases returned to baseline by day 6, 3) the increases were not dose dependent, 4) by contrast, no increases in total bilirubin were seen, 5) while minimal to mild centrilobular necrosis was observed at day 8.
for most of the treated animals, its grade was not related to the extent of ALT increase. This represents the first report of transient ALT increases in a rodent model and offers the possibility for discovery of biomarkers of adaptation.

1471 Application of Magnetic Carbon Nanotubes Facilitated Dispersive Micro Solid Phase Extraction of the Cyanide Metabolite (2-Aminothiazoline-4-Carboxylic Acid) in Biological Samples

S. Li, I. Petrikovics, and J. Yu. Sam Houston State University, Huntsville, TX.

The purpose of this presentation is to familiarize the audience with the application of magnetic carbon nanotubes facilitated dispersive micro solid phase extraction (Mag-CNT/d-µSPE) for the minor metabolite of cyanide, 2-aminothiazoline-4-carboxylic acid (ATCA), to biological samples. Confirmation of cyanide exposure by direct detection of cyanide in biological samples may be subjected to interpretation challenge due to its reactive and unstable nature. The concentration of cyanide in biological samples could fluctuate under improper storage conditions, which also increases the difficulties to associate cyanide concentration level in biological samples for cyanide exposure. The detection of biomarkers for cyanide, such as ATCA, was suggested to be an alternative approach to confirm cyanide exposure. In this research, Mag-CNT/d-µSPE was developed to extract ATCA from synthetic urine and bovine blood samples. Briefly, 2 mg of Mag-CNT was added to 100 μL of ATCA-spiked synthetic urine or protein-precipitated bovine blood. The samples were acidified with hydrochloric acid, vortex, and sonicated for 10 min. The Mag-CNT were isolated and the supernatants were decanted. The ATCA on the Mag-CNT was desorbed with 150μL of 5%(v/v) NH4OH/water with sonication. The desorbed supernatants were transferred to separate tubes, dried under vacuum at 65°C and derivatized with N-methyl-N-(trimethylsilyl) trifluoroacetamide (MSTFA) and subjected to GC/MS analysis. Method parameters, including calibration model, limit of detection (LOD) and quantitation (LOQ), bias, precision, carryover and interference study, were tested for both biological samples. The Mag-CNT/d-µSPE for urine samples demonstrated a satisfactory bias and precision within ± 20% at the low, medium, and high concentration levels. The LOD and LOQ for the urine samples were 15 and 30 ng/mL respectively with an average R2 value of 0.9985. No carryover or interference peaks were observed at the retention time of ATCA in all tested samples. Sample clean up prior to Mag-CNT/d-µSPE may be required for bovine blood due to complex matrix effects.

1472 Temporal microRNA Analysis in Multiple Brain Regions following Soman Exposure in Rats

A. Gautami1, R. Kumar1,2, L. Naidu1,2, D. Getnet1, G. Dimitrov1,2, B. Sowe1,2, X. Feng1,4, F. Rossetti1, J. Meyerhoff1,4, M. Pham6, R. Hammamieh1, L. Lumley6, and M. Jett1.1 US Army Center for Environmental Health Research, Frederick, MD; 2Frederick National Lab for Cancer Research, Frederick, MD; 3ORISE, Frederick, MD; 4Geneva Foundation, Frederick, MD; 5Clinical Research Management, Silver Spring, MD; and 6US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD. Sponsor: M. Madjezcyk

Soman is a potent organophosphate acetylcholinesterase inhibitor that results in increased levels of acetylcholine and leads to a cholinergic crisis upon exposure to high doses. This cholinergic crisis induces convulsions and seizures and can result in death if left untreated. Understanding the effects of soman is vital to developing a method of diagnosis and treatment for exposure. Acute and chronic effects of soman exposure are an increasing concern for military and civilian populations. The functional alterations that arise from exposure are associated with dysregulation of complex gene networks, and growing evidence implicates microRNAs as key regulators of these networks. In this study, we examined time and brain region-dependent changes in microRNA expression profiles associated with soman exposed seizure activity in rats. Adult male Sprague-Dawley rats were exposed subcutaneously to soman and heat, kidney, liver, lungs, spleen, and brain regions, including amygdala, hippocampus, hypothalamus, piniform, medial prefrontal cortex, parietal cortex and thalamus were collected after 72 hrs and 90 day exposure. RNA was extracted from each tissue and small RNA was sequenced using next generation sequencing on illumina platform. Initial data from piniform cortex demonstrate significant differences in expression patterns between animals that seized and those that didn’t seize. The miRNAs expression changes across brain tissue types showed hypomethylated to have a quite distinct response from other regions. The results demonstrate that soman exposure results in dynamic and complex temporal changes in microRNA-mRNA gene network structure. Ongoing work will fully characterize the miRNA genes network.

1473 Organophosphate Exposure of Aircraft Maintainers

S. T. Pfahler1,2, M. H. Rubenstein3, and J. E. Hardos1.1 Henry M. Jackson Foundation for the Advancement of Military Medicine, Wright-Patterson AFB, OH; 2Air Force Research Laboratory, Wright-Patterson AFB, OH; 3USAFA/AFH, Air Force Research Laboratory, Wright-Patterson AFB, OH; and 4USAFA/AFD, Air Force Research Laboratory, Wright-Patterson AFB, OH. Sponsor: J. Sterner

Air Force aircraft maintainers have been shown to come into contact with products containing organophosphates, primarily triecyl phosphate (TCP), tributyl phosphate (TBP), and triphenyl phosphate (TPP). These chemicals are often found in aircraft hydraulic fluids and turbine oils. This is particularly troublesome because these chemicals are cholinesterase inhibitors, which are believed to cause behavioral and neurological symptoms. Such symptoms include personality change, mood destabilization, suicidal thought, and memory and attention impairment. In order to assess aircraft maintainers’ exposure to these organophosphates, blood samples were collected before and immediately after volunteers’ shifts. Analyzing acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE) inhibition is believed to be an efficient method to measure the exposure to all organophosphates. Because acetylcholine is known to reside in the red blood cells (RBC), the RBC were isolated from the blood samples provided by the volunteers to assess AChE activity. Similarly, the plasma was isolated to evaluate BuChE activity. These separated samples were then analyzed with an Ellman assay to determine the levels of AChE and BuChE inhibition. Fortunately, only two of 83 volunteers showed concerning levels of cholinesterase inhibition. This level was defined as 50% decline of baseline cholinesterase, as this amount of inhibition may coincide with symptoms such as headache, vomiting, and cramping.

1474 Downregulation of Wild-Type Tumour Suppressor Protein in Nigerian E-waste Population: Risk of Disruption of Genome Protection Mechanism

O. G. Igharo1, E. L. Igharo2, I. I. Anetor3, O. O. Oladele4, and H. B. Osadolor5.1 University of Benin, Ugbowo, Benin City, Nigeria; and 2University of Ibadan, Ibadan, Nigeria.

Informal electronic waste (e-waste) reprocessing in Nigeria is reportedly the highest in Africa, predisposing exposed humans to risk of metal exposure. The management practices in Nigeria are crude and environmentally unsound. Most e-waste-born metal pollutants and metals have been reported to have potentials for metal carcinogenesis by their direct genotoxic effects and disordered metalloregulation of gene repair mechanisms. There is currently dearth of data on predictive biomarkers for evaluation of genotoxicity in the e-waste exposed population in Nigeria. This study aimed to evaluate the status of genotoxic biomarkers: wild-type tumour suppressor protein (wt-p53), DNA repair enzyme 8-oxoguanine-DNA glycosylase (OGG1), and oxidative DNA damage biomarker; 8-hydroxy-2-deoxyguanosine (8-OHdG), and correlate with blood levels of toxic metals and essential metals in 381 e-waste workers, 120 environmental e-waste exposed participants, and 131 age-matched unexposed controls in South-West Nigeria. From the blood samples obtained, Enzyme-Linked Immunosorbent Assay was used to determine genotoxicity biomarkers in serum while Inductively Coupled Plasma-Mass Spectrometry was used to determine essential metal levels in serum and toxic metal levels in whole blood. From the results, we observed significantly raised blood levels of toxic metals, and lower serum levels of Zn, Cu, Se and Co in the e-waste exposed populations. Additionally, there was a repressing of wt-p53 expression, accompanied by the upregulation of 8-OHdG in the e-waste groups. OGG1 activity, was slightly higher in e-waste workers than in controls, but this difference was not significant; in environmentally exposed participants, OGG1 activity, was slightly higher in e-waste workers than in controls, but this difference was not significant; in environmentally exposed participants, OGG1 activity, was significantly higher when compared with the e-waste workers and unexposed controls. These data appear to provide evidence of elevated body burden of genotoxic metals, decreased levels of genome-protective metals and repression of p53 expression coupled with raised oxidative DNA damage activity, all of which appear suggestive of the risk of disruption of genome protection mechanism in the e-waste exposed populations.

2019 SOT Annual Meeting
1475 Increased Autoantibodies to Glial Fibrillary Acidic Protein (GFAP) in Plasma of Veterans with Gulf War Illness (GWI)

M. B. Abou-Donia1, M. V. Brahmajothi1, and K. Sullivan1. 1Duke University Medical Center, Durham, NC; and 2Boston University School of Public Health, Boston, MA.

Following the 1991-1992 Gulf War, approximately one third of the U.S. troops out of 700,000, complained of chronic symptoms, which is now known as Gulf War Illness (GWI). This illness is characterized by multisymptomatic disorder that consists of joint pain, gastrointestinal problems, memory and difficulty concentrating. In this study, we identified and determined the levels of autoantibodies against two main glial proteins. One is glial fibrillary acidic protein (GFAP), which is an astrocytic protein that mainly contributes to white matter architecture, myelination, maintains the mechanical strength of astrocytes and provides integrity to the blood-brain barrier. The other one is S100B protein, which is expressed primarily in astrocytes, known to stabilize microtubule associated proteins; MAP-2 and Tau. The action of S100B is neurotropic at a nanomolar serum concentration and apoptotic at a micromolar concentration. Acute traumatic brain injury resulting in large destruction of astrocytes leads to massive (50- to 100-fold) release of S100B in serum, whereas levels of S100B in psychiatric disorders were only three times higher in patients compared to the controls. Correlating well with their neuroprotective action, we determined the level of autoantibodies specific to GFAP and S100B using a western blot assay in the plasma of veterans with GWI (n=68) compared to the non-veteran asymptomatic controls (n=26). We observed increased level of autoantibodies specific to GFAP protein in the plasma of veterans with GWI compared to controls. The increase was nearly nine-fold compared to healthy controls for GFAP and the significance was estimated by the Fischer’s exact test to be p-value less than 0.0001, but the autoantibodies specific to S100B showed an insignificant increase compared to the healthy controls consistent with the chronic condition of the GWI. Because of the long lasting nature of LgG, detection of autoantibodies studied would be an indicator of brain injury characteristic of GWI. Conclusively, autoantibodies to GFAP may signify a chronic CNS damage. Supported in part by DOD W81XWH-15-1-0641.

1476 PAH Exposure among Slaughterhouse and Slaughter Slab Workers Who Utilize Scrap Automobile Tires to Singe Meat in Ghana

A. Brown1, N. M. Johnson2, A. V. Cleve2, I. Lwaku2, and E. Afriye-Gyawu1, 1Georgia Southern University, Statesboro, GA; and 2Texas A&M University, College Station, TX.

In Ghana and many other African countries, it is common practice for slaughterhouse (SLH) and slaughter slab (SLS) workers to utilize scrap automobile tires as fuel to singe the fur of food animal carcasses intended for human consumption. This practice releases many toxic substances including polycyclic aromatic hydrocarbons (PAHs), carbon monoxide (CO), particulate matter, and other toxicants into the air via smoke. PAHs are a group of more than 100 organic compounds that is released during the combustion of tires, coal, oil, gasoline, trash, tobacco, and wood. Exposure to PAHs has been associated with a plethora of health issues such as respiratory impairment; irritation of skin, eyes, and airways; and cancer. Studies have shown that 1-OHP is a reliable biomarker of occupational and residential exposures to PAHs because 1-OHP is a metabolite of pyrene, one of the significant components known to be present in all PAH mixtures (Hu and Hou, 2015; Jongeneelen, 2001). Our previous studies suggested that the level of 1-OHP was differentially accumulated among SLH-SLS operators who use tires as fuel to singe meat; however, the health implications were not evaluated. Therefore, the aim of this study is to assess Kumasi SLS operators’ exposure to PAHs by quantifying their urinary 1-OHP levels using HPLC with fluorescence capability. Urine samples (n=59) were collected from SLH-SLS operators who utilized tires (363.43±61.65 ng/mg crt) compared to production workers (319.75±115.49 ng/mg cort) and those who utilized LPG (210.47±54.17 ng/mg cort). The urinary 1-OHP level of SLH-SLS operators who use tires as fuel to singe meat was significantly higher than workers who used LPG (5.02%). These higher exposure levels indicate potential health risks among the individuals, and results of these data revealed high rate of AFB, exposure in Kumasi slaughterhouse and SLS workers. Studies are on-going to evaluate the associations between maternal and childhood AFB exposure, and the growth and development of young animals.

1477 Aflatoxin Exposure Assessment in Ugandan Mothers and Children

K. Xue1, L. Tang1, J. Olivera Mejia1, M. Limorain1, J. Laueri1, L. Ausman2, J. Griffiths1, S. Ghosh2, P. Webb2, and J. Wang1. 1University of Georgia, Athens, GA; and 2Tufts University, Boston, MA.

Aflatoxin B1 (AFB1), a potent mycotoxin produced by Aspergillus flavus and Aspergillus parasiticus, is a ubiquitous food contaminant and a well-known liver carcinogen which has been categorized by IARC as a known human carcinogen (Group 1). Recent evidence has suggested the link between AFB exposure, exposure and impairments in growth and development of young animals and children, and AFB exposure may be one of major risk factors for childhood stunting in many low- and middle-income nations. In this study, AFB exposure was assessed via analysis of a validated expression biomarker, serum AFB1-lysine adduct, using HPLC-FLD based method for a total of 3326 serum samples (n=1551 from children and n=1774 from mothers), all collected on the fourth quadrant of 2017 for a birth cohort study conducted in Uganda. The overall detection rate of serum AFB1-lysine adduct was 69.67%, 82.49% for the children samples, and 95.89% for the mothers samples. The median level of serum AFB1-lysine for all collected samples was 2.63 pg/mg albumin, with first and third quartile at 1.12 and 6.80 pg/mg albumin. The overall geometric mean was 3.06 pg/mg albumin (95% CI: 2.92, 3.21). The mothers generally had higher levels of serum AFB1-lysine adduct than children (p<0.0001). The median level in the mother samples is 4.33 pg/mg albumin, with first and third quartile at 1.98 and 10.59 pg/mg albumin. The geometric mean is 4.80 pg/mg albumin (95% CI: 4.52, 5.11). The median level in children samples 1.39 with first and third quartile at 0.76 and 2.98. The geometric mean is 1.68 pg/mg albumin (95% CI: 1.58, 1.78). Significantly high levels of AFB1-lysine adduct (>50 pg/mg albumin) were found in 102 of the 3326 analyzed samples (3.07%), with 13 from the children group (0.84%) and 89 from mother group (5.02%). These higher exposure levels indicate potential health risks among this individuals, and results of these data revealed high rate of AFB exposure in Uganda mothers and children. Studies are on-going to evaluate the associations between maternal and childhood AFB exposure, AFB exposure and the growth and development of young animals.

1478 Use of Neopterin as a Biomarker of Immune Activation in Preclinical Species

A. Zurita, and J. D. Smith. Boehringer Ingelheim, Ridgefield, CT.

Neopterin is a pteridine metabolite that is produced following activation of macrophages and dendritic cells in humans and in other species. While the levels of neopterin in humans is characterized, the potential to use the measurement of neopterin as a biomarker of immune activation in preclinical species is not known. Here we describe the development of a sensitive LC-MS/MS method to quantify neopterin in blood samples. The validity of using neopterin to measure immune activation was demonstrated by ex vivo stimulation of blood samples. For the LC-MS/MS analysis, both control and spiked samples were processed by spiking with internal standard diluted in organic mobile phase followed by solid phase extraction, and analysis. The results of this experiment demonstrate increased neopterin in stimulated blood compared to unstimulated samples. The optimized method was successfully applied to samples from toxicological studies with preclinical species in which immune activation was anticipated. This work demonstrates the potential utility of neopterin as a biomarker candidate of immune activation with application to multiple preclinical species.

1479 Circulating Cell-Free DNA (ccfDNA) as a Liquid Biopsy Tool in Rodent Toxicology

Short fragment extracellular DNA (~180bp) normally circulates in blood at low levels. Cell death in tissues (normal turnover) is a primary source of circulating, cell free DNA (ccfDNA), both of nuclear and mitochondrial origin. CcfDNA was first described in the 1940’s but more recently its significance in diagnosis, staging and biomarker discovery has gained much attention as a point-of-care, minimally invasive form of liquid biopsy in a variety of clinical conditions such as cancer, fetal aneuploidy disorders, obesity, autoimmune disorders and organ transplantation. To date, few studies have investigated the use of ccfDNA in environmental health science. We explored the utility of ccfDNA in biomarker development for chemical toxicity and exposure in experimental animals by using successful examples of ccfDNA analysis of adult and neonatal rodents. Purified ccfDNA yields ranged from 4.8 ng per sample and displayed the characteristic DNA nucleosome fragmentation pattern of
CFT073 strain. This particular sin

1482 Evaluation of miRNAs as Biomarkers for MerTK-Mediated Retinal Degeneration
J. M. Panzica-Kelly1, B. Lehman2, T. Spires3, K. Katliniski3, J. Megill3, L. Berman-Booty1, and K. Augustine-Rauch1, 1Bristol-Myers Squibb, Pennington, NJ; and 2Bristol-Myers Squibb, Lawrenceville, NJ.

The roles of MerTK in immunity and cancer has made it a potential therapeutic target. MERTK also has an essential role in specialized phagocytosis of apoptotic cells, specifically in the retina and in various cancer cell lines. These functions are critical in the eye upon waking. MerTK mediates effectorcytic activity of the retinal pigmented epithelium, which is essential in clearing spent photoreceptors in the retina. Therefore, there is potential for retinal toxicity if MERTK is inhibited in the retina and identification of a biomarker for potential retinal toxicity would be advantageous for the therapeutics that block MerTK signaling. The miR182/183/96 cluster has been implicated in various retinal disorders including retinitis pigmentosa. In this study, we compared the expression levels of miR96, miR182 and miR183 in serum samples of wild-type, MERTK homozygous and heterozygous mice of at least 2 months of age. Retinas were evaluated histologically by thin plastic section. Moderate upregulation of miR182 and miR96 was observed in the homozygous knockout animals compared to wild-type mice. Very little to no change in expression of these microRNAs was observed in MerTK heterozygous mice. These results correlate with histological findings indicating a complete loss of photoreceptors and depletions of the outer nuclear and outer plexiform layers in the retinas of homozygous mice. No changes were observed in the retinas of heterozygous mice. The results of these studies suggest miR182 and miR96 may be promising biomarkers of MerTK-mediated retinal toxicity.

1483 Optical Densities as Measures to Assess In Vitro Therapeutic Equivalences, Antimicrobial Susceptibilities, Resistances, Toxicities against Escherichia coli CFT073
N. Garimella, US FDA, Silver Spring, MD.

There is an important requirement to develop generic evaluate and compare antimicrobial drugs activities and toxicities because of their demand to combat increased resistance of pathogenic bacteria to current antibiotics and to minimize toxicity levels. In vitro therapeutic equivalence studies of generic antimicrobials can add value to pharmaceutical equivalence studies and also can facilitate regulatory decision making for combination therapies. We used 24 kinetic measurements of bacterial growth in a standard, clear, 96-well plate, with a standard absorbance microplate reader to enable screening of three antimicrobial drugs in and their potential for delaying the growth of Escherichia coli CFT073 strain. This particular single strain was used to model uncomplicated urinary tract infection (UTI) in vitro. Three antibiotics, namely Ampicillin, Ciprofloxacin Hydrochloride and, Fosfomycin Disodium Salt, their dual and triple combinations were evaluated independently and in combinations by means of their consistently varied minimum inhibitory concentrations (MICs) in each well by maintaining constant density of E.coli. E. coli CFT073 at about the density of 50,000/well. These chemical-biology studies enabled not only the determination of in vitro therapeutic equivalences of antibiotics, but also their independent and combined influences on bacterial growth. Two to five times of order differences are consistently evident between 0 times MIC, 3 times MIC, 10 times MIC and 30 times MIC concentrations of the antibiotics. In conclusion, the generic antibiotic products can be quickly compared with their innovator drugs to predict their therapeutic equivalences, toxicities and to determine their resistance potentials.

1484 Comparison of Lactate Concentration with Different Anticoagulant

Lactate is organic anion of buffered lactic acid, the end product of glycolysis pathway and an indicator of the oxygen-containing state of cell tissue. Blood samples for quantitative lactate analysis usually use sodium fluoride/potassium oxalate as anticoagulant in order to prevent in vitro glycolysis and increased lactate production. However, sometimes the anticoagulant...
EDTA-K2 may be used to collect blood samples due to the reason of some compounds’ nature. The sodium fluoride is not available. The blood samples were collected into tubes with anticoagulant sodium fluoride and EDTA-K2, respectively. The lactate concentration was tested for 1, 2, 4, and 6 hours after blood collection and recorded as time 1, 2, 4, and 6, respectively. The parallel comparison of the same time slot and species was conducted between two anticoagulants. The statistical analysis of T-test and Wilcoxon were done based on homogeneity of variance of test data. For species monkey, there is no significant difference for the lactate concentration between tubes with sodium fluoride and EDTA-K2 at any time points (time 1, 2, 4 and 6) (p<0.05). For species dog, there is no significant difference for the lactate concentration between with sodium fluoride and EDTA-K2 at time 1 hour (p<0.05), but significant differences were observed at time 2, 4 and 6 (p<0.05). The test results showed that there was no obvious increase of lactate in species monkey under anticoagulant EDTA-K2 conditions. However, the concentration of lactate had mildly increased in species dog containing anticoagulant EDTA-K2. Our research indicates that EDTA-K2 is recommended as the anticoagulant for lactate analysis in monkeys but does not apply to the dogs.

1484a Performance of Neurofilament Light in Rat as a Translational Biomarker of Central and Peripheral Nervous System Toxicity
K. Vlasakova, C. Qin, T. Tsuchiya, M. Dey, Y. Zhou, and W. Glaba; Merck & Co., Inc., West Point, PA.

Target organ toxicity is often a reason for compound attrition during drug development. Use of safety biomarkers can help to monitor such toxicities early and efficiently in preclinical species, and allow translation to early clinical trials while ensuring patient safety. While accessible biomarkers for end-organ toxicities like liver, kidney or muscle are widely available across preclinical species and human, others remain in blind spots for the central (CNS) and peripheral (PNS) nervous system. Neurofilament light (NF-L) is an emerging biomarker that has been studied recently in humans for numerous neurological disorders including traumatic brain injury, amyotrophic lateral sclerosis, multiple sclerosis and Huntington’s disease. Here we evaluated the performance of NF-L (measured by Quanterix NF-Light® assay) in monitoring drug-induced CNS or PNS toxicity by using plasma, serum and CSF samples from in vivo rat studies with model CNS/PNS toxicants, as well as with toxicants not causing neuronal damage to address specificity. Representative toxicants included chlorpropionic acid, hexachlorophene, 3-nitropropionic acid, d-aminomethylamine, dexamethasone, vincristine, acrylamide and two MoV compounds. A standard histomorphologic assessment based on hematoxylin and eosin stained tissue sections of routine nervous tissue was conducted to diagnose nervous system injuries. In all evaluated CNS/PNS studies with the exception of dioxin/epoxide, NF-L increased in a dose- or time-dependent manner correlating to neuronal degeneration/necrosis in CNS or to axonal degeneration in peripheral nerves. In some cases, NF-L increases were observed in studies treated with CNS/PNS toxicants but without corresponding histomorphological changes, while no NF-L changes were noted in specificity studies presenting with severe liver, kidney, muscle or bone marrow toxicity. These results suggest higher sensitivity of NF-L as an in vivo biomarker in peripheral nerves compared to CNS. In plasma results of CNS datasets, a standard histomorphologic assessment on routine nervous tissue in detecting nervous system injuries. In conclusion, NF-L is an emerging sensitive and specific translational biomarker for use in rat, where it can be used to monitor for nervous system injuries. In conclusion, NF-L is an emerging sensitive and specific translational biomarker for use in rat, where it can be used to monitor for nervous system injuries.

1485 The Effect of Phthalates on the Population of Primaldial Germ Cells of Xenopus laevis before and after Gastrulation
N. Momplaisir1, A. Turgeon2, J. Flaws3, and J. Yang1. 1Tuskegee University, Tuskegee Inst, AL; and 2University of Illinois at Urbana-Champaign, Urbana-Champaign, IL.

Phthalates are a class of chemicals that are used in personal care products, medical devices, and many more industrial products. The biological effects of phthalates have been studied because they are ubiquitous and are linked to adverse human reproductive outcomes, such as fertility complications, decreased anogenital distance, and reduced testosterone levels. The effects of exposure to such chemicals are studied in later stages of development. However, in order to understand the outcomes of phthalate exposure on the reproductive system of an organism, it is important to study these effects at earlier stages of development and monitor the changes. Hence, it was hypothesized that a phthalate mixture decreases the number of primordial germ cells (cells that later become gametes) in early embryogenesis prior to zygotic genome activation. To test the above hypothesis, Xenopus laevis embryos were cultured and exposed to a relevant phthalate mixture at specific developmental stages which are before and after gastrulation. The phthalate mixture was based on the exposure levels found in urine metabolites of pregnant women in the Illinois area. It was composed of 21% di(2-ethylhexyl) phthalate (DEHP), 35% diethyl phthalate (DEP), 15% dibutyl phthalate (DBP), 8% di-isobutyl phthalate (DiBP), 5% benzyl butyl phthalate (BBzP), and 15% di-isononyl phthalate (DiNP) for 48 hours. A four-day assay referred to the whole embryo toxicity assay (WETA) was conducted using primary germ cell biomarker called xpat probe to locate the primordial germ cells. Exposure to the various phthalate mixture concentrations (1 µg/ml, 10 µg/ml, and 100 µg/ml) was shown not to affect the embryo viability within 72 hours. However, a significant reduction of primordial germ cells was shown in embryos treated before gastrulation of 10 µg/ml (p<0.0001) and 100 µg/ml (p<0.0004) when compared to the control group. Embryos exposed after gastrulation did not show any significant change in the primordial germ cell abundance in any of the treatment group. The data indicate that exposure to a biologically relevant phthalate mixture reduces significantly primordial germ cells before gastrulation in the early embryonic development of an organism where the zygotic genome is silent whereas, after gastrulation, the zygotic genome becomes active. More studies should be done to assess the link between zygotic genome activation and endocrine disrupting chemicals.

1486 Iodoacetic Acid Inhibits Follicle Growth and Alters Expression of Genes That Regulate Apoptosis and the Cell Cycle in Mouse Ovarian Follicles
A. V. Gonsioroski1, D. D. Meling1, L. Gao1, M. Plewa2, and J. A. Flaws1, 1University of Illinois at Urbana-Champaign, Urbana, IL; and 2Safe Global Water Institute, Urbana, IL.

Water disinfection was one of the most important public health advances of the last century because it greatly reduced the incidence of waterborne diseases. The reaction between disinfection products and organic and inorganic matter in source water generates the unintended formation of water disinfection by-products (DBPs). Exposure to DBPs has been associated with adverse developmental effects and it causes cytotoxicity and genotoxicity in mammalian cells. Further, iodoacetic acid (IAA), an unregulated DBP, was shown to be a reproductive toxicant in vitro. However, its effects on the ovary are not well known. This study was designed to determine whether IAA exposure affects ovarian follicle growth and expression of genes that regulate apoptosis and the cell cycle. Ovaries were collected from CD-1 mice (32 to 42 days old). Antral follicles (220 to 400 µm) were dissected from the ovaries and placed individually in 96-well culture plates. The follicles were treated with either 0.075% dimethyl sulfoxide (DMSO; vehicle control) or IAA (2, 5, 10, or 15 µM). The follicles were cultured for 96 h and follicle growth was measured every 24 h. After 96 h of culture, follicles were collected and snap-frozen at -80°C until RNA extraction. RNA was extracted, reverse transcribed, and subjected to quantitative polymerase chain reaction (qPCR) to analyze expression levels of apoptosis regulators (Bax and Bcl2) and cell cycle regulators (Ccn2, Ccn1, Ccnb1, Ccn2, Cd4 and Cdkn1a). IAA exposure (10 and 15 µM) significantly decreased follicle growth compared to controls, beginning at 72 h and continuing through 96 h of culture. Further, IAA exposure decreased expression of the cell cycle regulators Ccn2 (10 and 15 µM) and Ccn1 (15 µM) and it (10 and 15 µM) decreased expression of the anti-apoptotic factor Bcl2. In addition, IAA exposure (15 µM) increased expression of the pro-apoptotic factor Bax and the cell cycle regulator Cdk4 and it (10 and 15 µM) increased expression of the cell cycle inhibitor Cdkn1a. Collectively, these data show that IAA exposure inhibits follicle growth and upregulates pro-apoptotic factors and cell cycle inhibitors, whereas it downregulates anti-apoptotic factors and some cell cycle regulators, thus interfering with apoptosis and proliferation in ovarian follicles. Supported by NIH R21 E0528963 and NIH T32 E0507326.

1487 Metabolism of an Environmentally Relevant Phtalate Mixture in Mouse Ovaries

Phthalates are synthetic chemicals commonly used as additives in consumer products with widespread human exposure. While phthalates are manufactured as diesters, they are hydrolyzed in the environment and in the body to monoesters that may be more toxic than the parent compounds. Individual phthalates have been shown to be reproductive toxicants, but few studies have examined the toxicity of mixtures of phthalates. This study tested the hypothesis that neonatal and adult mouse ovariess are able to metabolize an environmentally relevant mixture of phthalates. Whole neonatal ovariess (postnatal day 4) and adult female ovariess from CD-1 mice were cultured in media treated with DMSO (vehicle control) or 0.1, 1, 10, or 100 µg/mL of a mixture composed of 35% diethyl phthalate (DEP), 21% di(2-ethylhexyl) phthalal
Phthalates are chemicals used as plasticizers, which increase flexibility of plastic, thus causing them to leach. Due to leaching humans are constantly exposed to phthalates at all ages. Phthalates are linked to health problems such as infertility due to interference with hormones and have been shown to affect preimplantation embryo development. Studies have shown that exposure to a single phthalate effects embryo development. However, there is limited data on the effects of exposure to relevant phthalate mixtures (PM) on preimplantation embryos (PE). The PM used in this study is composed of DEP (35%), DEHP (21%), DBP (15%), DINP (15%), DIBP (8%) and BBzP (5%). These phthalates and percentages are based from measurements obtained from pregnant women in the UIUC iKis study. The hypothesis was that environmentally relevant PM will interfere with PE development causing cellular arrest and increased fragmentation. Also, that the PM will decrease blastocyst cells within inner cell mass (ICM) and trophectoderm (TE). Female CD-1 mice at 39 days of age were superovulated then mated with C57BL6/B males. Zygotes were collected and distributed into one of six treatment groups, control, DMSO, 0.001 μg/mL, 0.01 μg/mL, 0.1 μg/mL, and 1 μg/mL. To determine whether exposure to the PM affects development, embryos were observed at the 2-cell, 8-cell, morula, blastocyst, and hatched blastocyst stages. In addition, the presence of fragmentation was assessed to determine quality. To determine whether the PM altered blastocyst cells within the ICM and TE, hatched blastocysts underwent immunofluorescence staining with Oct-4 to observe the ICM and Cdx-2 to observe the TE, cells were counted using Imaris Software. Exposure to the PM decreased the number of embryos that developed to the hatched blastocyst stage (0.001 μg/mL, 0.1 μg/mL, 1 μg/mL) and increased the percentage of fragmentation in treatment groups 0.01 μg/mL and 0.1 μg/mL. Although our results showed a decrease in embryo development when exposed to the PM, a small percentage were able to hatch. If staining showed that there was a decrease in the total number of cells within the ICM of embryos cultured in 1 μg/mL. Our results suggest that exposure to a relevant PM effects PE development, increases fragmentation, decreases the cell population within the ICM thereby, reducing the viability of PE.
Di(2-ethylhexyl) phthalate (DEHP) is used as a plasticizer in several consumer products and readily leaches from these products, leading to daily human exposure. Of concern, DEHP has been shown to have endocrine disrupting capabilities, and compounding this concern is a lack of knowledge on the effects of DEHP on fertility. Some manufacturers have elected to replace DEHP with other plasticizers. However, often less is known about these DEHP alternatives compared to DEHP itself. Diisononyl phthalate (DiNP) is one such understudied replacement. Thus, this study tested the hypothesis that adult exposure to DEHP or DiNP negatively affects female fertility. To test this hypothesis, adult female CD-1 mice (39–40 days) were orally dosed with vehicle control (corn oil), DEHP (20 or 200 µg/kg/day or 20 or 200 mg/kg/day), or DiNP (20 or 100 µg/kg/day or 20 or 200 mg/kg/day) for 10 days. Mice were euthanized in diestrus immediately following dosing or three or six months post-dosing. Estradiol, progesterone, and testosterone were analyzed in sera via enzyme-linked immunosorbent assays. A cohort of mice were bred immediately post-dosing and at three and six months post-dosing. Immediately post-dosing, DEHP and DiNP decreased testosterone (20 mg/kg/day DEHP, 100 µg/kg/day and 200 mg/kg/day DiNP, p ≤ 0.05) and estradiol (20 µg/kg/day DEHP, p = 0.055, 20 mg/kg/day DEHP, 100 µg/kg/day and 200 mg/kg/day DiNP, p ≤ 0.05) and increased progesterone levels (200 mg/kg/day DEHP, p ≤ 0.05, and 20 mg/kg/day DiNP, p = 0.0998). At three months post-dosing, DiNP decreased progesterone (100 µg/kg/day, p ≤ 0.05), increased estradiol (200 mg/kg/day, p = 0.083), and decreased progesterone levels (20 µg/kg/day, p = 0.082, 100 µg/kg/day, p ≤ 0.05). At six months post-dosing, DiNP decreased testosterone (100 µg/kg/day, p ≤ 0.05) and DEHP increased progesterone levels (200 µg/kg/day, p ≤ 0.05). Immediately post-dosing, no treatments affected male reproductive fertility. However, at three months post-dosing, DEHP and DiNP decreased the ability of females to become pregnant (20 µg/kg/day, p ≤ 0.05). At six months post-dosing, DEHP increased pregnancy loss (200 µg/kg/day, p ≤ 0.05). These data show that acute exposures to DEHP and a common DEHP replacement, DiNP, have long-lasting impacts on hormone levels and fertility for several months after exposure. 1495 Ancestral Exposure to Di(2-Ethylhexyl) Phthalate Disrupts Gene Expression and Pathways Critical for Mouse Ovarian Function in Three Generations

S. Rattan, H. Beers, E. Brehm, and J. Flaws, University of Illinois at Urbana-Champaign, Urbana, IL.

Di(2-ethylhexyl) phthalate (DEHP) is plasticizer found in polyvinyl chloride. DEHP can leach from these products and is a known endocrine disruptor. Previously we showed that prenatal DEHP exposure disrupts ovarian functions and female fertility in a transgenerational manner. However, little is known about the mechanism by which prenatal exposure to DEHP impacts ovarian functions and fertility in female mice across three generations. Therefore, this study investigated the changes in the gene expression in the ovaries from mice prenatally and ancestrally exposed to DEHP in the F1, F2, and F3 generations. Pregnant CD-1 mice (F0 generation) were orally dosed with tocopherol-ol-stripped corn oil (vehicle control) or DEHP (20, 200 µg/kg/day, 500, or 750 mg/kg/day) daily from gestation day 10.5 until birth (7-28 dams/treatment group). Pups born to these dams were considered the F1 generation. F1 females were mated with untreated males to obtain the F2 generation, and F2 females were mated with untreated males to produce the F3 generation. On postnatal day 21, female pups from each generation were euthanized and their ovaries were removed and frozen in liquid nitrogen and subjected to qPCR to quantify the mRNA expression of the phosphoinositide 3-kinase (PI3K) pathway, cell cycle regulators, steroid hormone receptors, insulin-like growth factors, and DNA methyltransferases. The results indicate that in the F1 generation, prenatal exposure to DEHP increased expression of PI3K factors and insulin-like growth factors. Further, it dysregulated expression of cell cycle regulators and steroid hormone receptors. In the F2 generation, prenatal exposure to DEHP dysregulated expression of PI3K factors and cell cycle regulators. It also decreased expression of steroid hormone receptors. In the F3 generation, ancestral exposure to DEHP decreased expression of PI3K factors, cell cycle regulators, steroid hormone receptors, insulin-like growth factors, and DNA methyltransferase. Collectively, these data indicate that prenatal and ancestral DEHP exposure causes transgenerational and trans-generational changes in the expression of genes in pathways that are critical for normal ovarian functions. Further, these data suggest that DEHP-induced changes in expression may influence DNA methylation. Supported by NIH PO1 ES022848, US EPA RD-83459301, T32 ES007326, and the Billie A. Field Fellowship.

1496 Prenatal Exposure to a Phthalate Mixture Changes Uterine Morphology and Differentiation in Mice in Multiple Generations

K. Li, M. Liszka, C. Zhou, J. A. Flaws, and R. A. Nowak, University of Illinois at Urbana-Champaign, Urbana, IL.

Phthalates are found in plastic containers, children’s toys, and medical supplies. They are endocrine disruptors and exposure to them leads to human health risks. Animal studies show that they disrupt ovarian development, reduce fertility and promote reproductive diseases in females. Most studies focus on a single phthalate, but humans are exposed to phthalate mixture (PM) daily. We hypothesized prenatal exposure to relevant doses of PM may change uterine morphology and function in mice for generations. The PM was based on urine phthalate composition of pregnant women: 35% diethyl phthalate, 21% di(2-ethylhexyl) phthalate, 15% dibutyl phthalate, 15% diisononyl phthalate, 8% diisobutyl phthalate, and 5% benzylbutyl phthalate. CD-1 dams were orally dosed with vehicle, or PM at 20 and 200 µg/kg/day, 200 µg/kg/day from pregnancy day 10.5 to birth. Uteri of F1, F2 and F3 female offspring (n=6-8/group) were collected, weighed, and processed for histological evaluation at 12 month. Samples were stained for H&E and immunohistochemistry for smooth muscle α-actin (SMA) and Ki67. Slides were scanned using Nanozoomer. Thickness of myometrial layers, size of endometrium, numbers of endometrial glands and proliferating cells in the luminal (LE) and glandular epithelium (GE) were measured. Data were analyzed by one way ANOVAs with multiple comparison against controls. No changes in size of endometrium and thickness of myometrial layers were similar in F1, F2 or F3 mice. We saw an increase in LE proliferation in the highest groups and a decrease in GE proliferation in the 200 mg/kg/day group in F2. In F1 500 mg/kg/day group, F2 200 µg/kg/day, 200 and 500 mg/kg/day groups, and F3 20 µg/kg/day, 200 and 500 mg/kg/day groups, we saw increased SMA expression in the endometrium, indicating presence of myofibroblasts and a fibrotic response. Glycosed cysts, large dilated glands and areas of epithelial hyperplasia were more prevalent in treated mice. These changes are linked to uterine pathologies such as endometritis and cystic hyperplasia in women. In conclusion, prenatal exposure to PM increases uterine morphological abnormalities of F1, F2 and F3 mice as they age, reflecting changes in the normal pattern of proliferation vs differentiation and inflammatory response. 1497 Effects of In Vitro Exposure to Di-n-butyl Phthalate and Mono-n-butyl Phthalate on Early Embryo Viability and Development

L. Rasmussen, E. J. Jauregui, and Z. R. Craig, University of Arizona, Tucson, AZ.

Di-n-butyl phthalate (DBP) is found in many consumer products including: plastics, beauty products, insecticides, medical devices, and oral medications. Phthalate exposure in women has been associated with decreased oocyte retrieval during in vitro fertilization protocols and greater incidence of early pregnancy loss. DBP is rapidly metabolized by non-specific lipases into mono-n-butyl phthalate (MBP) in the body. Previous studies have reported that MBP levels in the follicular fluid of women range from 1.08-2.63 ng/mL, current studies have not evaluated the effects of MBP at these concentrations on embryo development. This study was designed to determine whether environmentally relevant in vitro exposures to DBP and MBP affect development and ATP concentration in early mouse embryos. CD-1 females (35-50 days old, n = 10 mice per time point) were given intra-peritoneal injections of PMSG (5 IU) followed by hCG (5 IU) 48 hours later. Oviducts from each animal were collected at 24 hours post-breeding and embryos recovered (n = 13-51 embryos/sample) were subjected to qPCR to quantify the mRNA expression of the phosphoinositide 3-kinase (PI3K) pathway, cell cycle regulators, steroid hormone receptors, insulin-like growth factors, and DNA methyltransferase. The results indicate that in the F1 generation, prenatal exposure to DBP increased expression of PI3K factors and cell cycle regulators. It also decreased expression of steroid hormone receptors. In the F3 generation, ancestral exposure to DBP decreased expression of PI3K factors, cell cycle regulators, steroid hormone receptors, insulin-like growth factors, and DNA methyltransferase. Collectively, these data indicate that prenatal and ancestral DBP exposure causes transgenerational and trans-generational changes in the expression of genes in pathways that are critical for normal ovarian functions. Further, these data suggest that DBP-induced changes in expression may influence DNA methylation. Supported by NIH P01 ES026998 (ZRC).

1498 Measurements of Mono-n-butyl Phthalate in the Tissues of Cycling Adult CD-1 Female Mice after the Oral Administration of Di-n-butyl Phthalate

E. J. Jauregui, L. Rasmussen, and Z. R. Craig, University of Arizona, Tucson, AZ.

Di-n-butyl phthalate (DBP) is an endocrine disruptor commonly used worldwide as a plasticizer or solvent in many consumer products such as infant care, personal, and cosmetic products. Exposure to endocrine disruptors such as DBP is postulated to cause developmental and reproductive toxicity. While various studies utilizing mice have shown that DBP causes health problems, no quantitative evidence of the active metabolite of DBP, mono-n-butyl phthalate (MBP), in the tissues of adult cycling mice after oral exposure of DBP currently exists. Therefore, to investigate whether there are measurable MBP levels within the tissues of mice treated with DBP, we utilized a highly sensitive liquid chromatography/tandem mass spectrometry assay to determine MBP levels in liver, serum, and ovary of adult CD-1 female mice after one oral dose of DBP. We pipet-fed adult CD-1 mice (N=5 per treatment/time point) with tocopherol-stripped corn oil (vehicle) or one dose of DBP (1000 mg/kg) and collected liver, ovary, and serum at 2, 6, 12, and 24 hours after treatment. In mice treated with vehicle, background MBP levels were detected in serum (0.109±0.07 µg/ml) and liver (0.02±0.009 µg/g), but not in ovaries after 6 hours. In mice treated with DBP at 1000 mg/kg, MBP was detected in serum (15.74±2.46 µg/ml), liver (2.78±0.43 µg/g), and ovary (2.03±0.53 µg/g) at 2 hours, while MBP treated embryos showed a significant decrease in ATP production at 24 hours (DMSO: 193.27±26.23, n=5 wells,77 embryos, MBP: 69.77±15.16, n=4 wells, 49 embryos; p<0.05). ATP concentration did not differ between treatment groups at 72 hours when compared with control. These findings suggest that exposure to environmentally relevant concentrations of MBP do not affect early development but reduce ATP concentration in early embryos. This work was supported by NIH grants R01ES026998 (ZRC).
results in direct effects on the ovary. Future studies will be aimed at evaluating the distribution of MBP to various reproductive tissues following repeated oral dosing with various DBP dosages. This work was supported by NIAMS grant R01026998-01A1 (ZRC).

1499 Di(2-Ethylhexyl) Phthalate (DEHP) Decreases the Extrusion of the First Polar Body in Murine Oocytes at Different Reproductive Ages

L. Parra Forero1, A. Mojica Villegas2, E. Alfaro Pedraza3, and M. Hernández Ochoa4, 1Departamento de Toxicología, Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional (Cinvestav-IPI), Ciudad de México, D.F., Mexico; and 2Laboratorio de Toxicología de la Reproducción-Fertilitad, Departamento de Farmacia, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional, Ciudad De Mexico, Mexico.

Di-(2-ethylhexyl) phthalate (DEHP) is considered an endocrine disruptor that may impair zygote formation and survival of the embryo. These effects may be exacerbated in women that become pregnant at advanced ages due to reduction in the number of oocytes undergoing maturation, evidenced by the extrusion of first polar body. However, it is unknown whether the detrimental effects in advanced ages are exacerbated by DEHP exposure. This study evaluated the effect of DEHP exposure on the oocyte maturation in mice at different reproductive ages. Female CD-1 mice (3–4 weeks-old) were orally exposed to DEHP 20, 200 and 2000 μg/kg/day for 30, 60 and 120 days. The control group was administered with tocopherol-free mineral oil. Estrous cyclicity was evaluated daily by vaginal cytology. Following dosing, females were superovulated by injecting IP 5 IU of pregnant mare serum gonadotropin (PMSG), followed by 5 IU of human chorionic gonadotropin (hCG) at 48 h later. 18 h after hCG injection, females were euthanized by cervical dislocation, and the cumulus-oocyte complexes (COCs) were obtained from the oviducts to strip the cumulus cells. The oocytes were stained with DAPI and anti-a-tubulin, and then they were classified according to the degree of maturation, such as germinal vesicle stage (GV), metaphase I (MI), and metaphase II (MII). Significant differences in decreased number of COCs were observed in the 2000 μg/kg/day DEHP group treated for 30, 60, and 120 days (≈ 35%, 53%, and 75% reduction, respectively) compared to control. Similarly, the number of oocytes having polar body extrusion (MII) significantly decreased (≈ 55%, 46%, 62%) compared to control. These data suggest that DEHP impairs the resumption of meiosis in a time-dependent manner as mice age.

1500 Examining the Impact of DEHP Exposure via Food on Reproductive Function in Adult Men

S. E. Brown1, M. R. Monroe2, and D. A. Drechsel1, 1CardnoChemrisk, Boulder, CO; and 2University of Colorado Denver, Colorado School of Public Health, Aurora, CO.

Di-2-ethylhexyl phthalate (DEHP) is a widely used plasticizer that has been shown to exhibit endocrine-disrupting effects and reproductive toxicity. DEHP is found in various plastics including PVC-containing equipment, vinyl flooring, DEHP’s toxicological protective equipment, and food packaging. Because DEHP is not chemically bound to these plastics, it commonly leaches into the environment. It is estimated that approximately 90 percent of human exposure to DEHP is via food consumption, however occupational exposures are also commonly observed. Animal studies have shown that developmental exposures to DEHP can negatively impact the developing male reproductive system. However, few studies examine exposure and potential effects of DEHP on the adult male reproductive system. Here, we aim to investigate how human exposure to DEHP via food consumption may lead to effects on reproduction in adult men. A comprehensive search of the literature was performed to examine human exposures to DEHP, and reported effects of DEHP on the human adult male reproductive system. Five studies were identified that examined occupational exposure to DEHP in men. Four of these studies showed statistically significant relationships between occupational exposures to DEHP and impacts on spermatogenesis. Specifically, occupational exposures to DEHP were associated with decreased sperm concentration, increased sperm motility, increased sperm apoptosis, increased sperm reactive oxygen species (ROS), and effects on various hormones including testosterone, luteinizing hormone, and follicle stimulating hormone. Fourteen studies were identified that involved non-occupational exposure to DEHP, the majority of which demonstrated adverse effects on adult spermatogenesis; the observed effects were similar to those reported in the occupationally-exposed cohorts. However, several of these non-occupational studies also showed no significant effects on spermatogenesis. Although these studies were conducted in non-occupational scenarios, DEHP contributions from food were unclear.

Although there appears to be a correlation between DEHP exposures and altered adult male spermatogenesis, it is unclear how exposure to DEHP via food consumption contribute to the observed effects. Further investigation is needed to determine how these results may be affected by confounding factors and alternate (non-food) exposures to DEHP.

1501 Experimental Rat Cryptorchidism and Susceptibility to Dibutyl Phthalate or Acrylamide

N. Souza1, A. Cardoso2, L. Gomide3, G. Brianzi1, T. Lima1, H. Miot1, A. Martino-Andrade1, L. Arnold1, K. Pennington1, S. Cohen1, J. de Camargo1, and N. M. Nascimento Pontes1, 1São Paulo State University - UNESP, Botucatu, Brazil; 2University of Louisville, Louisville, KY; 3Faculty Southwest Paulista - FSP, Aveare, Brazil; 4Federal University of Paraná - UFPR, Curitiba, Brazil; and 5University of Nebraska Medical Center, Omaha, NE.

The increased incidences of male reproductive disorders may be associated with exogenous chemicals such as dibutyl phthalate (DBP) or acrylamide (AA). Cryptorchidism, the most common male congenital abnormality, is variably associated with hypospadias, impairment of spermatogenesis and testicular germ cell tumors. Surgical relocation of the testes to the scrotum, orchiopexy, is performed to prevent these effects. Our hypothesis is that experimental surgical cryptorchidism could enhance testicular susceptibility to exogenous chemicals. Three experiments with Sprague-Dawley rats were performed: 1) in utero and postnatal exposures to DBP or AA until postnatal day (PN) 112; 2) cryptorchidism and orchiopexy established surgically at PN 21 and PN 42, respectively, with termination on PN 98; and 3) in utero and postnatal exposures to DBP or AA, cryptorchidism and orchiopexy established surgically at PN 21 and PN 42, respectively, with termination on PN 112. Pregnant dams, F1 litters and F1 males were exposed to the chemicals by gavage, through milk, and by diet, respectively. The testes were evaluated histologically. The seminal vesicles, epididymis and testes were scored according to the severity of the lesions with the controls being 1.0. 1) Rats exposed only to DBP (score 1.5) or AA (score 1.1) presented a mostly preserved spermatogenesis. Some seminiferous tubules showed vacuolated germinative epithelium, germ cell apoptosis and a Sertoli cell only (SCO) pattern. 2) Cryptorchidism (score 3.3) resulted in decreased absolute testes weights, SCO tubules and spermatogenesis arrest. These alterations were reversed by orchiopexy (score 1.1). 3) Cryptorchidism/orchiopexy associated with continuous exposure to DBP (score 2.5) or AA (score 2.5) resulted in smaller absolute testes weights, spermatogenesis arrest, germ cell exfoliation and multinucleation, and SCO tubules. These data show that surgical cryptorchidism sensitizes the testes to DBP or AA.

1502 Interaction between Mono-(2-Ethylhexyl) Phthalate and All-Trans Retinoic Acid Alters Development of Ex Vivo Cultured Fetal Male Testis

D. J. Spade, and S. J. Hall. Brown University, Providence, RI.

Toxic effects of phthalate esters (phthalates) on the fetal testis are well-characterized, including reduced testosterone, altered seminiferous cord development, induction of multinucleated germ cells, and germ cell death. The anti-androgenic effects of phthalates vary across species more than seminiferous cord effects, suggesting that additional mechanisms are likely to be involved in phthalate toxicity. We have previously shown evidence that exogenous all-trans retinoic acid (ATRA) reduces seminiferous cord number, alters expression of genes related to sex determination, and induces expression of the ovarian protein FoxL2 in cells of rat fetal testes. Further, simultaneous administration of mono-(2-ethylhexyl) phthalate (MEHP) modulates the effects of ATRA on the rat fetal testes. We hypothesized that disruption of retinoic acid signaling is a mechanism of phthalate toxicity in mice, as well as rats. To test this hypothesis, mouse fetal testes were isolated on gestation day 14, cultured ex vivo with 10−6 to 10−4 M MEHP, 10−5 M ATRA alone, or 10−5 M ATRA plus 10−5 to 10−4 M MEHP. Seminiferous cord development was assessed by quantifying cord number per section in histological sections of cultured testes. FOXL2 expression was assessed by immunohistochemistry. As previously observed in the rat, ATRA exposure caused a significant decrease in seminiferous cord number. Co-exposure with MEHP resulted in a non-linear dose-response indicating an interactive effect of ATRA and MEHP on cord development. Preliminary FOXL2 analysis showed increased FOXL2 staining in ATRA and co-exposure samples. These results provide evidence that MEHP and ATRA interact to disrupt mouse fetal testes development and support the hypothesis that retinoic acid signaling is a target for phthalate toxicity in mice.

2019 SOT Annual Meeting
1503 Metabolite Profiling in Mouse Testis Fragments Treated with Endocrine Disrupting Chemicals

J. Sun, N. Nakamura, D. Sloper, and R. Beger, NCTR, Jefferson, AR.

The purpose of this in vitro model of mouse testis organs was to evaluate it as a reproductive toxicity test. In a previous published study, (Sato et al) was first to realize mouse testis fragments cultured in this manner could produce viable, fertilization-proven, sperm, which makes this method a possible alternative form of male reproductive toxicity testing. To evaluate this culture system, we exposed the cultured testis fragments to two known endocrine disrupting chemicals: ethinylestradiol (EE), and dibuthyl phthalate (DBP). Toxicological analysis using liquid chromatography/mass spectrometry (LC/MS)-based metabolomics was used to measure any metabolome changes in the chemical treated testis fragments. Testes from postnatal day 5, C57BL/6J mice were collected, testicular tunica removed, and the testes cut into four similar sized fragments. Two to three testis fragments were placed onto a 1.5% agarose gel cube and cultured in α-MEM including 0.4% Albumax I (day 0). On day 1 of culture, testis fragments were treated with 0.01 or 1 nM EE; or 0.1 or 10 μM DBP or vehicle (control). On day 20 of culture, the testis fragments were collected for LC/MS and histology analysis. Histological analysis demonstrated the percentage of seminiferous tubules with any dead cells increased dose-dependently. Metabolic analysis demonstrated metabolites involved in glycolysis pathway (UDP-glucose, glucose phosphate and pyruvate), in tricarboxylic acid cycle pathway (oxaloacetate, citric acid and aspartate), and arginine-creatine metabolism pathway (creatine, arginine, spermine and spermidine) and their altered levels by both EE and DBP treatments. These findings suggest that EE and DBP treatments might cause testicular toxicity with similar underlying mechanisms since both chemicals disturbed similar metabolism pathways but with varying results. To confirm these findings, further experiments using other testicular toxicants will be necessary.

1505 Gestational ENM Inhalation Compromises Placental Efficiency

Maternal engineered nanomaterial (ENM) inhalation during gestation is associated with uterine vascular impairments and endocrine disruption that may lead to altered gestational outcomes. We have previously shown that nanotitanium dioxide (nano-TiO2) inhalation impairs endothelium-dependent arteriolar dilation in uterine arteries of pregnant rats, and significantly decreases plasma estrogen. However, the mechanism underlying this dysfunction is not fully described. Fetal death has been shown in vivo and in vitro for synthesis of the hormone kisspeptin (Kiss), which is a potent vasoonconstrictor. Therefore, we examined how Kiss is involved in nano-TiO2-induced vascular dysfunction and placental efficiency. Pregnant (gestational day (GD) 6) Sprague-Dawley rats were exposed to nano-TiO2 aerosols (31.1 ± 1.1 μg per day; cumulative dose = 29.7 ± 1.0 μg; n = 6) or sham exposed (n = 6) to evaluate consequences of maternal exposure. Rats were sacrificed 24 hours after last exposure, at GD 20. Plasma was collected to evaluate circulating Kiss level. Wet and dry weights of placents and pups were measured and used to calculate placental efficiency (grams fetus/gram placental). Additionally, pressure myography was used to determine vascular reactivity in uterine arteries (nano-TiO2 exposed n = 7; sham n = 6). Uterine arteries were equilibrated for 1 h prior to experimentation. Contractile responses were determined via cumulative additions of 50 μL of Kiss (1 × 10⁻⁴ to 1 × 10⁻⁴ M). The steady-state diameter of vessels was recorded for at least 2 min after each dose. No difference was seen in plasma Kiss between groups. Wet placental weights were significantly increased in exposed (0.99 ± 0.03 g) versus sham rats (0.70 ± 0.04 g), whereas wet pup weights were significantly decreased in exposed rats (4.01 ± 0.47 g vs. 4.15 ± 0.15 g). These alterations led to a significant decrease in placental efficiency in exposed rats (4.52 ± 0.20) compared to sham (6.35 ± 0.5). Maternal ENM inhalation exposure significantly increased constriction (91.2% ± 2 vs. 98.6% ± 0.1) in uterine arteries when treated with Kiss. These studies represent evidence that pulmonary ENM exposure perturbs the normal gestational endocrine vascular axis via a Kiss dependent mechanism. Additionally, a decrease in placental efficiency due to exposure is likely to have long term consequences on adult health and morbidity. Support: ES015022 (TRN); U54GM104942 (Sh).

1504 Reproductive Toxicity and Oxidative Damage Induced by Titanium Dioxide, Zinc Oxide Nanoparticles, and Their Mixture in Mice

O. Fadoju¹, O. Ogunsuyi¹, O. Akanni¹, O. Adaramoye¹, S. Cambieri², S. Esowara², A. Gulteb², and A. Bakare², ¹University of Ibadan, Ibadan, Nigeria; and ²Luxembourg Institute of Science and Technology, Belvaux, Luxembourg.

The continuous release of Titanium dioxide (TiO₂) and Zinc oxide (ZnO) nanoparticles (NPs) from consumer products into the environment warrants safety risk assessment, as they may induce reproductive anomalies. There is dearth of information on interactive effects of TiO₂, ZnO NPs and their mixture (1:1) to alter spermatogenesis, reproductive hormone and oxidative stress parameters. The shape, hydrodynamic diameter (HD), and zeta potential (ζ) of TiO₂ and ZnO NPs were characterised using the transmission electron microscopy and dynamic light scattering, respectively. Swiss albino mice were intraperitoneally administered 9.38 - 150.00 mg/kg bw each of TiO₂ (100 nm) and dynamic light scattering, respectively. Swiss albino mice were intraperitoneally administered 9.38 - 150.00 mg/kg bw each of TiO₂, ZnO NPs and their mixture (1:1) and the mixture treated testis fragments. Testes from postnatal day 5, C57BL/6J mice were collected, testicular tunica removed, and the testes cut into four similar sized fragments. Two to three testis fragments were placed onto a 1.5% agarose gel cube and cultured in α-MEM including 0.4% Albumax I (day 0). On day 1 of culture, testis fragments were treated with 0.01 or 1 nM EE; or 0.1 or 10 μM DBP or vehicle (control). On day 20 of culture, the testis fragments were collected for LC/MS and histology analysis. Histological analysis demonstrated the percentage of seminiferous tubules with any dead cells increased dose-dependently. Metabolic analysis demonstrated metabolites involved in glycolysis pathway (UDP-glucose, glucose phosphate and pyruvate), in tricarboxylic acid cycle pathway (oxaloacetate, citric acid and aspartate), and arginine-creatine metabolism pathway (creatine, arginine, spermine and spermidine) and their altered levels by both EE and DBP treatments. These findings suggest that EE and DBP treatments might cause testicular toxicity with similar underlying mechanisms since both chemicals disturbed similar metabolism pathways but with varying results. To confirm these findings, further experiments using other testicular toxicants will be necessary.

1506 Dual Hit—Uteroplacental Hypoxia after Engineered Nanomaterial Exposure

J. D’Errico, and P. Stapleton, Rutgers, The State University of New Jersey, Piscataway, NJ.

Uteroplacental vascular remodeling and hemodynamic control are central to delivering oxygen and nutrients to support the placenta and developing fetus during pregnancy. Hypoxia has been identified as a contributing factor to placental dysregulation and the development of maternal-fetal disease, including intrauterine growth restriction (IUGR). Our laboratory has demonstrated that rodent exposure to engineered nanomaterials (ENM) early in pregnancy (GD 4) causes IUGR as evidenced by smaller placentas, more fetal reabsorption sites, and reduced fetal pup number and size. However, the cellular and molecular mechanisms that culminate to IUGR remain elusive. Therefore, we initiated a set of experiments to assess hypoxic signaling and placental adaption to direct ENM exposure. Using in vitro methodology, BeWo b30 trophoblast carcinoma cells were exposed to increasing concentrations of 20 nm TiO₂ (1, 10, 100 μg/mL) and analyzed with qPCR for changes in hypoxia signaling markers after 24 hours. At 100 μg/mL HIF1α (2.24 ± .31), eNOS (1.95 ± .27), VEGF-A (2.25 ± 3.3) and VEGFRI (2.03 ± .67) mRNAs were up-regulated. These markers were also elevated in western blot analyses. Exposures of human term placental explants presented similar findings, wherein HIF1α (2.1 ± .60), eNOS (1.3 ± .43), and VEGF-A (1.26 ± .72) mRNAs were upregulated. In ex vivo studies using rodent placental perfusion methodology, infusion of 900 μL of 20 nm rhodamine-labeled polyisoyrene or 20 nm gold sonicated in PSS into the maternal uterine artery significantly reduced fluid flow through the maternal uterine artery compared to baseline (after 60 minutes by 40% and 90 minutes by 55%), respectively. Moreover, fluid flow was significantly reduced through the fetal umbilical vein into fetal compartment as compared to baseline (within 10 minutes by 40% and 70 minutes by 60%, respectively). Overall, these studies indicate the upregulation of placental hypoxia signaling markers after direct ENM-trophoblast exposure. Further development of a hypoxic environment is enhanced given the decrease in fluid flow across the placenta after ENM infusion. These results, in combination with published work demonstrating uterine microvascular constriction after maternal ENM exposure demonstrate the development of a hypoxic uterine environment after ENM exposure. NIH-R00-ES024783 (PAS); T32-ES070148 (JND, JTS, LMA); P30-ES000022.
Numerous epidemiological and animal studies have demonstrated that exposure to ambient fine particulate matter (<2.5 μm in diameter [PM$_{2.5}$]) during gestation is associated with adverse obstetric outcomes including preterm birth (PTB). Early delivery has been linked to several lifetime health consequences for offspring, including behavioral and psychological abnormalities, and reduced immune and respiratory functions. In a previous study performed in this laboratory, B6C3F1 pregnant mice exposed to concentrated ambient PM (CAPs) by inhalation, demonstrated shortened (by 0.4 d) gestational duration compared to filtered air (FA) controls. The mechanisms underlying the association between PM$_{2.5}$ and PTB are not currently well understood. Since the placenta provides a crucial link between the intrauterine environment and fetal growth/development, it is a major target of PM and key for studying the effects on birth outcomes. Therefore, in this study, placentae from the previously developed pregnant mouse model (n=6 each from CAPs and FA groups) were subjected to whole transcriptomic profiling by RNAseq. A bioinformatic RNAseq analysis workflow (trimport, Salmon and edgeR) was used to identify differentially expressed genes between treatment groups. The 648 genes from the curated dBPTB (database Preterm Birth) were used for a candidate gene approach and were examined using gene counts obtained from RNAseq. Following PM$_{2.5}$ exposure, six PTB genes were downregulated in placentae (Ace, Ddah1, Col1a2, Chst15, Akap12, Ephx1) and one was upregulated (Chys3) (p<0.01). Gene Ontology demonstrated that these seven genes are involved in neutrophil-mediated immunity, arterial blood pressure regulation, amino acid binding, cell membrane function, metal ion binding, and aromatic compound catabolism among other functions that could be linked to PTB. Additional computational models, agnostically testing placental transcriptome-wide differential gene expression, revealed additional genes that were differentially expressed between the two treatment groups. These findings suggest that PM exposure influences the placenta genome thereby mediating PTB. Identification of these differentially expressed genes may contribute to intervention strategies to mitigate these adverse effects. Supported by: March of Dimes, NIEHS P30ES000206, and NIEHS P30ES0232315.

In the United States, the number of female welders has increased by more than two percent over the past decade. The U.S. Bureau of Labor Statistics predicts steady industry growth through 2024, and it is expected that many women will continue to fill these roles as the baby-boomer generation prepares to retire. Notable data currently exists on the potential reproductive effects of mild and stainless steel welding fumes on the placenta. Using human placental trophoblast cells (HTR-8/SVneo) from the first trimester, we aimed to identify the mechanisms of toxicity associated with stainless steel (SS) and mild steel (MS) welding rods. MS welding fumes are mainly composed of iron and manganese, while SS-welding fumes primarily contain hexavalent chromium and nickel. During embryogenesis and placentaion, cellular migration is a highly orchestrated and multi-step process that plays an integral role in providing the foundation for a successful pregnancy. In this study, exposure of HTR-8/SVneo cells to 100 μg/mL of SS welding fumes for 24 h using the RadiusTM Migration assay showed significant inhibition of cellular migratory ability, whereas cells exposed to MS were not affected. Using electron paramagnetic resonance, exposure of cells to SS also produced greater amounts of the hydroxyl radical when compared to MS. Results from a multiplex cytokine kit (Meso Scale Diagnostics, LLC) show that exposure of cells to SS causes a pro-inflammatory response, with significant increases of IL-8 and IL-15 observed. Finally, scanning electron microscopy was performed to better understand how particles are internalized by placental cells. For both MS and SS, welding fumes accumulated in vascular spaces, which could potentially explain the increased Endothelin-1 results observed using ELISA. Endothelin-1 is a potent vasoconstrictor that is necessary for fetal formation, but upregulated in the setting of inflammation. Our data showed that SS appears to have the most damaging effect on placental cells, which could be due the presence of hexavalent chromium, not found in MS. Further studies are needed to delineate the toxicity of the individual metals found in welding fumes and their effects on the female reproductive system.

Ovarian follicles progress from a primordial stage through primary, secondary, antral and finally preovulatory stages. The finite pool of primordial follicles constitutes the total ovarian follicle reserve. Exposure of female rodents to polycyclic aromatic hydrocarbons (PAHs) results in destruction of immature primordial and primary follicles. PM$_{2.5}$ is rich in PAHs, which are adsorbed onto particle surfaces; the effects of exposure to PM$_{2.5}$ on the ovarian reserve have not been investigated. Apolipoprotein (Apo) E null mice were exposed to concentrated ambient PM$_{2.5}$ or filtered air for 12 weeks, 5 days per week for 4h/day using a Versatile Aerosol Concentration Enrichment System. ApoE null mice are predisposed to develop atherosclerotic plaques; these mice were part of a study investigating vascular toxicity of PM$_{2.5}$. Mice were euthanized on the day of proestrus of the estrous cycle 24h after the final exposure. One ovary per mouse was processed for follicle counts. Primordial and primary follicles were counted blind to treatment in every 4th 20 μm section on a stereology system using the optical fractionator method. Secondary and antral follicles were followed through every section. Primary follicle numbers were significantly decreased by 51% (P=0.007, t-test), and primordial follicle numbers were nonsignificantly decreased (P=0.13) in PM$_{2.5}$-exposed mice. The overall small follicle count (primordial plus primary) was significantly decreased by 45% (P=0.03). Numbers of healthy secondary follicles that eventually become antral and cortical stage follicles were reduced by 22% in PM$_{2.5}$-exposed mice. The overall small follicle reserve was decreased by half in PM$_{2.5}$-exposed mice. Decreased ovarian reserve leads to premature ovarian failure, which increases the risk for cardiovascular disease in women. Thus our data provide a potential link between ovarian and cardiovascular effects of exposure to PM$_{2.5}$. Ongoing work is investigating the mechanism of follicle depletion. Supported by California Air Resources Board, 16DR005.

Chrysotherein (TCE), is an industrial solvent and widespread Superfund site contaminant. Despite epidemiological evidence associating exposure with adverse birth outcomes, the effects of TCE and its metabolite S-(1, 2-dichlorovinyl)-L-cysteine (DCVC) on the placenta remain undetermined. Theaproposed exposure and utilization of biofuels and production of small molecules is rich in metabolic and mitochondrial function are essential for placental cells. Our study investigated the effects of DCVC exposure on energy metabolism and mitochondrial function in placental cells. Human extravillous trophoblast cells, HTR-8/SVneo, were exposed to 5-20 μM DCVC for 6 or 12 hours. Targeted metabolomics were used to evaluate small molecule and metabolite concentrations from different energy metabolism pathways. Our experiments demonstrated an early increase in glycolysis as well as a partial upstream obstruction in the glycolytic pathway, resulting in lipid breakdown as a source of biofuel to provide intermediate glycolytic substrates that enter the pathway downstream of the obstruction. Additionally, an initial increase in TCA cycle activity was observed followed by a slight decrease in activity. Using a Seahorse XF Analyzer for monitoring concurrent oxygen consumption rate and extracellular acidification rate in real time, our experiments also demonstrated an increase in basal oxygen consumption, mitochondrial proton leak and decrease in energy coupling efficiency accompanied by sustained extracellular acidification indicative of glycolytic activity. These changes were followed by observed decreases in mitochondrial-dependent basal and maximum oxygen consumption rates and dissipation of mitochondrial membrane potential. Taken together, these results suggest that DCVC exposure causes substantial energy stress, necessitating alterations in biofuel sources and energy metabolism pathway utilization, further complicated by progressive mitochondrial dysfunction and resulting in decreased physiological adaptability. Our findings demonstrate the biological plausibility of DCVC-induced placental toxicity and provide new insights into the toxicological mechanisms of action of TCE and its metabolite DCVC.
Trichloroethylene (TCE) is an environmental contaminant shown to be associated with low birth weight and small for gestational age in human epidemiological studies, decreased fetal weight in Wistar rats, and impaired mitochondrial function in placental cells. Building upon this information, the present study conducted tricarboxylic acid (TCA) Plus and short chain fatty acid (SCFA) targeted metabolomics analysis on amniotic fluid samples to identify changes in metabolites induced by exposure to TCE. Rats were treated with 480 mg TCE/kg/day from gestational day (GD) 6 to GD 16, and amniotic fluid samples were collected on GD 16. We observed a statistically significant decrease for both fetal genders for the following metabolites: 6-phosphogluconate (6PG), guanosine diphosphate (GDP), adenosine diphosphate (ADP), adenosine triphosphate (ATP), and flavin adenine dinucleotide (FAD). Some metabolites decreased in a gender-specific manner including the following: fructose 1,6-bisphosphate (FBP) (male only), guanosine triphosphate (GTP) (male only), acetyl-CoA (aCoA) (male only), and uridine diphosphate (UDP)-D-glucuronate (female only). Finally, several lipid metabolites were both increased with TCE treatment for females only. Together, these results highlight alterations in indirect or direct energy supply (6PG, GDP, ADP, ATP, FAD, FBP, GTP, aCoA, phosphocreatine) and oxidative stress content (arginine, UDP-D-glucuronate) in the amniotic fluid as part of the response to TCE exposure. This also indicates that TCE exerts different effects on amniotic fluid metabolites in male and female fetuses. Future research is warranted to fully understand how these alterations could be part of the mechanism by which TCE exerts its toxicity during pregnancy.

Etiological, Clinical and Data Base Analyses of Human Infertility in USA, Suggest the Role of Environmental Pollutants in Increasing Infertility for Industrial and Urban Populations

Infertility in humans has been considered to be one of the impending health issues of social and economic aspects. As a whole, infertility is a very complex health issue involving multiple etiological aspects, such as reproductive, endometrial, environmental and genetic factors. There are several reports that warn about the progressively diminishing fertility rates around the globe. Both male and female factors have been attributed for the reduced fertility rates. Infertility rate is higher in USA than most of the industrial countries. There are no studies to investigate the factors involved in infertility rates from various states of USA. Hence, a comprehensive data base analysis (CDC data base, population data base, PubMed entrez and North Carolina State data bases) for the following aspects were undertaken: A) Fertility rate based on the birth rate information of various states, B) Fertility rate of individual countries in North Carolina as model state, and C) Collecting etiological data relevant to reproductive aging, important developmental periods, infectious diseases, chronic conditions and diseases, behavioral factors, iatrogenic causes, occupational and environmental hazards, and genetic influences. Based on the data analyses the following conclusions may be derived: A) Industrialized states tend to have lower fertility rate, B) Exposure to heavy metals (such as lead, zinc, mercury, cadmium, nickel) pollution may be one of the causes, and C) Differential distribution of the above mentioned etiological factors may have synergistic outcome on the fertility of the couples. Furthermore, the male and female related infertility factors may have differential distribution as per socio economic status, rural vs. urban life style and other unknown factors.

NTP Monograph on the Systematic Review of Occupational Exposure to Cancer Chemotherapy Agents and Adverse Health Outcomes

Many cancer chemotherapy agents are developmental toxicants, genetic toxicants, and/or known carcinogens. Despite the issuance of safe handling guidelines in 1980s, occupational exposure continues to occur. Based on the evidence of carcinogenicity and genetic toxicity associated with direct administration of these agents and current evidence of occupational exposure, NTP conducted a systematic review to: 1) evaluate whether occupational exposure is associated with any adverse health outcomes in humans, and 2) summarize the prevalence and levels of chemotherapy agents in the workplace measured by environmental monitoring and biomonitoring. A literature search was performed up to February 23, 2017 using PubMed, Embase, Scopus, Toxline, and Web of Science. Data were extracted, and risk of bias was assessed from relevant studies. Studies were grouped on an outcome basis, and these bodies of evidence were assessed to develop confidence ratings and level-of-evidence conclusions. The literature search and screening identified 110 epidemiological studies assessing possible adverse health outcomes and 171 studies evaluating exposure. NTP concluded that there is a moderate level of evidence that occupational exposure to cancer chemotherapy agents is associated with a higher incidence of spontaneous abortion, particularly when evaluating studies of nursing and pharmacy personnel. NTP also concluded that there is a moderate level of evidence that exposure to these agents in the workplace is associated with genetic toxicity based on consistent reports of higher levels of structural chromosome aberrations, micronucleus induction, and DNA damage measured by comet assay. Due to few studies per outcome and heterogeneity in the data, there was inadequate evidence to reach level-of-evidence conclusions on other health outcomes. Cancer chemotherapy agents were commonly detected in environmental samples of the workplace and urine or blood of workers handling these agents, including in data collected as recently as 2014 to 2016. Considering the potential for occupational exposure to these agents and their association with spontanous and reproductive effects during therapy, it is necessary to reduce exposures through training in safe handling procedures and provision and use of personal protective equipment and associated safety containment equipment. Identified research needs and data gaps included improved exposure characterization and broadening the range of workers monitored for exposure.
## 1515 Development of a Liquid Chromatography-Mass Spectrometry Method to Quantitate Deoxynivalenol in Harlan Sprague-Dawley (HSD) Rat Plasma, Amniotic Fluid and Fetal Homogenate

Deoxynivalenol (vomitoxin or DON) is a mycotoxin primarily produced by fungi of the Fusarium genus. It may be found in Fusarium-infected wheat, corn, and barley and hence there is potential for human exposure. Although some toxicity data exists for DON, data following perinatal exposure is generally lacking. The objective of this work was to develop a method to quantify DON in HSD rats to assess fetal and lactational transfer of DON in support of a National Toxicology Program (NTP) toxicology study. Standards were prepared by spiking 100 μL of matrix with 20 μL of DON spiking solution and 20 μL of 13C10-DON (internal standard, IS) in acetonitrile. Samples were extracted by adding 360 μL of acetonitrile followed by vortex mixing and centrifugation. The supernatants were dried, the residue was reconstituted in 150 μL of 20% aqueous acetonitrile and analyzed by liquid chromatography-tandem mass spectrometry. An Acquity UPLC BEH C18 column was used with mobile phases consisting of water and methanol. The electrospray ionization source was operated in negative ion mode. The MRM transitions were 295/265 and 310/279, for DON and 13C10-DON, respectively. The method was successfully qualified over a calibration range ~2 to 1000 ng/mL in male HSD rat plasma. The matrix standard curve was linear (r > 0.99). The lower limit of quantitation was 2.06 ng/mL and the limit of detection (LOD) was 0.354 ng/mL. The accuracy (determined as % relative error, RE) and precision (determined as % relative standard deviation, RSD) for the lowest matrix spiked level was ≤± 12% and 5.5%, respectively. The method was qualified for GD18 HSD dam plasma and fetal homogenate (in water) at ~5 and 500 ng/mL DON was stable in HSD GD18 maternal rat plasma and fetal homogenate when stored at ~70 °C for at least 29 and 43 days, respectively. The method was applied to samples from a dose range finding study where HSD dams were dosed via gavage from GD 6 to PND 28 with either 0 (control) or 1 mg/kg/day DON. DON was quantified in GD 18 dam plasma (17.7 to 21.1 ng/mL), amniotic fluid (9.65 to 14.8 ng/mL), and fetal homogenate (21.5 to 24.7 ng/mL) demonstrating fetal transfer. Although DON was found in PND 4 dam plasma (16.2 to 18.6 ng/mL), the levels in pup plasma were below the LOD suggesting absence of transplacental transfer.

## 1516 Propanol Acutely Changes Prolactin, Estrogen and Splenic Cell Populations in Female Mice

The herbicide propanol is used in rice fields globally. Earlier research has indicated that propanol enhances adaptive immune responses to heat-killed Streptococcus pneumoniae (HKS) immunization. This enhancement is dependent upon an intact hypothalamic-pituitary-gonadal (HPG) axis in female mice. It has been hypothesized that propanol alters reproductive hormones (progestosterone, prolactin and estradiol) as well as splenic immune cell populations as early as 24 hours in HKS-immune responses, in a gonadotropin releasing hormone (GnRH) receptor-dependent manner. To test this, 48 C57BL/6 female mice were assigned among 8 groups (6 mice each) in a 2x2x2 factorial arrangement of treatments: propanol (200 mg/kg i.p.), HKS (2x10^6 cfu i.v.) and GnRH receptor antagonist (antide; 60 ug i.q.) and their respective controls. Serum, spleens, ovaries and uteri were harvested 24 hours post immunization. Progesterone, prolactin and estradiol concentrations were measured by specific ELISA. Splenic T cells (CD4+ and CD8+), B cells and CD11b+ cells were analyzed by flow cytometry. Propanol increased the concentrations of prolactin (p=0.006) and the percentage of CD4+ cells (p=0.037) in the spleen, and it decreased concentrations of serum estradiol (p=0.0001), ovarian (p=0.022) and spleen (p=0.001) weight, correspondingly to decrease in numbers of splenocytes (p=0.028), B cells (p=0.017), and CD4+ cells (p=0.043) when compared to mice without propanol treatment. Propanol did not alter progesterone concentrations. Antide as a main effect reduced uterine (p=0.035) and ovarian (p=0.0001) weight, and ovarian area (p=0.0006). The percentage of CD11b+ cells (p=0.008) and CD4+ cells (p=0.006) in the spleen were also reduced, while spleen weight (p=0.006), numbers of splenocytes (p=0.046), B cells (p=0.017), and percentage of B cells (p=0.012) were increased. However, antide did not have interactive effects with propanol on any responses. In summary, antagonizing GnRH receptors with antide affected immune and reproductive variables but it did not modify propanol’s acute effect. This suggests the GnRH receptors are not necessary in the acute phase (24 hrs) of propanol/HKS challenge but that does not exclude other potential components of HPG axis.

## 1517 Disruption of Cholesterol Homeostasis through the Retinoid X Receptor in Human Ovarian Granulosa and Theca Cells after a Low-Dose Tributyltin Exposure

Y. Pu, S. Pearl, D. Martin, and A. Vega-Lopez.

Michigan State University, East Lansing, MI; and Sparrow Hospital, Lansing, MI.

Endocrine disrupting chemicals (EDCs) have been shown to interfere with reproductive function leading to sub- or infertility. Tributyltin (TBT) is one of such EDCs used as a chemical catalyst and biocide with human exposure ranging between ~0.1 and 85 ng/mL. We have demonstrated that TBT can stimulate cholesterol efflux in ovarian theca cells of four mammalian species. Since cholesterol is the steroid hormone precursor in steroidogenic cells, we aimed to investigate if a short-term, low dose TBT exposure will disrupt cholesterol homeostasis in human primary ovarian steroidogenic cells (granulosa and theca cells). To test this hypothesis we obtained human ovaries from 6 subjects (31–48 years old, without prior tumorigenesis or hyperandrogenism) from Sparrow Hospital (IRB: 17-1066M). Granulosa and theca cells were isolated and purified (n=3 for each cell type) with collagenase and cell density gradient. Cell viability and cytotoxicity were assessed by trypan blue stain and MTT assay, respectively. We tested pre-luteinized cells and luteinized (in vitro luteinization induction with LH) cells. Human granulosa and theca cells were exposed to an environmentally relevant dose of TBT (10ng/mL) and/or retinoid X receptor (RXR) antagonist (UV3003; 8μM) for 48h (pre-luteinized cells) or 72h (during luteinization). Steroidogenic enzymes and cholesterol transport genes were measured by RT-qPCR. Pre-luteinized and luteinizing granulosa and theca cells exposed to TBT upregulated ABCA1 expression. GREB1 upregulation was observed in pre-luteinized granulosa and theca cells. STAR was only upregulated in pre-luteinized granulosa cells, which may be a compensatory effect from TBT-induced ABCA1 upregulation. HSD3B1 and 17BHS expression remained unchanged. The RXR antagonist blocked the TBT-induced ABCA1 upregulation in both cell types. In conclusion, TBT, at an environmentally relevant dose, stimulates cholesterol extracellular efflux via the RXR pathway. Along with our work in other mammalian species, these results are supportive of TBT’s conserved mechanism on cholesterol trafficking in steroidogenic cells. The low dose used falls within current human exposure levels and thus warrants further work to understand the impact of organo-tin-induced cholesterol disruption in steroidogenic cells on female fertility. Supported by NIAMS 1K22ES026208 to AV-L.

## 1518 Sirtuin-1 Inhibitor EX-527 Hyperacetylates p53 and Attenuates CrVI-Induced Germ Cell Apoptosis

Texas A&M University, College Station, TX.

Environmental contamination with hexavalent chromium (CrVI) has been increasing in the United States as well as in the developing countries. Due to increased use of Cr and improper disposal of Cr wastes from the industries, CrVI levels in the soil, water and air have been constantly increasing. Exposure to CrVI predisposes human population to various diseases including cancer, infertility, and developmental problems in children. Previous findings from our laboratory reported that prenatal exposure to CrVI caused premature ovarian failure through p53-mediated mechanisms. Sirtuin 1 (SIRT1) is a NAD+-dependent histone deacetylase (HDAC) class III. SIRT1 deacetylates several histone and non-histone proteins such as p53 and NFκB. Current study determines a role for SIRT1-p53 network in CrVI-induced germ cell apoptosis and establishes physical interaction between SIRT1 and p53. Adult pregnant dams were given regular drinking water or CrVI (10 ppm potassium dichromate in drinking water, ad libitum), and treated with three different doses of SIRT1 inhibitor EX-527 (1, 5 and 50 mg/kg body weight, i.p.), during 9.5 -14.5 days post-coitum. On postnatal day-1, ovaries from F1 offspring were collected for various analyses. Results showed that CrVI increased germ cell apoptosis, down regulated SIRT1, upregulated acetyl-p53, activated apoptotic pathway, and inhibited cell survival pathway. CrVI inhibited physical interaction between SIRT1 and p53 in a spontaneously immortalized rat granulosa cell line. Treatment with SIRT1 inhibitor attenuated CrVI-induced mechanisms in a dose-dependent manner. Taken together, the present study suggests that targeting SIRT1 may be an ideal approach to rescue ovaries from CrVI-induced apoptosis.
**1519 Ataxia Telangiectasia Mutated Coordinates the Response to Phosphoramide Mustard-Induced Ovarian DNA Damage**

K. L. Clark, S. Ganesan, and A. F. Keating. Iowa State University, Ames, IA.

Phosphoramide mustard (PM), an ovotoxic metabolite of cyclophosphamide (CPA), is used in the treatment of autoimmune diseases and in anti-cancer chemotherapy, as it destroys rapidly dividing cells by inducing DNA double strand breaks (DSB). The ataxia telangiectasia mutated (ATM) protein is critical in the recognition and repair of DNA DSBs through activation of cell cycle checkpoints and DNA repair proteins. ATM gene mutations increase cancer risk, particularly breast and ovarian cancer. We and others have demonstrated that PM exposure leads to ovarian DNA damage and destruction of ovarian follicles, resulting in premature ovarian failure. Additionally, we have discovered that ATM inhibition prevents PM-induced follicular depletion, though the effects on oocyte quality remained to be determined. Thus, we hypothesized that the DNA damage response would be blunted in Atm−/− deficient mice and unhealthy follicles that normally would be triggered for repair and/or apoptosis would remain, resulting in impaired fertility and increased amounts of retained DNA damage. Briefly, wild-type (WT) C57BL/6 or Atm−/− were intraperitoneally dosed once with sesame oil (95%) or PM (25 mg/kg) and ovaries harvested 3 days thereafter. Body weight was recorded pre-dosing and vaginal cytology was monitored. The WT mice were heavier (P = 0.016) than the Atm−/− counterparts. Additionally, relative to WT controls, Atm−/− mice spent more time in the diestrous phase of their estrous cycle (P = 0.0009), indicative of premature ovarian aging. PM exposure induced (P < 0.05) loss of primordial, primary, secondary, and antral follicles in WT mice, however, in the Atm−/− mice, there was a depletion of primordial and primary but no impact secondary or antral follicle number. Interestingly, relative to the effects of PM exposure in WT mice, the reduction in primordial follicle number was lessened with ATM deficiency. Immunofluorescence staining revealed that PM induced the DNA damage marker, γH2AX, in the oocyte and granulosa cells, but that this response was diminished in follicles isolated from Atm−/− mice relative to the WT controls. In addition, there was a reduction in the level of cleaved caspase 3 in the Atm−/− PM-treated mice, relative to the WT counterparts. These data support roles for ATM in ovarian DNA repair and atresia and indicate the importance of this pathway in maintaining oocyte quality. Supported by the Bailey-Career Development Award from Iowa State University.

**1520 Estrogenic Activity of Polycyclic Aromatic Hydrocarbon Metabolites in Human Endometrium**

Polycyclic aromatic hydrocarbons (PAHs) are byproducts of incomplete combustion of organic materials, including fossil fuels, food, and tobacco. Cigarette smoking is associated with reproductive abnormalities in women, and some PAHs are uterine toxicants in rodents. Moreover, PAHs or their metabolites can activate estrogen receptors (ER), resulting in endocrine disruption. Once in the body, PAHs are metabolized by the family of CYP-450 enzymes to more water-soluble hydroxy-PAHs (OH-PAHs). Additionally, alkoxyreductase enzymes (AKRs) convert PAH trans-dihydriodiolis into PAH ortho (o)-quinones. Given the similarity between planar PAH and estrogens, we hypothesize that PAH and PAH metabolites activate ERs in estrogen target tissues e.g. endometrium. We used inducible alkaline phosphatase activity in Ishikawa cells, a human endometrial adenocarcinoma cell-line, and estrogen response element (ERE) luciferase activity as the read-out for ER activation. We tested the estrogenicity of various PAH and their metabolites, including benzo[a]pyrene (BaP), 3 PAH o-quinones (benzo [a] pyrene-7,8-dione (BPQ), benzo[a]anthracene-3,4-oxide and 3-methylcholanthrene-1,2-dione), and 3- OH-BaP in endometrial cells. We demonstrated that these compounds can induce ER activity with EC50 values in the low micromolar range, and that this activity is inhibited by Fulvestrant, an ER antagonist. We have also shown that nanomolar concentrations of BPQ induce the translocation of ERα into the nucleus to modulate cell cycle gene expression. Using high performance liquid chromatography and APC1 mass spectrometry in the selected reaction monitoring mode, we find that BaP can be metabolized to the estrogenic BPQ and 3-OH-BaP in Ishikawa cells in sufficient amounts to activate ER. Low nanomolar concentrations of BPQ increase Ishikawa cell proliferation to the same level observed with picomolar concentrations of 17-β-ethinyl estradiol, and both effects are blocked with Fulvestrant. Our work indicates that planar PAH metabolites may play a role in the disruption of ER signaling in the endometrium. Additionally, differences in reporter gene response and cell proliferation were noted, raising the question of whether or not the estrogenic effects are mediated through ER.

**1521 Chromium VI Exposure During Pregnancy Disorganizes Uterine Tissue Remodeling**

J. C. Behlen, and S. Banu. Texas A&M University, College Station, TX.

Hexavalent chromium (CrVI) is a heavy metal environmental endocrine disruptor. CrVI has been shown to be associated with a wide range of applications in the chemical industry, graphics industry, artistic paints, anticorrosion paints, electropolating, steel alloys, stainless steel welding, and a multitude of other uses. Increased use and improper disposal of Cr in the developing countries and in the US have increased Cr levels in the air, soil and drinking water. Significant contamination with CrVI has been found in approximately 30% of the drinking water sources in California. For a California chromium production group, Cr has been found in high levels in the drinking water sources from more than 34 cities in the US Women working in Cr industries and living in Cr contaminated area experience infertility problems and preterm abortions, and still birth. CrVI is rapidly transported inside the cell by specific transport mechanisms, and it leads to deregulate cellular differentiation that include DNA adduct formation, deregulated cell cycle, apoptosis and carcinogenesis. The preterm delivery rates are 12-13% in the US, 5-9% in UK, and 11.9% in Africa. A variety of risk factors has been linked to preterm birth including medical conditions of the mothers or fetus, genetic influences, behavioral and socioeconomic factors and iatrogenic prematurity. Maternal exposure to environmental contaminations has been considered as an important contributing factor. CrVI crosses the placenta. We hypothesize that pre-natal exposure to chromium disorganized uterine tissue remodeling by altering collagens, elastin, MMPs and TIMPs, as well as Xnpep2 that hydrolyses collagen. Pregnant rats (n=10) were treated or not treated with 5 ppm CrVI (potassium dichromate 5 mg/liter drinking water) from gestational days (GD) 0.5 to 4.5. On GD 18.5, the dams were euthanized by CO2 asphyxiation followed by cervical dislocation and the uterine arteries (UA) were collected for further analyses. Results indicated that CrVI reduced fetal weight, induced premature labor, increased uterine arteriolar stiffness, inner wall thickness and reduced the lumen diameter of the UA. Further, CrVI increased the deposition of collagens 1, 3 and 4, and elastin; decreased Xnpep2 and MMPs, thus increasing the UA wall thickness and reducing the lumen diameter of the UA. Thus, our results indicated that CrVI disorganized UA wall thickness, which may lead to restricted blood flow and increased pressure in the UA, leading to the intrauterine growth restriction (IUGR). This study was supported by a grant from NIH/NIEHS to S.K.B (R01ES025234-01A1).

**1522 Adverse Effects of Naphthenic Acids on Reproductive Health: A Focus on Placental Trophoblast Cells**

S. Raza-Villanueva, G. Ratnayake, L. Jamshed, P. J. Thomas, and A. C. Holloway. McMaster University, Hamilton, ON, Canada; and Environment and Climate Change Canada, Ottawa, ON, Canada.

The Alberta oil sands have the third largest oil reserves in the world containing an estimated 2.5 trillion barrels of recoverable bitumen. Bitumen extraction generates residual tailings water known as oil sands process-affected water (OSPW). Oil sands process-affected water contains several major classes of contaminants, the toxicity of OSPW has been primarily attributed to naphthenic acids (NA). It has been well established that NAs can negatively impact reproduction in non-mammalian vertebrates, but the effects on mammalian reproduction have largely been overlooked. A recent study reported that treatment of rats with NAs caused a decrease in litter size and birthweight, yet the mechanisms are unknown. As both of these pregnancy outcomes are related to placental dysfunction, the goal of this study was to determine the effects of NA exposure on placental cell function. Methods: Htr8/SVneo cells, a model of first trimester trophoblast cells, were exposed to vehicle, 0.25, 1.25, 25 and 125 mg/L of a commercial technical NA mixture (SigmaAldrich) for 24h; these concentrations are within the range of NA concentrations reported in OSPW. We assessed steroid production (progesterone [P4], estradiol [E2], testosterone [T]) and markers of inflammation ( interleukin-1β [IL1β], prostaglandin E2 [PGE2]) and oxidative stress (heme-oxigenase-1 [HMOX]1) induced in response to oxidative stress. Results: NA treatment significantly altered steroid production; P4 was decreased at all doses tested, whereas there was a significant increase in T production (125mg/L only) and no effect on E2 production. In addition, NA treatment resulted in increased markers of inflammation and oxidative stress. PGE output and expression of PTGS2, the key enzyme in prostaglandin production, was up-regulated in NA treated cells but not in NA treated cells. Not all NAs were PAHs but NA treatment was only seen at the highest dose tested. Similarly, 125mg/L NA significantly increased expression of IL1β and HMOX. Although it is well established that the commercial NA mixtures do not wholly represent those found in OSPW, these results provide proof of concept that NA exposure has the potential to perturb placental cell function. Future work will explore altered steroid production, oxidative stress and inflammatory stress are associated with numerous adverse pregnancy outcomes, these findings suggest that it is biologically plausible that reproductive toxicity of NAs in mammals may be mediated via placental dysfunction.
Inhibition of Cyclic Nucleotide Efflux by Placental MRP Transporters Enhances Trophoblast Syncytialization

L. Gorczyca, and I. Alekseenos. Rutgers, The State University of New Jersey, Piscataway, NJ.

In the placenta, multinucleated syncytiotrophoblasts arise from the fusion of cytotrophoblasts, a process regulated by cyclic nucleotide (cAMP and cGMP) signaling. Syncytiotrophoblasts secrete hormones and express efflux transporters, including the multidrug resistance-associated proteins (MRPs) 1 and 5. Understanding the interplay of cyclic nucleotides, efflux transporters, and syncytialization is important because aberrant cytotrophoblast functioning contributes to the pathogenesis of placental diseases and toxicities. In the present study, we sought to determine whether MRP transporters regulate the syncytialization of human placental cells. BeWo b30 trophoblasts were treated with vehicle, MK-571 (25 µM), B-8-Bromo-cAMP (100 µM), forskolin (25 µM), IBMX (200 µM), or their combination for up to 24 hr. Markers of trophoblast cell fusion (glial cells missing homolog 1, GCMI; synectin 2) and hormone secretion (human chorionic gonadotropin, hCGa and hCGb) were quantified by qPCR. Treatment of BeWo cells with MK-571, a pharmacological inhibitor of MRPs, increased intracellular concentrations of cAMP and cGMP by 15- and 19-fold, respectively. Moreover, MK-571 treatment up-regulated cell fusion and hormone secretion markers (GCMI, hCGa, hCGb, synectin 2) by 20-200% under basal conditions. Similarly, MRPI inhibition with MK-571 further enhanced syncytialization and hormone markers following stimulation with the permeable cAMP analog 8-Bromo-cAMP (2- to 6-fold), activation of cAMP synthesis with forskolin (20-160%), or inhibition of cAMP/cGMP breakdown by IBMX (50-150%). In addition, shRNAs were used to generate a stable BeWo B30 trophoblast cell line with reduced MRPI expression. Control and MRPI-knockdown cells were treated with vehicle or 8-Bromo-cAMP for 24 hr. In response to treatment with 8-Bromo-cAMP, the induction of GCMI, hCGa, and hCGb mRNA expression was higher in MRPI knockdown cells as compared to control cells. Furthermore, MRPI-knockdown cells were larger in size (including greater numbers of multinucleated cells) and exhibited decreased staining of the tight junction protein E-cadherin, pointing to enhanced syncytialization. In conclusion, MRP transporters participate in trophoblast cell fusion, which likely represents a novel mechanism regulating placentation and placental toxicities. Proteomic Profiling of Primary Human Villous Cytotrophoblasts Exposed to BDE-47

H. Chen1, K. E. Williams2, M. Kapidzic1, E. Kwan1, R. Aburajab1, C. L. Hunter2, S. J. Fisher1, and J. F. Robinson1. 1University of California San Francisco, San Francisco, CA; and 2AB SCIEX, Redwood City, CA.

The human placenta serves as the interface between the maternal and fetal compartments and is a target of various environmental stressors. Placental cytotrophoblasts (CTB) play critical roles in implantation, uterine infiltration, and vasculature development with perturbations in CTB function underlying severe pregnancy complications (e.g., preeclampsia, preterm birth). In vitro, primary human villous CTBs differentiate towards an invasive phenotype, representative of their characteristics in vivo. Recently, we demonstrated the utility of this model system to evaluate the toxicological potential of a common flame retardant, brominated diphenyl ether (BDE-47), identifying changes in functional and transcriptomic levels. In this study, we expanded our initial analyses of BDE-47 by profiling the proteome of CTBs using sequential window acquisition of all theoretical mass spectra (SWATH-MS). Protein homogenates were collected from CTBs (2nd trimester, n=60) at 0, 15, 24, or 39h, exposed to BDE-47 (1 or 5µM), vehicle (0.1% DMSO), or media only (control). In total, we commonly identified 3,026 unique proteins across samples. In controls, significantly higher protein expression was observed in 477 proteins (p<0.05), including molecules important in CTB differentiation processes such as metabolism (e.g., PAPPA2), maternal-fetal tolerance (HLA-G), invasion (MMP14), adhesion (ITGA5), vascularization (HSPG2) and extracellular matrix organization (NID1). In a concentration- and time-dependent manner, BDE-47 significantly disrupted expression of 323 proteins, including targets linked with CTB differentiation (e.g., HSPG2) and oxidative stress (e.g., NF-kB). Our results provide a proteomic framework of human villous CTB differentiation in vitro and indicates its sensitivity to developmental toxicants, with the potential to model environmental interactions in the human placenta. Myco toxin Zearalenone (ZEA) Induces Toxicity and Alters microRNA Expression in C57Bl/6 Mouse Placenta

C. Andersen3, R. Li1, L. Hu1, A. El Zowalaty2, Z. Wang1, and X. Ye1. 1University of Georgia, Athens, GA; 2NIEHS, Research Triangle Park, NC; 3South China Agriculture University, Guangzhou, China; and 4University of Massachusetts Medical School, Worcester, MA.

Zearalenone (ZEA) is a major mycotoxin derived from Fusarium fungi. With potential chronic exposure, ZEA poses a great risk to the general health of both animals and humans. ZEA in feed causes reproductive disorders in domestic animals such as swine. Previously we demonstrated in mice that ZEA diets (20-40 ppm) impaired female fertility. Since the placenta plays an essential role in female fertility and ZEA can be metabolically activated by placental enzymes, ZEA may have adverse effects on placental development leading to impaired female fertility. To determine the effects of ZEA on placental development, young virgin female mice were mated and checked for a vaginal plug the next morning. The day of vaginal plug detection was designated as gestation day 0.5 (D0.5). On D5.5 (post-implantation), the plugged females were randomly assigned into five groups and fed with 0, 0.8, 4, 10, and 40 ppm ZEA diets. Body weight was recorded daily. Mice were dissected on D13.5. There was an increased rate of implantation site resorption in 40 ppm group, placental hemorrhage in 10 and 40 ppm groups, reduced weight of live fetuses in 40 ppm group, and reduced weight of placentas with live fetuses in 40 ppm group. Placental histology indicates dose-dependent changes in the labyrinth layer, most dramatically in the 40 ppm group, such as dilated fetal capillaries filled with nucleated fetal blood cells, dilated maternal blood spaces filled with nucleated maternal blood cells, or areas with reduced size. These data indicate disorganized placentae in both ZEA treatment resulting in insufficient fetal-maternal interface for efficient nutrient and gas exchange, which may count for the reduced fetuses weight in the 40 ppm ZEA-treated group. ZEA treatment also led to lipid accumulation in the labyrinth layer of D13.5 placentas. Placental cells have unique epigenetic profiles to regulate gene expression during placental functions. Disrupted epigenetic profiles may lead to defective placental development. Our microRNA (miRNA) array analysis on the above D13.5 placentas in the 0, 4, and 40 ppm groups reveals a unique placental miRNA profile. Interestingly, several of the differentially expressed miRNAs by ZEA treatment were also dysregulated in the placentas from patients with preeclampsia. We continue investigating cellular and molecular mechanisms of ZEA-induced placental toxicity.

Per- and Polynonylalkyl Substances (PFAS) Effects on Mouse Mammary Epithelial Cells

T. Russ1,2, H. Cope1, V. Chappell1, and S. E. Fenton1. 1NIEHS, Durham, NC; and 2NIEHS Summer Connect Scholar, Durham, NC.

This study examines both legacy and replacement per- and polyfluoroalkyl substances (PFAS) for effects on the HC11 mouse mammary epithelial cell line. The mouse mammary gland is a sensitive target for the effects of perfluorooctanoic acid (PFOA), therefore PFOA was included as a positive control. HC11 cells were seeded in a 384-well plate at a density of 2,000 cells/well and incubated for 24 hours in RPMI media. Cells were then treated in a blinded fashion with half log concentrations of 20 PFAS (0.95 µM, 3 µM, 9.5 µM, 30 µM, 94.5 µM, and 300 µM) and incubated for 48 hours. During this time, proliferation and cell morphology were measured every 4 hours with an IncuCyte live cell imaging and analysis system. The HC11 cells were tested for cell viability using the CellTitre Glo (CTG) assay 48 hours after treatment. The positive control, PFOA, not only induced cytotoxicity and decreased proliferation rates, but also caused the HC11 cells to become enlarged at the highest concentration tested. Preliminary findings demonstrated that seven PFAS in the current library inhibited proliferation at a Low Effective Concentration (LOEC) of 300 µM (4 µM PFOA), 9.5 µM (n=1), 3 µM (n=1), or 0.95 µM (n=1), and several PFAS had little to no effect on proliferation of mammary epithelial cells. CTG assays estimated 50% Inhibitory Concentrations (IC50) of 299.7 - 8.5 µM, varying for each of the 15 PFAS that had an effect. Proliferation LOEC values were not always consistent with the IC50 values for a given PFAS, presumably due to morphological changes produced by some treatments. This led us to utilize cell count to normalize proliferation and cytotoxicity data. Further tests are being conducted on the 25 remaining chemicals in the library for prioritization of the most active mammary toxicants for future research projects in differentiated HC11 cells and mice. We hope to contribute dose-response information in a PFAS-sensitive target organ for use in risk evaluation of these chemicals.
1527 Impact of a Vermiculite-Nanocellulose Hybrid on Sperm Characteristics, Endocrine Balance, and Redox Status in Male Rats

The safety of vermiculite-nanocellulose (VEN) hybrid on the male reproductive system is not known. Hence we investigated the effects of VEN on the biochemical and hormonal indices of rats. Animals were orally exposed to VEN at 0, 5, 10 and 20 mg/kg body weight for 14 consecutive days. Administration of VEN had no effect on organo-somatic index of the testes. Although Gamma-glutamyl transferase, catalase and superoxide dismutase activities and hydrogen peroxide level remained unaffected, exposure of rats to VEN significantly depleted myeloperoxidase, glutathione peroxidase and malondialdehyde levels in the testes of treated rats, when compared to control. The spermogram of VEN-exposed rats showed a significantly higher sperm count and lower sperm morphology rates than control group. Treatment with VEN also significantly increased circulating concentrations of follicle-stimulating hormone and testosterone levels at the 20 mg/kg dose. Histo-architecture of the testes, in the treatment groups, revealed normal looking Leydig and Sertoli cells. Taken together, our study show that VEN could play an important role in male reproduction in rats, especially in the stimulation of hormononal secretion.

1528 Reproductive Toxic Effect of Cnestis ferruginea (de Candolle) Root Extract in Male Rats

Cnestis ferruginea (Conneraceae) is a shrub used locally as a bacteriolytic and antiinflammatory agent in the southern part of Nigeria. Many antimalaria medicinal plants have effects on the reproductive system. This study was carried out to evaluate the reproductive toxicity of the methanolic extract and purified fractions from the root of the plant in rats. The methanolic extract was administered orally at 500, 1000 and 2000 mg/kg bw to rats weighing 160-220 g in the test groups and distilled water to those in the control group for 5 (acute), 30 (sub-chronic) and 60 (chronic) days. Effects of the extract and purified fractions, on male fertility were assessed by sperm function analyses, testicular weight, mating experiment and histological examination of testes. The reproductive effects of the extract and purified fractions were compared with those of quinine sulphate. Plasma testosterone, luteinizing hormone (LH) and follicle stimulating hormone (FSH) concentrations were determined to elucidate the probable mechanism of action of the extract on male reproduction. Student’s t-test and analysis of variance were used to test for levels of significance. Acute oral administration of methanolic extract resulted in dose-dependent reduction in sperm count, viability, motility and morphology. There were decreases (P<0.05) in plasma testosterone concentration at 2000 mg/kg bw and the weight of testes at 500 mg/kg bw during the 5 day exposure. Prolonged administration of 500mg/kg bw of the extract caused significant reductions in sperm count, motility, viability, and morphology on the 30th and 60th day of treatment. Each of the six chromatographic fractions (1-6) from the extract administered orally (100, 1000 and 2000 µg/kg bw for 60 days) caused significant reduction (P<0.05) in the sperm counts, motility, viability, morphology and testosterone values. The methanolic extract and chromatographic fractions caused reversible degeneration of testes. However, fractions 3 and 4 caused the highest reduction (P<0.05) in fertility, FSH and LH levels. The reproductive effects of fractions 3 and 4, which contain quinolizidine alkaloid, were comparable to those of quinine sulphate. There was recovery from the reproductive and toxicity effects of the extract after 60 days of withdrawal. The results suggest that Cnestis ferruginea possesses reversible male antifertility effects which are due to quinolizidine alkaloids.

1529 Testicular Toxicity of Sub-chronic Low-Dose Methotrexate Exposure in Rat

Methotrexate (MTX) is a widely prescribed drug to treat neoplastic, autoimmune and inflammatory diseases. MTX antagonizes the folate pathway and leads to the inhibition of DNA and RNA synthesis, causing cytotoxicity and genotoxicity in various organ systems. In particular, testicular injury has been observed with MTX treatment in both preclinical models and clinically. The present study established a low-dose subchronic MTX exposure model in the rat with the ultimate goal of identifying distinct sperm RNA expression patterns with the purpose of testing whether these patterns could be used as biomarker panels for testicular toxicity assessment. MTX was administered intraperitoneally (IP) at the dose of 2, 5 and 10mg/kg to adult Fisher rats (n=10) weekly for 13 weeks. The animals were sacrificed one week after the last MTX injection. To characterize the testicular injuries, testes/epididymal weights, sperm count, sperm motility and testes/epididymal histology were assessed. Moreover, total RNA was isolated from epididymal sperm and RNA yield per sperm was calculated by normalizing the total RNA yield to sperm count. Sperm content and morphology were similar among the control and treated groups. MTX treatment at 10mg/kg significantly decreased testes weight. There was a clear dose-related effect of MTX exposure on testicular histopathology, including a loss of spermatocytes in late stages of the seminiferous epithelial cycle and a loss of round spermatids in early stages of the cycle. MTX also caused a seminiferous tubule diameter. Neither retained spermatid heads (RSH) nor Sertoli cell vacuoles were a prominent feature, only being observed in a minority of the high dose rats. Epidydymal round cells consistent with sloughed germ cells were dose-dependently increased. The RNA yield per sperm were not altered by MTX treatment. These data showed that a 13-week exposure to low-dose MTX caused testicular damage indicated by low testes weight and histopathological abnormalities.

1530 Effect of Serum Organochlorine Pollutants (DDTs, HCB and PCBs) Levels on Human Sperm Parameters

S. Ami1, M. Tzatzarakis2, S. A. Shah1, S. Eganhi1, H. Ali1, A. Suvorov3, F. Taheri1, S. Sultan1, a~C. A. A. Sattar4, C. Hopkins1, O. Avwioroko5, and A. M. Tsatsakis6. 1University of Ibadan, Ibadan, Nigeria; 2University of Massachusetts, Amherst, MA; 3National Institute of Health, Islamabad, Pakistan; 4University of Crete, Heraklion, Greece; 5Agiza Khan University, Karachi, Pakistan; 6University of Massachusetts, Amherst, MA.

Alarming decline in sperm count worldwide over the past decades is the indication of involvement of many environmental and lifestyle changes around the globe. The process of spermatogenesis is an easy target for disruption by various environmental pollutants. PCBs and DDTs have been studied widely as a causal factor in many diseases. This study was aimed to elucidate the relationship between the serum levels of PCBs, HCB and DDTs with sperm motility and concentration. Blood and semen samples from 70 men of age between 20 to 45 were collected in 3cc glass tube and serum was separated at the spot. Detailed questionnaire and consent forms were filled. Semen samples were used to analyze the sperm concentration and motility. One ml of serum was used for the determination and quantification of PCB congeners, HCB, DDT and its metabolites by using head space solid phase microextraction (HS-SPME-GCMS). SPSS 24.0 was used to analyze the data statistically. Semen analyses revealed that 41.4% of the men tested were normospermic, 37% azoospermic, 11% with oligospermia and 10% were found to be asthenospermic. All samples were found positive for HCB with a mean value of 0.37 ng/ml. All PCBs congeners were significantly correlated with sperm concentration (p<0.05) while no significant correlation was found between PCBs exposure and sperm motility. While for the DDTs, only op’DDT and op’DDE showed significant correlation (p<0.05) with sperm concentration. Results suggest that exposure to organochlorine pollutants can affect sperm production but have no effects on sperm motility. However further studies with high number of samples are needed to confirm the findings.

1531 Intra-testicular Testosterone Levels In Vivo vs. In Vitro

P. Del Valle1, L. Pence2, T. Schmitt1, R. Beger3, and N. Nakamura4. 1US FDA/NIH; 2US FDA/Silver Spring, MD; and 3US FDA/NCTR, Jefferson, AR.

The measurement of intra-testicular testosterone (T) levels is an important aspect of reproductive drug toxicity assessment and reliable in vitro models for spermatogenesis are needed for minimizing animal use. However, in vitro models have not yet been established since spermatogenesis is a complicated process. We have evaluated an in vitro organ culture system that Sato et al (2011) demonstrated vital mature sperm production. We confirmed mature sperm using their system but until now had not determined if the testis fragments produced T. To examine this, liquid chromatography-tandem mass spectrometry analysis was conducted to measure T levels in the cultured testis fragments (in vitro) and mouse testes (in vivo). We collected C57BL/6J mouse testes at postnatal day (PND) 14, 20, 28, 35 and 40. Mouse testis fragments were obtained at PND 5 and cultured in AlbuMAX™I medium for 35, 42, and 49 days (corresponding to PND 40, 47, and 54). Round spermatids in the testis fragments, that were observed at PND 20 in vivo, were first observed on day 23 of culture (corresponding to PND 28), suggesting germ cell differentiation in vitro is slower than in vivo. T levels in mouse testis were initially detected at PNDs 14 and 20 and increased from PND 28 through PND 40. In contrast, T was detected in tests fragments beginning at days 35 and 42 of culture, reaching a maximum on day 49 of culture. Although T production in...
vitro was delayed and lower than observed in vivo, we confirmed that the cultured testis fragments produced T, which follows a similar temporal sequence to that in vivo. Although further improvements to this in vitro organ culture system are still necessary, these findings suggest that this mouse testis organ culture system could provide a useful tool for future physiological studies. The views presented do not necessarily reflect those of the US FDA.

1533 Ethylene Glycol Monomethyl Ether Exposure Alters Cleavage of tRNA Fragments in Rat Sperm
A. R. Stermer, S. J. Hall, and K. Boekelheide. Brown University, Providence, RI.

Many male reproductive toxicants adversely affect fertility through mechanistic targets in one or more distinct cell types in the testis. Regardless of the primary cell targeted by a testicular toxicant, the common thread among these compounds is impairment of spermatogenesis and/or sperm quality. Ethylene glycol monomethyl ether (EGME) targets a specific germ cell subset, the primary spermatocytes, and leads to germ cell apoptosis at high levels of exposure. We hypothesized that the sperm that developed from EGME-exposed germ cells, and their epigenetic contents delivered to an oocyte upon fertilization, may be compromised. Specifically, we looked at tRNA fragments (tRFs) in sperm, because they have been shown to influence embryonic development. Rats were exposed to 0, 50, 60 or 75 mg/kg EGME for 5 days, and then sperm were collected 5 weeks later. Small RNA sequencing was performed on RNAs isolated from the sperm. The total amount of tRFs relative to library size did not change with treatment; however, the tRFs became longer as a function of treatment, significantly so at 60 and 75 mg/kg. At 60 and 75 mg/kg EGME, there was a shift in the fragment size distribution, with a decrease in peak between 22-27 nucleotides and an increasing peak of 28-33 nucleotides. Using the interactive genome browser, the fragmentation pattern of tRNAs was readily visualized; for example, the tRNA-GlyGCC were mostly 5' fragments which became progressively longer with increasing EGME exposure. Since 5'S-tRNA-GlyGCC has been implicated in the transmission of metabolic disease in mice, these data raise the concern that EGME disruption of normal tRNA fragmentation results in altered epigenetic contents of sperm and potential effects on embryogenesis.

1534 Sperm RNA as a Biomarker of Semen Quality across Species

Evaluation of human reproductive risk from environmental and pharmacological chemicals includes extrapolation from data collected using animal models. Since there is an urgent need to identify novel, non-invasive and reliable approaches to monitor the effects of environmental and therapeutic agents on male reproductive health, the present study investigated associations between spermatozoal RNA content and semen quality across species. Semen specimens were collected from men aged 18 to 55 years undergoing male factor infertility evaluation, treatment for autoimmune arthritis with methotrexate, and from proven fertile men. Semen samples were analyzed according to World Health Organization 2010 criteria. Rat and mouse semen specimens were collected from control animals via repeated needle punctures of the cauda epididymides. Sperm large and small RNAs were extracted after somatic cell lysis. The association of human spermatozoal large or small RNA contents with semen quality and lifestyle factors was evaluated using a generalized additive model and one-way ANOVA. Cross-species mRNA sequencing analysis was also performed, and large and small RNA contents per sperm were evaluated using one-way ANOVA with post-hoc Tukey test. In humans, sperm total count was inversely associated with spermatozoal large RNA content. Sperm motility was inversely associated with spermatozoal large and small RNA contents while large RNA content per sperm was significantly higher in semen samples showing abnormal numbers of round cells. Alcohol consumption was strongly associated with increased large RNA amount per sperm. Patients treated with a known testicular toxicant, methotrexate, showed 25 times more spermatozoal large RNA content than the control fertile group. Mouse sperm samples showed significantly increased spermatozoal large RNA content compared to humans. No differences were identified across species in small RNA content per sperm. In conclusion, spermatozoal large RNA content has the potential to predict sperm abnormalities and male reproductive risk following environmental and pharmaceutical chemical exposure in humans. mRNA sequencing data analysis is underway to identify sperm transcriptional similarities and differences among humans, rats, and mice.

1536 Toxicity of 1,4-Dinitrobenzene on TM4 Sertoli Cells: Its Influence on Mitochondria, Cell Monolayer, Androgen Binding Hormone and Stem Cell Factor Genes
J. O. Sangodele Olugbodi,1,2, M. Olaleye,1 T. Monsese,3 and A. C. Akinmoladun. 1. Federal University of Technology, Akure, Nigeria; 2. Bingham University, Kara, Nigeria; and 3. University of the Western Cape, Bellville, Cape Town, South Africa.

1,4-Dinitrobenzene (1,4-DNB) an industrial and environmental toxicant has been shown to affect the testes but the mechanism of action remains unclear. Sertoli cell plays a key role in spermatogenesis; however, the toxic effects of 1,4-DNB on Sertoli cells have not been studied. The hypothesis of this study is to unravel the mechanism of action of 1,4-DNB induced TM4 Sertoli cells toxicity. TM4 cell line, derived from mouse Sertoli cells were obtained from American Type Culture Collection (ATCC), USA and were exposed to 1,4-DNB (10, 30, 50 and 100 µg/ml) for 4 and 24 h and its activities on cell viability, activity of γ-GT enzyme, apoptosis, ROS and mitochondrial membrane were assessed. The present study showed that exposure of TM4 Sertoli cells to 1,4-DNB decreased the activity of γ-GT enzyme, inhibited cell viability, promoted apoptosis, mitochondrial membrane potential impairment and reactive oxygen species production. Findings from this study showed that exposure to 1,4-DNB destroyed tight junctional structure in Sertoli cell monolayers as evidenced by a decline in TEER value. The results from mRNA expression levels indicated that 1,4-DNB caused up regulation of androgen binding hormone and stem cell factor genes. In conclusion, 1,4-DNB have great potential to increase oxidative stress, inhibit spermatogenesis, expose Sertoli cells to external insults thereby compromising the blood-testis barrier and contributing to male-mediated reproductive toxicity.

1537 Evaluation of Multiple Generations of Rats following Developmental Bisphenol AF Exposures
M. Bharadwaj, J. Warmack, and S. F. Fenton. NIEHS, Research Triangle Park, NC.

Bisphenol AF (BPAF) is a fluorinated analogue of Bisphenol A, used in the manufacturing of consumer products. This study determined reproductive and endocrine-related outcomes in Sprague Dawley rat offspring following pre and post-natal exposure to BPAF. Timed-pregnant dams were randomly assigned to dose groups (Vehicle control; VC; n = 16; BPAF: n = 8 or 9). Dams were gavaged, twice daily starting on gestation day (GD) 6 through postnatal day (PND) 21 in groups that were blindly allocated, and body weight (BW) adjusted daily; 0, 0.25, 1.0, 2.5, or 25.0 mg BPAF/kg BW. Litter size, pup BW, and live/dead count were recorded on PND 1. Litter sizes were equalized on PND 4 (n = 8; 4, 4, 4, 4, 4). On PND 4 and 21, one pup/sex and their respective dams (PND 21) were euthanized and biological samples were collected for future transcriptomic and internal BPAF dose. All remaining female pups were orally gavaged with same doses and evaluated for pubertal timing. F1 females were mated with VC F1 males to produce F2 generation and early life data were collected. Mammary glands and ovaries were collected from F1 females for histological evaluation. The dam’s percent BW gain during gestation was significantly lowest in the highest dose group (p < 0.01) compared to VC. The gestational length and fetal loss during gestation (= total implantation sites – total pups born) were not affected. The loss of pups from birth until PND 4 (neonatal loss) was elevated in the highest dose group (18.9 ± 7.7 vs 45.8 ± 14.6%, p = 0.14). Regardless of sex, the pup BW at birth and PND 4 in the highest dose group were significantly lower than those from VC dams (p = 0.02 and p < 0.01; respectively). The age of vaginal opening (VO) for exposed females was not significantly different from the pups born from VC dams but the BW at VO in the highest dose group was significantly lower (p < 0.01). Conception rate was unaffected in the F1 females exposed to BPAF. In F1 transgenic fetal liver fibroblasts was higher in the high dose group (p < 0.01) and primary follicle counts were lower in dose groups 0.25, 1.0, and 2.5 mg BPAF/kg BW (p = 0.012, 0.02, and 0.14, respectively). Mammary glands exhibited higher stromal density in non-pregnant F1 females (p = 0.017). Data suggest that exposure at the highest dose level of BPAF tested altered several contraceptive endpoints in F1 female offspring. The persistent effects on body weight and elevated pup loss may be related to the potential disruption of normal hormonal activities. On-going studies will determine internal doses associated with the noted biological effects as well as transcriptomic changes in affected tissues.
The toxicological potential of cyclamen aldehyde, a widely used flavor and fragrance ingredient, was examined by conducting an enhanced OECD 415 one-generation reproduction study. Sprague Dawley rats (25 rats/sex/dose) were gavaged with cyclamen aldehyde at doses of 0, 25, 75, or 150 mg/kg/day in corn oil. Treated male and female rats were cohabitated with untreated female and male cohorts, respectively. F1-generation rats were not directly dosed but instead were exposed to the test material in utero during gestation and through postpartum maternal milk. High-dose P-generation males were reported to be infertile following mating with untreated females. The absence of motile sperm and altered sperm morphology were observed in 13/25 mid-dose and all of the high-dose group rats. Grossly visible masses were reported on one or both cauda epididymides among high-dose P-generation males. Microscopic examination of the epididymis revealed moderate to marked sperm granulomas. Only 1 untreated female rat assigned to mate with high-dose male rats became pregnant but was unable to deliver a litter. No apparent effects were observed in the development of pups up to 75 mg/kg/day. Thus, the NOAEL for male reproductive toxicity was considered to be 25 mg/kg/day. Significant decreases in implantation sites, number of delivered pups, pup survival and litter size, and increased pup mortality were observed among high-dose P-generation females. Ovary weights among high-dose females were decreased and the uterus weights of mid- and high-dose females were increased. In utero and lactation exposure to cyclamen aldehyde caused a significant reduction in pup body weights and body weight gains among mid- and high-dose group pups. Thus, the NOAEL for female reproductive toxicity and developmental toxicity was considered to be 25 mg/kg/day. Later studies indicate that the effect in rats is not relevant to human health, since rats selectively metabolize cyclamen aldehyde to its reproductive toxic metabolite responsible for effects reported in the present study. Furthermore, rabbits were observed to be the more relevant species to model human toxicity, as rabbit metabolism of cyclamen aldehyde were comparable to humans, and showed an absence of reproductive toxicity that were found in rats.

Biphenyl (BP) is an aromatic hydrocarbon with a rich toxicological dataset that has recently been tested in an EOGRTS, which included cohorts 2 (developmental neurotoxicity) and 3 (developmental immunotoxicity). Although limited in vitro data exists with BP, it selectively metabolizes cyclamen aldehyde to actuate certain endocrine receptors, these metabolites are transient in vivo and are quickly detoxified by phase II conjugation reactions. Moreover, ToxCast™ endocrine receptor assays do not suggest BP acting via an endocrine disruption (ED) mode-of-action (MoA). The EOGRTS has been conducted under the European REACH programme to assess various endocrine parameters as well as effects on nervous and immune system during critical windows of development. CritCD(SD) rats were fed diets containing 0, 300, 1000, and 2800 ppm BP throughout the entire study. Endocrine parameters evaluated included estrous cyclicity, ovarian follicle counts, reproductive indices, sperm parameters, anogenital distance, nipple retention, puberty onset, thyroid hormone, thyroid/pituitary/adrenal/reproductive organ weights and histopathology of these tissues. Two incidences of dystocia in each of the low and mid dose P1 dams were observed, resulting in breeding of the second generation to clarify these findings. However, no incidences of dystocia occurred in P2 BP-treated dams, and one incidence occurred in a P2 control dam, demonstrating that this finding was sporadic and unlikely to the treatment. The parents and offspring of both generations showed no evidence of treatment-related effects on reproductive parameters or on the estrogen-, androgen-, or thyroid-related endocrine pathways at any BP dose. There was no evidence of structural or functional changes in the nervous or immune system due to BP exposures during critical windows of development. Overall, it is concluded that BP, at doses up to 2800 ppm, does not act via an ED MoA nor does it affect immune or nervous system development.
Combined Fertility and Embryofetal Developmental Toxicity Study of Cytisine in Rats

W. Johnson1, M. Muzzio1, T. Thompson2, E. Knight3, and D. McCormick4

1IIIT Research Institute, Chicago, IL; 2B&D Services, Overland Park, KS; and 4National Cancer Institute, Bethesda, MD.

Cytisine ([1R,5S]-1,2,3,4,5,6-hexahydro-1,5-methano-8H-pyrido[1,2,3,4]diazicacin-8-one) is a plant alkaloid used in Eastern Europe for smoking cessation. Through its activity as a partial agonist of α4β2 nicotinic acetylcholine receptors, cytisine may attenuate symptoms of nicotine withdrawal. This study was performed to assess the potential reproductive and developmental toxicity of cytisine in rats. Groups of 22 CD rats/sex received daily oral (gavage) administration of cytisine (in sterile water) at doses of 0 (vehicle control), 0.4, 2, or 10 mg/kg/day beginning 4 weeks (males) or 2 weeks (females) prior to mating. Dosing was continued in males until Day 72 and in females until scheduled cesarian sections on Gestation Day 20. Six additional rats/sex/cytisine group were included for toxicokinetics (TK). Endpoints included plasma drug levels; TK; in vivo toxicity; estrus cyclicity; mating/fertility/fecundity; reproductive parameters and organ weights; semen analysis; fetal body weights; and fetal examinations to identify developmental toxicity. Plasma levels of cytisine (AUC) were significantly greater in all dose groups; systemic exposure was generally higher in females than in males. In the high dose group, T1/2 was 5.1 h in males and 6.6 h in females. No mortality or treatment-related gross toxicity was seen in any rat receiving cytisine. Statistically significant decreases in body weight gain were seen in both sexes in the high dose group (10 mg/kg/day); sporadic signs of food consumption were seen in high dose (10 mg/kg/day) and mid dose (2 mg/kg/day) groups. Cytisine had no effect on estrus cyclicity; sperm counts, morphology, or motility; reproductive organ weights in either sex; mating indices; or other parameters associated with fecundity or reproductive function. Fetal body weights were comparable in all groups; no evidence of cytisine developmental toxicity (increased incidences of malformations or variations) was identified in external, visceral, cephalic, or skeletal evaluations of fetuses. Cytisine doses of up to 10 mg/kg/day induced no evidence of developmental or reproductive toxicity in rats; cytisine toxicity was limited to reduced body weight gain in the high dose group (10 mg/kg/day). Supported by National Center for Complementary and Integrative Health through HHSN261201600015I from NCI.

Interspecies Comparison of Embryo-Fetal Data among Control Groups of Sprague-Dawley Rats, New Zealand White Rabbits and Gottingen Minipigs

F. Paradis1, F. Beaudry1, R. Kubaszky1, Y. Gilmore2, K. Hilli3, S. Ellemann-Laursen4, J. Hargitai5, F. Spezia6, R. Tavzar7, P. Singh8, A. Authier9, F. Duguay1, A. Makin1, and R. Forster1

1CiToxLAB, Laval, QC, Canada; 2CiToxLAB, Kansas City, KS; 3CiToxLAB, Ebjy, Denmark; 4CiToxLAB, Veszprem, Hungary; and 5CiToxLAB, Evreux, France.

Understanding species-dependent differences in relative incidence of spontaneous variations and malformations is important for reproductive and developmental safety assessment. The objective of this evaluation was to compare litter parameters and external, visceral, and skeletal malformations and variations across species in the Sprague-Dawley rat, New Zealand White rabbit and Gottingen minipig. Pregnant female rats (n=871), rabbits (n=465) and minipigs (n=70) from vehicle control groups were included in the analysis equating to 11460 rat, 4486 rabbit and 378 pig fetuses collected at term by cesarean section. Pre-implantation loss was more frequent than post-implantation loss in the rat and rabbit, whereas the opposite was observed in the minipig (rat: 10.9%, 4.7%; rabbit: 13.8%, 8.1%; minipig: 7.6%, 10%). Several external and visceral malformations and variations such as domed head, skin discolaration, cleft palate, abdominal edema, and anal atresia were observed in all three species. Visceral malformations of the heart and the major blood vessels were remarkably more frequent in the minipig: Ventricular and atrial septum defects were observed in 1.9 and 2.1% of the minipig and 0.2 and 0% in the rabbit whereas they were not observed in any rat fetuses evaluated in this study. Our results indicate that the minipig presents a higher spontaneous incidence of heart malformations consistent with humans, as congenital heart defects are the most common types of birth defects in humans (approximately 1% of births). A thorough understanding of the similarities and differences in spontaneous malformations in different species is important to interpretation of embryo-fetal development studies.
Automation of the In Vitro Micronucleus Assay for Genetic Toxicology Testing Using Imaging Flow Cytometry

M. Rodrigues. MilliporeSigma, Seattle, WA. Sponsor: R. Kulkarni

The in vitro micronucleus (MN) assay is a well-established method for evaluating genotoxicity and cytotoxicity. MN are formed from whole chromosomes or fragments that lag behind following metaphase and are excluded from the main nuclei following division. The presence of MN is indicative of chromosomal mutations and their quantification can be used as an endpoint in genotoxicity testing. Manual microscopy is typically used to perform the MN assay but is laborious and suffers from low throughput and inter scorer variability. Automated methods, including slide-scanning microscopy and conventional flow cytometry have been developed, but these methods have drawbacks including lack of cytoplasmic visualization and the inability to visually confirm the legitimacy of MN. Imaging flow cytometry (IFC) has the potential to overcome these limitations as it combines the speed and rare event capture capability of flow cytometry with the high resolution imagery obtained by microscopy. A method to perform the in vitro MN assay on the ImageStreamX MkII (ISX) has been developed. Images of several thousand mono-, bi- and polynucleated cells can be captured and automatically identified in the Image Data Exploration and Analysis Software (IDEAS®). Human TK6 cells were exposed to two clastogens and two aneugens (Mitomycin C, Methyl Methanesulfonate, Colchicine and Vinblastine Sulfate) and one negative control (Mannitol) for 3 hr. Following a 24 hr recovery period, cells were harvested, stained with Hoechst and run on the ISX. Several thousand images of micronucleated mono- and bi-nucleated cells as well as polynucleated cells were captured on the ISX, automatically analyzed, sorted and enumerated in IDEAS® in just a few minutes, allowing for the evaluation of both genotoxicity and cytotoxicity. Statistically significant increases in MN frequency with increasing dose were observed for all compounds tested when compared to solvent controls, except for Mannitol, as expected. The high throughput nature of the ISX overcomes many of the challenges of conventional techniques. More samples can be collected and scored, improving the statistical robustness of the MN assay and all collected imagery can be stored in dose-specific data files for re-evaluation. This work represents the first step towards the development of a fully automated approach for performing the in vitro MN assay to assess cytotoxicity and genotoxicity using IFC.

Benchmark Dose Modeling of In Vitro Genotoxicity Data from the Mouse Lymphoma Assay

N. Mei, and X. Guo. US FDA/NCTR, Jefferson, AR.

Applied genetic toxicology is now changing to quantitative risk assessment from qualitative hazard identification. Recently, quantitative analysis with point of departure (PoD) metrics and benchmark dose (BMD) modeling have been applied to in vitro genotoxicity data. Two software packages are commonly used for BMD analysis. In the previous studies, we conducted the mouse lymphoma assay to evaluate the mutagenicity of four pipeline nitrooxides having various substituent groups on the 4-position of the pipеридине ring and six cigarette whole smoke solutions (WSSs) prepared by bubbling machine-generated whole smoke. In the present study, we performed quantitative dose-response analysis on these genotoxicity data using the PROAST software and the US EPA’s BMD software (BMDs) and evaluated the inter-platform quantitative agreement in genotoxic potency estimates. We calculated the BMDs for 10%, 50%, 100% (i.e., 2-fold increase), and 200% increases over concurrent vehicle controls in order to better discriminate between the dose-responses, along with their BMDLs (the lower 95% confidence interval of the BMD) and BMDUs (the upper 95% confidence interval of the BMD). The BMD values and rankings estimated using the US EPA’s BMDs were reasonably similar with those calculated using the PROAST. These results indicated that both software packages are suitable for dose-response analysis using the mouse lymphoma assay, and that the BMD modeling results from these two software packages are comparable for rank ordering mutagenic potency.

Is It Appropriate to Set 5% CD71+ Reticulocytes of Control as the Toxicity Limit in the Flow Cytometry-Based Rat Blood Micronucleus Assay?

Since the 2014 version of OECD testing guideline 474, the required number of immature erythrocytes scored has increased from 2,000 to 4,000 in microscopy-based micronucleus (MN) assay; the throughput of the traditional MN assay becomes an issue, moreover, manually scoring slides for MN can be somewhat subjective and dependent upon staining quality. Fortunately, automated analysis and rat blood are formally accepted for in vivo MN assay by the current version of ICH 52/12 and OECD TG 474. The in vitro flow cytometry (FCM)-based method for evaluating MN frequencies in erythrocytes shows great potential for improving sensitivity, reproducibility, and throughput compared to the traditional method. The OECD TG 474 guideline defined that the proportion of immature erythrocytes to total erythrocytes in treated animals should not be less than 20% of control proportion by microscopy-based method and approximately 5% of control proportion when scoring CD71+ immature erythrocytes by FCM method. However, we had experienced that this limit setting may cause false positive. We would like to share a case study to attempt to draw attention while using the bone marrow toxicity limit in the FCM-based rat blood MN assay. In the original paper (LeBaron et al, Environ Mol Mutagen, 2012), the rational for setting the 5% target value is that %RET cytotoxicity evaluated in blood showed greater responsiveness than %PCe endpoint in bone marrow, which was consistent with majority compounds tested in our lab. However, all compounds selected in the paper are clastogens, which may obscure the effect on MN induced by toxicity. In our case study, the test article is an oral drug candidate for treating arthritis. It was tested negative in the Ames assay up to 5000 µg/plate, and in chromosomal aberration test in CHO-WBL cells up to cytotoxic concentrations. In the acute rat MN assay, 2-fold MN increases were observed only at the high dose group compared to the control in males, 55.75% and 87.64% RET reductions were observed at the mid and high doses respectively. In the repeat MN assay, the percentage RET reductions in the high dose group was lowered to 53.55%, the assay met the OECD valid criteria and no MN increase was observed at any dose. Our data suggests the positive data should be interpreted cautiously at toxic dose level, especially when above 80% RET reduction. We can’t clearly conclude that the toxicity will induce false positive in rat blood MN assay, but at least the dose level selection might have effects on any final call, even if both scenarios meet the OECD valid criteria.

Low Equimolar 90-Day Exposure of Fungicides Carbendazim and/or Thiram in Drinking Water Caused Persistent Genotoxicity

B. Rai, and S. Mercurio. Minnesota State University, Mankato, MN.

In Nepalese agriculture, carbendazim and thiram are the most commonly used fungicides to prevent Botrytis gray mold disease of chickpea, the major source of protein in the Nepalese diet. To our knowledge, none of these fungicides cause DNA damage either acutely by high doses or in 28 days by injection, which leads to distinct morbidity signs. Six-week-old male Swiss Webster mice (N= 5 per group) were exposed to untreated drinking water or 40 µM of either fungicide alone or together for 90 days to test for chronic effects at levels below water solubility limits to observe synergy, additivity or lack of effects. One group was analyzed at 90 days and one after a 45-day recovery period to check for persistence of damage. A unique more environmentally relevant result was that water or food intake and body weights throughout the experiment, and liver weights and kidney weights at sampling time were unaffected with no observed morbidity or aversion to intake at these concentrations. White blood cell viability was assessed at ~97% by Trypan blue exclusion following RBC lysis. Comet assay results from whole blood (WBCs) under alkaline conditions using a commercial kit at 90-day exposure or 45 days thereafter led to almost identical results. Controls mean tail DNA± SD were assessed (50 comets) at 9.76±6.30 at 90 days or 7.01±4.74 at 135 days (90 ±45) similar to undamaged CCO cells provided with the kits (8.9±6.1 and 9.7±6.3 for kits used at 90 and 135 day, respectively). Carbendazim, thiram or combination exposure resulted in similar significant (P<0.05) damage with mean tail DNA± SD of 33.0±20.4, 30.5±17.2 and 27.8±22.1, respectively, similar to commercially provided CC1 cells slightly damaged with etoposide (32.4±17.8). After a 45-day recovery period this same order of treatments caused mean tail DNA± SD of 27.5±12.9, 29.3±15.4 and 32.0±12.8, respectively, which again was not significantly different from CC1 cells (34.8±20.2). It appears when mice are given a chronic exposure of the combination of both fungicides in drinking water, there was no synergy or additivity, but rather a possible competition for absorption or toxicity. However, the most disturb-
ing result was the lack of any noticeable repair after an extended recovery period indicating that chronic low-level exposure in drinking water leads to persistence of genotoxic damage.

1550 Quantitative Analysis of Genotoxicity and Cytotoxicity of the Nitroxide Radical 2,2,6,6-Tetramethylpiperidin-1-oxyl (TEMPO) and TEMPO Derivatives

J. Sep1, S. Bryce2, Q. Wu1, S. Dial1, M. Moore1, N. Mei1, and X. Guo1. 1US FDA/NCTR, Jefferson, AR; and 2Litron Laboratories, Rochester, NY.

2,2,6,6-Tetramethylpiperidin-1-oxyl (TEMPO) is a low molecular weight nitroxide and stable free radical. TEMPO has been demonstrated to be cytoxic and mutagenic in mammalian cells. It remains unclear whether or not TEMPO derivatives induce similar cytotoxic and mutagenic effects as does TEMPO. In this study, we investigated the cytotoxicity and genotoxicity of TEMPO and three of its derivatives (4-hydroxy-TEMPO, 4-oxo-TEMPO, and 4-methoxy-TEMPO) in mouse lymphoma L5178Y Tk−/− cells. As results, all tested nitroxides induced dose-dependent cytotoxicity and genotoxicity. The cytotoxicity and genotoxicity were generally greater in the presence of exogenous metabolic activation (S9) except 4-hydroxy-TEMPO. The results showed that TEMPO was more cytotoxic than the three TEMPO derivatives. Tk mutants induced by all four nitroxides possess different loss of heterozygosities patterns compared to those of the untreated control. The four nitroxides caused concentration-dependent increases in mutant frequency and DNA damage as measured by the mouse lymphoma assay (MLA) and comet assay, respectively. Using a multi-endpoint DNA damage pathway assay, TEMPO and its derivatives were classified as clastogens, involving strand breakage and large alterations to DNA. Benchmark dose quantitative approaches indicate that the most potent nitroxide was 4-oxo-TEMPO in the MLA and TEMPO in the comet assay, respectively. In conclusion, TEMPO, parent compound, is relatively more cytotoxic and genotoxic than the different TEMPO derivatives. Quantitative dose-response approaches of the genotoxicity data were useful for rank ordering the genotoxic potencies of structurally similar compounds.

1551 Assessment of the Mutagenic Potential of Para-Chloroaniline and Aniline in the Liver, Spleen and Bone Marrow of Big Blue Rats with Micronucleus Analysis in Peripheral Blood

C. Koenig1, C. Beevers2, K. Pant3,4, and B. Young2. 1Arysta LifeScience, Cary, NC; 2Exponent International Ltd, Harrogate, United Kingdom; and 3MilliporeSigma, BioReliance Toxicology Testing Services, Rockville, MD.

Spleenic tumors have been reported in rat cancer bioassays with para-chloroaniline (PCA) and aniline. Development of these tumors is hypothesized to be due to hematotoxicity via the formation of methemoglobin (MetHb) and not direct DNA reactivity. To evaluate the mode of action for tumor formation a transgenic rodent in vivo gene mutation assay in Big Blue TgF344 rats was performed with parallel micronucleus analysis in peripheral blood. Male rats were gavaged daily for 28 days to 0.5, 15, and 60 mg/kg PCA and 100 mg/kg aniline, the basemolecular structure of PCA. On test day 10 the 60 mg/kg PCA dose was reduced to 30 mg/kg due to toxicity. On test day 4 and 29 peripheral blood micronucleus analysis was performed and on test day 29 clinical chemistry, hematology, and MetHb measurements were taken. At study termination, on test day 31, spleen (site of tumorigenicity), bone marrow (site of hematotoxicity), and liver (control tissue) were analyzed for clt transgene mutant frequency (MF). Repeat gavage exposure to PCA and aniline for 28 days did not produce an increase in clt transgene MF in analyzed tissues. An increase in micronuclei was seen at both time points at ≥15 mg/kg PCA and 100 mg/kg aniline. At the same dose levels, significant reductions in red blood cells, increases in absolute reticulocytes, and increased levels of MetHb were observed. Together these results support that generation of micronuclei and tumorigenically following exposure to PCA and aniline is due to compensatory mechanisms (e.g. increased cellular turnover) and not direct DNA reactivity.

1552 Presence of a Genotoxic Impurity, 2-Chloro-N,N-Dimethylaminoethylenenitrilechloroformide in Aroclor 1254-Induced S9 Fraction and Possible Relevance to Differential Frequencies of Spontaneous Revertants in the Presence vs. Absence of S9 Activation System

Historically, we have observed notable differences in the frequencies of spontaneous revertants between the activated and nonactivated conditions in Ames assay with the frequencies being notably higher for all strains in the presence of S9 enzyme mediated metabolic activation. As the S9 fraction and the cofactors added to the test mixture are different between the two conditions, the response is attributable to either the S9 fraction and/or cofactors. As a range of concentrations of S9 are used by different laboratories for regulatory submissions, it is important to evaluate the contributions of various components of the testing conditions in order to avoid false positives. A range of S9 concentrations such as 1.0, 2.5, 5, 10 and 20% combined with appropriate amounts of cofactors, were tested using TA 100 strain. There was a steady increase in the frequency of revertants across the range with a maximum increase of approximately 40% occurring at 20% concentration. In order to characterize the qualitative and quantitative differences in the profiles of chemical compounds between S9 extracts from Aroclor-induced and uninduced rats, an analytical evaluation of the same was conducted using HPLC/MS method. The results showed the presence of a genotoxic impurity, namely 2-Chloro N,N-dimethylaminoethylenenitrilechloroformide, in multiple batches of S9 preparations at significant detection levels. 2-Chloro N,N-dimethylaminoethylenenitrilechloroformide, acknowledged to be a process impurity in the manufacture of several chemicals and shown to have structural alerts for mutagenic and carcinogenic potential by QSAR models was not present in uninduced S9 fraction preparations. It can be concluded that 2-Chloro N,N-dimethylaminoethylenenitrilechloroformide impurity is specific to S9 preparations made from animals treated with Aroclor only. These findings are of high significance because the additive and/or synergistic effects with the test compounds could result in the generation of false positives in Ames assay and suggest that the components of the test system used to evaluate mutagenicity in the activated condition should be carefully selected. 1Prashant B. Zate et al (2017), Confirmation and Quantification of Genotoxic Impurity 2-Dimethylaminomethyl chloride hydrochloride (DMC HCl) by GCMS in Chlorpheniramine/Chlorphenamine Maleate, IOSR Journal of Applied Chemistry 10:21-26.

1553 The Effect of Ingredients on the In Vitro Mutagenicity of the Gas Phase from a Heated Tobacco Product

A heated tobacco product has been developed which reduces exposure to toxicants compared to cigarette smoke. The tobacco is heated to 250°C to avoid combustion. Flavour ingredients are added to the tobacco. Their stewardship included in vitro tests of the product’s aerosol emission to measure the effect of added flavour ingredients on the emission’s genotoxicity. The aerosol has a particulate and a gas-vapour phase. As published elsewhere, the flavour ingredients tested had no effect on particulate phase genotoxicity. This poster summarises the results for the gas-vapour phase. The test articles were gas-vapour phase extracts (GVP) from the heated tobacco product with and without flavour ingredients and GVP from a reference cigarette. Conditioned tobacco products were machine-puffed using Health Canada puffing parameters. The emissions were drawn through Cambridge filter pads to remove the particulate phase. GVPs were collected in an ice-cold aqueous buffer and tested within three hours. GVP concentration was expressed as the equivalent concentration of TPM. The in vitro tests were for bacterial mutagenicity (Ames test) and mammalian mutagenicity (mouse lymphoma assay, MLA). All tests were conducted according to OECD guidelines in an independent laboratory complying with GLP. Test results were valid in terms of concurrent control responses and historical ranges. The reference cigarette GVP was cytotoxic in the Ames test and mutagenic in one of the five bacterial strains (TA100 ± S9). At concentrations up to 5000μg TPM equivalent per plate, the GVPs from the heated tobacco products were not cytotoxic or mutagenic. All three GVPs were cytotoxic and mutagenic in the MLA. GVP from the heated tobacco products only induced mammalian mutation at concentrations approximately ten times higher than that of the reference cigarette. Adding flavours to the heated tobacco product had no effect on the in vitro mutagenicity of its GVP.
Genotoxicity Evaluation of α, β Unsaturated Aldehyde Class of Fragrance Materials in the Alternative Chicken Egg Genotoxicity Assay (CEGA) Compared to the Results with Other Regulatory Approved In Vitro and In Vivo Genotoxicity Assays

Y. Thakkar1,2, and A. Agi1. 1Research Institute for Fragrance Materials (RIFM) Inc., Woodcliff Lake, NJ; and 2New York Medical College, Valhalla, NY.

The genotoxic potentials of three α,β unsaturated aldehyde fragrance materials, 2-phenyl-2-butenal, nona-2 trans-6-cis-dienal and 2-methyl-2-pentenal, were assessed in the Chicken Egg Genotoxicity Assay (CEGA), using the comet assay to detect hepatic DNA strand breaks. These compounds were selected for testing based on their chemical structures together with the results in regulatory approved in vitro and/or in vivo genotoxicity studies conducted according to OECD guidelines. Groups of at least 10 fertilized chicken eggs received 3 daily injections of either vehicle, positive control (quinolone), or test substances at various dose levels, on days 9 to 11 of incubation. Eggs were terminated 3 hours after the last dose, and livers were collected for analyses. Three tested fragrance materials did not produce statistically significant DNA strand breaks when compared with the solvent control, thus, they were negative in the comet assay, whereas the positive control produced statistically significant positive results. Additionally, when compared to the in vitro in vivo test outcomes for this class of materials, CEGA results were in 100% concordance with those of the in vivo genotoxicity studies. Results, however, differed from in vitro tests, which can be explained by different endpoints measured in the egg model and higher rates of false-positive results in the in vitro testing systems. Thus, our results support the conclusion that CEGA can be considered as a potential animal alternative testing strategy for assessment of genotoxic potential of fragrance materials, which may generate false positive outcomes in in vitro test systems.

3D Skin Micronucleus and Comet Assay as an Animal Alternative Model for Genotoxicity Positive Materials in Traditional In Vitro Studies: A Case Study on p-Methoxycinnamaldehyde

K. Joshi, Y. Thakkar, and A. Agi. RIFM, Woodcliff Lake, NJ.

Evaluation of cytogenetic damage in the 3D primary human skin model offers a biologically relevant in vitro approach to assess genotoxicity following dermal exposures. The 3D Reconstructed Skin Micronucleus (RSMN) and the 3D Full Thickness Human Skin Comet assays provides an animal alternative follow-up testing for materials that are positive in the traditional in vitro assays. p-Methoxycinnamaldehyde, a fragrance material, was evaluated in multiple assays to assess its genotoxic potential. The BlueScreen™ assay was conducted as an initial screen in the presence and absence of metabolic activation (S9), which resulted in a positive outcome. In the Ames assay, the material produced a positive result only in TA100 strain in the presence of S9 and negative in all other strains in the presence or absence of S9. In the in vitro micronucleus assay, the material was considered positive for inducing micronuclei in the presence and absence of S9. In the in vivo Micronucleus and Comet Assays, p-methoxycinnamaldehyde did not induce significant increase in the micronucleated reticulocytes or DNA damage in liver, when compared to the concurrent vehicle controls. To follow-up the positive Ames and in vitro micronucleus assay results and to compare the in vivo assays, the 3D Skin Comet and Micronucleus Assays were conducted. The results indicate that p-methoxycinnamaldehyde was negative for the induction of micronuclei and DNA damage in the RSMN assay in EpiDerm™ and in the 3D Full Thickness Human Skin Comet assay, respectively. Based on the results from the 3D skin models, the material was considered to have no genotoxic potential.

Re-evaluation of Genotoxicity Data for 4,4′-Methylene Dianiline to Improve Data Quality for Hazard Assessment

I. Krueger1, and A. Chappelle2. 1Coveros LLC, Pittsburgh, PA; and 2International Oxyanate Institute, Chadds Ford, PA.

4,4′-methylene dianiline (MDA) has been assessed and classified by different authorities as a carcinogen and mutagen [IARC (1986), EU (1993)] primarily based upon studies conducted by the NTP (1983) that demonstrated carcinogenicity. The underlying Mode of Action (MoA) of tumor formation is still not completely understood; however for risk assessment, a genotoxic linear non-threshold approach is assumed. Recent recommendations from OECD, US FDA, ECVM and IWGT on the conduct and interpretation of genotoxicity test data provide a framework to systematically re-evaluate genotoxicity data to improve the reliability and quality of the underlying data for hazard assessments. This approach was exercised with MDA data. Studies were identified via a literature search of publicly available records. Only assays from primary literature were included. A total of 28 genotoxicity assays were re-evaluated and re-scored according to protocols outlined in Klimisch et al. (1992) using current recommendations for genotoxicity testing and data interpretation. The re-evaluation reveals that many of the in vitro mammalian cell assays have shortcomings when compared with current recommendations, like artificial test conditions (inappropriate high cytotoxicity, pH-value shift) and insufficient documentation of test results. Insufficient documentation and excessive toxicity above the maximum tolerated dose (MTD) was also found for some of the in vivo assays. In spite of the shortcomings of some of the in vitro and in vivo test systems which would likely be excluded from hazard assessment; there is sufficient evidence from reliable studies to support the conclusion that metabolically-activated MDA is genotoxic. Findings from well conducted in vivo tests [Pig-a gene mutation assay (Sanada et al. 2014), micronucleus assay (Sanada et al. 2015)] suggest that MDA genotoxicity may be related to a cumulative effect. Thus, repeated dosing studies may be more appropriate to investigate genotoxic effects of MDA versus the standard, single high-dose approach. In conclusion, it might be beneficial for hazard assessments to re-evaluate existing data in light of current knowledge for endpoints like genotoxicity. This will improve the data quality of hazard assessments and gain a better understanding of the underlying MoA. In the case of MDA, such a re-evaluation points to a cumulative effect of MDA genotoxicity, which can be used to more effectively design and conduct studies on this endpoint.
An outbreak of bladder cancer was reported recently among workers who handled aromatic amines in chemical factories in Japan, and aromatic amines have been used for long time there. All of the ten cases of cancer had the records of exposure to o-toluidine, a known human carcinogen classified into Group I chemical by the International Agency for Research on Cancer, and nine cases were also exposed to 2,4-dimethylaniline (2,4-DMA). Information about the genotoxicity and carcinogenicity of 2,4-DMA is limited and inconsistent. The International Agency for Research on Cancer classifies 2,4-DMA as a Group 3 chemical, indicating no evidence of carcinogenicity to humans. Our study aimed to clarify the genotoxic effects of 2,4-DMA and its possible contribution to the occurrence of occupational bladder cancer. Human urothelial (1T1) and hepatocyte (WRL-68) cells were treated with 2,4-DMA at different concentrations for 1-24 hr, and phosphorylated histone H2AX (γ-H2AX), a marker of DNA double strand breaks, was detected by western blot and immunofluorescence staining. To explore the mechanism underlying the genotoxic effects, reactive oxygen species (ROS) production following 2,4-DMA exposure and the mediation of CYP2E1 were evaluated. It was shown that 2,4-DMA generates γ-H2AX in a dose-dependent fashion in both cell lines. The double-strand breaks formed in 1T1 cells after 2,4-DMA treatment was confirmed by the bisbenzimide staining fluorescence electrophoresis. In the mechanistic investigations, we found that 2,4-DMA induces intracellular ROS, an effect clearly attenuated by disulfiram, a strong inhibitor of CYP2E1. Furthermore, CYP2E1 inhibitors and the antioxidant, NAC, also attenuated γ-H2AX generation following exposure to 2,4-DMA. Our results suggest that γ-H2AX is formed following exposure to 2,4-DMA via ROS produced by CYP2E1-mediated metabolism. Continuous exposure to genotoxic aromatic amines over a long period of time may have contributed to the development of bladder cancer. Our results provide insights into the carcinogenicity risk of 2,4-DMA in occupational bladder cancer outbreaks at chemical plants in Japan.

O€\textsuperscript{6}-alkylguanine-DNA-alkyltransferase is a constitutively expressed enzyme in E. coli that is encoded by the ogt gene. Its main function is to repair DNA damaged by alkylation, a common pathway for genotoxicity. To gain greater insight into its DNA repair function, we have exposed wild-type (WT, MG1655) and ogt-deficient (JW1329-1) strains of E. coli to the DNA alkylating agents ethyl methanesulfonate (EMS) and N-ethyl-N-nitrosourea (ENU). Intercellular genetic variance, a next generation sequencing analysis that reliably identifies mutations by comparing sequencing datasets from colonies/clones derived from single cells, revealed that ogt deficiency led to greater levels of DNA damage. EMS exposure generated G:C→A:T transitions almost exclusively, while ENU exposure generated G:C→A:T and A:T→G:C transitions in equal amounts. For both EMS and ENU, the mutation spectra were unchanged between WT and ogt-deficient mutants. These data suggest that ogt plays an important role in DNA repair, and it repairs mutagenic ethylation products at G:C and A:T base-pairs equally well.

Commercially purchased whole human blood and cryopreserved isolated human peripheral blood lymphocytes were evaluated for use in the in vitro chromosomal aberration assay. Initial testing was conducted in whole human blood with 5 donors and a long period of time to assess storage limitations. Cultures where propagated in triplicate and stimulated with phytohemagglutinin-M (PHA-M) to induce cellular division. The cultures were exposed to dimethyl sulfoxide (DMSO, 1%) at 48 hours post propagation, for a total of 4-hours with 59-activation and 22-hours without 59-activation. The cultures were harvested 22-hours post treatment and evaluated for mitotic index. Follow-up testing was conducted in whole human blood with 4 donors at 2, 5, and 7-days post-draw to assess shorter storage time and reproducibility of stimulation post storage. In addition, positive control responses were evaluated during the follow-up testing. Cultures were propagated in duplicate and stimulated with PHA-M. At 48-hours post propagation, the cultures were exposed to DMSO and cyclophosphamide or mitomycin-C. The cultures were harvested 22-hours post treatment and evaluated for mitotic index and cytogenetically analyzed for structural and numerical aberrations. Additional testing was conducted to assess the propagation capabilities of cryopreserved isolated human peripheral blood lymphocytes. The isolated lymphocytes were thawed and propagated in duplicate with PHA-M. At 48-hours post propagation, the cultures were exposed to DMSO and cyclophosphamide or mitomycin interaction of Aromatic Amines Related to the Occurrence of Bladder Cancer among the Exposed Workers

An Extended Evaluation of Commercially Purchased Blood and Cryopreserved Isolated Human Peripheral Blood Lymphocytes for Use in the In Vitro Chromosomal Aberration Assay

Integrated In Vivo Genotoxicity Testing to Follow-Up the Positive Ames Test of a Meptyldinocap Metabolite

Flow Cytometric Analysis of the HPBL In Vitro Micronucleus Assay—Proof of Concept

Integrated In Vitro Chromosomal Aberration Test to Meptyldinocap Metabolite
performed at two dose levels which equate to LOAEL and NOAEL for meptyldinocap. In this study, male and female Cr:CD1 mice (n=6) were fed diets supplemented with 0, 200 or 750 ppm X12335709 for 28 days. Blood samples were collected 7 days prior to the first dose for pre-exposure and on day 28 for post-exposure for gene mutation (CD59 marker for Pig-a) and MNT evaluations. The positive controls in this study were 20 mg/kg N-Nitroso-Niethylurea (days 1-3) and 40 mg/kg 4-hydroxy-1,3-benzoquinone (days 1-5) for Pig-a and micronucleus tests, respectively. During the study, the color of the urine was similar to the color of X12335709, indicating that animals had systemic exposure to X12335709. Adverse effects were not observed at any dose level, and both the Pig-a assay and MNT results were negative for mutagenicity and clastogenicity, respectively. The negative Ames assay, in vivo transgenic Big Blue® mice via inhalation exposure as well as dominant lethal study. In a 2-year carcinogenicity study via dietary route, increased benign liver tumors were observed in high dose male F344 rats at 25 mg/kg bw/day. To further examine whether genotoxicity is an initial key event in the tumorigenicity of 1,3-D, a fully OECD 488 compliant study was designed to be consistent with the cancer bioassay including selection of species, sex, exposure regimen. Twenty-four F344 homozygous Big Blue® male rats (six/group) were exposed daily to 1,3-D via diet (treatment groups) or placebo mixed in diet, for 28 consecutive days, at target dose levels of 0, 12.5, 25 or 50 mg/kg bw/day and left untreated for an additional 3 days for fixation. Animals were necropsied and liver and kidneys were collected at day 31. Genomic DNA was isolated from liver and kidneys, lambda phage shuttle vectors were recovered and inserted into empty lambda bac- teriophage capsids, creating infectious phage. Phage were adsorbed onto permissive E. coli G1250 host cells and plated out for plaque formation for mutants only under selective temperature conditions (24 ± 0.5°C) and total plaque formation (both mutant and wild-type phage) under non-selective (37 ± 1.0°C) temperature conditions. The mutant frequency (MF) of the cII gene were then determined for liver and kidneys. The results show the mean MFs for liver are 32.2, 23.4, 21.5, 33.4 and for kidneys are 19.1, 22.4, 25.4, 19.8, respectively, with the highest MF for liver. No statistically significant differences between treatment groups and the placebo group in either tissue. The positive control, ENU significantly induced (>3-fold) MF for both tissues, indicating the utility of the test system to detect induced mutants following exposure to a known mutagen. In conclusion, 1,3-D is negative for causing a statistically significant increase in mutations at the cII gene in the liver and kidneys of male Big Blue® rats. This conclusion coupled with previous in vivo genotoxicity results further confirms that 1,3-D is not an in vivo genotoxicant.

1553 1,3-Dichloropropene In Vivo Mutation Study in Male Big Blue Transgenic F344 Rats via Dietary Treatment

C. Terry 1, B. Gollapudi 2, R. Settivari 3, and Z. Yan 1. 1Corteva Agriscience, Agriculture Division of DowDuPont, Indianapolis, IN; 2Exponent, Alexandria, VA; and 3Corteva Agriscience, Agriculture Division of DowDuPont, Newark, DE.

1,3-Dichloropropene (1,3-D) is a pre-planting soil fumigant injected into soil for effective management of nematodes. Genotoxicity of 1,3-D has been extensively tested across all endpoints via GLP studies. While the in vitro Ames test exhibits mixed results, all in vivo studies are uniformly negative. Those studies include in vivo transgenic Big Blue® mice via inhalation exposure as well as dominant lethal study. In a 2-year carcinogenicity study via dietary route, increased benign liver tumors were observed in high dose male F344 rats at 25 mg/kg bw/day. To further examine whether genotoxicity is an initial key event in the tumorigenicity of 1,3-D, a fully OECD 488 compliant study was designed to be consistent with the cancer bioassay including selection of species, sex, exposure regimen. Twenty-four F344 homozygous Big Blue® male rats (six/group) were exposed daily to 1,3-D via diet (treatment groups) or placebo mixed in diet, for 28 consecutive days, at target dose levels of 0, 12.5, 25 or 50 mg/kg bw/day and left untreated for an additional 3 days for fixation. Animals were necropsied and liver and kidneys were collected at day 31. Genomic DNA was isolated from liver and kidneys, lambda phage shuttle vectors were recovered and inserted into empty lambda bacteriophage capsids, creating infectious phage. Phage were adsorbed onto permissive E. coli G1250 host cells and plated out for plaque formation for mutants only under selective temperature conditions (24 ± 0.5°C) and total plaque formation (both mutant and wild-type phage) under non-selective (37 ± 1.0°C) temperature conditions. The mutant frequency (MF) of the cII gene were then determined for liver and kidneys. The results show the mean MFs for liver are 32.2, 23.4, 21.5, 33.4 and for kidneys are 19.1, 22.4, 25.4, 19.8, respectively, with the highest MF for liver. No statistically significant differences between treatment groups and the placebo group in either tissue. The positive control, ENU significantly induced (>3-fold) MF for both tissues, indicating the utility of the test system to detect induced mutants following exposure to a known mutagen. In conclusion, 1,3-D is negative for causing a statistically significant increase in mutations at the cII gene in the liver and kidneys of male Big Blue® rats. This conclusion coupled with previous in vivo genotoxicity results further confirms that 1,3-D is not an in vivo genotoxicant.

1564 Analysis of the Genotoxic Potency of Pyrrolizidine Alkaloids Using HepaRG Cells in Conjunction with the GammaH2AX Assay

A. Peijnenburg 1, J. Louisse 1, D. Rijkers 1, W. Jansen Holleboom 1, E. Molthof 1, R. Settivari 3, and Z. Yan 1. 1Agriculture Division of DowDuPont, Indianapolis, IN; 2INRA, Toulouse, France.

Pyrrolizidine alkaloids (PAs) are secondary metabolites which occur in a large number of plant species and can be found as contaminants in food and feed. Several chemical classes of PAs can be distinguished according to the type of necine base and the esterification mode (mono-esters, open chain or cyclic diesters). In laboratory animals, the main toxicities resulting from treatment with 1,2-unsatuated PAs are genotoxicity, carcinogenicity and hepatotoxicity. It has been demonstrated that PAs have to be metabolically converted in order to exert their toxicity. The mutagenic risks of PAs for humans cur-
3Rs Friendly Study Design Facilitates Combined Rat Liver Micronucleus, Blood Micronucleus, and Pig-a Assays: Proof-of-Concept with Ten Diverse Genotoxicants

Regulatory guidelines stress the value of assessing multiple tissues and the most appropriate endpoints when evaluating chemicals for in vivo genotoxic potential. Yet conducting several independent studies to consider multiple endpoints and/or tissue compartments is resource intensive, and conventional approaches for scoring genotoxicity endpoints are inefficient. To address these issues with current practices we attempted to i) devise a resource-sparing treatment and harvest schedule that is compatible with liver and blood micronucleus (MN) endpoints, as well as the Pig-a gene mutation assay, and ii) utilize flow cytometry-based methods to score each of these biomarkers. Experiments were performed with 25-week-old C57BL/6 mice. Three groups were exposed to three 3-day cycles of hydroxyurea, quinoline, benz(a)pyrene (BP), cyclophosphamide (CP), diethylnitrosamine (DEN), cisplatin (CisP), 2,6-dinitrotoluene, 1,2-dimethylhydrazine, temozolomide, or vinblastine. Nine agents were dosed weekly for five cycles. In vivo MN and Pig-a responses were observed. For example whereas BP induced a clear increase in Pig-a mutant cells and a modest induction of blood MN, CP slightly affected Pig-a mutation but caused a robust blood MN response. BP nor CP induced liver MN. DEN caused a subtle Pig-a response, no induction of blood MN, and a robust liver MN response. Only one genotoxic agent, CisP, caused increases across every endpoint. Collectively, these results reinforce the importance of evaluating chemicals' genotoxic potential in both hematopoietic and liver compartments. These data also suggest it is possible to markedly enhance the efficiency by which several genotoxicity endpoints and two tissues can be evaluated through the use of flow cytometric scoring in conjunction with a resource-sparing study design that provides better utilization of fewer animals relative to current practices.

The in vitro MultiFlow DNA Damage Assay multiplexes γH2AX, p53, phospho-histone H3, and polypliodization biomarkers into a single flow cytometric analysis. The current report describes a sequential data analysis strategy based on data generated from exposure of human TK6 cells to a previously described 85 chemical training set and a new, more pharmaceutical-centric test set (n=40). In each case, exposure occurred for 24 hr over a range of concentrations, and cell aliquots were removed at 4 and 24 hr for analysis. The data analysis pipeline described herein begins with a machine learning ensemble in addition to a rubric that considers fold increases in biomarker responses. The intra-lab reproducibility was further demonstrated with additional data, and these analyses were found to group certain chemicals, especially aneugens, according to their molecular targets. Finally, a third tier utilizes benchmark dose analyses and MultiFlow biomarker responses to rank genotoxic potency. The relevance of these rankings is supported by the strong agreement found between benchmark dose values derived from MultiFlow biomarkers compared to those generated from parallel in vitro micronucleus analyses. Collectively, the results suggest that a tiered MultiFlow data analysis pipeline is capable of rapidly and effectively identifying genotoxic hazards while providing additional information that is useful for modern risk assessment—MoA, molecular targets, and potency.

Development of Real-Time Human Cell Analysis Method for Identification and Categorization of Genotoxic Chemicals

Genotoxicity is a significant health concern leading to cancer and birth defects. Current testing methods are limited in that they can only detect a subset of genotoxic agents and suffer from potential interferences of cytotoxicity. Therefore, for a thorough assessment of genotoxic activity, a battery of end-point assays is required. Using human cell lines with intact DNA damage response pathways, we developed a Real Time Cell Analysis (RTCA) method that continuously monitors impedance values reflecting integrated signals from cell number, attachment, and morphology, generating kinetic Time-Dependent Response Profiles (TCRPs) indicative of mechanism of action. Upon exposure to genotoxic agents, DNA repair pathways are activated, leading to physiological and morphological changes that are recapitulated in the kinetic profiles, generating three distinguishable TCRPs for aneugens, clastogens/mutagens, and non-genotoxic agents, whilst simultaneously capturing cytotoxicity. An algorithm for TCRP analysis was developed to classify these sub-groups and a 50 compound screening library was formed composed of 33 genotoxic compounds working through different mechanisms, and 17 non-genotoxic compounds from OECD reference compounds list. Sensitivity and specificity of the TCRP method were tested with the Pig-a assay, with 32 out of 33 genotoxic positive agents identified, and 16 out of 17 negative agents tested as non-genotoxic. In addition, when combined with micronucleus (MN) flow assay, the workflow can further distinguish clastogens from mutagens. To our knowledge, this is the first testing method that can identify and classify multiple categories of DNA reactive chemicals, including clastogens/mutagens and aneugens. This model, when validated, can be used as a first tier high-throughput quantitative screening system for genotoxic agents.

Development of a 3D Genotoxicity Testing Battery Using Reconstructed Skin Models

The European regulation prohibits the use of animals in genotoxicity testing for ingredients used in cosmetics. Irreversible events at the chromosomal level are commonly evaluated by either scoring micronuclei or chromosome aberrations using cell-based assays, when assessing genotoxicity. These assays in 2D suffer from a poor specificity, and this is exacerbated in chemicals with skin as first site-of-contact due to the irrelevance of dermal exposure, lack of normal cell cycle control and intercellular microenvironment, as well as comparable metabolic capacity to native human skin. Reconstructed 3D human skin tissues overexpressing limitations of 2D in vitro assays, were therefore chosen in this study to build up a testing battery, enabling prediction of genotoxicity for chemicals. The current study was conducted on two commonly used in vitro genotoxicity assays using reconstructed skin models, an epidermis model EpiskinTM was used for micronucleus assay and comet assay was developed with a full thickness skin model. The EpiskinTM Micronucleus Assay was developed, and a formal multi-center validation study was conducted in China with two authority laboratories. The first phase was conducted with six chemicals selected by Cosmetic Europe Genotoxicity Taskforce: Phenantherene, Mannitol, D-limonene, 5-Fluorouracile, Vinblastine and ENU. Results showed correct predictive capacity in a 100% inter-laboratory test. To further demonstrate the characterization of EpiskinTM was conducted. Both gene expression and enzymatic activity analysis showed comparable metabolic capacity of EpiskinTM to human native skin and confirmed the correct classification of this assay for positive compounds requiring metabolic capacity (exc. 2-AAF). For comet assay, the protocol was firstly set up with two genotoxins (ANQO and MMS). A stable baseline level was established to extrapolate positive responses. The intra-lab reproducibility was further demonstrated with addi-
tional four genotoxic carcinogens at non-cytotoxic range of concentrations and the results showed good concordance with in vivo data. Altogether, these results indicate that genotoxicity assays using reconstructed skin models offer promising results for the safety assessment of chemicals with a dermal route of exposure, the availability and validity of these assays are expected to contribute to the in vitro genotoxicity testing strategy, the 3D genotoxicity testing battery could be used as ‘2nd tier’ assays to follow up on positive results from standard in vitro assays.

### 1571 Extension of the ToxTracker Reporter Assay for Classification of Compounds with an Clastogenic or Aneugenic Mode of Action

The distinction between a clastogenic or aneugenic mode of action is important for safety considerations. For clastogenic compounds that are directly DNA reactive, there is likely to be no safe level of exposure, while for aneugens that do not directly react with DNA, there might be a threshold below which there is no adverse effect. ToxTracker is a mammalian stem cell-based reporter assay that detects the activation of specific cellular signalling pathways upon exposure to compounds (Hendriks et al, Tox Sci 2016). ToxTracker contains six different GFP-tagged reporters that allow the discrimination between the induction of DNA damage, oxidative stress and protein damage in a single test. To assess whether ToxTracker can provide further insight into the mode of action of genotoxic compounds, we analysed various clastogenic as well as aneugenic compounds. The clastogens cisplatin and etoposide activate both markers for DNA double strand breaks (Rtkn) and replication stress (Bsc1). In contrast, aneugenic compounds that interfere with microtubuli, such as VCR, were defective in MMS-associated sister chromatid exchange. One hypothesis is that Shu1 suppresses the Srs2 helicase that promotes potential recombinogenic lesions into a mutagenic pathway. To test this hypothesis, we made csm2 srs2 double mutants. The mutants exhibited slow growth, like the csm2 mutant, but were still deficient in DNA damage-induced recombination. These studies have led to the hypothesis that the SHU complex participates in a pathway of mutation avoidance by directly participating in assembly of a Rad51 complex. Future studies will investigate whether the SHU complex suppresses mutagenicity after exposure to multiple genotoxins. These studies will thus elucidate the mechanisms that suppress carcinogen-associated mutation.

### 1572 Adaptation of the ToxTracker Reporter Assay for the Genetic Toxicology Assessment of Petroleum Products

G. Hendriks, R. Derr, P. Racz, P. J. Boogaard, and H. Ketelslegers.

Certain poorly refined petroleum streams that contain relatively high levels of 3-7 ring polycyclic aromatic hydrocarbons (PAHs) are known to have mutagenic properties and cause skin tumors in mice. Since the guideline carcinogenicity test has obvious time, cost and animal-welfare constraints, screening assays were developed such as the IP346 assay and Modified Ames test. To further underpin these assays and increase their predictivity by including a mechanistic component, 18 petroleum substances (PS, highly- and poorly refined, with various levels of 3-7 ring PAHs) were tested in the ToxTracker reporter assay. PS are a panel of six validated mouse embryonic stem cell lines each containing a GFP reporter to detect induction of DNA damage, oxidative stress and protein damage in a single test. In parallel, all 18 petroleum extracts were also tested in the Modified Ames mutation assay. All tested highly refined base oils were classified as non-genotoxic in ToxTracker and non-mutagenic in the ModAmes test. Three petroleum distillate aromatic extracts (DAE) and four heavy fuel oil (HFO) extracts with higher levels of 3-7 ring PAHs, activated the genotoxicity reporters in ToxTracker and induced mutations in the ModAmes test. The poorly refined petroleum extracts also triggered oxidative stress and protein damage responses, in line with the (in vivo) toxicology of these extracts. Overall, results observed with ToxTracker correlated with those obtained from the established ModAmes assay. However, two technical issues related to the PAH content of PS were identified which are currently being further investigated: Firstly, PAHs are known to be autofluorescent, which could interfere with analysis of the GFP reporters. Therefore, activation of the six ToxTracker biomarker genes by the PS with high PAH levels was also confirmed by quantitative RT-PCR. Secondly, 3-7 ring PAHs generally require metabolic activation to become genotoxic. We evaluated the metabolic capacity of the ToxTracker cells by testing various PAHs with a defined battery of aprotic extracts from a S9 metabolic system. Furthermore, the S9 protocol form the ModAmes test was adopted in ToxTracker. Based on this, optimization of the ToxTracker protocol to address the specific complexities for (petroleum) UV/CB substances around autofluorescence and application of the S9 metabolizing system will improve the adequate genotoxicity assessment of PS.

### 1573 Genetic Control of Mutation Avoidance after Exposure to Carcinogens

H. Baldino, and M. Fasullo, SUNY Polytechnic Institute, Albany, NY.

Aflatoxin (AFB1) is the most potent hepatocarcinogen known. The signature p53 mutation, p53-249<sup>th</sup>, found in AFB1-associated liver cancer suggests that AFB1 is a strong carcinogen because it is a mutagen. However, there is variability in the human response to AFB1 and polymorphisms in some DNA repair genes that participate in double-end break repair, such as XRCC1 and XRCC3, are risk factors for liver cancer. To understand genetic factors that suppress AFB1-associated mutagenicity we performed a genome profile for aflatoxin resistance in budding yeast, since many DNA repair and metabolism genes are orthologous to humans. To achieve this the human CYP1A2 was introduced into the deletion library to activate AFB1. Prominent among 86 genes that confer AFB1 resistance, are genes involved in error-free template switch mechanisms. These include genes in the SHU complex, consisting of CSMD2, PSY3, SHU1, and SHU2 that suppress methyl methanesulfonate (MMS)-associated mutations at the CA1 locus. Epistasis analysis revealed that CSMD2 and RAD51 are in the same epistasis group while CSMD2 and RAD4, which participate in nucleotide excision repair, are in different epistasis groups for AFB1 resistance. We observed that csmd2 mutants exhibit higher frequencies of AFB1-associated mutations but lower frequencies of AFB1-associated error-free template switching. Additional studies showed that csmd2, psy3, shu1, and shu2 were defective in MMS-associated sister chromatid exchange. One hypothesis is that Shu1 suppresses the Srs2 helicase that promotes potential recombinogenic lesions into a mutagenic pathway. To test this hypothesis, we made csm2 srs2 double mutants. The mutants exhibited slow growth, like the csm2 mutant, but were still deficient in DNA damage-induced recombination. These studies have led to the hypothesis that the SHU complex participates in a pathway of mutation avoidance by directly participating in assembly of a Rad51 complex. Future studies will investigate whether the SHU complex suppresses mutagenicity after exposure to multiple genotoxins. These studies will thus elucidate the mechanisms that suppress carcinogen-associated mutation.

### 1574 Investigation of the DNA Damage Response in Chemoresistant versus Chemosensitive Ovarian Cancer Cells

A. Abdulwahed, M. Karbaschi, N. Quinete, D. J. Azzam, H. G. Tempest, and M. S. Cooke, Florida International University, Miami, FL.

Ovarian cancer is the fifth leading cause of cancer related deaths in women. The majority of patients are diagnosed at an advanced stage of the disease and many will experience disease recurrence. Several platinum compounds, including cisplatin, are currently used as anticancer drugs in the treatment of ovarian cancer. However, ovarian cancer patients often develop chemoresistance to current platinum/taxane chemotherapy regimens upon recurrence and these therapies tend to be the most effective at the time of diagnosis. Resistance in ovarian cancers. Modified comet assay was used to measure inter-strand cross-link (ICL) formation and repair, together with cellular base and nucleotide excision repair in chemosensitive (SKOV-3) and chemosensitive (OCI-P5x and A2780) ovarian cancer cells. Although the peak of cisplatin-induced cross-link formation for all three cell lines was at 12 h, and confirmed by ICP-MS, we noted a significant attenuation of ICL formation in the chemoresistant versus the chemosensitive cell lines. We also observed that for A2780 and OCI-P5x cells, ICL formation was higher in the chemoresistant cells than in the chemosensitive cells. The results indicate that the chemoresistant cells have a higher capacity to repair ICLs, suggesting that the chemoresistant cells are more able to repair DNA damage and are therefore better able to withstand the DNA damage induced by cisplatin. The results suggest that the chemoresistant cells are more able to repair DNA damage and are therefore better able to withstand the DNA damage induced by cisplatin.
considerably more resistant to damage formation, at all doses of cisplatin. These data provide a basis for further studies to improve our understanding of the differential DNA damage response associated with chemoresistant and chemoresistant ovarian cells. Elucidating the mechanisms of chemoresistance may ultimately lead to novel therapeutic interventions that may resemitize or prevent the development of chemoresistance.

**1575 Mutagenicity Study of a New 2-Phenylbenzotriazole, a Derivative of the Water Contaminant C.I. Disperse Violet Azo Dye**

*State University of Campinas (UNICAMP), Campinas, Brazil. Sponsor: G. Umbuzeiro, Society of Environmental Toxicology and Chemistry*

2-phenylbenzotriazoles (PBTA) are formed during the reduction reaction of dinitrophenyl azo dyes during the textile dyeing process. Some PBTA have already been described and found in the aquatic environment. The dinitrophenyl azo dye C.I. Disperse Violet 93 has been found in rivers in Brazil but their corresponding PBTA has never been described. This work is part of a project where a new PBTA derived from the C.I. Disperse Violet 93 was synthesized and characterized as N-(2-(6-aminio-4-bromo-2H-benz[d][1,2,3]triazol-2-yl)-5-(diethylamino)phenyl)acetamide. The objective of this study was to study its mutagenic activity using the Salmonella/microsome assay. We used the miniaturized protocol Microplate Agar (MPA) in the presence and absence of metabolic activation performed by rat liver S9 with 4 strains of Salmonella: TA98, TA100, TA102, and YG97a. We included two additional strains: the YG1108, a derivative of TA1535, which is highly sensitive to alkylating compounds, and the YG1041, a derivative of TA98, which is highly sensitive to compounds containing nitro/amino groups because of the increased expression levels of nitroreductase and O-acetyltransferase enzymes. The compound was tested diluted in dimethyl sulfoxide at limit of solubility, 0.83 µg/ul. Positive results were found for TA98, TA100, YG97a and YG1041 in the presence of S9. YG1041 was by far the most sensitive strain. Therefore N-(2-(6-aminio-4-bromo-2H-benz[d][1,2,3]triazol-2-yl)-5-(diethylamino)phenyl)acetamide has the ability to cause frameshift and base pair mutations in the Salmonella test. It is likely that the CYP enzymes provided by S9 are oxidizing the amino group to a hydroxylamine, which is further acetylated by the OAT enzymes, highly expressed in the YG1041. This would explain the high response of this compound to this strain in the presence of S9. Experiments are under way to verify its ability to cause DNA damage in vivo using comet assay in aquatic animals.

**1576 Ultra-Rare In Vitro Mutations Are a Sensitive and Specific Biomarker of Endogenous and Environmental Genotoxic Exposure**

*Twist Strand Biosciences, Seattle, WA; 1Amgen Research, Amgen, Thousand Oaks, CA; and 2MiliporeSigma/BioReliance, Rockville, MD.*

Somatic mutation accumulation is driven by endogenous and environmental processes. These processes imprint subtle, but characteristic patterns on the genomes of cells, and tell the story of life-integrated genotoxic exposure. Trinucleotide mutation signatures offer a rich target for exploitation as a biomarker for disease as they are often the result of frameshifts in introns that are modulated by exposure dynamics, tissue development, and lifestyle choices. However, detection in this setting remains challenging. The COSMIC trinucleotide mutation signatures are curated from the genomes of thousands of human tumors. The etiologies of these signatures have been studied in a wide range of tumors. We hypothesize that the presence of these signatures in healthy tissue during the long, and potentially informative period of cancer risk, prior to detectable tumor formation. Standard techniques for de novo mutation detection rely on clonal amplification of progenitor cells, for example, when researchers survey passenger mutations in a tumor, or when exposed cells in culture are grown out into easily assayable clones. These methods are fraught with confounders, such as bottlenecks and selective pressures, which alter or obscure the founder mutations. Duplex Sequencing is a tag-based DNA sequencing error correction method that enables detection of rare mutations at mutation frequencies of normal human tissues (~10e-8). Duplex Sequencing can be applied to the DNA of any tissue, of any organism, at any time, without the need for tumor formation or ex vivo cloning. To benchmark Duplex Sequencing detection of treatment-specific signatures in vivo, we assayed 5 tissues from mutagen treated mice before the any evidence of neoplastic disease. We observe mutation signatures corresponding to the context-specific mode of action of the mutagen with high correlations to previously published signatures from human and mouse tumor samples. Remarkably, these signatures are also present within the blood of the mice, suggesting the potential for using blood as the substrate for a non-invasive biomarker test of mutagenic exposure in model organisms and humans. This work highlights opportunity for increased understanding of carcinogenesis with Duplex Sequencing, which will enable the use of mutagenic signatures as an early biomarker of genomic insults, and of novel methods to mitigate cancer risk.

**1577 Naringenin Attenuates Genotoxicity Mediated by Oxaliplatin in Mice**

*Prince Sattam bin Abdulaziz University, Alkhobar, Saudi Arabia.*

Naringenin (NG) is a naturally occurring bioflavonoid that possess anti-oxidant and protective effects against DNA damage. Oxaliplatin (OX) is a third-generation platinum based anti-cancer drug used to treat various human malignancies, even though it mediates genotoxic effects in normal cells. The aim of this study is to examine the protective effects of NG on OX-induced DNA damage in mice. A total of 50 male mice (BALB/c) were randomly divided into five groups (10/group). Group I served as a control and was orally administrated 20mg/kg of NG. While group IV and V were orally administrated 20 and 40 mg/kg NG (NG20 and NG40), respectively, for ten consecutive days. On the tenth day of the experiment, animals in groups III, IV, and V were given a single intraperitoneal injection of OX (7 mg/kg) to induce genotoxicity. After 24 hr of OX treatment, mice were sacrificed. Measurements of GSH, GSSG and 8-OHdG levels and chromosome aberration analysis were carried out to evaluate DNA damage. GSSG and 8-OHdG levels were significantly induced by OX treatment by 1.24±0.21 nM/106 cells and 2.91±0.18 ng/L, respectively, compared to the control groups, while NG20 and NG40 treatments significantly reduced the induction of GSSG and 8-OHdG levels mediated by OX treatment to 0.96±0.16 nM/106 cells, 0.84±0.16 nM/106 cells, 2.31±0.43 ng/L and 1.81±0.39 ng/L, respectively. Both NG doses significantly counteracted the reduction of GSH mediated by OX treatment (2.9±0.3 nM/106 cells) by 4.1±0.4 and 5.2±0.4 nM/106 cells, respectively. Chromosomal aberration test showed a significantly higher proportion of chromosomal aberration at 32.33±2.97% mediated by OX treatment compared to the control group at 8.44±1.01%, while NG20 and NG40 significantly reduced the frequency of chromosomal aberration to 20.67±28.88% and 15.39±2.75%, respectively, in dose dependent manner. In conclusion, these findings suggest that NG significantly reduced the DNA damage induced by Oxaliplatin possibly due to its anti-oxidant effect and propose it as a potential chemoprotective agent against genotoxicity associated with chemotherapy.

**1578 Comparative Cardiovascular Parameters in Bama and Göttingen Minipigs**

The minipig has been accepted and recognized as a suitable alternate non-rodent species in both biomedical research and new drug development. Investigations demonstrated the advantages of miniature pig when used as the model for evaluating drug candidate: it has similar cardiac anatomy, metabolism and electrophysiology when compared with human. The Göttingen minipig is well known and routinely used for regulatory cardiovascular safety pharmacology study. Meanwhile, the Chinese Bama minipig, one of the miniature pig breeds, is increasingly used in China due to the features of genetically stable, highly inbred and cost and availability. The objective of this study was to compare the electrocardiographic parameters between Göttingen and Bama minipigs. In addition, we also compared the electrocardiographic parameters collected by both telemetry and non-telemetry. The study results indicated no breed difference or sex difference in the heart rates, RR, PR, QRS and QT intervals between Göttingen and Bama minipigs. The non-telemetry heart rate was generally higher than that collected with telemetry method. Diurnal rhythm was noted in heart rate and QT/QTc interval for Bama miniature pigs. In conclusion, the electrocardiographic parameters are comparable between the Göttingen and Bama minipigs, and also the strain of Bama minipig is considered suitable for cardiovascular safety pharmacology study.
1579 Immunology Historical Data of 2-4 Years Cynomolgus Monkey (Macaca fascicularis) from Hainan, China

The Cynomolgus monkey (Macaca fascicularis) is a well-known non-human primate species commonly used in non-clinical research especially in the toxicology studies of the biopharmaceutics. Since the historical pretest data is limited for immunology parameters in the Cynomolgus monkey, the data collection and evaluation was conducted from 7 toxicity studies in Wuxi AppTec Suzhou Facility from 2015 to 2018. Animals were 2-4 years Cynomolgus monkeys and the supplier is Hainan Jingang Biotech Co., Ltd. Pretest and control animal data from completed and ongoing toxicology studies were used to summarize the immunological historical data of three aspects: B and T Lymphocyte phenotyping (up to 338 monkeys, 169/sex), cytokine analysis (up to 310 monkeys, 155/sex) and immunoglobulin and complement analysis (up to 136 monkeys, 68/sex). At initiation of dosing, monkeys body weights ranged from 2.3 to 4.0 kg for males and 2.1 to 3.6 kg for females. Blood samples for B and T Lymphocyte phenotyping, cytokine, immunoglobulin and complement analysis were obtained from a cephalic or a femoral vein. Blood collected for B and T Lymphocyte analysis were Anticoagulant with K2EDTA. Serum for cytokine, immunoglobulin and complement analysis were obtained by standard refrigeration. B and T Lymphocyte phenotyping was conducted using a qualified flow cytometry method (Becton-Dickinson FACSCanto II Flowcytometry System). Cytokine analysis was conducted using a qualified Cytometric Bead Array method based on flow cytometry (Becton-Dickinson FACSCanto II Flowcytometry System). Immunoglobulin and complement concentrations in the serum were measured using a validated immunoturbidimetric method based on biochemistry analyzer (Hitachi 7180 Biochemistry Analyzer). Results of the B and T Lymphocyte (Total T cells, Helper T cells, Cytotoxic T cells, B cells), immunoglobulin and complement (C3c, C4, IgG, IgA and IgM), and cytokines (IL-2, IL-4, IL-5, IL-6, TNF-α and IFN-γ) were showed as mean, standard deviation (SD) and Coefficient of Variance (CV) to demonstrate the historical data and the variation between studies and individual animals.

1580 Potential Endocrine-Disrupting Effects of Graphene Oxide Nanomaterial on Japanese Medaka Fish

A. Dasmahapatra, D. Powe, T. Dasari Shareena, and P. Tchoungwou. Jackson State University, Jackson, MS.

Due to the unique physico-chemical properties, graphene oxide (GO) has shown great potential for biomedical, energy and electronic applications. As a result, release of GO into the ecosystem especially into the aquatic environment is inevitable; however, the potential risks on aquatic life are almost unknown. We have evaluated the toxic potential of GO on Japanese medaka fish (Oryzias latipes) reproduction. GO was synthesized by modified Hummer’s method in the laboratory and was characterized by Fourier transform infrared (FTIR), field emission scanning electron microscopy (FIB-SEM), transmission electron microscopy (TEM), AFM (Atomic Force Microscopy) and Zetasizer Nano ZS. The reproductively active adult medaka were injected (25 µg/g with GO (274.1±46 nm in diameter) and allowed for normal breeding for three weeks; the eggs laid were evaluated for developmental abnormalities including hatching. Moreover, histological studies were performed on the gonads (testis and ovary) of the parents three weeks post injection. It was observed that even though GO administration to adult fish was unable to induce any significant effects on fecundity and developmental abnormalities in hatched larvae, the testicular degeneration as evidenced by germ cell synctiata in males and significant follicular atresia in ovary of females indicated a potential endocrine disrupting effect. As GO is a known inducer of oxidative stress, testicular degeneration in males and disruption of folliculogenesis in females are probably the result of oxidative damage.

1581 Attenuation of Lung Inflammation and Emphysema-Like Changes following Cigarette Smoking Cessation or Switching to Aerosol Inhalation from an NTV

Mainstream cigarette smoke (CMS) is one of the risk factors for development and progression of respiratory diseases, such as chronic obstructive pulmonary disease (COPD). Novel tobacco vapor product (NTV) is a product with low-temperature heating technology. Previous study found that the vapor from NTV showed distinctively lower yields of potentially harmful constituents than CMS. We used a murine model of COPD to investigate the effects of chronic exposure to NTV aerosol, compared with CMS from 3R4F reference cigarettes (3R4F); and the effects of cessation and switching to NTV after 2 months of CMS exposure. Female C57BL/6 mice were exposed to 3R4F CMS (700 µg total particulate matter (TPM)/L), filtered air (FA) or NTV aerosol (700 µg TPM/L) for up to 6 months. In both groups, after 2 months of CMS exposure, mice were exposed to FA (cessation) or NTV (switching) for 4 months. All groups underwent intermittent exposure (i.e., 4-hour daily exposure arranged as two 2-hour periods with a 30-minute break of FA exposure). After completion of exposure, mice were examined for emphysema-related changes as well as several toxicological endpoints. Two-month CMS 3R4F CMS exposure led to upregulated inflammation-related gene expression in lungs and increased proteolytic enzyme activities in bronchoalveolar lavage fluid, associated with alveolar destruction, and perturbed lung function, indicating emphysema-like changes; whereas exposure to NTV aerosol did not induce these effects at any time points. The effect of NTV aerosol on biological processes was very similar to that of FA. Both cessation and switching attenuated the effect of 3R4F to levels similar to FA. These data clearly show that NTV aerosol has little impact on biological processes (inflammatory responses, emphysema-like changes and impaired alveolar damage), compared with 3R4F CMS in a murine model of COPD. Furthermore, it suggests that effects of switching to NTV on these processes might be similar to those of cessation.

1582 Positive Control Study of Urethane and MNU in TgRasH2 Mice

J. Hopper, and B. Saladino. BASI, Mount Vernon, IN; and Seventh Wave Laboratories, LLC, Maryland Heights, MO.

The TgRasH2 [CByB6F1-Tg(Hras)2Jic, (TgRasH2)-hemizygous (+/-)] mouse is the genetic model for detecting carcinogenic potential of genotoxic and non-genotoxic test articles in 26-week assays and has been found a suitable model by the US FDA. A positive control group is recommended for inclusion. This study compared the efficacy of urethane and N-methyl-α-nitrosourea (MNU) as positive control carcinogenic substances for validation of the TgRasH2 mouse carcinogenicity assay. Ten mice/sex/group were administered urethane (1000 mg/kg) or saline by intraperitoneal injection on Days 1, 3, and 5, or MNU (75 mg/kg) on Day 1. Animals administered MNU or urethane were sacrificed after 16 weeks of observation and saline control animals after 26 weeks. One control male and another female, and two females administered urethane, and one male and three females administered MNU were found dead or sacrificed moribund between Weeks 13 and scheduled sacrifice, all attributed to generalized debilitation resulting from tumors. Neoplasia in the saline controls was rare. The control male sacrificed moribund had a gastric squamous cell carcinoma, a bronchiolo-alveolar adenocarcinoma, a hepatocellular adenoma, and a Harderian gland adenoma. A Harderian gland adenoma was also present in one control male sacrificed at Week 26. All animals administered urethane experienced transient decreased activity, unsteady gait, and impaired righting after administration which was related to the anesthetic effect of urethane. Skeletal muscle changes were present in all animals of all groups, consistent with a degenerative myopathy described in TgRasH2 mice. All animals treated with urethane had proliferative lesions in the lung (bronchiolo-alveolar hyperplasia, adenoma, and carcinoma) and spleen (hemangiosarcoma). All animals treated with MNU had atrophy of the stomach (gastritis) and squamous cell carcinoma as well as multi-centric lymphoma, consistently affecting the thymus. Results indicate that examining lungs and spleen at Week 16 from animals administered urethane, or examining stomach and thymus at Week 16 from animals administered MNU is sufficient to reliably demonstrate carcinogenicity in the positive control group.

1583 Biochemical Studies on Toxicity of Yoyo Bitters (A Polyherbal Preparation) on Kidney and Liver Functions of Wister Rats

Use of herbal preparations in the treatment of diseases especially in Asia and Africa is becoming increasingly popular. However, there is dearth of scientific evidence on the toxic effects and pharmacological claims of most of them. Toxicity of a popular Nigerian herbal preparation (Yoyo Bitters) on the kidney and liver of Wister rats was investigated over a period of forty-one days in Wister rats (cases) and forty others (controls) all weighing averagely 120gm. Cases were fed with normal rat chow and given the herbal preparation in a single dose of 200 mg/kg bwt. Control rats were given normal rat chow only. The NAS, alkaline phosphatase, ALT and AST were significantly higher in cases than in controls. The highest increase was observed in alkaline phosphatase (51% increase) followed by ALT (24% increase), AST (19% increase) and NAS (10% increase). The Urea, total protein, albumin, total bilirubin and creatinine had significantly higher values in cases than in controls. The highest increase was observed in creatinine (13% increase) followed by albumin (10% increase), total protein (10% increase) and total bilirubin (6% increase). The highest decrease was observed in urea (24% decrease) followed by total protein (14% decrease) and albumin (11% decrease). The ALT and AST activities were higher in male rats than in female rats while NAS, alkaline phosphatase and total bilirubin activities were higher in female rats than in male rats. In conclusion, the results showed that Yoyo Bitters has significant hepatorenal effects on Wister rats.
ALP, alanine amino transaminase (ALT) and Aspartate amino transaminase (AST) were also estimated as liver function indices spectrophotometrically in cases and controls at specific intervals of the study. Mean values ranged from 5.50±0.70 - 8.30±0.46; 7.50±1.80 - 24.90±10.00; 0.70±0.20 - 0.85±0.01 and 1.40±0.80 - 6.50±2.20 for plasma calcium, inorganic phosphorus, creatinine and uric acid in cases respectively. Values for inorganic phosphorus, creatinine and uric acid were significantly different. Mean liver function values ranged from 1.40±0.06 - 0.60±0.20 and 0.64±0.10 in cases against 0.92±0.20 and 0.27±0.20 in controls for total and conjugated bilirubin respectively. Mean enzyme activities ranged from 201±28 - 88±35, 172±100 - 52±23 and 426±71 - 146±90 in cases as against 340±51, 158±61 and 347±136 in controls for ALT, AST and respectively. A scattered plot and correlation analysis of the data showed a flat curve and no significant correlation in the levels of these parameters except in the uric acid which showed a significant proportional increase over the 42-day period of the experiment. Administration of this herbal preparation did not show a significant alteration in the function of the liver and kidneys and may not be an indicator for the changes in both glomerular and tubular functions of the kidney in the experimental animals. Observed hyperuricemia may be more of antioxidant properties of the preparation.

**1584 Development of a Nonchemical Stress Model for Environmental Studies: Effect of Maternal High-Fat Diet on Postnatal Cardiac Stem/Progenitor Cells**

Stem cell biology research has demonstrated a critical role of cardiac stem/progenitor cells (CSCs/CPCs) in heart homeostasis, injury repair, function, and disease susceptibility at all life stages. The impact of environmental toxicants and chemical stressors influences the effects which chemical and/or pollutant exposures may have on postnatal CSCs/CPCs is unknown. To address this uncertainty, research was conducted to examine the impact which maternal diet has on CSCs/CPCs levels in their offspring with intention of employing this model to study the effects of these AEDs on low frequency epileptiform spike activity. Following SE, individuals may develop spontaneous recurrent seizures (SRS) or epilepsy that often leads to severe neurological deficits and lower quality of life. Though dozens of US FDA-approved antiepileptic drugs (AEDs) are on the market, it is unknown which, if any, would be effective against NA-induced SRS. We designed this experiment to test five AEDs (levetiracetam, phenobarbital, valproate, carbamazepine, and clonazepam) in telemetry-instrumented mice over a 30-day period following a sublethal, supraconvulsant soman (GD) challenge. Starting 24 hours after SE, mice were repeatedly dosed with an AED or vehicle for 14 days, followed by a 14- day washout period. Dosing regimens were based on published pharmacokinetic data. Levetiracetam had no apparent effect on SRS number, duration, or onset of SRS. Although phenobarbital-treated mice exhibited a delay in SRS onset compared to vehicle, mice developed phenobarbital resistance prior to the end of the treatment period. Data are still being acquired on the effects of valproate, carbamazepine, and clonazepam on SRS activity. Continued analysis will focus on the effects of these AEDs on low frequency epileptiform spike activity. Although we have not found a suitable AED candidate to repurpose for our SRS treatment, we have developed a reliable animal model of treatment resistant epilepsy. With this animal model, AED candidates could be better characterized and more appropriately prescribed for epilepsy patients.

**1585 Increased Non-biliary Cholesterol Excretion during Alpha-Naphthylisothiocyanate (ANIT)-Induced Cholestasis in Mice**

Y. Tanaka1, T. Ikeda2, H. Ogawa2, and T. Kamisako1. 1Kindai University Faculty of Medicine, Osaka, Japan; and 2Tezukayama Gakuen University, Sakai, Japan. Sponsor: C. Klaassen.

Excessive cholesterol accumulation in the body promotes the development of atherosclerotic cardiovascular disease. Bile has been considered the main route of elimination of cholesterol from the body. However, recent evidence suggests that the small intestine plays a role in excreting serum cholesterol through a process known as transintestinal cholesterol excretion (TICE). During cholestasis, increased serum bile acids are excreted into urine and cause numerous adaptive changes in bile acid homeostatic gene expression in kidney as well as liver. Accordingly, it is hypothesized that non-biliary cholesterol excretion and changes in the expression of cholesterol homeostatic genes occur in extrahepatic organs during cholestasis. To test this hypothesis, eight-week-old male C57BL/6 mice were administered alpha-naphthylisothiocyanate (ANIT) (75 mg/kg po) and 72 hours later liver, kidney, duodenum, jejunum, ileum, blood, and fecal samples were collected. Total bilirubin, ALP, and ALT were elevated in serum of ANIT-treated mice. Bile acid and cholesterol concentrations in serum and liver were increased after ANIT. These data indicate that ANIT induces both cholestasis and hypercholesterolemia. Furthermore, fecal and urinary cholesterol concentrations were also increased 72 hours after ANIT. In liver, ANIT did not alter Abcg5, Abcg8, Npc1, Ldlr, and Srb1 mRNA expression compared to control mice. In duodenum, ANIT tended to increase the cholestero uptake Ldlr mRNA expression. In jejunum, ANIT increased the mRNA of Srb1 as well as Ldlr, and decreased mRNA expression of Abca1 and Abcg5. In ileum, ANIT did not alter mRNA expression of cholesterol transporters and receptors. In kidney, ANIT tended to increase Srb1, Npc111, and Abcg8 mRNAs. These data indicate that in addition of ANIT being cholesstatic it is also hypercholesterolemic. The induction of intestinal Ldlr and Srb1 and trends of induced renal Srb1 and Abcg5 may be adaptive responses to ANIT-induced cholestatic liver injury and responsible for the increased fecal and urinary cholesrerol excretion, respectively.

**1586 Evaluation of Repurposed Antiepileptic Drugs to Treat Spontaneous Recurrent Seizures in Instrumented Male C57BL/6 Mice following a Sublethal Soman Exposure**

D. L. Nguyen1, M. R. Eisen1, C. Aarding1, E. N. Dunn1, K. M. Haines1, A. N. Santoro1, P. M. Bodner1, C. A. Ondecie1, P. B. Dubie1, H. S. McCarren1, P. H. Beske2, and P. M. McNutt1. 1USAMRICD, Aberdeen Proving Ground, MD; and 2Battelle, Columbus, OH.

Exposure to nerve agent (NA) can result in rapid onset of generalized status epilepticus (SE), which if uncontrolled can cause permanent brain damage and death. Many efforts have focused on ways to stop the initial seizure, but few have addressed the long-term complications and complications of exposure. Following SE, individuals may develop spontaneous recurrent seizures (SRS) or epilepsy that often leads to severe neurological deficits and lower quality of life. Through dozens of US FDA-approved antiepileptic drugs (AEDs) are on the market, it is unknown which, if any, would be effective against NA-induced SRS. We designed this experiment to test five AEDs (levetiracetam, phenobarbital, valproate, carbamazepine, and clonazepam) in telemetry-instrumented mice over a 30-day period following a sublethal, supraconvulsant soman (GD) challenge. Starting 24 hours after SE, mice were repeatedly dosed with an AED or vehicle for 14 days, followed by a 14- day washout period. Dosing regimens were based on published pharmacokinetic data. Levetiracetam had no apparent effect on SRS number, duration, or onset of SRS. Although phenobarbital-treated mice exhibited a delay in SRS onset compared to vehicle, mice developed phenobarbital resistance prior to the end of the treatment period. Data are still being acquired on the effects of valproate, carbamazepine, and clonazepam on SRS activity. Continued analysis will focus on the effects of these AEDs on low frequency epileptiform spike activity. Although we have not found a suitable AED candidate to repurpose for our SRS treatment, we have developed a reliable animal model of treatment resistant epilepsy. With this animal model, AED candidates could be better characterized and more appropriately prescribed for epilepsy patients.

**1587 Validating Zebrafish for Safety Drug Screening: A Comparison of Zebrafish and Rodent Toxicity Data**

In recent years, the zebrafish has become a valuable model. It is gaining popularity in the field of safety pharmacology due to its unique biological advantages. There is a gap between high-throughput in vitro studies and low-throughput in vivo studies during the drug discovery pipeline. The use of zebrafish in drug screening could fill that gap and become an important asset to assess toxicity and efficacy of novel drugs. Zebrafish has, from early developmental stages, fully functional organs from a physiological point of view and large transparent progeny, which develops externally and make them ideal for non-invasive approaches, such as in vivo imaging. Despite these advantages, the use of zebrafish is still scarce in current drug discovery pipelines and requires further validation to achieve a full adoption by the regulatory agencies. Zebrafish assays will only be useful if they can show high predictive power. Thus, we used our toxicological data (LC50) obtained in zebrafish embryos and have compared with LD50 values obtained from rodents (mice and rats), to evaluate the predictivity of the model. Besides, we performed drug bioavailability studies of the same compounds in zebrafish embryos to address the role of drug permeability in toxicity assessment. The aim of this study is to examine how the covariance of zebrafish and rodent toxicity is influenced by factors such as compound type, absorption, metabolism and mechanism of toxicity. For this purpose, we have compared the effects of ten compounds administered in rodents (oral, intraperitoneal and intravenous) have been compared to our
drug incubation. For the compounds examined here, we have seen that drug incubation better correlates with LD50 values obtained via intravenous route, than with intraperitoneal or oral respectively. Furthermore, we have analysed if the log P (partition coefficient value could have any impact in the drug toxicity seen in the embryos. Our preliminary results suggest that even though there is no strong correlation between LC50 and log P, those compounds which are more hydrophilic (less lipophilic) and therefore more water-soluble tend to be less toxic than the ones which possess high log P values (more lipophilic, less hydrophilic, less water-soluble). Our results will allow placing the use of zebrafish-based drug screening in an even better position for biomedicine discovery purposes. More work is required, but we hope that this and other translational validation studies could help to promote the zebrafish as a potential alternative model to toxicology testing.

1588 Strength of Litter Effect and Litter Size Effect in Body Weight Data across Multiple Toxicity Studies in Harlan Sprague-Dawley Rats

In developmental and reproductive toxicology (DART) studies of toxic substances in rodents, characterization of dose effects can be confounded by clustering of responses by litter, which can occur due to shared genetics and shared maternal and lactation environments. Using an extensive National Toxicology Program (NTP) database, we present analyses of rodent fetal and pup body weights and their relation to litter size as the rat ages. The intra-class correlation (ICC), a measure of the strength of litter effect, is highest during the pre-weaning period, such that the effective sample size (ESS) is very close to the number of litters contributing pups. Over the first 100 postnatal days, ICC values decline yet stabilize at a value corresponding to an ESS that is closer to the number of litters than to the number of pups on study. Body weights show an inverse relationship with litter size during the pre-weaning period, providing evidence that competition for milk supply may be a key determinant of growth rate. When pup weights are adjusted for litter size, a litter effect is still evident during the pre-weaning period, indicating that siblings have more in common than just the fetus count in utero. These results show that the interpretation of toxicity studies should include appropriate statistical modeling of litter structure.

1589 Disease Sensitive and Resistant Mouse Strains Identified in a Mouse Aging Study

K. R. Shockley\(^1\), R. A. Herbert\(^1\), K. S. Janardhan\(^2\), A. R. Pandiri\(^1\), M. K. Volland\(^1\), B. A. Merrick\(^1\), and J. K. Dunnick\(^1\). \(^1\)NIEHS, Research Triangle Park, NC; and \(^2\)ILS, Research Triangle Park, NC.

Genetic variability is an important factor in age-related development of disease. The NIEHS/NTP has conducted a multistrain “Mouse Aging Study” to examine genetic diversity as a variable for development of non-neoplastic and neoplastic diseases (lesions). Ten mouse strains representing ~90% of genetic diversity in laboratory mice were selected for this study. Preliminary evaluations indicate that there is a strain dependent susceptibility for neoplasms of the liver, lung, uterus, ovary, mammary tissue, skeletal muscle, and lymphoid organs. The incidence of neoplastic lesions ranged from 10% - 87% in the 10 mouse strains aged for 2 years (corresponding to about 70 human years). The data from this study complements information in the Jackson Laboratory Mouse Phenome Database and the Mouse Tumor Biology Database. Current safety assessments based on only a few animal strains with limited genetic diversity do not fully capture the range of variations in disease susceptibility to environmental hazards and drugs. Data on background disease susceptibility from the Mouse Aging Study allows more appropriate selection of mouse strains for toxicity studies and enhances the ability to identify mouse models to characterize diseases associated with aging. This study can also contribute information that may be useful for identifying genetic variants that influence susceptibility or resistance to disease development.

1590 Optimized Methods for Irradiation and Chemical Myeloablation in NSG Mice Prior to Human Hematopoietic Stem Cell (Gene) Therapy

L. Kelamangalath\(^1\), J. Pellman\(^1\), R. Yoder\(^1\), B. McIntosh\(^2\), and T. Oppeneer\(^1\). Covance Inc., Greenfield, IN; Covance Inc., Madison, WI; and \(^3\)Biomarin Pharmaceutical Inc., Novato, CA. Sponsor: M. Sievert

NOD.Cg-Prkdcscid I2rgtm1Wjl/SzJ mice (NSG) remain the gold standard for cell mediated gene therapy using transduced human hematopoietic stem cells (HSCs). Nearly complete ablation of the bone marrow of NSG mice is critical for successful xenotransplantation of the transduced cells and can be evidenced by the identification of the transduced HSCs in the peripheral blood and tissues. In this study, bone marrow ablation was approached by two different methods following IACUC approval: one by exposure to gamma irradiation, the other by administration of busulfan, a clinically utilized myeloablating agent. Because mice susceptibility to irradiation varies between strains and with age, it is necessary to optimize the dose of irradiation to achieve nearly complete bone marrow ablation. For irradiation intensity optimization, male NSG mice of 9 to 12 weeks of age were exposed to irradiation intensities of 2.00, 2.25, 2.5, 2.75 or 3 Gys, and female mice of 9 to 12 weeks of age were exposed to 2.25 or 2.75 Gys under a gamma irradiator. Post-irradiation exposure, clinical signs and body weight were closely monitored for a period of 28 days. For the males, the LD\(_{50}\) was approximately 2.5 Gy with 4 out of 7 males surviving until Day 28. In females, 3 out of 4 females survived at 2.75 Gy and all survived at 2.25 Gy. Considered together, the data indicated that 2.25 Gy as optimal irradiation intensity in male NSG mice, and 2.5 Gy as optimal intensity in female NSG mice. Another approach for bone marrow ablation was by intravenous infusion of busulfan, a clinically used bone marrow ablating agent. Busulfan was administered intravenously at an optimal dose of 15 mg/kg/day in male and female NSG mice for 3 consecutive days approximately 24 hours apart; the last dose of busulfan was administered approximately 24 hours prior to the cell implantation. This dose of busulfan was well tolerated by NSG mice and nearly complete bone marrow ablation was evidenced by consistent cell engraftment in NSG mice. Thus, it can be concluded that busulfan administration provides a translatable approach for xenotransplantation.

1591 Establishment of a Small Nonhuman Primate Colony for Ethical Reuse of Animals in Preclinical Safety Studies, Including Small and Large Molecule Research

The intensified development of biologics has necessitated increased safety testing in Nonhuman Primates. Since biologic drugs are either substantially or fully humanized, the Nonhuman Primate (NHP) is often the most relevant model when predicting human safety. Another challenge posed by biologics concerns the development of antidrug antibodies (ADA) in response to drug exposure which typically precludes the re-use of an animal for safety assessment. All of this runs counter to our goal of minimizing the use of NHPs in preclinical development. To overcome these challenges a small non-terminal chronic testing NHP colony was established as a global platform to enable the re-use of NHPs across all therapeutic areas requiring chronic toxicity testing of both biologic and low molecular weight (LMW) compounds. In order to screen NHPs and determine their suitability/availability for reuse, a generic qualitative ELISA based ADA binding immunoassay was developed to identify ADA positive and negative samples from previously exposed animals. NHPs testing positive are no longer suitable for use in biologics studies but are made available for LMW studies. Animals testing negative can be put on study using an unrelated biologic to which they have not been previously exposed or undergo a drug specific ADA screen prior to being dosed with a previously tested compound. To date the NHP colony has been expanded to contain 55 animals. Out of the 39 cyno samples collected from the colony which directly relates to the number of animals put on large molecule studies approximately 6 samples have tested positive for ADAs. These results indicate that 33 (~80%) animals can be reused for other studies. The development of this innovative screening assay and the reuse of animals for chronic safety testing represents a potential reduction in the number of NHPs used in preclinical development.
Electrolyte Quantification in Aqueous and Vitreous Humor of Common Preclinical Species

Ocular health assessment supporting standard preclinical ocular examination has generated interest in ocular toxicology testing. Few studies have quantified aqueous and vitreous humor electrolyte contents across species. This study aimed to quantify electrolytes in aqueous and vitreous humor from four preclinical species. Aqueous and vitreous humors were collected from rabbits (n=7), dogs (n=9), monkeys (n=10) and minipigs (n=7). Vitreous and aqueous humors were analyzed by Cobas 6000<sup>®</sup> c (plasma/serum mode).

Electrolyte concentrations (mmol/L) in aqueous and vitreous humor were comparable between species. Vitreous electrolyte concentrations were: phosphorus (0.3±0.07 to 0.3±0.19); calcium (1.4±0.18 to 2.3±0.33); sodium (132.8±16.5 to 157.0±17.5); potassium (5.1±0.57 to 5.3±0.36); chloride (99.4±14.53 to 116.18±5.48). Aqueous electrolyte concentrations were: phosphorus (0.72±0.05 to 0.90±0.08); calcium (1.25±0.10 to 2.18±0.04); sodium (142.00±6.11 to 153.67±4.58); potassium (3.8±6.06 to 5.26±0.99); chloride (97.80±4.07 to 116.60±2.97). Humor concentrations of sodium, potassium and chloride were generally similar to species-specific serum levels; however, phosphorus and calcium concentrations were slightly below serum levels.

This study provided a baseline/reference of humor electrolytes. Electrolyte measurement from aqueous and vitreous humor could be a useful parameter in the assessment of ocular toxicity in toxicology studies. Electrolyte composition of these anatomical segments may also have implications relative to test compound chemistry after intra-ocular delivery.

A Simple In Vivo Model for Monitoring CYP3A Induction and Inhibition

J. J. Cali, D. Ma, and A. Niles. Promega Corporation, Madison, WI.

In vitro cytochrome P450 (CYP) assays are used to predict in vivo drug interactions caused by CYP inhibition or induction. Inhibitors are typically identified in biochemical assays and inducers in cultured cells such as primary hepatocytes. However, it is desirable to confirm the predictive implications of in vitro results in an animal model. As CYP3A enzymes are prominent drug metabolizers involved in drug interactions in humans and animals we set out to establish a simple model for monitoring CYP3A induction and inhibition in vivo. To that end we used 2-(4-diisopropoxymethyl)-4,5-dihydrothiazol-2-yl)benzod[<i>d</i>]thiazol-6-ol (luciferin isopropyl acetal) as a probe CYP3A substrate in live mice. This probe is converted by CYP3A enzymes in vitro to a D-luciferin ester that is detected by luminometry in a luciferase formulation. Reactions with luciferin isopropyl acetal are highly CYP3A selective in humans and rodents and it was also used for bioluminescent imaging of cyto3a activity in the livers of live mice expressing a luciferase transgene. From this background we reasoned that endogenous cyto3a activity in wt mice (e.g. in liver) would convert the probe and if there is significant renal elimination of the reaction product it would appear in urine. This would be detectable by luminometry when urine samples are mixed with a luciferase formulation. The initial rate of metabolite appearance would reflect the cyto3a conversion rate. A maximum tolerated dose study with FVB/N mice showed no signs of probe toxicity, indicating it is well tolerated after IP injection. FVB/N urine samples did produce luminescence after IP probe injection indicating the probe is converted to a luminogenic product that is eliminated in urine. Signals peaked in samples collected at about 1 hour post injection and declined thereafter. Pretreatment of the mice with the cyto3a inducers pregnenolone 16a contraceptive or dexamethasone enhanced AUCs from samples collected in the first 3 hours post probe-injection. In contrast the cyto3a inhibitor troelodamycin reduced AUCs. To control for urine concentration, luminescence from these samples was normalized to urinary creatinine levels. The appearance in urine of a luminogenic product of the cyto3a-selective probe and modulation of the initial elimination rate by cyto3a induction and inhibition is consistent with cyto3a-dependent probe metabolism. This supports the notion that luciferin isopropyl acetal can be used as an in vivo probe for predicting drug interactions due to cyto3a induction or inhibition.

Assessments of Sexual Maturity in Three Lineages of Miniature Swine

S. E. Boley, D. F. Brocksmith, and G. F. Bouchard<sup>1</sup>, Sinclair Research Center, LLC, Auxvasse, MO; and Sinclair Bio Resources, LLC, Auxvasse, MO.

Sexual maturity can have multiple definitions depending on the area of research being discussed. Medical reproduction can be defined by the peak of reproductive capabilities, however, in toxicology studies it can be defined as the presence of reproductive gametes. The main objective of this study was to determine the onset of sexual maturity in males and females of three lineages of miniature swine, namely, Hanford, Sinclair S-1, and Yucatan, from data gathered in toxicology studies. A second objective was to evaluate the predictability of clinical measurable variables in identifying the onset of sexual maturity in the same strains of miniature swine. For the purpose of this study, sexual maturity was defined as having spermatogonial and spermatozoa in the epididymis in the males or the presence of corpora lutea in the female from histological evaluation of the testes or ovaries. The retrospective evaluation of histological findings of control males and females of different ages assigned to toxicology studies were assessed for sexual maturity. We found that all females reached sexually maturity before 16-19 wks of age regardless of the lineage. Males had reached sexually maturity by 19 wks for Yucatans, and 22 wks for Sinclair S-1 and Hanford. Several other clinically measurable variables were assessed as well from satellite animals and compared to the histological findings in an effort to determine the predictability of each variable in predicting the onset of sexual maturity. In males, testicular weight and the presence of preputial sperm appeared to be good indicators of sexual maturity. However, in the female, many clinical measurable variables such as vulvar measurements, swelling and discharge were found to be unreliable. In addition, estrus behavior is not a good indicator in miniature swine. The first objective of this study was reached in that the sexual maturity in these three lineages of miniature swine is well defined. We have shown that there are many methods of assessing sexual maturity in miniature swine, however many of them have been shown to be unreliable, especially for the female. Developing new clinical methods for assessing sexual maturity will be critical as the miniature swine increases in popularity for translational biomedical research.

Miniature swine have many advantages over other species for biomedical research such as their anatomical and physiological similarities to humans. However, one of the disadvantages of the miniature swine for biomedical research such as pharmaceutical toxicology can be the size of the animal. With a larger size test animal, a larger amount of test material is required to complete the toxicology study thus increasing cost of the study. The objective of this study was to utilize genomic selection, phenotype and body weight, to reduce the total body mass in adult Sinclair S-1 miniature swine. Initially, a large baseline single nucleotide polymorphism (SNP) bank was established for each breeder of the Sinclair miniature swine colony. The SNPs were then used to calculate genomic estimated breeding values for body weight of the breeding animals. Finally, we developed a computer algorithm to manipulate a large dataset of phenotypic and genomic data to determine the optimal mating combinations to result in a reduction in adult body mass. Utilizing this genomic selection criteria, we have observed an 8% decline in body size per year in the Sinclair S-1 miniature swine. After 5 years of this genetic selection, the body weight reduction outcome of the 4th generation at 6 months of age, is a significant (p<0.05) reduction in body weight in both males (35.1%) and females (25.1%). Further concurrent studies are being conducted to standardize the clinical pathology, biometric and reproductive variables, as well as validation studies for compound kinetics, dermal irritation, and feeding regimen assessment. We have developed a genomic selection tool based on body mass to down size the Sinclair S-1 miniature swine over the course of the next several generations. As the pig becomes the accepted translational model for biomedical research, we believe that strategically downsizing the Sinclair S-1 miniature swine will allow it to be the model of choice for preclinical toxicology studies.
**1596 Cardiac Ultrastructure Damage and Pathological Remodeling after Halogen Inhalation in Rats**

S. Ahmad, J. Masjoan Juncos, W. Bradley, W. Chih-Chang, I. Zafar, P. Powell, N. Mariappar, L. Dell’Italia, and A. Ahmad, University of Alabama at Birmingham, Birmingham, AL.

We have demonstrated that inhaled halogen gases cause extensive acute cardiac injury and dysfunction. Whether the acute injury persists and causes long-term effects in the heart is unknown. This gap in knowledge limits the potential for development of effective therapies. We sought to determine the role of halogen/bromine (Br) in causing delayed cardiopulmonary dysfunction and to establish the potential underlying mechanisms and effects on cardiac function and ultrastructure. Br, inhalation (600 ppm, 45 min) in adult Sprague Dawley rats caused acute (3-24h) increases in bronchoalveolar lavage fluid (BALF) protein and circulating troponin I, fatty acid binding protein (fHABP) and NT-proBNP. BALF protein returned to normal at 48h after exposure. However, troponin, fHABP and NT-proBNP remained elevated at 28d post exposure. Heart weight/body weight ratio was increased at all time points suggesting cardiac hypertrophy. Immunohistochemistry revealed extensive cardiac tissue damage and increased endocardial fibrosis. Significant increase in collagen was demonstrated by hydroxyproline assay in the bromine exposed rat hearts at 28 d after exposure. Echocardiography revealed significant diastolic and systolic dysfunction in rats surviving bronchoalveolar inination at 7-28 d after bromine inhalation. Thus, a single exposure of bromine may have persistent chronic adverse effects on the heart.

**1597 Maternal and Embryo-Fetal Historical Background Control Data in the Hsd: Sprague Dawley Rat**

M. Horn¹, D. Williams², and R. Parker². ¹Envigo, Indianapolis, IN; and ²Envigo, East Millstone, NJ. Sponsor: L. Conney

Maternal and embryo-fetal historical background control data supports improved interpretation of lesions in reproductive toxicity studies. A maternal and embryo-fetal toxicity study was performed to generate historical background control data in the Hsd:Sprague Dawley rat model. One hundred previously nulliparous and virgin time-mated female Sprague Dawley rats, allotted in four subsets of 25 rats each, were housed under standard housing and husbandry conditions with ad libitum access to a standard diet (18% protein, 6% fat) and water. Rats were administered tap water (10 mL/kg body weight) by oral gavage once daily from gestational day 6 to 17. Body weight, food consumption, and clinical observations were monitored throughout the in-life phase of the study. On gestational day 20, animals were euthanized and submitted for Cesarean section and necropsy. A macroscopic postmortem evaluation was performed on all animals, including counts of corpora lutea and implantations and uterine weights. Fetuses were removed, weighed, sexed, and examined externally for defects as well as soft tissue abnormalities and skeletal anomalies. Placentas were examined and weighed. One hundred dams were pregnant and 100 litters were evaluated. There were 1,488 fetuses examined externally; 698 had fixed visceral evaluations and 790 fetuses had skeletal evaluations. Detailed analysis of maternal data, including body weight, food consumption, and pregnancy outcome will be presented. Fetal data including uterine and placental weights, in addition to fetal examinations, including external, soft tissue (visceral), and skeletal will also be presented. These data support the use of the Hsd:Sprague Dawley rat as a valuable toxicity model and will assist in interpretation of lesion data in future studies with this model.

**1598 Strain-Chemical Curation at the Rat Genome Database**

S. Wang¹,², J. S. Lauderkerk¹,², T. G. Hayman¹,², J. R. Smith¹,², M. Tutaj¹,², M. Hoffman¹, M. A. Tutaj¹,², M. R. Dwinell¹, and M. Shimoyama¹,². ¹Medical College of Wisconsin, Milwaukee, WI; and ²Marquette University, Milwaukee, WI. Sponsor: Y. Huang

Rats have been used as experimental models for many decades to study physiological and pathological processes. To facilitate the use of rat data derived from these models, the Rat Genome Database (RGD) has endeavored in qualitative and quantitative curation of rat strain data using controlled vocabularies. The strain-associated antigens are integrated with genes and alleles for comprehensive query at the RGD. For example, from the hypertension disease model SS-Pleko7mHSd1/1, users can find the disease-associated gene Plekha7 mutant allele and associated phenotypes in qualitative terms or quantitative measurements. To expand the scope of strain curation, RGD is now launching a project to target rat strains and chemical/drug curation. The project is focused on curating mutant rats, either spontaneous or genome-edited, which exhibit drug/chemical-induced phenotypes different from wild type rats. Examples are the spontaneous LE/OIrBarth rat strain and the zinc-finger nucleases-induced F344-Nle21emm/++ rats. Their altered susceptibility to inducing agents is captured by associating inducing agents, rat strains, inductions, phenotypes and quantitative measurements for these phenotypes in the database. The incorporation of chemical-induced qualitative phenotypes and quantitative measurements of mutant rat strains at RGD will empower researchers to make the best use of publicly available data.

**1599 Evaluation of the Potential for Fibrous Talc to Cause Mesothelioma Based on Available In Vitro and In Vivo Animal Studies**

D. G. Dodge¹, and M. K. Peterson². ¹Gradient, Bend, OR; and ²Gradient, Leavenworth, WA.

Elongate mineral particles (EMPs), also sometimes called mineral fibers, refer to any mineral particle with a length-to-width ratio of at least 3:1 and a length ≥5 μm. Asbestos is an EMP and, depending on the type, has long been causally related to the development of mesothelioma in humans. Fiber dimensions, durability, and surface characteristics are thought to be some of the key determinants of asbestos carcinogenicity. Experiences with asbestos have generated interest in the potential for non-asbestos EMPs to pose cancer risk, including mesothelioma, in humans. Asbestos-like EMPs used in cosmetic applications have a predominantly plate-like (non-EMP) structure, while EMPs mined for industrial applications can be found in the form of long, thin fibers that meet the definition of an EMP and, further, can be of the more specific dimensions thought to be important for asbestos to cause mesothelioma. We have identified studies in which historical samples containing fibrous talc have been characterized for mineral composition and dimensions using various analytical methods (e.g., energy dispersive spectroscopy) and that have been employed alongside asbestos-containing samples in in vivo implantation and/or in vitro experiments designed to examine outcomes relevant to mesotheliogenic potential. These studies provide evidence that fibrous talc, including fibrous talc in samples where the dimensions are consistent with the most potent forms of asbestos for inducing mesothelioma, does not cause mesothelioma or other relevant outcomes in experiments where asbestosform amphiboles did. These findings are consistent with animal and epidemiology evidence in supporting that talc, unlike some types of asbestos, does not possess the important characteristics sufficient to cause mesothelioma. These findings also support that there is more to EMP pathogenicity than fiber dimensions, such as mineral type and crystal structure.

**1600 Intratubine Infusion of AMD3100 in Ewes: Elucidating the Importance of CXCL12 at the Fetal-Maternal Interface**

S. Z. McIntosh, K. E. Quinn, A. K. Ashley, and R. L. Ashley. New Mexico State University, Las Cruces, NM.

Early pregnancy is characterized by complex interactions between fetal trophoblast cells and maternal endometrium, which direct major peri-implantation events including localized inflammation and endometrial modifications to establish proper placental development. Because pro-inflammatory mediators are important for conceptus interdigitation in endometrium, a better understanding of the molecular pathways regulating this localized inflammation is needed to advance knowledge of the process by which the endometrium becomes receptive to embryonic implantation. We identified CXCL12 as a critical driver of placental angiogenesis, but this pleiotropic chemokine and its receptor, CXCR4, are also important to cell survival and proliferation as well as inflammation, and may facilitate uterine receptivity. As such, we hypothesized that CXCL12 regulates endometrial inflammation during implantation in ewes. We demonstrated that CXCL12 stimulates TNF production in cultured ovine endometrial cells. Further, to establish functional implications of CXCL12 at the fetal-maternal interface, we developed an in vivo model to inhibit local signaling of this chemokine-receptor pair using a potent CXCR4-specific inhibitor, AMD3100. Osmotic pumps were surgically installed on day 12 of gestation in sheep and delivered AMD3100 or PBS directly into the uterine lumen ipsilateral to the corpus luteum for 7 days. On day 20 of pregnancy, endometrial tissues were collected and evaluated for inflammatory mediators and endometrial modifications using western blotting and immunohistochemistry. Post-infusion, protein abundance of TGF81 in aglandular endometrium was less (p<0.05) in ewes receiving AMD3100 than control, while synthesis of all other cytokines assessed was similar. Conversely, glandular endometrial expression of IL12 and IFNG following local AMD3100 infusion. Immunohistochemical observation of endometrial epithelial morphology revealed a persistence of co-
1601 A Six-Month Subcutaneous Infusion Qualification in Beagle Dogs

R. Tavcar1, E. Langlois-Forget1, J. Haruna1, S. M. Maghezzi2, S. Author1, and B. Forster1.
1 Citoxlab North America, Laval, QC, Canada; and 2 Citoxlab France, Evreux, France.

The ability to continuously administer drugs subcutaneously is critical to attain appropriate exposure of some pharmaceuticals which offer advantages over traditional administration routes in preclinical development models. The objective of this study was to assess the tolerance and background observations following continuous subcutaneous infusion of saline via a surgically implanted catheter in Beagle dogs for up to 6 months. Five male and five female Beagle dogs underwent surgical implantation of a medical grade subcutaneous catheter. The tip of the catheter was positioned in the lumbar region and the catheter was exteriorized at the dorso-cervical region through a subcutaneous tunnel via a cath-in-cath/port system. Normal saline was continuously infused at a rate of 0.1 mL/hour generally for 1 month (3/sex) or between 4 and 6 months (2/sex). Animals were evaluated for clinical signs, body weight, limited clinical pathology and histopathology. The dorso-lumbar area facilitated clinical evaluation of the dosing site and the infusion rate was achieved with dosing accountability values generally within acceptance criteria (+/- 5%). The animals showed normal bodyweight gain, and limited clinical pathology changes. Results obtained from this study provided sufficient evidence that the surgically implanted catheter was well tolerated and did not result in unexpected background changes other than those normally observed with surgically implanted catheters. Specifically, a mixed cellular inflammatory reaction was observed surrounding the subcutaneous catheter infusion site. There was no difference in the inflammatory reaction following saline infusion over a period of 4, 5 or 6 months.

1602 Evaluation of Aflatoxin B1-Induced Human Hepatotoxicity in Humanized Liver Chimeric Mice and Fresh Human Hepatocytes Isolated from Chimeric Mice

Y. Ishida1,2, C. Yamasaki1, Y. Yoshizane1, S. Furukawa1, A. Yanagi1, Y. Ogawa1, and C. Tateno1,2.
1 PhoenixBio Co., Ltd, Higashi-Hiroshima, Japan; and 2 Liver Research Project Center, Hiroshima University, Hiroshima, Japan.

Chimeric mice with humanized livers have been considered a useful in vivo model for not only drug metabolism and pharmacokinetics studies, but also for the prediction of human hepatotoxicity. Recently, we reported that fresh primary human hepatocytes isolated from chimeric mice (PX-B cells) showed high platability and could be cultured for several weeks with high hepatic function in a conventional 2D culture condition. In the present study, we examined whether humanized liver mice and PX-B cells have the potential to be used for evaluation of human hepatotoxicity induced by aflatoxin B1 (AFB1), a well-known compound that shows species-specific hepatotoxicity. First, control (CD1) mice and CDNA-uPA/SCID mice with humanized livers showing high replacement index (>70%) were administered corn oil, AFB1 (3 mg/kg), and carbon tetrachloride (CCL4, 50 mg/kg) respectively for 7 days. CCL4 treatment induced increase in serum ALT activity and body weight loss in both control mice and humanized liver mice. In contrast, AFB1 treatment promoted the elevation of serum ALT activity and body weight loss in chimeric mice with humanized livers, but not in control mice. The results of human ALT1-specific ELISA revealed that significant increase in serum human ALT1 was induced by AFB1 treatment but not CCL4. Consistent with these results, histological examination indicated that AFB1 treatment promoted vacuolization in human hepatocytes, but not in mouse hepatocytes in the chimeric mice livers. To examine AFB1 toxicity, PX-B cells were cultured with or without AFB1 for 7 days. The cytotoxicity of AFB1 was evaluated by real-time cell analysis (RTCA) and WST-1 assay. The results of RTCA indicated that AFB1 showed dose-dependent cytotoxicity to PX-B cells, and the LC50 value on day 3 (0.83 μM) was comparable to that of primary human hepatocytes reported in previous studies. The results of WST-1 assay suggested that 7 days of AFB1 treatment showed more severe cytotoxicity to PX-B cells than treatment with AFB1 for 1 or 3 days. Treatment with aminobenzotriazole (500 μM), a nonspecific CYP inhibitor, could reduce AFB1 cytotoxicity, indicating that AFB1 metabolite(s) reduced the viability of PX-B cells. These results suggest that chimeric mice with humanized livers and PX-B cells are useful in vivo and in vitro tools to predict human hepatotoxicity, respectively.

1604 Electronic Waste: An Evolving Global Health Concern and Risk Assessment Challenge

B. Sonawane.
TRACS, LLC, North Potomac, MD.

As the demand for electronics increases, the amount of electronic waste (e-waste) steadily accumulates at a rapid pace. An estimated 65 million tons of e-waste were created globally in 2017, with further increases projected in the years ahead. E-waste is composed of an alarming combination of several hazardous substances. A systematic review looking at health outcomes related to e-waste exposure showed that increases in spontaneous abortions, stillbirths, and premature births, and reduced birth weights and birth lengths, are associated with exposure to e-waste. Direct and indirect exposures are a threat to human health and vulnerable groups such as fetuses, children, pregnant women, the disabled, and workers in the informal sector. Because of this threat, they need specific protection. The majority of e-waste recycling is conducted in low-to-middle-income countries informally, by workers using primitive techniques such as burning, with little or no safeguards in place for human and environmental health. This session will provide an overview of the e-waste problem and present research findings from studies conducted in India and Vietnam. The session will end with a presentation that will discuss the multi-factorial problem of e-waste due to limited studies and the multiple routes of exposure to multiple classes of hazardous substances in the context of vulnerable populations. These presentations will inform a panel that will discuss risk assessment challenges (exposures to a mixture of chemicals from multiple sources) and provide a forum to discuss strategies to reduce exposures to e-waste.
1605 Federal Efforts in Rapidly Assessing Hazard and Risk to Emerging Threats and Emergency Response

M. J. Devito, NIEHS/NTP, Research Triangle Park, NC.

Under the authorization of a variety of federal statutes, several federal agencies are involved in protecting public health from emerging environmental threats and in emergency response. These federal agencies have developed programs that can provide regulators with a rapid assessment of the potential hazard and risk associated with exposures in times of emergency response. These approaches combine rapid literature assessments, computational toxicology, and in vitro toxicology. These same approaches are also being applied to evaluate emerging issues related to chemical exposures. This session will highlight these efforts at the US Department of Defense, the Agency for Toxic Substances and Disease Registry, the US EPA, and the NIEHS National Toxicology Program.

1606 Immune-Epithelial Cell Crosstalk in Lung Toxicology and Disease

A. Venosa, University of Pennsylvania, Philadelphia, PA.

Understanding the mechanisms involved in mediating the pollutant-based deficits in pulmonary health remains an area of continued interest within SOT and in the field of public health. The lung represents a unique toxicological target due to its continuous exposure to the gaseous components of the environment and its function as a major first pass organ. The environment of the lung surface is a unique system consisting of both barrier and immunological defenses. A key aspect of the system is the interaction between resident cells of the lung (both parenchymal epithelial cells and resident immune subsets) and recruited inflammatory cells. It is the goal of this session to address the molecular mechanisms involved in the resident/recruited response to toxicants. Therefore, the session will highlight current developments in the fields of lung biology, immunotoxicology, and pharmacology. The pulmonary response to toxicant exposure consists of a number of complex processes, including direct and indirect inflammatory, injury, inflammation, and resolution. Much of this response is regulated by the resident cells of the lung surface, including both type I and type II epithelial cells and the alveolar macrophages. Proper recruitment and activation of circulating inflammatory cells is essential to mount the appropriate inflammatory and resolution responses. Therefore, epithelial-immune crosstalk is critical in the regulation of the pulmonary response to toxicants. To this end, high-throughput phenotyping of resident and infiltrating cells has highlighted novel pathways involved in cell-cell communication during progression and resolution of lung injury.

1607 Alveolar Type II Cells Initiate and Modulate Inflammation in Lung Surfactant

A. Venosa, University of Pennsylvania, Philadelphia, PA.

The missense isoleucine to threonine substitution at position 73 (I73T) in the Surfactant Protein-C (SP-C) gene, an alveolar type-2 cell (AT2) restricted protein, has been linked to sporadic and familial cases of idiopathic pulmonary fibrosis (IPF). This disease is associated with intermittent inflammatory episodes, termed “acute exacerbations”, marked by altered gas exchange, alveolitis, and diffuse alveolar damage. To model lung injury resulting from epithelial AT2 cells dysfunction, we generated an inducible SP-C-I73T transgenic mouse. Tamofoxifen administration to SP-C-I73T mice resulted in early increases in mutant spfctc73T mRNA and proSP-C-I73T protein expression accompanied by diffuse lung injury, vascular leak, increased BAL cell counts, and significant mortality. By 6wk, lungs of surviving SP-C-I73T mice showed marked alveolar septal thickening, diffuse collagen deposition, and foci of aSMA+ cells consistent with IPF phenotypes. The immunohistochemistry analysis of AT2 from SP-C-I73T mice revealed early and persistent (3-14d) epithelial expression of a wide array of recruitment factors including MCP-1, IL-5, Eotaxin, IL-6, CCL-17, and KC, findings corroborated by ELISA analysis of lung BAL. Flow cytometry was adopted to temporally characterize the effects of AT2 cell dependent recruitment on effector cell crosstalk. SP-C-I73T induction was associated with significant reduction in SiglecFhiCD11bloC64hiCD11chi resident macrophages, paired with transient (3-7d) reduction in expression of the antiinflammatory receptor CX3CR1. This was mirrored by sequential accumulation of Ly6C+ monocytes (3d), Ly6G+ neutrophils (7d) and SiglecFhiCD11blo eosinophils (2wk) in the lung. PCR analysis of BAL cells and tissue immunohistochemistry confirmed phenotypic shift from proinflammatory (iNOS and IL-6) at 3d, to an antiinflammatory/profibrotic activation state (Arg1, FIZZ-1) at 2wk. Pharmacological depletion of resident macrophages (ltd.) and infiltrating monocytes (i.o.) with clodronate liposomes revealed that resident immune cells are protective in epithelial cell injury, while peripheral Ly6Chi monocyte may worsen injury outcome. These data demonstrate that this IPF model is a valid tool for examining epithelial/inflammatory crosstalk and thus provides a novel tool to characterize the inflammatory response to toxicant induced epithelial cell injury.

1608 Extracellular Vesicle: An Emerging Mediator of Intracellular Crosstalk in Lung Inflammation and Injury

Y. Jin. Boston University School of Medicine, Boston, MA. Sponsor: A. Venosa

Acute lung injury (ALI) / acute respiratory distress syndrome (ARDS) is a highly complex process which can be triggered by various stimuli, including both non-infectious (sterile) and infectious ones. Inflammatory lung responses are one of the key features in the pathogenesis of this devastating syndrome. How ALI/ARDS associated inflammation is developed remains incompletely understood, particularly after exposure to sterile stimuli. Emerging evidence show that extracellular vesicles (EVs) regulate intercellular communications and inflammatory responses in various diseases. We characterized the generation and function of pulmonary EVs in the setting of ALI/ARDS, induced by sterile stimuli (oxidative stress, cigarette smoke or acid aspiration) and infections (LPS/gram negative bacteria). EVs detected in the broncho-alveolar lavage fluids (BALF) were highly upregulated after exposure to both types of stimuli. After sterile stimuli, alveolar type-1 epithelial (ATI) cells were the main source of the BALF EVs. Interestingly, infectious stimuli-induced BALF EVs were mainly derived from alveolar macrophages (AMs), rather than epithelial cells. Functionally, BALF EVs generated in both the non-infectious and infectious ALI models promoted the recruitment of macrophages. Furthermore, BALF EVs differently regulated the cytokine productions, TLR expressions and inflammatory mediators in AMs in vivo. Regardless of their sources of generation, BALF EVs significantly contributed to the development of lung inflammation in both the “sterile” and “infectious” ALI. Collectively, our results provide novel insights on the mechanisms by which EVs regulate the development of lung inflammation in response to sterile “infectious” stimuli, potentially providing novel therapeutic and diagnostic targets for ALI/ARDS.

1609 To Each Their Own: Molecular Mechanisms of Inter-Individual Variability in the Effects of Inhaled Toxicant Exposure

S. McCullough, US EPA, Chapel Hill, NC.

Traditional approaches to identifying susceptible populations have relied on factors such as age, genotype, and disease status to explain variability in exposure outcomes; however, these are neither sufficient to faithfully identify
differentially responsive individuals nor are they modifiable factors that can be leveraged to mitigate the effects of toxic exposures. The epigenome is dynamic and shaped by an individual’s environment. We previously determined that the ozone-mediated induction of pro-inflammatory genes IL-8, IL-6, IL-1a, and IL-1β is dependent on the concerted activation of the EGRF/MEK/ERK and MKK4/p38 mitogen activated protein (MAP) kinase pathways in primary human bronchial epithelial cells (pBECs). We then validated these findings in vivo by comparing the activation of cellular networks in bronchial epithelial cells collected from healthy volunteers following controlled exposure to filtered air or ozone. As effector kinases, activated ERK and p38 translocate into the nucleus to drive changes in gene expression. We hypothesized that the impact of these signals on exposure-induced gene expression was mediated by epigenetic modification states within the regulatory regions of exposure-induced genes. We then characterized the relationship between the baseline abundance of six epigenetic markers with established roles as key regulators of gene expression - trimethyl histone H3 lysine 4, acetyl H3K27, p38/MEK/ERK phosphorylated (p38/MEK/ERK), acetyl/ubiquitylated histone H3 (H3K27, polyubiquitinylated H3), dihydroxy methyltetrahydrofolic acid (dihydroxy methyltetrahydrofolic acid) - and the variability in the O3-induced expression of inflammatory and oxidative stress genes in an ALI model using pBECs from a panel of donors. The relationships that we observed led to our proposal of the “Epigenetic Seed and Soil” model in which the baseline abundance of particular chromatin modifications within the regulatory regions of specific toxicant-responsive genes correlates with the magnitude of their exposure-mediated induction. The model is also applicable to the use of baseline epigenetic data to predict exposure responses in cell and tissue types throughout the body. Identifying the role of the epigenome in toxicant responsiveness will provide an additional dimension to our understanding of the mechanisms underlying inter-individual variability in exposure effects and provide new insights into identifying populations.

1612 Patterns of Co-exposure and Its Implications for Understanding the Health Effects of Mixtures

T. Webster. Boston University School of Public Health, Boston, MA.

While current chemical testing tends to focus on individual chemicals, the exposures that people actually experience involve mixtures of chemicals. The number of mixtures that can be formed from the thousands of environmental chemicals is enormous, and testing all of them would not be realistic. In recent years, the ongoing revolution in exposure science and analytic chemistry (e.g., non-targeted analysis) is permitting better assessment of exposures to more and more chemicals at lower cost. It appears likely that we will be facing the biggest data challenge in exposure science in the not very distant future, and novel statistical methods are needed for analyzing these data. Collaboration between mixtures toxicologists and exposure scientists has great promise. Exposure science has a very important role to play by (1) determining the combinations of chemicals to which people are actually exposed, removing the limiting problem facing toxicologists; (2) identifying highly correlated exposures that might be better studied using whole mixtures methods than component-based methods; and (3) providing information needed by epidemiologists studying exposure to mixtures. A critical problem is understanding the patterns of exposure; for example, which exposures tend to occur together and how does this tendency depend on demographic and other factors? This session will bring together exposure scientists and mixtures toxicologists to examine methods for analyzing patterns of co-exposures; apply them to large datasets, such as National Health and Nutrition Examination Survey (NHANES) biomonitoring data and personal care product purchasing database; and discuss their implications for research on the health effects of exposure to mixtures in toxicology and epidemiology.

1610 Mechanisms of Exposure-Based Injury in the Resident Tissues of the Lung

L. Van Winkle. University of California Davis, Davis, CA.

Lung injury and repair incorporates complex interactions that integrate across the multitude of tissues and cells in the lung. Key to these responses are integrated signals between immune cells and the lung epithelium. In the lung there are two anatomically distinct epithelia: conducting airways and alveolar epithelia. The conducting airway epithelia has a unique composition and consists of a subpopulation of sensory cells such as Club and Clara cells that sit on a layer of extracellular matrix surrounded by attenuated fibroblasts forming a unit called the epithelial mesenchymal trophic unit. Similarly the alveolar compartment consist of AT1 and AT2 epithelial cells that are in close apposition to fibroblasts but also endothelium. Frank epithelial toxicity is a component of the in vitro exposure-based injury and can be influenced by cell type, cell state (age, sex, prior exposure, antioxidant status) and location within the lung. In mice exposed acutely to inhaled naphthalene, age and sex influence the degree of injury, with female exhibiting 4 fold more epithelial damage in proximal airways at 3 weeks of age than at 1 week of age, while males are protected. The age at time of exposure can also significantly influence the degree of injury following inhalation of particulate matter and this has been shown to be related to the ability of the epithelium to generate an effective anti-oxidant response. For example, neonatal rats are more susceptible to toxicity from ultrafine PM leading to decreases in airway epithelial glutathione pools that are not seen in adult rats. In addition to outright toxicity, exposure can change the steady state of the lung and initiate metaplasia, proliferation and regeneration of tissue components. Mucous metaplasia in rodents is a common response to ozone exposure. For epithelial cells in the lung one of the earliest changes in response to injury is in the distribution, abundance and type of secretory protein production which is regulated not only by the toxicant but also by the type and state of inflammation. Regulation of secretory protein expression is well understood in surfactant protein D expression. Specific examples from injury and repair models involving a variety of toxic exposures including nanoparticles, ozone, naphthalene and PM will be used to support key points.

1611 Inflammatory Responses of Resident and Recruited Immune Cells to Inhaled Toxicants

K. Gowdy. East Carolina University, Greensboro, NC.

Macrophages and monocytes are present in tissue as distinct populations with unique functional roles. In the lung, the macrophage populations include alveolar and interstitial macrophages whereas during inflammation, there is an influx of exudative/infiltrating macrophages that are derived from circulating monocytes. During tissue injury and inflammation, these myeloid cells have diverse and nonredundant roles in both the initiation of inflammation as well as the resolution through their production of lipid mediators. Evolving research has provided insight that inhaled toxicants (ozone, cigarette smoke, particulate matter) can alter the pulmonary lipid metabolism, producing more proinflammatory lipid mediators (prostaglandins, leukotrienes) and suppressing the production of specialized proresolving lipid mediators (protectins, maresins, resolvins). Exposure to inhaled toxicants, can specifically increase the alveolar macrophage release of proinflammatory lipid mediators, however the lipid metabolism of other macrophage/monocyte subpopulations after toxicant exposure is currently understudied. Therefore, identifying the consequences of inhaled toxicants on the lipid metabolism of specific pulmonary macrophage and/or monocyte subsets will define mechanisms behind how these toxicants can modulate pulmonary immunity and inflammation. This session will highlight the role of lipid metabolism for pulmonary macrophage/monocyte subsets and their lipid metabolism in lung injury and repair in multiple models of inhaled toxicant exposure. Currently, an avenue of research that we are pursuing is investigating pulmonary lipid metabolism after ozone exposure, with emphasis on the production of specialized pro-resolving lipid mediators. Our data indicate that ozone exposure suppresses the pulmonary production of specialized proresolving lipid mediators, that is most pronounced in the interstitial macrophage population. These data as well as those by other laboratories link immune cell function with lipid metabolism to provide mechanistic insights for potential therapeutic interventions.
1614 Hierarchical Structure of Patterns of Correlations between Biomarkers of Exposure and Their Implications for Studying the Health Effects of Mixtures

T. Webster, Boston University School of Public Health, Boston, MA.

This presentation will provide a short introduction to the symposium and then discuss the use of hierarchical clustering to examine patterns of correlations amongst exposures. We computed correlation coefficients between biomarkers in NHANES (the ongoing National Health and Nutrition Examination Survey) and several other general population cohorts. We defined a distance metric based on correlation coefficients and applied agglomerative clustering using average linkage. The resulting data were displayed using a heat map of the clustered correlation matrix. Results were striking: several cohorts show a block diagonal structure indicating that some groups of compounds tend to be highly correlated within groups but have low correlation with each other. Potential reasons for this pattern include commonalities (and differences) of physical chemical properties and exposure sources. These results suggest that health studies of such groups of compounds should not confound each other but may still have the possibility for interaction.

1615 Market Basket Data as a Tool to Sharpen Aggregate and Cumulative Chemical Risk Assessment

Surveys to acquire information on consumer product use, including use of household cleaning products and personal care products (PCP), can provide valuable information on potential chemical exposures and population habits and practices associated with these products. However, surveys take considerable effort to conduct and may become dated over time as new products emerge and markets change. Market basket data offers a potentially efficient mechanism to capture current product use patterns. Frequent itemset mining and association rule mining were used to analyze a database of PCP purchases for sixty thousand households over a one-year period in 2012. Robust co-occurrence patterns and associations were found for several PCP product categories and were consistent with use surveys. Furthermore, PCP purchase patterns varied by demographics explored (race, education, income, and family composition). We conclude that purchase data can fill a critical data gap when use survey data is absent, and can inform aggregate and cumulative risk assessment when coupled with product ingredient databases.

1616 Identification of Prevalent Exposure Biomarkers in the US Population Using NHANES

D. Kapraun, and J. Wambaugh, US EPA, Research Triangle Park, NC.

This presentation will examine a second approach to analyzing NHANES data using frequent itemset mining (FIM), a technique traditionally used for market basket analysis. We analyzed data from the 2009–2010 cycle of the continuous National Health and Nutrition Examination Survey (NHANES) to identify combinations of chemicals that frequently co-occur in people. We identified 90 chemical combinations consisting of relatively few chemicals that occur in at least 30% of the U.S. population. Certain combinations were far more prevalent in vulnerable populations, for example the combination of monoisobutyl phthalate and mono-n-butyl phthalate was much more prevalent in children than in the general population. This work demonstrated how FIM can be used in conjunction with biomonitoring data to narrow the large number of combinations of chemicals that could be formed from NHANES chemicals down to a smaller number of prevalent chemical combinations.

1617 Understanding and Predicting Patterns of Co-exposure

R. Zaleski, ExxonMobil Biomedical Sciences, Inc., Annandale, NJ. Sponsor: T. Webster

Biomonitoring data has proven very useful for understanding what substances an individual may be co-exposed to, and it can also be used to determine the relative magnitude for each of the constituents comprising the co-exposures. For example, NHANES co-exposure patterns for an analysis of several phthalate esters demonstrated that at upper percentiles of total exposure typically one ester dominates an individual’s exposure, but at median total exposure levels multiple esters contributed. Co-exposure insights that can be obtained from biomonitoring data to date have been limited to the domain of the biomonitoring data set; i.e., observations can be made only for those chemicals for which biomonitoring data are available. The ability to extend our understanding to co-exposure patterns for substances beyond current biomonitoring sets will be an important predictive capability. Could a combination of physical chemical properties, toxicokinetics, uses (exposure source) and function lead to this? Expanding current biomonitoring studies to include additional contextual information will be important to develop and achieve this capability. Further, given the wide range of co-exposure combinations that can occur from natural and man-made sources, the ability to focus in on co-exposures that are most meaningful for health assessment is needed.

1618 Using Pregnancy Cohort Data to Identify Human-Relevant Mixtures for Experimental Evaluation in a Whole Mixture Risk Assessment Strategy

C. Gennings, Icahn School of Medicine at Mount Sinai, New York, NY.

Experimental studies of mixtures are generally limited to convenient single chemical classes, while real human exposure is clearly not thus limited. In this presentation we will take a whole mixture strategy using the following four steps in a case study of mixtures of endocrine disrupting chemicals (EDCs): (1) identify single chemicals in human data of EDCs - measured in blood/urine of pregnant women in a cohort study that are associated with neuro-developmental effects in children; (2) define and construct a “typical” mixture from the cohort consisting of the “bad actors” identified in step 1; (3) experimentally test this reference mixture in an in vivo model to estimate a dose response relationship and determine a point of departure (POD) associated with an adverse health outcome; and (4) for the subpopulation of pregnant women determined to have a sufficiently similar mixture to the reference mixture, generate a “similar mixture risk indicator” (SMRI) to determine the level of concern for exposure relative to the POD. The SMRI is finally used to demonstrate the relative risk of adverse neurodevelopment as measured by this metric of risk assessment.

1618a An Evaluation of HTS and Mixtures: From Component-Based to Whole Mixtures Studies

M. DeVito, NIEHS/NTP, Research Triangle Park, NC.

One of the challenges in understanding mixtures is the huge number of possibilities. Clearly, traditional testing methods alone cannot provide a means to address the mixtures issues. In Tox21 we have studied both component based approaches as well as whole mixture approaches using high throughput screening (HTS) approaches. While the HTS approach has the advantage in throughput, it also has limitations. The challenge to HTS approaches is that “do-overs” are exceptions. Once 10,000 substances and mixtures are screened, it is rare to go back and re-run a couple dozen that did not have adequate dose response information. Thus, dose selection becomes critical in the study design to ensure that the dose range selected provides adequate dose response information. In addition, pairing mixtures HTS results with sufficient HTS chemical analysis of the stability of the mixtures is critical in ensuring that the HTS results can be adequately interpreted. Despite these limitations, a major advantage of the HTS approach is that it allows for preparing numerous mixtures that include mixing ratios of the chemicals that span possible human exposures as well as mixtures that test the boundaries of our dose addition models. Testing both relevant human exposures and the boundaries of our models will lead to more accurate hazard and dose response assessments of mixtures.
1619 Scaling Barriers: Cellular Dynamics and Models of Blood-Brain Barrier Developmental Toxicity

K. Saili, US EPA, Research Triangle Park, NC.

This session will focus on a critical vascular interface, the blood-brain barrier (BBB), with regard to embryology and toxicology. The BBB is a core of the neurovascular unit (NVU) comprising microvascular endothelial cells, pericytes, astrocytes, microglia, and neurons. These cell types function in various capacities throughout development to regulate the distribution of substances from the circulatory system to the developing brain (i.e., toxicokinetics). Although historically described as “leaky,” the leading perspective in the field has recently shifted toward an understanding that the BBB is functional and intact as it forms. BBB research tends to focus on toxicokinetics, but less is known about the toxicodynamic impact that drugs and chemicals may have on the developing BBB. Moreover, it is unclear whether such impacts would lead to developmental neurotoxicity (DNT). Evidence from mouse models and human genetics suggests that a model of BBB development and function has a role in the etiology of neurobehavioral disorders such as autism spectrum disorder, supporting the hypothesis that chemical disruption of the developing BBB may also lead to DNT. While current models representing the state-of-the-science in this field have not demonstrated a direct link between BBB perturbation by chemical exposures and subsequent DNT, this hypothesis remains to be adequately tested. Alternative models may provide tools toward understanding this “black box” in BBB toxicity. This session will address the integrative biology and systems toxicology underlying BBB toxicodynamics and highlight the cutting-edge in vivo, in vitro, and in silico models currently utilized for early life-stage considerations. The presenter lineup will begin with an overview that frames the importance, yet paucity, of developmental BBB research, followed by talks progressing from in vivo to in vitro and in silico BBB models. The first Co-Chair will provide an introduction to the session theme by describing key cell types and timing of embryonic BBB development across species. This introduction will cover other areas of the brain (e.g., circumventricular organs) and their barriers; provide an overview of the state of the art in BBB models that will be described in more detail by the session presenters; and briefly survey traditional, toxicokinetic models and BBB transporters. The first presentation will introduce the cortical BBB and describe a mammalian in vitro model to investigate the role of microglia in establishing BBB integrity during embryonic development. The next presenter will discuss an embryonic, transgenic zebrafish model being used to investigate the role of pericytes in mediating developmental BBB toxicity. The next presenter will introduce a 3D in vitro model designed to test BBB permeability to therapeutic antibodies. The final presentation will discuss novel multiscale in silico models for unscrambling complex cellular dynamics of BBB development in a computational neurovascular unit (cNVU) system, whereby toxicity pathways interact with fundamental morphoregulatory signaling (e.g., Wnt, Shh, Delta/Notch) during windows of vulnerability to developmental neurotoxicants. To wrap up the session, the second Co-Chair will emphasize the importance of establishing alternative BBB models that reduce animal testing, in addition to providing translational context for developmental BBB research by discussing the importance of these studies in relation to children’s environmental health protection.

1621 Environmental Contaminant Exposure Reduces Pericyte Coverage of the Developing Cerebral Vasculature

J. Plavicki, and M. Yue. Brown University, Providence, RI; and University of Wisconsin - Madison, Madison, WI.

Pericytes are a critical component of the blood brain barrier (BBB) that help maintain vascular stability and also modify barrier properties of brain endothelial cells by influencing efflux transporter expression. Correspondingly, loss of pericyte coverage is associated with cerebral hemorrhage and disrupted BBB development. Exposure to tetrachlorodibenzo-p-dioxin (TCDD) is known to produce hemorrhaging in the brain, and the periphery. However, why TCDD exposure produces hemorrhaging is unknown. To examine whether loss of pericyte coverage could contribute to the observed hemorrhaging phenotype, we exposed double transgenic embryonic zebrafish carrying fluorescent reporters for pericytes and endothelial cells (tdgpf-Il:GFP, kdrFl:dsRed2) to TCDD and counted the number of pericytes present in the midbrain and hindbrain. We found that a 1 part per billion and a sub-lethal 50 parts per trillion exposure resulted in a significant reduction in pericytes in the developing brain. To determine whether pericyte-specific activation of the aryl hydrocarbon receptor (AhR) is sufficient to produce hemorrhaging, we are using a pericyte-specific transgenic line to drive the expression of a constitutively active and corresponding control. In addition, we are examining whether pericyte-specific AhR activation alters BBB permeability. This presentation will also explore the application of the embryonic zebrafish BBB model to identify additional putative BBB disrupting compounds and further investigate the mode of action by which they elicit developmental neurotoxicity.

1622 BBB On-a-Chip: 3D In Vitro Models of the Human Blood-Brain Barrier

The blood-brain barrier (BBB) ensures a homeostatic environment within the central nervous system and protects the brain from harmful substances. At the same time, it largely prevents therapeutics from crossing, thereby making it difficult to treat brain diseases. Moreover, the BBB plays a crucial role in initiating or aggravating damage to brain tissue, for instance in multiple sclerosis, stroke, or Alzheimer’s disease. Restoration of BBB function is therefore a promising therapeutic avenue. To study mechanisms of barrier function and to explore approaches for improved drug delivery, we established two microfluidic 3D cell culture models of the BBB, both of them comprising human brain microvascular endothelial cells, pericytes, and astrocytes. The first model, developed by Mimetas, uses a 3-lane OrganoPlate® based on a 384-well microtiter plate and allows for parallel culture of 40 perfused microvessels. The second model, utilizing Nortis technology, closely mimics the multicellular anatomy of the in vivo BBB in a 3D tubular microvessel perfused under physiological flow rates. We supplement our BBB toolkit by the simple but scalable Transwell system, traditionally used in the field. In all models, we incorporate cells of human origin, either immortalized lines or derived from induced pluripotent stem cells. In addition to validating the BBB phenotype by immunocytochemistry and transcriptomic profiling, we confirmed barrier function and adopted assays to demonstrate receptor-mediated transport of antibodies, dynamics of leucocyte-endothelial interactions, and pharmacological modulation of barrier permeability. Moreover, these systems could be adapted to screen chemical libraries to identify toxicants that may impact BBB integrity by promoting a pro-inflammatory environment. These novel human, thus translatable BBB models provide a valuable toolkit for both high-throughput screening and detailed characterization of BBB function, supporting fundamental BBB research, drug discovery, and study of neurological disorders.

1620 Applying a Mouse Model of Embryonic Macrophage Depletion to Elucidate the Role of Microglia in Blood-Brain Barrier Development

K. Saili, US EPA/NCCT, Research Triangle Park, NC.

Microglia, the resident brain macrophage population, communicate with other cell types of the neurovascular unit (NVU) during normal brain development. We used a mouse model of embryonic macrophage depletions to test the hypothesis that microglia are essential for proper blood-brain barrier (BBB) formation. Macrophage depletion was achieved by injecting anti-colony stimulating factor 1 receptor (a-CSF-1R) antibody at 6.5 and 7.5, when yolk-sac macrophages are being generated, thereby transiently blocking the CSF-1 signaling pathway required for maintenance and differentiation of yolk-sac macrophages (microglial precursors). Flow-cytometry and immunohistochemistry indicated that this procedure specifically affects yolk-sac macrophages, thereby leading to a dramatic depletion of microglia as well as other embryonic macrophages throughout embryogenesis. To test whether macrophage depletion impacts BBB permeability, 70 kDa FITC-Dextran was injected into the hearts of embryonic macrophage-depleted fetuses and fluorescence was measured in the brain. Fluorescence imaging indicated a greater amount of FITC-Dextran diffusion in macrophage-depleted brains compared to wildtype controls, suggesting reduced BBB integrity and confirming a role in BBB development and function. This new mouse model will facilitate a greater understanding of the role of microglia in orchestrating BBB formation and function during embryonic brain angiogenesis, and will be used to test whether putative neurovascular toxicants impact NVU formation through a microglia-dependent process.
Development of a functional blood-brain barrier (BBB) is a complex process regulated by multiple cell types at different developmental stages. One important aspect of the developing neurovascular unit (NVU) involves interaction between invading endothelial cells, neuroprogenitor cells comprising the subventricular plexus, and microglia, the resident macrophages of the central nervous system (CNS). Microglia serve as an important mediator between neurotoxicology and immune function and dysregulation of these cells during development is hypothesized to disrupt BBB formation via decreased vessel branching and compromised vessel stabilization. To address the complexities of chemical exposure on the developing BBB, a cell agent-based model (ABM) was developed to predict the formation of the NVU with specific focus on the interaction between invading endothelial cells and microglia. Building upon a previous model of vasculogenesis, the current ABM characterizes the complex interaction between microglia and invading endothelial cells by incorporating multiple signaling pathways (Notch/dll4, CSF-1, VEGF-A, VEGF-C, sFlt1) in a biological framework. Molecular targets in the ABM were linked to signatures of neurovascular disruption through in vitro assay results in US EPA’s ToxCast high throughput screening dataset. Specifically, colony stimulating factor 1 receptor (CSF-1R) served as a marker of microglia abundance in the developing neuroepithelium. Concentration response effects using the NVS, ENZ, hCSF-1R assay in ToxCast were translated to chemical-specific effects on microglia abundance. Simulations of chemical-induced reduction in microglia resulted in a compromised NVU vasculature represented by decreased blood vessel branching and sprouting, which mimicked in vivo reports. The integration of in vitro data with in silico models provides a path forward to mechanistic prediction of developmental neurovascular toxicity and demonstrates a methodology for screening chemicals in silico and validating these biological paradigms using cell-based in vitro assays. Further development of the NVU will facilitate predictions of perturbations to the complex biology of the developing NVU from available in vitro data and predict disruptions in BBB viability. Declaration: This work does not reflect US EPA policy.

This session will focus on a critical vascular interface, the blood-brain barrier (BBB), with regard to embryoology and toxicology. The BBB is a core of the neurovascular unit (NVU) comprising microvascular endothelial cells, pericytes, astrocytes, microglia, and neurons. These cell types function in various capacities throughout development to regulate the distribution of substances from the circulatory system to the developing brain (i.e., toxicokinetics). Although historically described as “leaky,” the leading perspective in the field has recently shifted toward an understanding that the BBB is functional soon after it forms. BBB research tends to focus on toxicokinetics, but less is known about the toxicodynamic impact that drugs and chemicals may have on the developing BBB. Moreover, it is unclear whether such impacts would lead to developmental neurotoxicity (DNT). Evidence from mouse models and human genetics suggests that altered BBB development and function have a role in the etiology of neurobehavioral disorders such as autism spectrum disorder, supporting the hypothesis that chemical disruption of the developing BBB may also lead to DNT. While current models representing the state-of-the-science in this field have not demonstrated a direct link between BBB perturbation by chemical exposures and subsequent DNT, this hypothesis remains to be adequately tested. Alternative models may provide tools toward understanding this “black box” in neurotoxicology. This session will address the integrative biology and systems toxicology underlying BBB toxicodynamics and highlight the cutting-edge in vivo, in vitro, and in silico models currently utilized for early life-stage considerations. The presenter lineup will begin with an overview that frames the importance, yet paucity, of developmental BBB research, followed by talks progressing from in vivo to in vitro and in silico BBB models. The first Co-Chair will provide an introduction to the session theme by describing key cell types and timing of embryonic BBB development across species. This introduction will also briefly cover other areas of the brain (e.g., circumventricular organs) and their barriers; provide an overview of the state of the art in BBB modeling; and be described in more detail by the session presenters: and briefly survey traditional, toxicokinetic models and BBB transporters. The first presentation will introduce the cortical BBB and describe a mammalian in vivo model used to investigate the role of microglia in establishing BBB integrity during embryonic development. The next presenter will discuss an embryonic zebrafish model being used to investigate the role of pericytes in mediating developmental BBB toxicity. The next presenter will introduce a 3D in vitro model designed to test BBB permeability to therapeautic antibodies. The final presentation will discuss novel multiscale in silico models for unraveling complex cellular dynamics of BBB development in a computational neurovascular unit (cNVU) system, whereby toxicity pathways interact with fundamental morphoregulatory signaling (e.g., Wnt, Shh, Delta/Notch) during windows of vulnerability to developmental neurotoxins. The symposium will conclude with a panel discussion and Q&A session moderated by Dr. Slikker.
Integration of NAMs in Risk Assessment: The Read-Across Approach of the EU-ToxRisk Project

S. E. Escher, Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany. Sponsor: M. Leist

The integration of NAMs, new approach methodologies into a comprehensive risk assessment framework is challenging, in particular for complex endpoints such as repeated dose or reproductive toxicity. In EUToXRisk, scientists with different types of expertise develop integrated approaches to testing and assessment (IATAs) for these two endpoints. We believe that the in vitro and ex vivo models selected from the EUToXRisk toolbox will provide a better understanding of adverse outcome pathways moving human toxicology towards mechanistic risk assessment. In this talk, we present the concept and outcomes of the read-across case studies from the EUToXRisk programme. We report on the recent results and limitations of integrating cellular and molecular physiology, system biology and high-content technologies (omics, HCl) using modelling to uncover the causal relationships with apical findings arising from traditional in vivo. We will set a focus on the analysis and comparison of transcriptomic data within and between the case study compounds. This data integration will be illustrated by one case study based on structural analogues and one case study in which structurally diverse compounds share a common mode of action. In both case studies the IATA will predict the hazard of the target compound(s) after repeated low dose exposure. Besides qualitative hazard assessment EUToXRisk aims to derive threshold values, below which compounds are considered to be safe. Therefore, we will show the application of the newly developed ‘in vitro distribution model’ that estimates the intracellular concentration of compounds in the tested cell or tissue model. The intracellular concentration is the starting point to model the oral equivalent dose with IVIVE-PBPK models, which are also under development in EUToXRisk.

International Acceptance of Read-Across Based on NAMs

H. Kamp, BASF SE, Ludwigshafen, Germany.

Hazard assessment of substances such as (agro-)chemicals and pharmaceuticals requires a significant amount of toxicological testing, which is currently based to a large extent on animal studies, and often very costly as well as additionally an ethical challenge. One way to overcome animal testing is the use of alternative methods (3R methods) or nowadays so-called new approach methodologies (NAMs). On the other hand, for the safety assessment of chemicals, a powerful tool to avoid animal testing is read-across, which is basically a comparison between two similar chemicals and the usage of data from one chemical (called source compound) to assess the corresponding other chemical (target compound). This concept is of particular importance under the European chemicals policy REACH. According to current guidance given by regulatory agencies (e.g., the Read-Across Assessment Framework, RAAF, ECHA 2015), similarity is basically defined as structural (and physico-chemical) similarity. The similarity, however, can be substantiated by kinetic or toxicological information. Current experience with read-across cases that have been submitted to regulatory authorities show, however, that many read-across cases have so far not been accepted. Besides the fact that in some cases the structural similarity was questioned, many of the rejected cases have been insufficient in proving toxicokinetic or toxicodynamic similarity to an acceptable extent. Reasons for non-acceptance as well as best practices will be shown using rejected as well as accepted read-across cases from industry. These will comprise toxicokinetic as well as toxicodynamic similarities. From this, recommendations for robust read-across cases will be presented, that can not only help for the development of a good read-across for chemicals, but also enable the regulators for the assessment of, e.g., environmental metabolites of pesticides or impurities in pharmaceutical active ingredients. It goes without saying that these approaches provide key measures for the safety assessment of cosmetics, for which animal testing is completely banned in some areas, e.g., Europe.

Automated Read-Across and Good Practices

T. Hartung, Johns Hopkins University Center for Alternatives to Animal Testing (CAAT), Baltimore, MD.

Modern information technologies have made big data available in safety sciences. The challenge is now to make big sense of these data. Read-across is gaining momentum with increasing data availability and consensus on how to process and report it. It is predominantly applied to in vivo test data as a gap-filling approach but can similarly complement other incomplete data sets. Big data are first of all repositories for finding similar substances and ensure that the available data is fully exploited. Substance similarity analysis was used to determine clustering of substances with similar hazard labels. The European Chemical Agency warehouses the largest dataset of in vivo and in vitro toxicity tests. This data was extracted using linguistic search engines into a structured, machine readable and searchable database. An expanded database was built with 70 million structures of which 30% have biological/chemical properties and for about 20k mostly animal-study-based classification data. The latter were predicted for the six hazards by a novel read-across SAR. Leave-one-out cross-validation for models built on 58,219 known binary chemical health hazards (6 hazards, 43,996 positive, 14,223 negative chemicals) found in 42,479 cases sufficiently similar chemicals allowing predictions for 87% of cases. As structural neighbors correlate with certainty of prediction, any estimate is associated with an uncertainty measure. Here, a new web-based tool REACHacross developed with Underwriters Laboratories is presented, which aims to support and automate structure-based read-across for acute oral and dermal toxicity, eye and skin irritation, mutagenicity and skin sensitization. Together with the currently developed Good Read-Across Practice guidance, this will facilitate the application of high quality read-across. Next, a data fusion approach was implemented building a single model for nine hazards using not only the information within one hazard but all labeling categories including chemico-physical information. The new hazards are acute inhalation, acute and chronic aquatic toxicity. Data fusion boosted accuracy to an extent that no minimum similarity was required, i.e. estimates were done for all chemicals with BAC 88%. Overall, with average 91% sensitivity these predictions outperform repeat animal studies.

A View across the Atlantic: Synopsis and Opportunities

S. Fitzpatrick, US FDA, College Park, MD.

For many of the chemicals found in food, cosmetics, and dietary supplements, CFSAN/US FDA has limited toxicological data and no legal authority to request these data from the sponsors of the compounds. CFSAN/US FDA needs new toxicological approaches that can generate needed information to assure the safe use of these compounds for consumers. Critical to CFSAN/US FDA’s ability to reach sound decisions and to retain the public’s trust are high-quality data and a scientific review process that is thorough, unbiased, and transparent. Regulators must also determine how much evidence is sufficient to determine that a new tool is qualified to make safety decisions that potentially affect millions of consumers. Read-across has the potential to be a useful tool for US FDA because it uses the already available data of a data-rich substance to evaluate the potential toxicity of a data-poor substance which is considered similar enough to the source substance to use the same data as a basis for the safety assessment. In order to learn more about this tool, US FDA and CAAT co-sponsored two workshops on Good Read-Across Practices. The first was in Brussels on February 26, 2016. The second was at US FDA’s Wiley Campus in College Park on March 1, 2016. US FDA and CAAT also sponsored an additional Read Across Workshop in conjunction with the 2017 SOT Meeting. Currently CFSAN/US FDA has partnered with Underwriters Laboratories to assess whether its Reach-Across Program can be a useful predictive tool for assessing the toxicity of chemicals of concern for US FDA.

A Herculean Switch? Rethinking Chemical Carcinogenicity Assessment

S. Papininen, Corteva Agriscience, Indianapolis, IN.

The two-year rodent cancer bioassay has been the standard regulatory requirement to predict carcinogenicity following human exposure to chemicals, including industrial chemicals and agrochemicals, food additives, pharmaceuticals, and environmental pollutants. Decades of experience conducting two-year rodent cancer bioassays have not found a better way to predict human cancer pathogenesis. There have been questions about the scientific limitations and usefulness of the bioassay, especially in light of the resources, time, and animal use associated with the test. Moreover, further questions on the relevance of these data to assess human health risk arise due to the use of very high dose levels in these studies, which are several orders of magnitude higher than real-world human exposures. To address concerns over the human relevance of the assay, a shift in thinking process has paved a path to many cross-sector efforts to rethink carcinogenicity assessment. The first presentation will provide a historical perspective on development and adoption of the rodent cancer bioassay and the efforts to moderate its use in 2007. The second presentation will focus on alternative testing methods to carcinogenicity assessment to improve the efficiency of chemical risk assessment and produce data that are more relevant to protecting human health. The third presenter will share a global perspective on efforts to develop integrated approaches to testing and assessment and adverse outcome pathways to better understand the mech-
Anisms that lead to carcinogenicity in humans and that can be used to design alternatives to the currently used bioassay. The fourth presentation will describe a decision tree and criteria developed within the agrochemical sector and share the results of how they have been used to retrospectively analyze the need for the cancer bioassay in regulatory decision-making. The final presentation will share the US EPA Office of Pesticide Programs’ perspective on alternative methods of testing, including a weight of evidence approach incorporating all the relevant data available including exposure, and will share their vision going forward on waiver criteria for rodent cancer bioassays. Overall, the session will include presentations from scientists across different sectors and enable a panel discussion between the speakers and audience on the value of the cancer bioassay, which has been used as a standard for decades by global regulatory bodies despite being resource, time, and animal intensive. Finally, the session will discuss alternative approaches that could be used to assess carcinogenicity, identifying remaining gaps and shedding light on ongoing global efforts on this subject.

**1632 History of the Rodent Cancer Bioassay in Chemical Risk Assessments and What Did We Learn?**

A. Hayes, University of South Florida, and Michigan State University Institute of Integrated Toxicology, Tampa, FL.

For more than half a century, the rodent cancer bioassay has been used to identify chemicals that may have the potential to cause cancer in humans and has long been used by worldwide regulatory authorities for assessing carcinogenicity and managing risk. Although the cancer bioassay has been embedded in institutional practice for decades, it has long been the subject of controversy. Numerous workshops, retrospective analyses, and review articles have identified issues surrounding the bioassay, and many have questioned the predictability, utility, and even the necessity of this assay when other more appropriate means of achieving information to determine the cancer potential in humans and inform risk management decisions are available. While there remain strongly held opinions on the bioassay, the 21st century trend in toxicology is to promote hypothesis-driven, tier-based testing that draws on a broad array of information from several sources, including predictions from computational and molecular approaches. While many papers in the scientific literature discuss potential improved alternatives to the rodent cancer bioassay, there has not been a concerted effort to bring disparate views together with the objective of identifying a definitive alternative approach that could be implemented today. This talk will discuss when and why the bioassay was developed, what we have since learned about its relevance, and steps that have been taken to modernize the carcinogenicity testing approach.

**1633 Alternative Testing Paradigms to Assess Chemical and Pharmaceutical Carcinogenicity**

C. Wood, Boehringer Ingelheim Pharmaceuticals, Inc., Durham, NC. Sponsor: S. Papineni

Current interest in modifying toxicity testing requirements is driven by needs to improve the efficacy and efficiency of chemical risk assessment, incorporate new higher-throughput types of data into regulatory review, and reduce the number of animals used in testing. An important focus of these efforts is the long-term rodent carcinogenicity study, which has been a standard testing requirement for registration of food-use agrochemicals and other high-priority chemicals for more than 30 years. Recently, a proposal to change the international guidance for carcinogenicity testing of pharmaceuticals was submitted to the International Conference on Harmonisation. This change in the handling of data from non-carcinogenicity studies that would justify whether or not a long-term rodent bioassay would impact the overall cancer risk assessment of a compound. This presentation will address alternative methods for cancer risk assessment and whether a similar type of waiver system could be applied to environmental chemicals. Proposed approaches include paradigm testing schemes, empirical models, and biomarker panels based on specific pathways of chemical carcinogenesis. Recent case studies investigating the use of subchronic histopathology indicators, hormonal activity, quantitative genomic biomarkers, and in vitro bioactivity screens to predict carcinogenicity (or lack of it) in the rodent test species will be presented. New integrative testing paradigms that incorporate predictive accuracy of short-term tests with both human relevance and exposure considerations.

**1634 Moving Forward in Carcinogenicity Assessment: An International Perspective**

R. Corvi, EURL ECVAM, Ispra, Italy. Sponsor: S. Papineni

Several opportunities are available to exploit recent advances in approaches to move away from the two-year cancer bioassay in rodents. Initiatives, including data- or knowledge-driven approaches and those that focus on a disease outcome to establish chemical screening and testing methods, were discussed at a recent workshop organised by the EU Reference Laboratory for Alternatives to Animal Testing (EURL ECVAM) and the European Society of Toxicology In Vitro (ESTIV). Non-genotoxic carcinogens are of particular concern, because they contribute to an increased cancer risk and a variety of mechanisms that are not yet directly assessed by international regulatory approaches. Under the auspices of the Organisation for Economic Cooperation and Development, a working group is currently developing an integrated approach to testing and assessment to address non-genotoxic carcinogenicity. The assay by targeting cancer on their hallmark of cancer that address early to mid and later key events with increasing associations to adversity (e.g., cell proliferation, immunosuppression, cytoskeleton modifications, and angiogenesis). In addition, inspired by the pharmaceutical proposal for refining the criteria for when carcinogenicity testing may or may not be warranted, the European Partnership for Alternative Approaches to Animal Testing (EPAA) is carrying out a project to evaluate whether a similar approach is also applicable to the carcinogenicity assessment of agrochemicals. The aim is to provide evidence that data from 3-month repeated dose toxicity studies together with mode of action data can, in some cases, be leveraged to predict human relevant carcinogenic potential of agrochemicals. Despite a seemingly diverse range of strategic developments across various initiatives and sectors, a number of common critical elements are emerging. For example, there is a clear need to incorporate mechanistic reasoning into carcinogenicity hazard assessment, and to integrate all available information, including data from epidemiology, traditional and alternative toxicology tests, and from novel data streams (e.g., omics, high-throughput technologies). Such cross-sectorial knowledge sharing and harmonization will build confidence in new approach methods and ultimately lead to more effective and efficient safety assessment.

**1635 A Weight of Evidence Approach to Assess Carcinogenicity Potential and Retrospective Analysis of Agrochemicals**

S. Papineni, Corteva Agriscience, Indianapolis, IN.

The two-year cancer bioassay in rodents has been considered the gold standard to assess carcinogenicity across multiple sectors. Following decades of experience conducting the bioassay, the value of this study has become the subject of debate in the scientific community owing to its significant use of animals and limitations, including the relevance of findings to humans. Advancements in technology and our understanding of key events in the development of carcinogenesis have spurred multiple efforts across sectors to make this study a conditional requirement instead of a default study. There is an effort ongoing within the agrochemical sector leveraging the knowledge gained from other sectors, especially the pharmaceutical sector, which is assessing the feasibility of revising the current ICH S1 guideline on rodent carcinogenicity testing. This presentation will provide an update on an ongoing collaborative effort among the agrochemical industry, the animal protection sector, and regulatory agencies to develop a decision tree and criteria to assess the need for a two-year cancer bioassay for agrochemicals. This approach considers knowledge of intended targets, genetic toxicology study results, histopathological evaluation of repeat dose studies, and other information. This presentation will present the results of retrospective analysis carried out to validate the usefulness of the criteria to assess the need for a cancer bioassay.

**1636 Commitment at the US EPA/OPP to Reduce and Replace Animal Use: Looking at Carcinogenicity and Beyond**

The US EPA’s Office of Pesticide Programs (OPP) is committed to implementing strategies and programs to improve risk assessments while reducing animal use in pesticide testing. For example, OPP has developed and implemented a transparent, stepwise process for evaluating and implementing alternative methods of testing for acute oral, dermal, and inhalation toxicity, as well as eye and skin irritation and skin sensitization. Furthermore, OPP has published guidance on waivers for acute and subchronic neurotoxicity, subchronic inhalation, subchronic dermal, and immunotoxicity studies.
Irritation tests by adopting the ISO 10993-23 standard for medical device irritation testing. Consequently, the test protocol will now be adapted and included in a new ISO 10993-23 standard for medical device irritation testing.

W 1638 Time for a Change: The ISO 10993 Standards and Irritation Testing of Medical Devices
K. Coleman, Medtronic plc, Minneapolis, MN.

The ISO 10993 standards have governed biological evaluation of medical devices for a quarter century. These standards address animal welfare, materials characterization, toxicity testing, risk assessment and other issues surrounding biocompatibility assessment of medical devices. Skin irritation is a biological effect that must be considered for virtually every medical device regarding biocompatibility assessment of medical devices. OECD Test Guideline 439 describes the use of reconstructed human epidermis (RHE) as an in vitro test system for classification of skin irritation by neat chemicals. This test, which was developed in the 1940s, has been used worldwide for decades. In the 1980s a modified version was added in the Tripartite Agreement for Medical Device Biocompatibility, and in the 1990s it was included in the ISO 10993-10 standard on irritation and sensitization testing. The test is considered a gold standard for medical device irritation assessment; however, it has some shortcomings. This presentation will provide a brief overview of the ISO 10993 standards, discuss the biology of skin irritation, review the Draize rabbit skin irritation test, and tell the backstory of the search for a replacement including the completion of an in vitro irritation feasibility study.

W 1639 Modification and Use of Reconstructed Human Epidermis (RHE) Models
A. Turley, Nelson Laboratories LLC, Salt Lake City, UT.

The ISO 10993 standards have governed biological evaluation of medical devices for a quarter century. These standards address animal welfare, materials characterization, toxicity testing, risk assessment and other issues surrounding biocompatibility assessment of medical devices. Skin irritation is a biological effect that must be considered for virtually every medical device regarding biocompatibility assessment of medical devices. OECD Test Guideline 439 describes the use of reconstructed human epidermis (RHE) as an in vitro test system for classification of skin irritation by neat chemicals. This test, which was developed in the 1940s, has been used worldwide for decades. In the 1980s a modified version was added in the Tripartite Agreement for Medical Device Biocompatibility, and in the 1990s it was included in the ISO 10993-10 standard on irritation and sensitization testing. The test is considered a gold standard for medical device irritation assessment; however, it has some shortcomings. This presentation will provide a brief overview of the ISO 10993 standards, discuss the biology of skin irritation, review the Draize rabbit skin irritation test, and tell the backstory of the search for a replacement including the completion of an in vitro irritation feasibility study.

W 1640 Creating Irritant-Infused Polymers for Extraction and Irritation Analysis
B. Rollins, ConvaTec, Greensboro, NC.

After years of tissue development, the final hurdle for the round robin validation study using reconstructed human epidermis (RHE) tissues for medical devices was the development of extractable controls. Previous RHE/medical device feasibility studies were completed without irritant polymers, so for the round robin study, positive control materials were created by infusing polymers with known irritants. In order to successfully incorporate hydrophilic and hydrophobic irritant chemicals, a variety of medical device polymers were investigated. The final four polymer-releasing irritants were chosen based on their irritation potential, octanol/water partition coefficient, miscibility with polymer matrices, and use in the medical industry. Verification was performed through extraction and chemical analysis, along with RHE tissue irritation testing prior to their inclusion in the round robin validation study. In this presentation, we will discuss the development of the four novel compounds through unique mixing and curing methods, the challenges encountered during development including the various irritants, concentrations, mixing, and curing processes executed to determine the amount needed to elicit an appropriate irritant response without destabilizing the polymers, and the variety of irritants that were trialed.

W 1641 The Application of Reconstructed Human Epidermis (RHE) Models as In Vitro Skin Irritation Tests for Detection of Irritant Activity in Medical Device Extracts
W. De Jong, National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands. Sponsor: A. Turley

Assessment of skin irritation is an essential component of the safety evaluation of medical devices. Testing the irritant capacity of medical device extracts is currently performed by either topical or intradermal injection in rabbits according to ISO 10993-10 as part of the ISO 10993 series for the biological evaluation of medical devices. OECD Test Guideline 439 describes the use of reconstructed human epidermis (RHE) as an in vitro test system for classification of skin irritation by neat chemicals. An international round robin study was conducted to evaluate the RHE method for determination of skin irritant potential of medical device extracts. Four irritant polymers and three non-irritant controls were obtained or developed that had demonstrated their suitability to act as positive or negative test samples. The RHE tissues (EpiDerm™ and SkinEthic™ RHE) were dosed with 100 µL aliquots of either saline or sesame oil extract. Incubation times were 18 h (EpiDerm™) and 24 h (SkinEthic™ RHE). Cell viability reduction > 50% was indicative of skin irritation. Both the EpiDerm™ and SkinEthic™ RHE tissues were able to correctly identify virtually all of the irritant polymer samples either in the saline or sesame oil extract. Our results indicate that RHE tissue models can detect the presence of strong skin irritants at low levels in dilute medical device polymer extracts. Therefore, these models may be suitable replacements for the rabbit skin irritation test to support the biological evaluation of medical devices. Consequently, the test protocol will now be adapted and included in a new ISO 10993-23 standard for medical device irritation testing.

W 1642 Taking Full Advantage of the MDDTs: Using Tools for Regulatory Risk Management in the Medical Device Development Process
H. Scharen. US FDA, Silver Spring, MD. Sponsor: A. Turley

The medical device development tools (MDDTs) process provides a new route for interested parties to present novel testing methods to the US FDA. Throughout the medical device development process, MDDTs can be used in the evaluation of medical devices; these tools help manufacturers understand the safety, effectiveness, and performance of medical devices. Qualified MDDTs provide assurance that the measurement techniques produce scientifically meaningful and valid results within the Context of Use (COU). The COU describes the specific way the MDDT should be used in device evaluation and regulatory submissions including the output/meter from the tool. Tool categories include biomarker tests, clinical outcome assessments (such as clinician reported rating scales), and non-clinical assessment models (such as in vitro models to replace animal tests). This presentation will provide an
overview of when the MDDT process is appropriate, a review of the overall process for qualifying a MDDT, and how the MDDTs apply to testing procedures. The qualification process for in vitro irritation testing will be used as a case study with attention given to the practical questions of cost and protocol ownership.

**1643 Applying Systems Biology Approaches to Understand the Joint Action of Chemical and Nonchemical Stressors**

**C. Rider, NIEHS, Research Triangle Park, NC.**

Toxicology has evolved from a strictly observational science to a more predictive one that relies on knowledge of stressors (chemical or nonchemical) and the biological systems with which those stressors interact to identify health hazards. Furthermore, the introduction of the exposome concept brought into sharp focus the fact that humans are routinely exposed to a great number of chemical and nonchemical stressors over the course of a lifetime. Chemical stressors can arise from everyday use of personal care products and consumer products, occupational exposures, and exposure to pollutants through contaminated air, water, and/or food. Nonchemical stressors include physical stressors (e.g., heat and cold, radiofrequency radiation, biological agents such as allergens and viruses), and psychosocial stressors (e.g., noise, exposure to violence), which involve both exposure and perception. The traditional reductionist view reflected in toxicology by the study of one chemical at a time falls short of the promise of high-throughput technologies, a focus on biological pathway disruption, and acknowledgement that real-world exposures are complex. In response to the evolution of our thinking in toxicology and exposure science, a rational approach to address the challenges of mixtures has emerged. This conceptual framework incorporates systems biology and mixture toxicology. Mixtures approaches take a more mechanistic approach that links independent independent groups have developed projects or case studies to work through this conceptual framework. Examples of endpoints include disruption of male reproductive tract development, atherosclerosis, stasis of, and cancer. Although these efforts are in various stages of development, a detailed review of the available programs will provide opportunities to identify challenges, key knowledge gaps, share information, and foster collaboration and cooperation to move the field forward. Case studies, such as the ones presented here, will inform cumulative risk assessment by providing a path forward for determining which stressors to include and how we might move away from a chemical-centric perspective to one focused on the diseases that are of greatest concern to public health.

**1644 Understanding Biological Pathways across Toxicological Tools**

**J. E. Rager, University of North Carolina at Chapel Hill, Chapel Hill, NC.**

Research surrounding systems-level effects of chemical and nonchemical stressors has expanded over recent years, alongside the increasing feasibility of multi-target and -omic-based investigations. Databases relevant to systems biology have also grown, serving as central repositories for toxicological response information that can be leveraged to better understand molecular events resulting from multiple stressors. What remains underdeveloped are methods to effectively relate such data to individual disease phenotypes. Recent progress has been made through the implementation of organizational schemes, including Adverse Outcome Pathways and the Ten Key Characteristics of Carcinogens. These recent advances will be discussed alongside examples of how chemical-induced biological pathway perturbations have been related to disease outcomes, while highlighting the current data gaps and limitations in tools available to understand systems-level effects of chemical and nonchemical stressors.

**1645 Mixtures That Target Male Reproductive Tract Development**

**J. M. Conley, US EPA/ORD, Research Triangle Park, NC.**

Two of the most commonly occurring human birth defects are hypospadias of the phallus and cryptorchidism of one or both testes. Further, reductions in adult sperm counts have been reported in multiple countries. Increases in the prevalence rates of these disorders over the past several decades have been reported and exposure to environmental chemicals has been suggested as a causal factor. A variety of environmental chemicals that operate via a range of molecular mechanisms have been shown to produce male reproductive tract disorders following in utero exposures in laboratory animal experiments. For example, androgen receptor (AR) antagonists (such as vinclozolin) and some phthalates, which decrease testicular testosterone but do not interfere with AR activity, have both been shown to elicit dose-dependent increases in male reproductive tract malformations. During the last 10-15 years we have used a mixtures approach to analyze these chemical-induced mechanisms of male reproductive tract disruption into an Adverse Outcome Pathway (AOP) network. The AOP network converges on adverse outcomes of the developing male reproductive tract and serves as a conceptual model for the design and evaluation of complex mixtures studies. An underlying hypothesis of these mixtures studies is that although the chemicals target different molecular initiating events, their convergence at critical key events will ultimately lead to dose additive adverse effects when exposure occurs as a complex mixture. Results indicate that, despite acting through disparate molecular mechanisms, chemicals impacting male reproductive development act cumulatively to produce adverse effects similar to those observed in human populations. Moving forward, AOP networks provide a mechanistically-based framework for grouping chemicals, addressing mixture hazards, and in conducting cumulative risk assessments. Abstract does not necessarily reflect US EPA policy.

**1646 A Model Disease to Determine the Interaction of Chemical and Nonchemical Stressors**

**D. J. Carlin, NIEHS, Research Triangle Park, NC.**

A critical research area which requires further exploration is the biological mechanisms and effects of exposure to both environmental chemicals (e.g., air pollution, PAHs, metals) and non-chemical stressors (e.g., psychosocial, lifestyle, quality-of-life, poor nutrition, physical stressors) over time and the roles they may play in modifying the development of disease. Recently, the National Institute of Environmental Health Sciences (NIEHS) and the National Heart, Lung, and Blood Institute (NHLBI) held a workshop that brought together experts to discuss the state-of-the-science pertaining to underlying biological pathways associated with, when combined, chemical and non-chemical stressors in relation to atherosclerosis (ATH). ATH is a foremost candidate for identifying health effects associated with chemical and non-chemical stressors since much is known about the morbidity and mortality of this multifactorial disease. This presentation will discuss utilization of the Adverse Outcome Pathway (AOP) framework to evaluate this disease and its mechanisms as a novel approach to combine information from studies to elucidate knowledge of biological pathways, account for species differences or similarities, incorporate genetic and lifestyle susceptibility, and identify research needs. Specifically, discussion will focus on how disparate stressors (e.g., environmental chemicals and non-chemical stressors) may interact together in order to result in ATH. Approaches and research needs include: characterizing qualitative and quantitative impacts of exposure to the combination of chemical and non-chemical stressors, developing new models and methods for assessing the toxicity of multiple co-occurring environmental hazards, and analyzing the effects associated with susceptible and vulnerable populations. This case study presents the use of a systems biology and AOP network approach for identifying factors that induce atherosclerosis, and may serve as a model how to determine the role that chemical and non-chemical stressors play in the development of other diseases.

**1647 The EuroMix Project on Mixtures That Target Steatosis**

**A. Lampen, BfR, Berlin, Germany. Sponsor: C. Rider**

EuroMix is a Horizon 2020 EU project which aims to develop an adverse outcome pathway (AOP) and quantitative test strategy (bioassay toolbox) regarding combined mixture effects of food relevant residues and contaminants. The EuroMix approach includes prioritization of chemicals based on in silico predictions and bioassays, followed by establishment of quantitative exposure assessment groups based on mode of action and/or adverse outcomes. As an example, an in vitro bioassay toolbox for measuring liver steatosis according to the concept of AOPs was developed by including key steps of the AOP using a
human liver cell model. A toolbox comprising reporter gene assays, low density arrays, qRT-PCR, AdipoRed assay, high content cell imaging, LC-MS/MS and GC-FID, as well as Seahorse XS Cell Mito Stress test was used to analyze nuclear receptor activation, gene and protein expression, lipid accumulation and mitochondrial disruption in human HepaRG cells. Different food relevant compound mixtures have been tested and an in vivo proof of concept experiment was performed. As an example, the pesticides thiabendazole and clothianidin sharing a similar or dissimilar mode of action (MoA) regarding liver steatosis (mainly PXR mediated vs. nuclear receptor independent) were successfully shown to induce steatosis in vitro. Analysis of equipotent mixtures of these compounds using dose response (BMD) modelling revealed dose addition effects of either chemicals with similar or dissimilar MoA. The results demonstrate the suitability of the in vitro toolbox for liver steatosis to assess mixtures with a similar or dissimilar MoA. In the next step the bioassay toolbox was focused to a smaller test set reflecting the steatosis AOP in regard to developing a fast and high throughput approach for testing mixtures. Finally, an integrative proof of concept experiment starting with in silico predictions of steatosis relevant chemicals (form QSAR and molecular docking of relevant nuclear receptors) and ending with the established toolbox testing of single compounds and mixtures will be performed.

1648 Converging on Cancer with Systems Toxicology
C. V. Rider. NIEHS/NTP, Research Triangle Park, NC.

The Hallmarks of Cancer described by Hanahan and Weinberg represent the biological pathways that are critical in cancer development. The ten Hallmarks are not discrete events, but interrelated cellular processes that are perturbed during cancerization. The Halifax Project used the Hallmarks of Cancer as a starting place to develop a hypothesis for the effects of environmental mixtures on cancer development. Through this effort, cancer biologists and environmental scientists were brought together to discuss the role of chemical mixtures in cancer development and progression. They hypothesized that environmental chemicals present below levels of concern (based on their individual dose-response data) will contribute to the development of cancer by acting on the 'Hallmark' pathways. The hypothesis was nominated by the Environmental Working Group to the National Toxicology Program to stimulate research on the role of environmental mixtures in cancer. This presentation will highlight the conceptual development of a testing program to address the convergence of environmental chemicals on the network of pathways involved in cancer development. For example, the angiogenesis Hallmark will be discussed in terms of environmental chemicals that have been implicated at inducing angiogenesis and in vitro screening tools that could be used to evaluate candidate chemicals for inclusion in the program. The application of in silico approaches to combine multiple pathways and predict the joint effects of chemicals that target the Hallmark pathways will be discussed.

1649 NextGen Renal Proximal Tubule Toxicity Screening: Novel Cellular Model and Complex Culture Platforms
S. Lu. Pfizer, Inc., San Diego, CA.

Active renal secretion in the proximal tubules is a major drug elimination route, making the kidney susceptible to drug-induced injury. High blood flow to the kidneys significantly contributes to exposure to potential nephrotoxins that enter the cells mostly basolaterally via organic anion and organic cation transporters or apically via reabsorption processes. Many drugs associated with proximal tubule damage are polar, such as acyclovir (cLogP -2.2) and cidofovir (cLogP -2.0), exhibiting poor passive permeability, and hence require active transporters or receptors. To investigate the nephrotoxic potential of lead compounds, in vitro systems should emulate the renal physiologic environment, including functional transport machinery. Cell lines or primary cells traditionally used in 2D kidney toxicity screening lack the appropriate transporter expression, in vivo structure, and function and are unable to predict preclinical/clinical kidney toxicity. Recent biotechnological developments provide more sophisticated and promising models, including 3D culture platforms and reprogrammed renal tubular epithelial cells, which could be utilized to create a more physiologically relevant platform with the potential to improve the prediction value for proximal tubule toxicity screening. The session will provide a general overview of these state-of-the-art biotechnological advances to facilitate the discussion about the path forward for in vitro kidney toxicity screening with high reliability and mechanistic insight.

1650 Early Screening for Nephrotoxicity Employing Transporter Overexpression Cell Lines
S. Lu. Pfizer, Inc., San Diego, CA.

Nephrotoxicity due to drugs and environmental chemicals accounts for significant morbidity and mortality during drug development. As an example, the nephrotoxicity associated with proximal tubule toxicity is hydrophilic — suggesting that active uptake via transporters drives the cell accumulation for such low permeable drugs. However, cells commonly used in in vitro toxicity studies lack transporter expression which contributes to false negative results. Here we used OAT1, OAT3 and OCT2 over-expressing HEK293 cells to improve assay sensitivity for nephrotoxic compounds. This result correlates with the compound uptake data. In addition inhibition of OAT1 and OAT3 (probenecid) and OCT2 (quinidine) reduced the toxicity associated with test compounds indicating that the increased toxicity is associated with increased cell accumulation. These results demonstrate the utility of using transporter over expression cell line to help understand the mechanism of toxicity and potential use as a screening tool.

1651 Directly Reprogrammed Induced Renal Tubular Cells (iREC) for Renal Toxicity Testing
S. Lienkamp. University Medical Center Freiburg, Freiburg, Germany. Sponsor: S. Lu

Direct reprogramming by forced expression of transcription factors can generate desired cell types from differentiated cells without the prior induction of pluripotency. We recently identified four transcription factors that facilitate the direct conversion of mouse and human fibroblasts into induced renal tubular epithelial cells (iRECs). These cells exhibit epithelial features, a global gene expression profile resembling their native counterparts, and functional properties of differentiated renal tubule cells, such as active endocytosis and tubule formation in organoids and decellularized ECM scaffolds. While directly reprogrammed tubule cells offer a potential road to regenerative approaches, a more tangible goal is their use in disease modeling and toxicity screening. iRECs are sensitive to clinically used nephrotoxins and respond by expression of renal injury molecules. For example, treatment with cisplatin changes the metabolic profile of iRECs similar to that of in vivo models. A toxicity induced metabolic signature found in the exometabolome of iRECs was not observed in fibroblasts or other renal epithelial cells (IMCD-3). Therefore, direct reprogramming may be an attractive in vitro strategy to advance patient specific nephrotoxicity testing.

1652 Challenge Accepted: Update on NC3R NephroTube Challenge
M. Wilmer. Radboudumc, Nijmegen, Netherlands. Sponsor: S. Lu

The general aim of the NephroTube Challenge is to develop a multi-compartmental microfluidic device that models renal tubular injury observed in nephrotoxicity. This demands a triad of 1) a human renal cell line with intact transporter function and metabolic activity, 2) sophisticated microfluidics compatible with high-throughput analysis, and 3) high level expertise in toxicology. Developing and implementing of such device has the potential to reduce animal experimentation and improve predictivity of drug-induced kidney injury during drug development. During the NC3Rs CRACK-IT NephroTube Challenge, human immortalized proximal tubule epithelial cell lines (CiPTEC and RPTEC) cultured in a multi-compartmental microfluidic tier-plate (Organato*P) were evaluated as a high-throughput screening tool to assess drug-induced kidney injury. Our kidney-on-a-chip device was exposed to twelve compounds known for their nephrotoxic potential (including cisplatin, tenofovir, tobramycin and cyclosporin A) for 24 and 48h. The format allowed multiple read-outs for toxicity, including cell viability, LDH, NAG, miRNA secretion, gene expression profiling, drug transport interactions and assessment of barrier integrity. Inter-laboratory variation was limited and robustness of the cell-based assays could be demonstrated. Together, the microfluidic tier-plate Organato*P seeded with CiPTEC or RPTEC provides a platform for high-throughput screening which will allow the biomarker discovery to analysis upon exposure to drugs of different classes. Further validation using chemical compound libraries and implementation in drug development is required to demonstrate the value of such models to reduce animal experiments and improve drug safety.
Our lab has developed a 3D model of the human kidney proximal tubule as an ex vivo microphysiological system (MPS) for preclinical toxicity testing. Polymyxins are potent antibiotics but their use is restricted because of nephrotoxicity. To mitigate nephrotoxicity, structural analogues of polymyxins are being developed. Using our MPS, we assessed the safety of polymyxin B and the analogues NAB739 and 741. Following polymyxin B treatment, the US FDA qualified urinary biomarker of acute kidney injury, kidney injury molecule-1, as well as a panel of injury-associated microRNAs, was significantly increased in device effluents. Transcriptional profiling identified cholesterol biosynthesis as the primary pathway induced by polymyxin B. In contrast, we observed minimal changes in gene expression and no significant upregulation of urinary biomarkers in response to the NABs. Our findings demonstrate the improved safety of NAB739 and 741, reveal cholesterol biosynthesis as a novel pathway affected by polymyxin B, and support the use of microphysiological models for safety assessment.

Cannabinoid (CBD) containing products are commercially available without prescription for anxiety, inflammation, chronic pain, and psychological ailments. They are available in a plethora of flavors in oral, sublingual, and inhalable forms (e.g., e-cigarettes) without regulation by the US FDA. We assessed the immuno-toxicological effects of CBD oil by hypothesizing that CBD oil containing products induce oxidative stress and inflammation in macrophages, epithelial cells, and fibroblasts. Products containing CBD at different concentrations (100mg, 350mg, and 550mg) were tested for acellular reactive oxygen species (ROS) production by DCFH-DA fluorescent dye. Cellular ROS levels were assessed by celROX green in monocytes. Epithelial cells (Beas 2B), macrophages (U937), and human lung fibroblast cells (HFL-1) were treated with varying CBD concentrations (between 0.0035 mg/mL and 0.14 mg/mL), and the inflammatory mediators, IL-8 and MCP-1, were measured in the conditioned media by ELISA and cytokine arrays. Furthermore, monocytes and epithelial cells were stimulated with LPS along with CBD as individual and combined treatments to test the antioxidant and anti-inflammatory effects of CBD. The inflammatory regulation mechanism was evaluated by measuring the NF-κB activity in monocytes. CBD generated significant dose-dependent acellular and cellular ROS levels. IL-8 was induced with CBD treatment in various cells. However, the MCP-1 levels were decreased with CBD treatment showing anti-inflammatory effects. LPS stimulated cells showed inhibition of NF-κB activity in CBD treated macrophages. Moreover, CBD significantly attenuated IL-8 and MCP-1 cytokine responses in LPS stimulated macrophages. Cytokine array data depicted differential cytokine response due to CBD in different cell types. Commercially available CBD solutions increase ROS production, thus inducing an inflammatory response. However, inflammation potentiated by LPS can be attenuated or augmented by CBD. Therefore, CBD may be used as an anti-inflammatory agent for an ongoing inflammatory response, but should not be used otherwise. Our data suggest that commercially available CBD oil (if inhaled via e-cigarette aerosol) should be regulated, as unnecessary exposure could potentially cause harm to the consumers. Supported by the Toxicology Training Program grant T32-ES007026.
Chemical agents such as industrial chemicals, pesticides, and chemical warfare agents can induce uncontrolled seizure activity (neuronal hyperexcitability). Oxidative stress and a perturbed glutathione (GSH) redox status are implicated as pathogenic factors in the etiology of seizures and epilepsy. However, whether and how cellular GSH redox status modulates neuronal hyperexcitability is unclear. We hypothesized that the modulation of cellular GSH redox status with thiol containing compounds would attenuate neuronal hyperexcitability in vitro and in vivo. 2,3-dimercaptopropanol (DMP), a thiol-containing compound significantly (p<0.001 vs vehicle control) increased intracellular glutathione levels in mixed rat primary cortical cultures at 4 and 24h. Next, we determined if DMP could dampen "seizure-like" activity in vitro induced by 4 Aminopyridine (4AP), a toxin that inhibits potassium channels. In mixed rat primary-neuronal-glial cultures, incubation with 30µM or 100µM DMP for 4h significantly (p<0.01, p<0.0001 vs 1mM 4AP) decreased 4AP-induced neuronal hyperexcitability. Next, we assessed whether DMP can increase intracellular GSH levels in an in vivo model system. To test this, zebrafish larvae were treated with different DMP doses for 4h. DMP significantly (p<0.01 vs vehicle control) increased intracellular GSH levels in a dose-dependent manner in zebrafish larvae. Finally, we tested the ability of DMP to decrease 4AP-induced seizure behavior in zebrafish larvae. Larvae pre-treated with 100µM DMP for 4h exhibited decreased 4AP-induced seizure behavior. Taken together, the data suggest that the thiol-containing compound DMP alters GSH redox status and controls neuronal hyperexcitability both in vitro and in vivo.

Oxidative stress and release of pro-inflammatory mediators are well established signaling events following inhaled chemical exposure; however, our understanding of the distinct cellular and molecular pathways involved in inhalation toxicity remain limited due to studies centered around a single airway cell type (i.e., epithelial cells), and lack of physiologically-relevant studies on diverse cell types beyond the epithelial barrier. Utilizing an in vitro organotypic model that recapitulates the "trans-epithelial" nature of analogous exposures in vivo, we investigated the effect of the model toxicant (diesel exhaust particulates (DEP)) on human bronchial epithelial cell (HBEC) and lung fibroblast (HLF) oxidative stress and pro-inflammatory signaling. We hypothesized that trans-epithelial exposure to DEP drives oxidative stress and pro-inflammatory response through an imbalance of oxidant/antioxidant gene expression and alternative cellular signaling pathway activation within the airway microenvironment. Temporal (2-24 hours) gene expression analysis demonstrated peak HMOX-1 response at 6 hours in HBEC and HLF, while IL-8 peaked at 4 hours in HBEC and 10 hours in HLF, by which time HM0X-1 had declined substantially. Genes involved in glutathione homeostasis and H2O2 signaling (NQO1, TRX1, PTGS2 and GCLM1) were alternatively regulated in response to DEP exposure. Live-cell imaging with a dual fluorescent biosensor for glutathione oxidation and intracellular H2O2 accumulation (roGFP2/Hyper red) showed that treatment with DEP led to an increase in overall oxidation in both cell types, which was attenuated by pre-treatment with the free radical scavenger, N-acetyl-cysteine (NAC). Upregulation of antioxidant response and pro-inflammatory genes in our studies suggested a role for key stress-response pathways (MAPK, NF-kB and Nrf2) in DEP-dependent oxidative stress and pro-inflammatory signaling. The kinetics of MAPK, NF-kB and Nrf2 pathway activation by DEP exposure were determined via time-course (2-24 hours) immunoblotting and densitometry analysis; confirming DEP-mediated and time-dependent phosphorylation of key cellular targets. This study is the first to characterize the dynamics of oxidative stress and pro-inflammatory signaling within the airway microenvironment following trans-epithelial chemical exposure and provides novel insight for the development of therapeutic and/or preventative interventions to reduce adverse effects of inhaled chemical exposure.

Hydroxia induces lung inflammation and injury, which significantly impacts patient morbidity and mortality. Prior studies show protective effects of cytochrome P450 (CYP1A1) enzymes against hyperoxic lung injury. Nrf2 is an important transcriptional regulator of antioxidants and loss of Nrf2 leads to exacerbation of hyperoxic lung injury with reduced antioxidant expression in lung tissue and mortality in mice. Studies to rescue the Nrf2-/- phenotype against oxygen injury are lacking. In this investigation, we tested the hypothesis that hyperoxia induces lung inflammation and inflammation in Nrf2-/- mice compared to wild type (WT), and that this phenotype will be rescued by the free radical scavenger, N-acetyl-cysteine (NAC). Lung Cyp1a1 transcription was elevated with BNF treatment and loss of Nrf2 leads to hyperoxic lung tissue and mortality in mice. Studies to rescue the lung injury phenotype in Nrf2-/- mice suggests that augmented CYP1A expression by BNF may contribute to the beneficial effects. Further studies could lead to the development of BNF and other flavonoids for the prevention/treatment of hyperoxic lung injury.

Oxidative stress and reactive oxygen species (ROS) released during acute inflammatory processes contribute to airway injury in allergic asthma (1). Innate immune cells, including monocytes/macrophages and neutrophils, are key contributors to inflammatory mediators including ROS (1). Monocytes/macrophages are critical in the regulation of tissue damage by reacting to initial oxidative stress (1). Limitations include the lack of understanding of monocytes/macrophages and neutrophils in the development of therapeutic and/or preventative interventions to reduce adverse effects of inhaled chemical exposure. JUUL and vaping pens are emerging electronic nicotine delivery systems (ENDS) in western populations. They have become increasingly popular among youth due to compartmentalized packaging, appealing flavors, and as health supplements. Moreover, these ENDS are also perceived as a healthier alternative to traditional cigarettes, thus have become a public health concern. The health effects caused by JUUL and vape pens are currently unknown. We hypothesized that JUUL and vape pens constituents, primarily the flavoring agents, will induce cytotoxicity, oxidative stress, and inflammation. Acellular reactive oxygen species (ROS) levels generated by various JUUL flavors (cool mint, mango, crème brulee, Virginia tobacco, and cool cucumber) and vaping pens (vitamin B12, sleep, energy, and performax) were evaluated by DCFH-DA fluorescent dye. These flavors were also assessed for their ability to deplete glutathione (GSH) and form oxidized glutathione (GSSG). To evaluate cellular effects due to acute exposure, lung epithelial cells (Beas 29) and macrophages (U937) were exposed to aerosols generated by JUUL and vape pens. Cytotoxicity was determined by measuring the cell viability by (AO/PI) staining; IL-8 cytokine levels were measured in the conditioned media by ELISA to assess the inflammatory response. The reduced ROS levels induced in the control group. JUUL cool mint produced the highest levels of ROS in JUUL peaking at 29 µM H2O2 equivalence. Vitaminvape B-12 produced the highest levels of ROS for vape pens peaking at 121 µM H2O2 equivalence. These flavors had differential effects on GSH levels compared to the control group. These flavors did not significantly affect cell viability, but induced differential IL-8 levels in the exposed cells. Our data show that JUUL and vape pens flavor may trigger a pro-inflammatory response mediated by oxidative stress. These data suggest that JUUL and vape pens are not a risk-free method of vaping and the constit-
In Vitro Exposure of Lung Cells to Electronic-Cigarette Aerosols at the Air-Liquid Interface Is Cytotoxic, Alters Gene Expression and Levels of Reactive Oxygen-Nitrogen Species

Louisiana State University, Baton Rouge, LA.

Over 8 million US adults are regular e-cig users. Emerging evidence indicates that e-cig aerosols adversely affect lung function; however, the cellular and molecular mechanisms underlying these effects remain unknown. To examine the effects of e-cig aerosol exposures on lung cells in an in vitro exposure system representative of human pulmonary deposition, confluent human lung epithelial cells (H292), human pulmonary fibroblasts (MRC-5), and mouse embryonic fibroblasts (NIH-3T3) were exposed to butter-flavored (diacetyl) e-cig aerosols at the air-liquid interface (ALI) in a Virtrocell exposure system connected to a third-generation e-cig (SCIREQ). Exposures were conducted following a standard transpulmonary topology profile for 1-hr per day for 1, 3, or 6 consecutive days. Following ALI exposures, cell viability and cytotoxicity were assessed; exogenous nitric oxide (NO), and reactive oxygen species (ROS) levels were measured in the culture media; and gene expression was analyzed by qRT-PCR. E-cig aerosol-exposed H292 cells had significantly reduced numbers of viable cells and increased levels of lactate dehydrogenase (LDH), a marker of cytotoxicity, (>87 and 114%, 3 and 6 days, respectively) compared to air controls. While NO levels were markedly reduced at >63% and 6 days (>92%), extracellular ROS levels increased by >40% at both time-points. A 1-day e-cig exposure supported these results with significantly augmented mRNA levels of HMOX1 (oxidative stress), HPRT1 (hypoxia), h<sub>2</sub>mall (apoptotic), and IL-6 (inflammation). Similarly, e-cig decreased cell viability and increased LDH levels in MRC5 (>18%) and NIH3T3 (>145%) cells at both time-points. At 3 days, e-cig decreased exogenous NO levels (MRC5: >33%; NIH3T3: >85%) and increased the ROS activity (MRC5: 49% and NIH3T3: 113%). There is a time-course relationship where e-cig exposure appears to decrease NO production. Further, human lung epithelial cells may be more sensitive to e-cig aerosols than lung fibroblasts. Overall, long-term exposures to e-cig aerosol may induce detrimental effects in the lungs due to cytotoxicity, enhanced oxidative stress, low levels of NO, and altered expression of key genes associated with oxidative stress, airway remodeling and inflammation.

Target Safety Assessments: Evaluation of the Toxicological Risk of Targeting FRS (Phenylalanyl-tRNA Synthetase) in the Treatment of Malaria

J. Barber1, C. Sadler1, D. Baud4, P. Willis1, and R. Roberts2,3. Apconix, Alderley Edge, United Kingdom; 1Medicines for Malaria Venture, Geneva, Switzerland; and 2University of Birmingham, Birmingham, United Kingdom.

Phenylalanyl-tRNA synthetase (FRS) is a highly conserved enzyme that catalyzes the ligation of phenylalanine to its cognate transfer tRNA during protein synthesis. Due to its vital role as part of the translational machinery, FRS has been identified as a potential target to treat the malaria parasite. However, since target-related toxicity accounts for >50% of all drug project failures, it is vital to understand the potential unintended consequences of target modulation in non-plasmodium (mammalian) species to assist in the determination of the required plasmodium/human safety ratio. We conducted a comprehensive in silico target safety review to understand the role of FRS in normal physiology as a basis for evaluation of the potential toxicity of FRS inhibitors. Based on published literature, it is clear that eukaryotic cellular harbours two different types of FRS: the heterotetrameric cytosolic alpha (FRSA) and beta forms, and the monocmeric mitochondrial forms. Pathogenic variants in FRSA (encoding the human mitochondrial FRS) have been associated with phenotypes ranging from spastic paraplegia to fatal infantile Alpers encephalopathy. FRS1 knockout mice are homozygous lethal. Heterozygote phenotypes include abnormal bone morphology, decreased bone mineral density, decreased circulating chloride and sodium levels, impaired glucose tolerance and increased total body fat amount. Based on these observations, we predict that potential target organs of toxicity caused by inhibition of FRS could include bone, heart, immune system, kidney, and the reproductive system. Specifically, there may be a risk of abnormal bone development, perturbed glucose metabolism, immunosuppression, nephotoxicity, reduced liver function, myopathy and an increased risk of epilepsy. Based on this toxicological profile, inhibition of host FRS could be a serious limitation; therefore, the specificity and selectivity of compounds will be a key for their success. However, a single genomic copy of mitochondrial FRS is targeted to the parasite mitochondria and is exclusive to malaria parasites within the apicomplexan phyla, hence drug targeting of FRS presents a unique opportunity to potentially target malarial FRS specifically. Nonetheless, it would be sensible to conduct an early rodent investigative study looking at in life effects and potential target organs to help identify whether the risks in an silico analysis has identified actually occur in vivo with inhibitors of FRS.

Efficacy and Preclinical Pharmacokinetics and Toxicology of L-Propargylglycine, a Prototype Inhibitor of Sleep Disordered Breathing (Sleep Apnea)

D. McCormick1, M. Muzzio1, G. Murillo1, and N. Prabhakar2. IIT Research Institute, Chicago, IL; and University of Chicago, Chicago, IL.

More than 25 million Americans demonstrate sleep disordered breathing (SDB). In addition to interfering with normal sleep patterns, SDB has been linked to serious secondary pathologies that include cardiac arrhythmia, hypertension, and stroke. However, no effective drug therapies are available to treat SDB. We have recently reported that hypersensitivity of the carotid body is an important mechanism underlying SDB, and that this carotid body hypersensitivity results from enhanced generation of H<sub>2</sub>S by cystathionine γ-lyase (CSE). In the present studies, we used a well-known inhibitor of CSE, L-propargylglycine (L-PAG), as a prototype agent to investigate the hypothesis that CSE inhibition is an effective means to prevent SDB. L-PAG is a potent inhibitor of SDB in the HO-2-/- knockout mouse model. L-PAG doses ≥ 90 mg/kg completely inhibit SDB. L-PAG is rapidly absorbed after oral dosing and T<sub>max</sub> = 0.25 to 0.5 hr, and oral bioavailability is 100%. Plasma concentrations of L-PAG increase in proportion to dose, and are directly related to efficacy in SDB inhibition: 30% efficacy is seen at plasma levels of ~50 μM (oral dose of 10 mg/kg), and 100% efficacy in SDB inhibition is seen at plasma levels ≥ 500 μM (oral doses ≥ 90 mg/kg). Evidence of gross toxicity was seen only after single dose administration of L-PAG at 750 mg/kg (plasma level of ~4500 μM), providing an efficacy to toxicity ratio of ≥ 8 (toxic dose versus 100% inhibitory dose) to as much as 75 (toxic dose versus 30% inhibitory dose). A 7-day repeat-dose screening toxicity study of L-PAG and its enantiomer D-PAG was performed in C57BL6 mice. At doses of up to 100 mg/kg/day (an L-PAG dose that completely inhibits SDB in HO-2-/- mice), neither L-PAG nor D-PAG had significant effects on survival, clinical signs of toxicity, body weights, hematology, clinical chemistry, or gross pathology at necropsy. L-PAG also had no effect on in vitro hERG activity. However, screening Ames tests of L-PAG and D-PAG in TA98 and TA100 tester strains demonstrated that both agents are mutagenic (both with and without metabolic activation); D-PAG was the more potent mutagen. These data demonstrate that CSE inhibition provides a viable mechanism for prevention and treatment of SDB. However, the mutagenicity of L-PAG makes it unsuitable for further preclinical or clinical development. NHLBI grant SU5H3HL123610.

Optimising Kinase Selectivity for Non-Oncology Indications

The development of kinase inhibitors for non-oncology indications demands a stringent safety profile. Each indication and/or patient population will determine the acceptable tolerability profile. Early focus on selectivity is therefore required and best addressed with a cross-functional approach. Unified kinase profiles and data analysis within and across projects are needed, and enable a better understanding of selectivity requirements and potential associated adverse effects. Tools to correlate the latter to certain off-target kinase hits and pathways involved are extremely valuable to determine a path forward. Although providing an exhaustive list of ‘kinases to avoid’ is not feasible, literature-based analysis of frequent off-target kinase hits is a first step to assess if building selectivity should be considered. Once undesirable kinase hits have been identified, pIC<sub>50</sub>s should be generated to enable ligand based SAR. However, enough datapoints are needed to explore the potential of this QSAR model and enable the prediction of off-target kinase hits for future compounds. The availability of crystal structures of ideally both target and related off-target kinases is another valuable tool to enable selectivity by design. These models are crucial since in vivo toxicity studies should only be performed once sufficient selectivity has been achieved to adequately inform further development of the compounds. The ultimate goal is to enable the development of kinase inhibitors with an acceptable risk-benefit profile for non-oncology indications.
P-glycoprotein (P-gp, MDR-1) is an ATP-dependent efflux transporter that is highly expressed in the gastrointestinal epithelium, liver, pancreas and kidneys, as well as the capillary endothelial cells that establish the blood-brain barrier. P-gp interacts with a diverse array of small molecule xenobiotics, including many drugs. Drugs that are substrates of P-gp are actively expelled from the cell, whereas drugs that are inhibitors of P-gp effectively abrogate the transporter function. Either interaction with P-gp can greatly impact the efficacy, potency, and safety of a co-administered drugs, shifting its rate and maximal concentration of absorption, distribution, metabolism, and eventual excretion (ADME). Assessing a drug’s potency as a non-substrate, substrate or inhibitor of P-gp, and thus its potential liability for inducing downstream drug-drug interactions (DDI), is a critical component of the drug development process mandated by the US FDA. In the current study we validate a new and sensitive cell-based P-gp activity assay and demonstrate its utility in the rapid screening of drug candidates to identify those that interact with P-gp. A small library of drugs was screened, and those presenting incidental activity as a P-gp substrate or inhibitor were classified and ranked by potency. Selected individual P-gp inhibitors were then administered to upcycled human hepatocytes in combination with a dose-regimen of individual second drugs that were also identified to be substrates of P-gp and previously characterized as modulators of CYP gene expression, or as hepatotoxins. In combination, these data reveal the significant impact of P-gp interactors on altering CYP expression profiles and increasing hepatotoxicity liabilities. The in vitro P-gp assay provides an important early predictor of potential downstream DDI.

In Vitro P-Glycoprotein (MDR-1) Activity Assay, Coupled with Cyp Induction and Hepatotoxicity Assessments, Is an Early Predictor of Drug-Drug Interaction Liabilities

E. Maddox1, S. Maalouf1, J. P. Vanden Heuvel1,2, and B. Sheft1,1INDIGO Biosciences, Inc., State College, PA; and 2Penn State University, University Park, PA.

Rod-shaped, adult canine cardiomyocytes (ACCs) are widely used as an in vitro test system in the fields of cardiosafety (e.g., to test if compounds cause arrhythmias) and drug discovery (e.g., to test if compounds may have beneficial effects in heart failure). However, current methods for quantifying drug effects on contraction in ACCs are low-throughput, as the cell preparations contain dying cells (round shape) vs. healthy cells (rod shaped), and investigators must manually search through the preparations and identify healthy cells for subsequent analysis. We developed high throughput methods for analysis of contraction function in ACCs using the Kinetic Image Cytometer® (KIC), which acquires digital movies from cells at a high frame rate (e.g., 30 to 1,500 frames per second) and which features pacing electrodes. To quantify contractile function at the level of calcium transients, ACCs were seeded into 96-well plates, loaded with Fluo-4, and incubated with test compounds. The KIC navigated to each well, autofocused, paced at 1 Hz for 60 seconds (to equilibrate the contractile function), and then recorded at 30 fps for 10 seconds (while continuing to pace—totaling ~ 80 sec per well). Video analysis algorithms were developed to recognize the healthy ACCs and simultaneously quantify calcium transients and contractile movements on a cell-by-cell basis. Analogously, action potentials and contractile movements were quantified from the ACCs using the fluorescent voltage indicator BeatST1. High throughput methods were also developed to quantify contractile motion of the ACCs for cells in which thioflavin-T was added with whole blood microsomal fractions (featuring conjugated fluorophores) and to quantify both contractile motion (edge detection) and sarcomere shortening for ACCs illuminated in bright field (label-free analysis of contraction). These KIC methods eliminated manual intervention during plate scanning and demonstrated strong positive effects of isoproterenol on calcium transients and contractile movements of the ACCs. The high throughput KIC techniques thus increase the number of ACCs analyzed for greater statistical power, and the speed of the experimental workflow using this cell type for cardiosafety and drug discovery.

High-Throughput Analysis of Contractile Function in Adult Canine Cardiomyocytes via Kinetic Image Cytometry

P. M. McDonough1, R. C. Basa1, R. S. Ingermanson1, B. Azimi1, N. Abi-Gerges1, P. E. Miller2, and J. H. Price1,2,1Vala Sciences Inc, San Diego, CA; 2AnaBios, San Diego, CA; and 3Scriitton Institute, San Diego, CA.

Cardiovascular toxicity is a prominent reason for late-stage failures in drug development. Current in vitro cardiovascular safety testing primarily focuses on ion channelopathy and cardiomyocyte (CM) contractility measurements. In recent years, human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) have been widely adopted as a physiologically relevant cell model for cardiac safety/toxicity assessment due to displaying a repertoire of ionic currents and channels. However, the contractile apparatus of hiPSC-CM as well as the calcium handling mechanisms are still reminiscent of fetal phenotypes and therefore limit their ability to be utilized for assessment of compounds which modulate the force of contraction (Roberson C. et al, 2013). In order to overcome this limitation we applied long-term electrical pacing using a high throughput pacing apparatus, which can electrically stimulate up to 6 96-well plates simultaneously, to enhance the functionality of hiPSC-CM. Human iPSC-CMs were subjected to continuous and progressive increase in applied electrical pacing for 15 days. The contraction of hiPSC-CMs were recorded using impedance measurements and calcium dynamics was evaluated using Ca2+ transient assays which measures the intensity change of fluorescent Ca2+ dye. Our data clearly demonstrate that 1) hiPSC-CMs possess an inherent negative impedance amplitude-frequency relationship which is reversed after electrical pacing; 2) contraction of paced cardiomyocytes as measured by impedance amplitude increased by positive inotropic compounds and reduced by negative inotrope; non-paced cells either didn’t show any apparent responses to positive inotropes or only showed negative response; 3) calcium handling machinery was improved in paced cells as reflected by significant increase in amplitude of Ca2+ transient peak after caffeine treatment, while non-paced cells showed no response. In addition, enhanced Ca2+ transient response to isoproterenol was observed in paced hiPSC-CMs demonstrating 100% increase in transient amplitude of Ca2+ transient peak compared to 10% increase in non-paced cells. In summary, our data suggests that contractile maturation of hiPSC-CMs can be improved after employment of chronic electrical pacing, resulting in enhanced cell response.

Assessment of Cardiac Contractile Force Modulator Using Functionally Mature Human iPSC-Derived Cardiomyocytes

X. Zhang1, M. Yu2, A. Okonomopoulou3, C. Willits4, K. Green2, and Y. A. Abassi1,1ACEA Biosciences Inc., San Diego, CA; and 2Myokardia, San Francisco, CA; Sponsor: C. Jin

1668 In Vitro P-Glycoprotein (MDR-1) Activity Assay, Coupled with Cyp Induction and Hepatotoxicity Assessments, Is an Early Predictor of Drug-Drug Interaction Liabilities

1667 Investigation of the Mechanism of a Small Molecule-Associated Coagulopathy

S. Kakiuchi-Kiyota1, H. Boeller1, M. B. Brooks2, A. P. Stablein2, C. Chou1, Z. Zhong1, and P. Kataolos1, Genentech Inc., South San Francisco, CA; and 2Cornell University College of Veterinary Medicine, Ithaca, NY.

Although prothrombin time (PT) and activated partial thromboplastin time (aPTT) are routinely measured to assess blood coagulation in preclinical general toxicity studies, there are few reports of small molecule off-target, which results in clinically significant prolongation of these screening tests. However, after 7-day repeat dosing of compound X in the Cynomolgus monkey, dose- and time-dependent increases in PT and aPTT were identified, which correlated with clinical signs of melena and hematomas; and macroscopic/microscopic evidence of hemorrhage in multiple organs were noted at all doses. These findings were not recapitulated in rats at comparable exposures. To determine the mechanism of toxicity, more in depth coagulation studies were performed using aliquots of banked citrate plasma. Coagulation factor assays revealed marked decreases in Vitamin K (Vit) K-dependent factors (FII, FIX, FXI, Protein C) without significant decreases in non-Vit K-dependent factors (FV, FXII), suggesting selective perturbation of Vit K metabolism. Thrombin generation was markedly decreased, consistent with the profound decreases in Vit K-dependent procoagulant factors and clinical signs and histologic findings of hemorrhage. There was no evidence of fibrinogen deficiency or dysfunction. When high-dose group plasma was mixed with control group plasma (1:1), PT corrected to normal, indicating that hemorrhage and protracted clotting times were due to factor deficiencies and not inhibition. To determine whether similar coagulation abnormalities could be generated in vitro, normal monkey or human plasma was spiked with compound X before coagulation testing. No compound-induced in vitro prolongation of clotting times occurred, demonstrating that compound X does not directly interact with clotting factors. Our results suggest that compound X may impair the activity of recycling enzymes associated with hepatic Vit K metabolism and/or interfere with Vit K intestinal absorption.

1669 Assessment of Cardiac Contractile Force Modulator Using Functionally Mature Human iPSC-Derived Cardiomyocytes

X. Zhang1, M. Yu2, A. Okonomopoulou3, C. Willits4, K. Green2, and Y. A. Abassi1,1ACEA Biosciences Inc., San Diego, CA; and 2Myokardia, San Francisco, CA; Sponsor: C. Jin
to positive inotropic compounds and improvement of calcium handling prop-
erties, which provides a more enhanced model system for assessment if in-
tropic compounds.

1670 Models and Strategies for Building Diversity and Inclusion in Toxicology
C. Curran, Northern Kentucky University, Highland Heights, KY.

Diversity and inclusion in science are more than a strategic goal for univer-
sities, government labs, and industry. Recent findings demonstrate that
diverse scientific teams produce more innovative science and more highly
 cited publications. However, many institutions struggle with implementing
effective programs to increase representation by women, underrepresented
minorities, and those from countries with fewer educational and scientific
resources. This session will bring together leading experts from the Society of
Toxicology, the National Institutes of Health, and the University of Maryland,
Baltimore County’s Meyerhoff Scholars Program to share successful models
and strategies for recruitment and retention of STEM trainees and career de-
velopment toward independent research careers. The topics to be discussed
include (1) an overview of the SOT Undergraduate Diversity Program’s 30
years of experience in recruiting new toxicology trainees and the Committee
on Diversity Initiatives’ efforts to expand global opportunities in toxicology
training, (2) the NIH perspective on supporting career success in biomedical
research where the number of underrepresented minority trainees is increas-
ing while success at the early career stage is lagging, (3) the successful imple-
mentation of the Meyerhoff Scholars Program, which encourages positive
peer pressure among highly capable underrepresented minorities and struc-
tured mentoring toward advanced degrees in STEM fields, and (4) guidance on
successfully navigating a career transition from academia to industry. The
session will conclude with questions from the audience and a general discus-
sion of inclusion and diversity in toxicology training and mentoring.

1671 “Not Your Father’s ED”: Expanding the Definition and Understanding of Endothelial
Dysfunction (ED) Due to Inhaled Toxicants
D. Conklin, University of Louisville, Louisville, KY.

Endothelial Dysfunction (ED) has referred traditionally to any decrement in
endothelium-dependent vascular function. This typically involves nitric oxide
(NO) production/signaling, as NO is one of the most ubiquitous messengers.
This selective definition remains important today, as loss of NO production/
bioavailability can contribute to a number of pathological sequelae, in-
cluding hypertension, erectile dysfunction, and thrombogenesis/stroke. Our
understanding of endothelium biology and ED now incorporates other dys-
functional changes, including angiogenesis, vascular permeability, release of
matrix metalloproteinases (MMPs), expression of adhesion proteins, and loss of
endothelial repair, to name a few, into an ever more inclusive definition of
ED. New technologies and tools applied in the assessment of said func-
tions have spurred innovative measures of myriad ED-related outcomes and
a better appreciation of the functional capacity of endothelium. The session
will span a continuum of complementary methodological approaches, from
flow-mediated dilatation in humans to angiogenesis assays in vitro and in vivo.
As an overall theme for exploring emergent measures of ED, the symposium
will focus on ED induced by inhaled toxins, which provides a real-world, con-
temporary problem and an unresolved mystery by which inhaled air toxics
air pollution, nanoparticles, e-cigarette aerosols) exert extrapulmonary influ-
ence over the systemic endothelium.

1672 Diverse Methodological Approaches to Investigate the Endothelial Impacts of
Toxicants and Systemic Inflammation
M. J. Campen, University of New Mexico, Albuquerque, NM.

The vascular endothelium exists as a barrier between systemically-absorbed
toxicants and target organs, and is therefore a crucial modulator of toxicity. Our
laboratory has developed a battery of in vitro and ex vivo assays that rely on
in vivo exposures to ensure realistic delivery and inclusion of off-target out-
comes such as generation of secondary inflammatory factors. These assays
additionally permit translational correlates and interspecies comparisons. Our
assays address four crucial functions of endothelial cells: regulation of vascu-
lar tone, inflammation, barrier integrity, and wound healing/angiogenesis.
These assays rely on serum, plasma or whole blood from exposed research
animals or clinical subjects. Incubation of endothelial cells or isolated vessels
with serum allows for interaction of all solute factors with the endothelial
surface receptors. Applying such models, we have established that inhaled
toxicants (nanotubes, ozone, diesel exhaust) drive systemic inflammatory sig-
nals carried by the circulation, and this outcome is consistent in humans and
laboratory models. Application of serum or plasma to endothelial cells and
vessels to assay vascular health impacts has a clear role in discovery-oriented
environmental and occupational health research, but may also have value in
clinical diagnostics, prognostics, as well as safety assessments for novel phar-
macaceuticals and supplements.

1673 Flavored Additives in Tobacco Products Induce Endothelial Cell Dysfunction
J. Fetterman, and N. Hamburg. Boston University, Boston, MA. Sponsor: D.
Conklin

Use of electronic cigarettes (e-cigarettes) has increased exponentially over
the last decade, and flavored tobacco products greatly increase appeal to
youth. Flavored additives in tobacco products are deemed safe for inges-
tion, but the cardiovascular effects of inhaled flavors are unknown. We devel-
oned a screen of endothelial cell (EC) toxicity to examine effects of flavorings.
Freshly isolated EC from users of menthol-flavored tobacco cigarettes had
impaired A23187-stimulated nitric oxide production compared with EC of
non-smokers. Treatment of EC of non-smokers with either menthol or eu-
genol decreased A23187-stimulated nitric oxide production. Additionally,
human aortic EC were incubated with vanillin, menthol, cinnamaldehyde, eu-
genol, dimethylpyrazine, diacetyl, isoamyl acetate, eucalyptol, and acetylpyr-
azine (up to 100 mM) for 90 min, and cell death, reactive oxygen species pro-
duction, expression of the proinflammatory IL-6, and nitric oxide production
were measured. Some flavors (vanillin, menthol, cinnamaldehyde, eugenol,
aceetylpyridine) induced inflammation and impaired A23187-stimulated ni-
tric oxide production consistent with endothelial dysfunction; while some in-
duced cell death and reactive oxygen species at high concentrations. Heating of
the flavors to temperatures as in e-cigarettes did not alter EC toxicity. Our
data suggest that exposure of EC to flavoring compounds used in tobacco
products may induce adverse EC effects relevant to cardiovascular toxicity.

1674 Air Pollution and Endothelial Progenitor Cells (EPCs): Measuring Loss of Endothelium
Repair Function
D. J. Conklin, P. Haberzettl, and T. E. O’Toole, University of Louisville,
Louisville, KY.

Exposure to fine particulate matter (PM2.5) air pollution is associated with
the depletion of circulating endothelial progenitor cells (EPCs) as well as
vascular injury and dysfunction. It remains unclear if PM2.5 exposure affects
EPC function. Thus, we studied the effects of (and the mechanisms whereby)
PM2.5 on EPC-mediated recovery of tissue perfusion after hind limb ischemia
(HLI) – an in vivo assay of angiogenesis. In comparison with EPCs isolated
from mice breathing filtered air, EPCs from mice exposed for 6h per day for 9
consecutive days to concentrated ambient PM2.5 (CAP) had defects in both
proliferative and tube formation functions. However, 9-days of CAP exposure
in mice overexpressing lung extracellular superoxide dismutase (ecSODTg)
did not affect circulating EPC levels, VEGF-stimulated Akt phosphorylation in
the aorta, plasma NOx levels or EPC tube formation as in WT mice. EPCs from
WT mice exposed to CAP failed to augment basal recovery of tissue perfusion
when injected into naive mice subjected to HLI; an effect absent in EPCs from
ecSODTg mice exposed to CAP. Exposure to PM2.5 impairs EPC abundance
and function and prevents EPC-mediated stimulation of vascular recovery after
HLI. This defect is attributed to pulmonary oxidative stress and endothe-
lium dysfunction.

1675 Endothelial Heterogeneity: Diverse Anatomic and Physiologic Determinants of
Toxicological Assessments after Inhalation Exposures
T. R. Nurkiewitz, West Virginia University, Morgantown, WV.

The endothelium is a single layer of cells that line the entire cardiovascular
system. Because of the considerable heterogeneity in the cardiovascular sys-
tem, endothelial structure and function can be quite different among discrete
sections. Notably, the microcirculation, which is comprised of all the vascula-
ture contained within a given tissue (arterioles, capillaries, venules and lym-
phatics) possesses diverse endothelial heterogeneity. We have developed mi-
crovascular techniques to directly assess the impact of toxicant exposures on
endothelial function. Intravital microscopy is a whole-animal in vivo approach
used to directly observe microvascular function in skeletal muscle, the mesentery and uterus (virgin and pregnant). Microvessels can be dissected from any tissue and studied ex vivo with the isolated, perfused and pressurized arteriole technique. These collective approaches have been used to assess extrapulmonary toxicity after inhalation exposure to diverse toxicants, including engineered nanomaterials, particulate matter and 3D-printer emissions in various stages of development and pregnancy. The diverse impacts of such toxicities will be discussed in terms of regional and segmental endothelial heterogeneity. Physiologically, this alters mechanotransduction and volume blood flow; which in turn compromise the ability to maintain cardiovascular homeostasis. The impact of these microvascular toxicities will be discussed from a bench-to-bedside, cardiovascular health perspective.

1676 Stem Cells and Metals Toxicity: From Tissue Regeneration and Repair to Carcinogenesis

E. Tokar, NIEHS, Research Triangle Park, NC.

Humans are exposed to metals on a daily occurrence. These exposures can occur during all stages of life, and could result in toxic effects in all organ systems, leading to aberrations in development and other biological processes. Stem cells (SCs) are highly specialized cells that are found in nearly all tissues and organs. Alterations in normal SC functions can adversely affect development and health, and can play key roles in disease etiology. The objective of this session is to highlight the various ways that metals can target and alter SCs during biological processes such as differentiation, tissue repair and regeneration, and carcinogenesis. The first presentation will focus on how chronic arsenic exposure alters muscle SC function to diminished regeneration, and how the effects of this metalloid on the microenvironment appear to play a key role in these alterations. The second presentation will discuss the effects of early-life methyl mercury exposure on muscle development and resultant motor function deficits, including the key roles of several candidate genes that act at the level of muscle SCs and/or regulate myocyte differentiation, mitochondrial biogenesis, and mtDNA transcription. The third talk will describe how subchronic manganese exposure affects adult neurogenesis by reducing the number of neural SCs in the hippocampal dentate gyrus and inhibiting the differentiation of neural stem/progenitor cells to mature neurons. The implications of these effects in Parkinson’s disease will be presented. The fourth presentation discusses how arsenic targets SCs and alters SC signaling pathways during carcinogenesis and the emerging evidence of how the metalloid can “recruit” SCs via altering exosome cargo and the tumor microenvironment. The final presentation focuses on how the stage of life during cadmium exposure can lead to differences in the number of breast SCs and their differentiation. Mechanisms underlying these differences and in breast cancer formation induced by this heavy metal will be presented. This session will be of interest to scientists involved in SCs, metals, development, or cancer research, and will be ideal for those who desire mechanistic understanding of the pathogenic and toxic effects of metals on SCs.

1677 Arsenic-Induced Alterations in the Muscle Extracellular Matrix Drive Stem Cell Dysfunction and Impaired Regeneration

Arsenic (As) contaminates drinking water from natural deposits in the earth. Over 140 million people worldwide are exposed to drinking water that exceeds government As standards. Increasing attention has been paid to declines in functional mobility resulting from chronic As exposure, which poses a significant risk for causing skeletal muscle myopathies and atrophy, impairments that are among the greatest factors contributing to declines in functional mobility and strong predictors of mortality. However, questions of health impacts of life-long environmental exposures remain, including mechanisms by which exposures negatively impact the cellular microenvironment, stem cell (SC) phenotype, and tissue maintenance and healing capacity. Studies of muscle pathology in mice following As exposure via drinking water (10-100 µg/L for 5 weeks) demonstrate As vitiates muscle SC (MuSC) function, resulting in a severely diminished regeneration and force recovery after injury. The microenvironment (niche) is critical for supporting muscle maintenance and MuSC regenerative potential. Niche alterations, including matrix disruption, fibrosis, and ectopic lipid droplet accumulation, often precede and/or accompany declines in the muscle maintenance and healing capacity. The influence of the niche on tissue regeneration involves tightly regulated, bi-directional communication between resident SCs and micro-environmental factors, including extracellular matrix (ECM) components and neighboring cells, including connective tissue fibroblasts (CTFs). We have shown As disrupts the myomatrix by promoting perivascular fibrosis, driving ectopic lipid accumulation and reorganizing ECM integrity. This increased ECM depo-

sition is consistent with impaired myofiber regeneration. Our findings further suggest CTFs isolated from As-exposed muscle exhibit a phenotype with elevated expression ECM remodeling proteins. Moreover, myomatrix alterations following As exposure contribute directly to an impaired muscle healing response after injury. When naive human MuSCs are seeded onto decellularized ECM constructs derived from As-exposed muscle, there is an increased fibrogenic conversion of MuSCs, as compared to MuSCs seeded onto control constructs. These findings suggest As-induced alterations of the myomatrix and matricellular regulators inhibit MuSC function and impair skeletal muscle regeneration.

1678 Muscle Stem Cells and Myogenic Targets of Methylmercury Toxicity

M. Rand. University of Rochester School of Medicine and Dentistry, Rochester, NY.

Methylmercury (MeHg) is an environmental toxin that targets the developing nervous system. Animal and human population studies show that early life MeHg exposure elicits motor and cognitive deficits. Mechanistic studies have therefore focused on neuronal targets. Thus, the possibility that motor function deficit can stem from MeHg alteration of muscle development has been largely overlooked. Our prior screens for developmental MeHg susceptibility genes with Drosophila have identified several genes that constitute core muscle developmental pathways that act at the level of muscle stem cells, namely, the Notch receptor pathway and myoblast fusion genes such as Kirre and Sticks and Stone. We have also observed overt MeHg muscle phenotypes including perturbation of myogenesis in the fly embryo that parallel adverse effects on developing motor neurons. At later developmental stages, MeHg perturbs formation of adult indirect flight muscles during pupal metamorphosis, which also results in a deficient eclosion behavior. We have now extended our investigation using a transgenic strategy of targeting Mrp1 transporter expression in a tissue specific manner to induce MeHg export and cell autonomous protection against MeHg toxicity. Targeted Mrp1 expression in muscle lineages gives a greater overall developmental tolerance to MeHg than Mrp1 expression in neural lineages. Additional functional assays in transgenic flies have identified a downstream target gene of the Notch receptor, the bhlh transcription factor Enhancer of Split mDelta that mediates MeHg toxicity in muscle development. Further studies on mammalian myotube formation using the C2C12 mouse myoblast model find a concentration-dependent inhibition of myoblast differentiation and fusion events. MeHg specifically and persistently affects expression of myogenin, a transcription factor involved in myocyte differentiation. Moreover, factors involved in mitochondrial biogenesis and mtDNA transcription and translation show a decreased expression with MeHg, implicating mitochondria in mediating MeHg-induced change in myogenic differentiation. Ongoing studies will elaborate myogenic phenotypes following prenatal exposure in mice. By characterizing a myopathic component of MeHg neurotoxicity we are expanding the current understanding of how motor deficits are likely to arise from early life MeHg exposure.

1679 Toxicity of Mn Exposure on Neural Progenitors and Adult Neurogenesis

W. Zheng, Purdue University School of Health Sciences, West Lafayette, IN.

Adult neurogenesis taking place in brain hippocampal dentate gyrus (HDG) functions to supply newborn neurons for normal brain functionality. Our published data establish that subchronic Mn exposure can disrupt adult neurogenesis in subventricular zone (SVZ). This presentation further provides the evidence that Mn exposure disturbs adult neurogenesis in HDG. To trace newly generated neural progenitor cells, adult rats were given a single injection of BrdU at the end of 4-wk Mn exposure. Immunostaining data revealed that the majority of BrdU signals were co-localized with S0X2, a selective marker for newly generated neural stem/progenitor cells. Mn exposure caused a 30% reduction of these cells in HDG as compared to controls. To track the fate of BrdU-labeled cells in the HDG, another set of adult rats received BrdU injections for 3 consecutive days followed by 2- or 4-wk Mn exposure. A significant time-dependent migration of newborn cells from the S0X2 toward the granule cell layer was observed in both control and Mn-exposed HDG. Triple-stained neuroblasts and mature neurons further revealed that Mn exposure significantly inhibited the differentiation of immature neuroblasts into mature neurons in the HDG. Based on these observations, the implication of an impaired neuronal repair mechanism in Mn-induced Parkinsonian disorder and possible therapeutic target will be discussed.
Emerging evidence suggests that stem cells (SCs) are a key target cell population for arsenic carcinogenesis. A cancer SC (CSC) overabundance is seen in rodent tumors induced by transplacental and whole-life exposures to arsenic and in human adult (differentiated) cell lines malignantly transformed by the metalloid. Furthermore, human SC lines rapidly acquire a CSC phenotypic barrier in the presence of high-level arsenic exposure. This CSC-like phenotype is characterized by increased self-renewal, drug resistance, and clonal expansion. The presentation will start with a discussion of the various mechanisms involved in arsenic-induced CSC formation and overabundance, including the dysregulation of SC population dynamics, the alteration of tumor suppressor genes (TP53), and key signaling pathways (i.e., Wnt, Sonic Hedgehog, Notch) involved in SC CSC regulation, and the epigenetic regulation of the KRAS oncogene. Next, the presentation will describe how arsenic impacts the microenvironment through SC “recruitment” by altering extracellular and cell membrane cargo, including oncogenes (KRAS, VEGFA, MYB, EGFR), inflammation-related (COX2, IL1B, IL6, TGFβ1, TNFA), apoptosis-related (CASP7, CASP9, BCL2) genes, and cancer-associated microRNAs. Some of the effects described above are shared with other carcinogenic metals, while other effects appear to have opposing effects on SCs. The presentation will end with a brief comparison of the SC-related effects between arsenic and other carcinogenic metals, including cadmium, nickel, and chromium.

Systems Toxicology Approach to the Science of Safety Evaluation
M. Davis, Bristol-Myers Squibb, Princeton, NJ.

Systems toxicology is a transformational subdiscipline within toxicology that applies approaches from systems biology to toxicity-related questions. The session will bring together several advances within systems toxicology that are focused on diverse applications and opportunities in drug safety. Each presenter will share examples of successes and challenges they have experienced with applying “omic methods, definitive approaches (e.g., CRISPR, knockouts/ins), and network analysis to toxicology evaluations. The first talk will provide an overview of the challenges inherent in extrapolating safety signals across species to understand human risk. Immune responses provide a natural model to facilitate our understanding of complex and interactive events, and the second talk will address immunotoxicity in the context of systems approaches that can be applied to understanding the complexity of immune system interactions. The third presentation will focus on the promise and challenges of microphysiological platforms in systems toxicology. The final talk will provide mechanistic insights into species-specific metabolism, with emphasis on how systems approaches can facilitate the selection of biomarkers consistent with rat and human biology. Key insights about how computational models can serve as platforms for contextualizing experimental data and making functional predictions will be shared. The collective content of the session will highlight how we might use sophisticated, integrated systems and modeling to inform safety decisions in drug discovery.

Application of a Microphysiology (MPS) Platform for Systems Toxicology
D. Taylor, University of Pittsburgh, Pittsburgh, PA. Sponsor: M. Davis

This talk will focus on a platform developed for constructing human organs on chips including the evolution of human, 3D, microfluidic, MPS devices to model toxicology for drug development and to model progression of diseases for drug discovery using quantitative systems pharmacology (QSP). To mimic in vivo complexity and functionality of the liver for studying drug efficacy, metabolism and toxicity a 4-cell type liver MPS platform has been developed. In addition, IPCS-derived liver cells from patients enable capture of heterogeneity of genetic and disease backgrounds. The liver MPS can be used as a stand-alone liver or coupled to other organ MPS such as the intestine and pancreas through the vascular channel. It is also possible to quantify immune cell infiltration in the liver MPS along with its applications in toxicology and non-alcoholic fatty liver disease. The critical need to implement an MPS database to manage, analyze and model the data will also be discussed.
The comparative analysis of metabolic networks can provide mechanistic understanding of species-specific differences of metabolism and associated biomarkers and drug targets for various applications. The laboratory rat has been used as a surrogate to study human biology for more than a century. We have generated the first genome-scale reconstruction of Rattus norvegicus metabolism, iRno, and a significantly improved reconstruction of human metabolism, iHsa. Comparative analyses with these models captured metabolic features that distinguish rats from humans. After reconciling network differences between iRno and iHsa, we integrate toxicogenomics data from rat and human hepatocytes to generate biomarker predictions in response to 76 drugs. We validate comparative predictions for xanthine derivatives with new experimental data and literature-based evidence delineating metabolite biomarkers unique to humans. Our results provide mechanistic insights into species-specific metabolism and facilitate the selection of biomarkers consistent with rat and human biology. These models can serve as powerful computational platforms for contextualizing experimental data and making functional predictions for clinical and basic science applications.

Brain health is essential for human well-being across all life stages. Brain development and function are impacted by both genetic and environmental factors. Environmental factors, including exposure to environmental contaminants, are implicated in the etiology of a number of developmental, psychiatric, and neurodegenerative disorders. The zebrafish is a powerful model for assessing the impact of toxicants on brain development and function. Zebrafish embryos are externally fertilized, which enables direct exposure of the developing embryo, obviating the requirement for maternal exposures. In addition, developing embryos are transparent, which allows for in vivo imaging of the developing brain. Overall, development occurs rapidly, including formation of the nascent nervous system by three days of life. Furthermore, a suite of behavioral assays have been developed as functional readouts of toxicant effects on nervous system development and function, and these have been routinely adapted to medium-to-high-throughput screens for hazard identification and chemical prioritization. In this session, researchers will describe how they have leveraged the zebrafish model to investigate different mechanisms of action by which toxicant exposure alters brain development and function. The first presentation will reveal the essentiality of the aryl hydrocarbon receptor (AhR) in blood-brain barrier (BBB) formation and how AhR agonists perturb BBB development. The second talk will introduce the microbiota-gut-brain axis and how developmental exposure to exogenous estradiol compromises neurobehavioral development in a microbiota-dependent manner. The third talk will illuminate the role of GABAergic perturbations by environmental chemicals using a gene editing approach. The fourth presentation will show a mechanistic link between domoic acid exposure, myelination defects, and impaired startle response. The fifth talk will highlight new analytical chemistry approaches that can be used to elucidate mechanisms by which xenobiotics disrupt cholinergic, serotonergic, dopaminergic/adrenergic, histaminergic, and glutamnergic/GABAergic neurotransmitter systems. An excellent 2018 zebrafish session surveyed the multiple uses for larval and adult zebrafish including screening environmental chemicals for developmental toxicity, identifying epilepsy drugs, examining chemical-microbiota interactions when estimating chemical hazard. This abstract does not necessarily reflect US EPA policy.

The brain demands a continuous supply of oxygen and nutrients, while at the same time protecting from blood-borne substances and toxicants. Specialized brain endothelial cells along with neurons, astrocytes, pericytes, and the basement membrane form the blood brain barrier (BBB); a combination of physical and chemical barriers that regulate the entry of blood-borne substances into the brain. Previous research demonstrated that the aryl hydrocarbon receptor (AhR) is necessary for mammalian vascular development and is activated in the zebrafish vasculature following exposure to AhR agonists. To test whether global AhR activation disrupts neurovascular development, we exposed zebrafish to the prototypical AhR agonist, 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD). TCDD exposure resulted in cerebral hemorrhaging, neurovascular malformations, and loss of pericytes. To determine whether AhR activation also disrupted BBB development, we used transgenic zebrafish to examine glucose transporter 1 (glut1) expression, a marker of differentiated brain endothelial cells that have acquired barrier properties. In addition, we examined the expression of breast cancer resistance protein (bcrp) and p-glycoprotein (pgp), two important efflux transporters expressed in brain endothelial cells. RT-qPCR results demonstrated glut1 as well as bcrp were significantly reduced following TCDD exposure. However, pgp expression was unchanged. We are using transgenic fish to determine if endothelial-specific activation of AhR recapitulates the observed phenotypes. Together, our results indicate that global AhR activation impairs both neurovascular development and BBB formation. Given that ability to visualize BBB development and function in real time and in vivo in zebrafish, the model is poised to significantly contribute to our understanding of the developmental genetics underlying barrierogenesis, facilitate the development of strategies for manipulating barrier properties to treat disease and effectively deliver drugs to the central nervous system, and provide insight into how toxicant exposures contribute to BBB dysfunction. Supported by NIHES RO1ES023848.

Estrogenic chemicals are widespread environmental contaminants. During early vertebrate development, estrogen receptor signaling is critical for nervous system function. Because host-associated microbiota influence neurodevelopment and can metabolize xenobiotics, we hypothesized that microbiota can biotransform exogenous estradiol (E2) and modify the E2 effect on neurobehavioral development. To test this hypothesis, colonized zebrafish were continuously exposed to five non-teratogenic E2 concentrations (0.34–3.5 μM) from 1 to 10 days post–fertilization (dpf). At 10 dpf, 165 RNA gene sequencing was used to evaluate changes in microbial community composition and predicted metagenomic function. Locomotor activity was assessed in colonized and axenic (microbe-free) zebrafish exposed to 0.4 or 1.2 μM E2 using a standard light/dark behavioral assay and zebrafish tissue was collected to conduct targeted and non-targeted mass spectrometry. E2 exposure did not alter microbial composition or function in colonized larvae. However, light-phase locomotor hypoactivity was observed in E2-exposed colonized larvae as opposed to normal behavior in axenic larvae exposed to E2. Both colonized and axenic larvae exposed to E2 exhibited hypoactivity in the dark phase. Measured parent E2 concentrations and abundance of predicted direct E2 metabolites (E2 sulfate and E2 glucuronide) were significantly higher in axenic relative to colonized zebrafish, while abundance of putative secondary metabolites (estrone sulfate and estrone glucuronide) was similar in axenic and colonized zebrafish. These data suggest a correlation between chemical-induced neurobehavioral effects and microbiota-based metabolism of exogenous chemicals. More broadly, this work supports the inclusion of chemical-microbiota interactions when estimating chemical hazard. This abstract does not necessarily reflect US EPA policy.
There is growing appreciation for the potential of chemical exposures to trigger seizures, which can result in acquired epilepsy. Identifying platforms to screen chemicals for neurotoxic potential and elucidating the mechanisms by which chemicals disrupt the balance of excitatory and inhibitory circuits in the brain to trigger seizures, remain critical data gaps. There are also significant questions regarding mechanism(s) by which chemicals interact with genetic susceptibilities to influence seizure thresholds. Our lab is leveraging larval zebrafish as a powerful model for addressing these questions. Larval zebrafish express the full genetic complement of ionotropic and metabotropic glutamate receptors, GABA(A/B) receptors, and associated regulatory proteins that are expressed in mammalian systems. However, zebrafish offer significant advantages over rodent models, in terms of adaptability to higher throughput technologies and genetic tractability. This presentation will describe the use of larval zebrafish to study the molecular mechanisms by which chemicals trigger seizures, and to screen chemicals for seizureogenic and anti-seizure activity. Topics to be covered include: (1) the discovery of unique patterns of electrical spike activity elicited by chemically distinct GABA(A) receptor blockers, (2) the development of a locomotor assay in larval zebrafish as a higher throughput behavioral assay to screen chemicals for seizureogenic and anti-seizure activity.

### Early Developmental Exposure to Low Levels of Domoic Acid, a Harmful Algal Bloom Toxin, Disrupts Myelination, Leading to Behavioral Effects

J. Panlilio, N. Aluru, and M. E. Hahn, MIT/Woods Hole Oceanographic Institution (WHOI), Woods Hole, MA.

Harmful algal blooms (HABs) produce toxins such as domoic acid (DomoA) that accumulate in seafood and affect human health. While regulations prevent the harvest of seafood with concentrations causing acute toxicity, studies in rodents have shown that low-level exposure to DomoA during early development can have long-lasting, adverse effects on neurodevelopment. We used transgenic zebrafish to identify the cellular and molecular mechanisms of developmental toxicity including cell type targets identified by DomoA, perturbations to nervous system structure, and effects on behavior. We exposed zebrafish to DomoA (0.14-0.18 ng/embryo) by caudal vein microinjection. Exposure to DomoA at 2dpf, but not 1 or 4dpf, caused myelination defects ranging from thinning to the absence of myelin sheaths. Time-lapse imaging showed that DomoA exposure at 2dpf perturbs the initial formation of myelin sheaths from 2.5-3dpf. Exposure to DomoA at 2dpf reduced the number of myelinating oligodendrocytes but not oligodendrocyte precursor cells. Whole embryo RNA sequencing showed differentially expressed genes associated with myelin (mbp, mbpa) and axon cytoskeleton (nelfa, nelfb, nefma, nefmb), suggesting disruption of pathways necessary for maintaining axonal and myelin sheath structures. DomoA-exposed larvae had an impaired startle response, a behavior that requires proper myelination in the circuit. These findings provide mechanistic insights into neurotoxicity of DomoA exposure during critical periods of neurodevelopment by identifying the vulnerable period of developmental exposure during oligodendrocyte differentiation and myelin sheath formation, characterizing DomoA-induced structural changes in myelin sheaths, identifying underlying changes in gene expression, and determining the functional consequences for startle behavior. The implications of these results for hazard assessments for low-level DomoA exposures in humans during key periods of pregnancy and early childhood development will be discussed. Supported by NIH P01ES021923, NSF OCE-1314642.

### A Novel Approach to Identify Neurotoxic Modes of Action

J. Legradi. Vrije Universiteit, Amsterdam, Netherlands. Sponsor: J. Plavicki

Exposure to neurotoxic chemicals contributes to the development and progression of neurological disorders and negatively impacts the health of ecosystems. However, neurotoxicity testing is not currently required for new chemicals. In addition, best practices to assess the neurotoxicity of new and existing chemicals are unclear. Given the increasing numbers of chemicals in commerce and the physiological and morphological complexity of the nervous system, it is a major challenge to test all substances for their neurotoxic potential. New advanced neurotoxicity assessment strategies are therefore needed to fulfill these demands. We are developing a novel neurotoxicity assessment approach which uses behavioral phenotypes in zebrafish embryos to identify neurotoxic modes of action. For this we exposed zebrafish embryos to 39 compounds including pyrethroids, carbamates, organophosphates, neonicotinoids, phthalates and brominated and fluorinated flame-retardants. We then used a widely used light-dark transition test to identify distinct behavioral profiles of exposed embryos. To link these profiles to neurotoxic MoA we use three different omics platforms. We quantified metabolic changes in neurotransmitter systems including the dopaminergic/ adrenergic, glutamnergic/GABAergic, serotonergic, histaminergic and cholinergic systems. In addition, we performed nontargeted proteomic analyses. The transcriptomic changes were analyzed using a custom Neurotox multiplex qPCR array containing 42 neurodevelopmental genes. Data analyses revealed that metabolic changes on neurotransmitter systems correlate well with behavioral responses. The proteomic profiles were mainly influenced by the timing of exposure (bioactivation). The transcriptomic profile could not be linked to the other omics methods and the behavioral tests. Additional tests with chlorpyrifos-oxon, indicate that this might be caused by feedback mechanism in the neurotransmitter systems. Overall, this work reveals complex relationships that are required for neurobehavioral development and function and elucidated common and unique mechanisms by which environmental chemicals disrupt vertebrate neurodevelopment.

### Emergent Mechanisms of Cytochrome P450 Gene Regulation: Defining an Improved Roadmap toward 21st-Century Pharmacogenomics

A. Annalora, Oregon State University, Corvallis, OR.

To understand the interplay between nuclear receptor (NR) signaling and the expression of phase I, II, and III drug metabolizing systems, one must appreciate the role that endo-xenobiotic exposures play in organizing both gene expression and alternative gene splicing events. The human transcriptome is shaped by an array of different factors, including genetics, chemical exposures, diet, and metabolic diseases; this complex process is mediated primarily by differential recognition of gene promoters and canonical splice-sites by either the DNA Polymerase II transcriptional complex or the spliceosome; the structural organization of these multi-subunit, gene-processing complexes are subject to modulation by ligand-activated NR proteins that allow highly specific cell type or cellular microenvironments. Systems approaches are quickly expanding our ability to assess the impact of endo-xenobiotic exposures on gene expression and metabolism. The goal of the session is to integrate cutting-edge research focused on various systems approaches to toxicology that are providing novel insights into the global determinants of Cytochrome P450 (CYP) gene regulation as needed to synthesize a more coherent model of NR-mediated regulation of both transcription and gene splicing. The workshop will highlight research aimed at deconvoluting the overlapping contributions that endogenous substrate, xenobiotic, and microbiome-mediated metabolism play in crafting cellular responses to the environment, in pursuit of an improved pharmacogenomic framework for advancing both predictive toxicology and precision-based approaches to medicine. The presentations will also explore how alternative model systems, such as the organ-on-a-chip technology, are providing new opportunities to manipulate CYP gene expression and splicing in a highly personalized manner that promises to usher in a new era of safe and effective gene-directed therapeutics.

### Meta-Transcriptomics Analysis of Alternative Splicing in the Cytochrome P450 Superfamily: Decoding Novel Mechanisms of Gene Regulation and Function, Environmental Toxicity, and Disease

A. J. Annalora, Oregon State University, Corvallis, OR.

Alternative pre-mRNA splicing in the cytochrome P450 (CYP) superfamily dramatically expands the complexity of the CYP transcriptome. A meta-transcriptomics analysis of alternative CYP splicing identified nearly 1,000 splice variants among 57 human CYP genes linked to tissue-specific, genetic, chemical exposure and disease. The transcriptome expansion that underlies this phenomenon is mediated by a complex array of cell-specific splicing factors, oxidative stress, heavy metal toxicity and xenobiotic exposures that can alter: 1) the quantity and quality of pre-mRNA; 2) the assembly and stability of the spliceosome; and 3) the activation of nuclear receptor (NR) genes that modulate both gene expression and splicing events based on cues from the environment, metabolome and microbiome (Toxicology. 2012. 296:1–12). CYP proteome expansion arising from this diversity may
1695 Gut Microbiome: A Novel Frontier for Xenobiotic Metabolism in the Host Liver

J. Cui. University of Washington, Seattle, WA.

Accumulating data in the literature have demonstrated the critical roles of intestinal bacteria on the host intermediary metabolism including obesity and type II diabetes. Relatively less is known regarding the impact of intestinal bacteria on the hepatic drug-processing gene expression and xenobiotic metabolism. RNA-sequencing demonstrated that in livers of germ-free mice, there was a marked decrease in the hepatic expression and enzyme activity of cytochrome P450 (CYP) 3A, which is a major class of phase-I enzyme involved in the biotransformation of over two-thirds of the drugs prescribed in the market; in contrast, there was a marked increase in the hepatic expression and enzyme activity of CYP4A, which is important for lipid metabolism. Chromatin immunoprecipitation and qPCR results suggested that this was likely due to attenuated pregnane X receptor signaling but enhanced peroxisome proliferator-activated receptor signaling. During liver development, the presence of intestinal microbiota markedly impacted the normal ontogeny of many hepatic drug-processing genes in a gender-specific manner. Introducing exogenous bacteria by probiotics or conventionalization also influenced the hepatic drug-processing capacities. Finally, the environmental chemical polycyclic aromatic hydrocarbons (PAHs) mediated alterations in many hepatic drug-processing genes depended on the presence of a normal configuration of the gut microbiome, and the germ-free condition altered the amount of certain phenolic metabolites of PAHs in vivo. In conclusion, gut microbiome critically impacts the expression of drug-processing genes and the metabolism xenobiotics of the host liver.

1696 Intestinal Epithelial Cell Receptors as Modulators of Host-Microbiota Communication

A. Patterson. Pennsylvania State University, University Park, PA.

A complex network of host receptors and microbiota within the gastrointestinal tract work in concert to process and absorb dietary nutrients, detoxify xenobiotics, and establish a homeostatic system that regulates metabolism and inflammation. Emerging evidence suggests ligand-activated transcription factors of the nuclear receptor superfAMILY and the basic helix-loop-helix/per-art-sim (PAS) family not only receive and process chemical signals derived from microbial-dependent metabolic activity, but also transmit these signals to distant organs, including the liver. For example, small intestine signaling of the farnesoid X receptor (FXR), an essential regulator of bile acid, lipid, and glucose metabolism, is modulated through gut microbiota-dependent metabolism of bile acid metabolites produced in the liver. Additionally, studies of the aryl hydrocarbon receptor (AhR), a xenobiotic sensor, have revealed microbial metabolites derived from dietary nutrients including tryptophan as critical regulators of both intestinal and hepatic inflammation. Dissection of the host-microbiota interaction has been facilitated by use of transgenic mouse models, host and microbiome sequencing, and mass spectrometry- and NMR-based metabolomics. Identification and characterization of microbial metabolites and their relationship with host receptors will provide new avenues for studying host-microbiota communication networks and identifying new therapeutics to modulate this interaction in human disease.
cochemical properties. If the uncertainty and domain of applicability can be characterized and quantified, then these methods would allow for a timely, risk-based prioritization strategy characterizing dose relationships between in vitro bioactivities and predicted human exposure. Presenters will consider the state-of-the-science between traditional and higher-throughput methods, and the associations between them, such as extrapolation techniques, model confidence, acceptable uncertainty, and context applicability. Understanding the state-of-the-science in in silico toxicokinetics for government and industry applications will aid the inclusion of such techniques when limited data are available.

**W 1700 Implementation and Evaluation of State-of-the-Art In Silico Models for In Vitro and In Vivo Endpoint Predictions**

D. Mucks. RISE (Research Institutes of Sweden), Södertälje, Sweden. Sponsor: J. Wambaugh

Model evaluation and applicability domain determination allow for a timely, risk-based prioritization. Both of these concepts are an important - and often overlooked - part of the quantitative structure/activity/property relationship (QSAR/QSPR) model development process. However, evaluation and domain determination can be directly addressed when using state of the art Machine Learning (ML) and Deep Learning (DL) approaches. Conformal Prediction provides a framework for existing ML and DL methods to address this issue by using a mathematical approach to better estimate prediction reliability through linking the applicability domain to the QSAR/QSPR model in use and not just basing it on training data alone. Recently developed novel DL approaches (i.e. Google TensorFlow, Theano) give promising initial results on a variety of datasets and also provide the opportunity for utilization of transfer learning approaches, meaning simultaneous usage of multiple datasets and endpoints in the model training process. Implementation of such approaches has become easier over the past decade with the popularity and rapid development of freely available high-level programming languages (i.e. Python, R) and workflow engines (i.e. KNIME, Rapidminer). Careful integration of these in silico models into a combined framework with traditional approaches (i.e. in vivo) and kinetic models can give a good overall estimate of uncertainty and reliability for the in vitro and in vivo predictions, allowing uncertainty to be directly propagated into the risk-assessment of novel and data-poor compounds.

**W 1701 Applying In Silico-In Vitro Extrapolation (IS-IVIVE) Techniques to Predict Exposure and Guide Risk Assessment**

M. Lawless. Simulations Plus, Lancaster, CA.

The ability to accurately predict absorption/systemic pharmacokinetics (PK) directly from 2D structure can be very helpful in assessing the risk associated with a drug or chemical. We have developed an in silico-in vitro-in vivo extrapolation (IS-IVIVE) workflow that scientists can efficiently apply to predict compound exposure in animals or humans. This requires the integration of QSAR models to estimate necessary input parameters e.g., fraction unbound to plasma proteins, fraction unbound in tissues, and CYP metabolism, that inform mechanistic absorption/PBPK models. Cytochrome P450 metabolism is a key component of this methodology. We use a series of QSAR models to predict sites of metabolism, metabolites, and kinetic parameters (Km, Vmax, and Clint) for five major human CYP isoforms. This allows one to simulate linear/nonlinear metabolism of the parent compound and track metabolites. We have also recently developed a series of clearance classification models based on the Extended Clearance Classification System (ECCS) which provide additional information that can be useful in identifying which clearance pathways (metabolism, hepatic uptake, or renal) is likely responsible for driving a compound’s elimination. This IS-IVIVE method has been applied to investigate toxicokinetic profiles of various environmental compounds and pharmaceuticals to assist with risk assessment activities, e.g., drug-drug interactions.

**W 1702 Quantitative Property-Property Relationship for Screening-Level Prediction of Intrinsic Metabolic Clearance**

C. Kirman. Summit Toxicology, Bozeman, MT.

A quantitative property-property relationship model was developed to predict intrinsic metabolic clearance for 403 chemicals across a broad range of chemical properties and validated using a published set of metabolic clearance measurements. Measurements were predicted using octanol-water and water-air partition coefficients that are readily available or can be quickly estimated for most chemicals. These two chemical properties were determined to be statistically significant predictors of metabolic clearance, with > 90% of predictions being within a factor of 10 of their measured value, and > 60% being within a factor of 3. The resulting metabolic clearance estimates, with appropriate confidence bounds, can be readily incorporated into a generic physiologically based pharmacokinetic model for a wide range of chemicals, which can be used to estimate steady-state blood concentrations resulting from environmental exposures. The level of precision associated with this approach (i.e., within an order of magnitude) allows a screening level estimation of this important metabolic parameter for a wide range of chemicals.

**W 1703 Designing QSARs for Metabolic Clearance and Plasma Protein Binding in Diverse Chemical Space Using Pharmaceutical Data**

B. Ingle. ICF International, Research Triangle Park, NC.

High-throughput toxicokinetic models can be a useful tool in screening for chemical risk, yet limited experimental data is available for two important parameters: fraction of a chemical unbound to plasma proteins and hepato-cellular metabolic clearance rate. Open source quantitative structure-activity relationships (QSAR) for fraction unbound and metabolic clearance were developed using several machine learning algorithms and curated in vitro data (a library of mostly pharmaceutical compounds with >1000 plasma binding measurements, >3000 metabolism rates). Models were evaluated using both pharmaceutical and environmentally relevant chemicals. Although models were trained largely on pharmaceuticals, most of the environmentally relevant chemicals evaluated within this work were within the applicability domains. Therefore, these models offer reliable in silico predictions for both pharmaceuticals and chemical sets representative of the types of pollutants and products regulated under the Frank R. Launenberg Chemical Safety for the 21st Century Act. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA.

**W 1704 Using Chemical Structure Information to Develop Predictive Models for In Vitro Toxicokinetic Parameters to Inform High-Throughput Risk Assessment**

P. Pradeep. US EPA/ORISE, Research Triangle Park, NC.

Toxicokinetic parameters for metabolic clearance and fraction of the chemical unbound to plasma proteins are critical for relating exposure and internal dose when building in vitro-based risk assessment models. However, conducting in vivo toxicokinetic studies to characterize these parameters has time and cost limitations. Data gap filling techniques such as read-across and quantitative structure-activity relationships (QSARs) are commonly used to predict hazard in the absence of empirical data. This talk presents: (1) an evaluation of the suitability and limitations of chemical structure information to predict TK parameters of interest (fraction of chemical unbound) in silico using a dataset of 1487 environmentally relevant chemicals, (2) the utilization of predicted TK parameters within a set of in vitro models to calculate steady-state concentration in plasma to determine an oral-equivalent dose, and its comparison with AroClO exposure estimates for an external set of 235 chemicals, and (3) implications of variability in experimental and predicted TK parameters, and physico-chemical properties on the uncertainty in resultant oral-equivalent dose estimates. Overall, these models could allow for an informed risk assessment and chemical prioritization of data-poor chemicals. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA.

**W 1705 Shifting Currents in Predictive Toxicology and Safety Evaluation with In Vitro and Alternative Approaches**

M. Fortin. Jazz Pharmaceuticals, Ewing, NJ.

Transformative approaches, such as organotypic in vitro models and high content screening, are redefining the science of toxicology. However, the path to their integration in toxicity testing programs remains somewhat elusive. Toxicity testing, a necessary element of product development and the foundation of human health risk assessment, has traditionally relied heavily on in vivo animal studies. The advent of in vitro and computational technologies holds promise to drastically change and improve the testing paradigms of the future. Beyond the obvious benefit of reducing animal testing,
embracing high-throughput predictive models can both provide valuable information to aid in molecule design and provide guidance for targeted toxicological testing strategies. This session will focus on innovative methods, such as toxicogenomics, 3D microtissues, and in vitro high content analysis, that are being used to characterize the safety profile of molecules and products, and their application to predictive and mechanistic toxicology testing approaches. Emphasis will be given to methods that are currently being employed to characterize the safety profile of molecules and products and inform decision-making. The targeted audience would be those interested in understanding how these tools are being leveraged in real-world applications, such as integrated approaches to testing and assessment (IATA) strategies to help guide in vitro and in vivo testing programs. To this end, experts from industry, government, academia, and non-for-profit were gathered to discuss the current state-of-the-science. The talks will present how cutting-edge research tools and next-generation alternative models are being integrated in the safety evaluation of environmental chemicals, pharmaceuticals, and plant protection products. Topics covered will include the value of in vitro transcriptomics to predict in vivo apical findings and identify points of departure; the use of a systems approach to predict and mechanistically classify kidney toxicity in vitro; the use of in silico and in vitro models in discovery toxicology; and the utility of 3D tissue models for screening endocrine disruptors. Following the presentations, a Q&A will be held to engage the audience. Attendees will leave with a deeper understanding of the realm of potential applications of next-generation toxicology models. They will also gain insight into the strengths, limitations, and future development opportunities of in vitro and alternative models for predictive toxicology.

**W 1706 Evaluation of In Vivo and In Vitro High-Throughput Transcriptomics for Safety Assessment**

W. Gwinn, NIEHS/NTP, Research Triangle Park, NC.

Initial efforts at high throughput safety assessment focused on assays that evaluated a single pathway, for example estrogen receptor activation. While chemical throughput was considerable in this approach, biological space queried was limited to a single pathway at a time. More recently high throughput transcriptomics has been proposed as an alternative screening approach. While this high throughput transcriptomics covers more biological space, its cost is likely to decrease the number of chemicals that will be queried. In ongoing studies at the NTP, we have evaluated high throughput transcriptomic approaches using short-term in vivo models and in vitro models combined with in vitro-in vivo extrapolation (IVIVE). This initial evaluation has focused on hepatotoxicants that act through a variety of pathways such as genotoxicity, reactive intermediates and receptor mediated mechanisms. Transcriptomic dose response data was analyzed using BMD Express 3.0 and benchmark doses for individual chemicals were estimated based on the median benchmark dose of individual genes in a pathway. The use of transcriptomic screens reveals in points of departures within a factor of 5 compared to points of departures estimated from long term toxicity studies. These data suggest that transcriptomic screening approaches provide reasonable estimates of points of departures for apical endpoints when pharmacokinetics are appropriately considered.

**W 1707 Using a Systems Approach to Predict and Mechanistically Classify Kidney Toxicity In Vitro**

S. Ramm, AstraZeneca, Boston, MA.

The failure to predict toxicity of new chemicals and therapeutics early in the development process before they reach humans remains a critical problem. In this presentation, a systems biology approach using primary human kidney cells, that combines multidimensional datasets and machine learning will be presented. Imaging of 1000 gene and >600 live-cell high-content imaging feature read-outs for a library of well-characterized kidney toxicants (e.g. gentamicin, Cd, cisplatin) were characterized and ranked by their predictive capacity using Random Forest machine learning. The biomarkers we identified not only predicted nephrotoxic compounds with greater accuracy than standard measures of cell death and viability, but could also be validated in 3D kidney models. Network analysis of similarities in toxic phenotypes based on high-content image analysis was also performed, which offered insights into potential mechanisms of toxicity for candidate drugs. Finally, we validated our predictive biomarkers and mechanistic network analyses through their ability to accurately predict kidney toxicity in 4 out of 6 drug candidates that only exhibited toxicity in late stage development. In summary, a new approach to generate panels of biomarkers that can be measured using high-throughput in vitro screening to enhance the accuracy of nephrotoxicity risk assessment.

**W 1708 Integration of In Vitro and In Silico Models for Predictive Toxicology in Discovery Molecule Development**

J. L. LaRocca, Corteva Agriscience, Indianapolis, IN.

The discovery and development of novel molecules is a complex, interdependent process, which requires analysis of thousands of compounds to meet the stringent requirements for animal use. Embracing high throughput predictive models for assessment of potential hazards of molecules early in discovery can help drive in decision-making, with the ultimate goal of generating products of the future with a more favorable human health profile than the past. To this end, we assessed the predictive utility of cytotoxicity endpoints by comparing in vitro IC50 values of 2D and 3D HepG2 cells to reported rat 90-day in vivo NOAEL and LOAELs for 22 pesticides. Using a linear mixed-effects model accounting for a grouping structure of pesticide class (fungicide, insecticide or herbicide), we demonstrated in vitro cytotoxicity are correlated with in vivo endpoints. Given that molecules can have varying absorption and bioavailability profiles, which can impact in vivo vs. in vitro points of departure but are not accounted for in in vitro systems, we integrated PBPK software to aid in placing in vitro cytotoxicity values into a more biologically relevant context for internal exposure. Finally, integration of transcriptomics into early-stage discovery programs can help predict points of departure for risk assessment. In vitro and in vivo points of departure for multiple fungicides were compared to in vivo apical endpoints, which suggest toxicogenomic bioactivity can provide an early indication of in vivo toxicity. These data demonstrate that harnessing in vitro cytotoxicity, in silico PBPK models, and in vitro and in vivo toxicogenomics can predict in vivo points of departure, which can aid in molecule prioritization decisions in the discovery phase.

**W 1709 Screening Estrogenic Endocrine-Disrupting Chemicals with Human MCF-7 3D Microtissues by In Vitro Pathology**

K. Boekelheide, Brown University, Providence, RI.

As outlined in the National Research Council report "Toxicity Testing in the 21st Century: A Vision and a Strategy," there is a need to develop more efficient and physiologically relevant models for evaluation of chemical safety and toxicity. Human MCF-7 breast cancer cell 3-dimensional (3D) microtissue cultures assessed by in vitro pathology are being developed as an improved screening assay for estrogenic endocrine disrupting chemicals (EDCs) compared to traditional 2D models. Growth in agarose hydrogels, these cells self-assemble into microtissues reminiscent of normal in vivo human mammary epithelial tissue with lumen-forming glands, up-regulated cell-type specific differentiation markers, and more complex responses to estrogenic stimulation when compared to the same cells grown in 2D. In vitro pathology assessment of MCF-7 3D microtissues includes a 3D proliferation assay, a differentiated morphology assay, and a transcript assay. The 3D proliferation assay identifies nuclei in 3D microtissue z-stack confocal slices as a measure of proliferation. The differentiated morphology assay detects glandular lumens and then determines their volumes. The transcript assay measures the most significant and highest-fold change transcripts following 3D MCF-7 microtissue exposure to estrogenic pathway agonists (APOD, BMP4, CCNA1, CLDN1, CYP1A1, CYP19A1, ERBB2, ESR1, MYC, PDZK1, TGFb3). This combination of simple and reproducible assays is amenable to high-throughput confocal imaging and molecular analysis, offering a unique opportunity for the safety evaluation of estrogenic EDCs over a broad concentration range.

**W 1710 In Vitro Hepatic Model Systems for Investigative and Predictive Toxicology Applications**

E. LeCluyse, LifeNet Health Institute of Regenerative Medicine, Research Triangle Park, NC.

Prediction of compound-induced hepatotoxicity in humans from in vitro data continues to be a significant challenge for the pharmaceutical and chemical industries. Historically, in vitro 2D hepatic model systems are limited by their inability to maintain phenotypic cellular characteristics over time in culture, especially the stable expression of clearance mechanisms, key bioactivation enzymes, and the cellular interactions during the quenching and resolution of hepatocellular injury. As such, phenotypically stable multicellular systems are required to investigate the key initiating events and the adaptive events, such as inflammation, proliferation, and fibrosis, over prolonged exposure periods. Increasingly sophisticated in vitro humanized test systems and emerging computational models are being introduced to improve our ability to more accurately predict hepatotoxic compounds during development. This workshop segment will present recent advances in tissue culture technol-
ógies and strategies for in vitro-in vivo extrapolation for human risk assessment using quantitative systems pharmacology. Case studies with some of the leading-edge culture devices that represent more physiologically-relevant, organotypic in vitro surrogates of human liver will be discussed. The important role of non-parenchymal cells as targets of toxicity and mediators of hepatotoxic responses will also be highlighted. These emerging culture technologies could have a major impact on global public health. RRs and new computational modeling approaches are drastically improving our ability to accurately predict and understand the hepatotoxic potential of new compounds.

1711 Strategies to Mitigate the Health Impacts of Air Pollutants in Susceptible Populations

H. Tong. US EPA, Research Triangle Park, NC.

The World Health Organization (WHO) has estimated that indoor and outdoor air pollution causes approximately 7 million premature deaths worldwide each year, and 40,000-60,000 premature deaths in the United States alone. Implementation of the regulations of the Clean Air Act has brought forth substantial improvements in air quality and attendant benefits to public health. Yet tens of millions of Americans still live in areas where levels of air pollutants exceed US EPA’s National Ambient Air Quality Standards (NAAQS). Furthermore, some studies have shown that there is no threshold for exposure to particulate air pollution below which exposure is safe, implying that susceptible individuals may be at risk of adverse health effects not only in nonattainment areas but also in communities that are in compliance with NAAQS. Two main intervention strategies to further reduce adverse health impacts of air pollution are reducing personal exposure to air pollution and reducing vulnerability to adverse health effects. Ifair pollution and various intervention approaches have been proposed under each approach, it is uncertain if there is sufficient scientific basis to support their use, or if there are potential health risks associated with their use. The goal of the session is to discuss selected approaches within each of these two strategies. The session will open with a review of US EPA regulations to improve air quality and an overview of interventions aiming to reduce personal exposure to and alleviate adverse health effects of air pollution. This will be followed by five presentations on selected interventions to discuss potential benefits and risks of each strategy. Specifically, interventions focusing on reducing vulnerability to adverse cardiac and pulmonary effects of environmental pollution, such as dietary supplementation strategies and contact with greenery, and interventions focusing on reducing exposure levels to air pollution, such as use of cleaner cookstoves in Guatemala and use of physical barriers and personal behavior changes, will be presented. The session will conclude with a panel discussion with the audience that addresses the following questions: (1) What are the top priorities to reduce the health impacts from air pollution? (2) What are strategies to reduce exposure and vulnerability to adverse health impacts of air pollution at an individual level in susceptible populations? (3) What is a preferred solution to household air pollution: better stoves or cleaner fuels? (4) What are the potential mechanisms for intervention? (5) What measures can be used to mitigate the health impact of air pollution at the community level? (6) What other nontraditional approaches can be used to mitigate the health impact of environmental pollutants? Following this session, attendees will have a better understanding of the research needs and opportunities to deploy such approaches to mitigate damage from air pollutants.

1712 Better Stoves or Cleaner Fuels: What Is the Evidence Base That Is Needed to Decrease the Burden of Household Air Pollution?

J. R. Balmes, University of California Berkeley, and University of California San Francisco, San Francisco, CA. Sponsor: H. Tong

Household air pollution (HAP), arising from the combustion of dirty-burning fuels in an unventilated home for cooking and heating (e.g., wood, charcoal, dung, coal) is estimated by WHO to cause around 4 million premature deaths a year, mainly from cardiopulmonary diseases, making it one of the commonest underlying drivers of morbidity and mortality in low- and middle-income countries (LMIC). Although not included in the WHO estimates, the use of kerosene for lighting contributes additional morbidity and mortality. Acute lower respiratory illness (ALRI) in young children and chronic obstructive pulmonary disease (COPD) in adults remain two of the primary drivers of HAP-related burden of disease, although there is indirect evidence for cardiovascular disease (CVD) as well. The observational epidemiological evidence for the associations between exposure to HAP and the burden of disease has been considered sufficiently strong that intervention trials have been designed and conducted to reduce exposures. Unfortunately, after the initial success of the first randomized controlled trial (RCT) of a cleaner cookstove to prevent child ALRI in Guatemala, results of most of the subsequent RCTs have been disappointing. Given the burden of disease in LMIC, it would be extremely helpful to have better HAP exposure-response data. Stove distribution programs without knowledge about how clean is clean enough may be doomed to failure. Policy makers in resource-limited settings need this information to guide investment strategies to maximize public health impacts.

1713 Vitamin E (Gamma-Tocopherol)-Based Intervention for Environmental Airway Disease

N. Alexis, University of North Carolina at Chapel Hill, Chapel Hill, NC. Sponsor: H. Tong

Epidemiologic evidence has suggested that increased dietary vitamin E intake is associated with reduced incidence of allergic disease and asthma. Alpha tocopherol (aT), an isoform of vitamin E, and commonly available supplement and pharmaceutical product, has shown disappointing results as a therapeutic agent capable of mitigating features of asthma. Gamma tocopherol (γT), however, the predominant isoform of vitamin E found in diets, has been shown to have both anti-inflammatory and antioxidant actions. Our Center has pursued a program of preclinical and early phase clinical trials of γT as a novel therapeutic for treatment of airway inflammation in animal models and human studies. This abstract will review our γT studies in rodent models of pollutant-evoked airway inflammation, as well as our human intervention studies that have examined allergen-induced eosinophilia and mucin responses in asthma. Not only is γT-induced neutrophilia in healthy and asthmatic volunteers. In summary, we have shown that in a rodent model of allergic asthma and air pollutant (ozone and LPS)-induced airway inflammation, γT reduced allergen-induced eosinophilia, mucin responses and LPS-induced neutrophilia, prostaglandin E2, and MUC5AC levels. We have also shown that 1 week of treatment with a γT-enriched mixed tocopherol preparation reduced the neutrophilic response to inhaled LPS challenge in a phase I randomized, double-blinded, placebo-controlled crossover study of healthy adults. In asthmatics, we have observed that a two-week supplementation with γT reduced features of asthma including sputum eosinophils, mucins and the acute LPS-induced neutrophilic response in the airways. In asthma, it is interesting to speculate whether γT can be used as a complementary or steroid-sparing treatment for asthma and in healthy individuals, whether γT is an effective treatment strategy for mitigating the adverse health effect of air pollution exposure.

1714 Dietary Interventional Approach to Ameliorate the Health Effects of Air Pollution

J. M. Samet, US EPA, Research Triangle Park, NC.

Exposure to ambient air pollution is the fourth leading cause of mortality and a major cause of human morbidity around the world. The identification of efficacious interventional approaches to mitigate the adverse health effects of airborne pollutants requires rapid translation to public health impact. While no single physicochemical agent or property of air pollution has been identified as the causative agent, oxidative stress has been proposed as a toxicological mechanism that is common in many disparate components of air pollution. The antioxidant properties of certain vitamins and polyunsaturated fatty acids derived from dietary sources have been shown to confer a broad range of health benefits, suggesting that they might provide protection against the deleterious effects of air pollution. Our studies have shown that in human subjects exposed to fine and ultrafine particulate matter, fish oil supplements containing high levels of omega-3 fatty acids can ameliorate cardiac rhythm changes and improve blood lipid effects, while olive oil pills can protect against aberrations in vascular function. These studies afford mechanistic insight into the toxicology of ambient air pollutants and suggest that dietary interventions are an effective strategy that can protect exposed populations.

1715 Personal Solutions to Air Pollution: What Does the Evidence Recommend?

H. M. Kipen, Rutgers, The State University of New Jersey, Piscataway, NJ.

A substantial proportion of exposure to outdoor-generated (and of course indoor-generated) air pollutants occurs while individuals are indoors because individuals spend most of their time indoors. When concentrations of ambient air pollutants exceed levels associated with increased risk of health problems, air-purifying actions taken to reduce indoor pollution levels and the health effects are sometimes recommended. Beyond behavior change, we have demonstrated that air-filtering techniques are effective at lowering indoor pollutant levels. Such techniques are widely used in the more polluted areas of the
1716 Urban Green Spaces Reduce Stress-Related Allostatic Load and Enhance Resilience to Environmental Insults  
A. Egorov. US EPA, Chapel Hill, NC. Sponsor: H. Tong
Exposure to urban green spaces has been linked to reduced cardiovascular morbidity and mortality, diabetes, and depression, as well as improved pregnancy outcomes. Relaxation and chronic stress alleviation, beneficial exposure to natural allergens and microbes, and enhanced physical activity are some of hypothesized pathways to these salutogenic effects. It has been hypothesized that enhancing contacts with natural living environment in urban settings can enhance innate resilience to detrimental effects of environmental stressors including air pollution. US EPA’s epidemiological studies in North Carolina aim to assess the effects of long-term exposure to residential greenness on stress-related physiological dysregulation known as allostatic load. Allostatic load estimates are based on multiple biomarkers of immune, metabolic and neuroendocrine functions. A recently completed pilot study demonstrated a highly significant ($p < 0.0001$) inverse association between residential greenness and allostatic load, as well as reduced odds of having a potentially unhealthy level of individual biomarkers, such as catecholamines, dehydroepiandrosterone, salivary a-amylase, fibrinogen, C-reactive protein, vascular cell adhesion molecule-1, and selected proinflammatory cytokines. These associations persisted after adjusting for traffic air pollution levels and body mass index, suggesting that living in green areas might be a protective pathway to healthy weight loss, stress mitigation and immune system modulation. Other studies demonstrated that exposure to air pollution can affect the same biomarkers in the opposite direction. Thus, this pilot study contributed to a growing body of evidence that contacts with the living nature reduce vulnerability to environmental insults including air pollution. For this ongoing study with an expanded set of immune system biomarkers includes analysis of gut microbiome to assess links between residential greenness, microbiome, and immune function. A prospective component of this study aims to evaluate if reduced allostatic load increases resilience to short-term environmental insults.

1717 Bayesian Evaluation of Physiologically Based Pharmacokinetic (PBPK) Modeling for Perfluorooctanesulfonate (PFOS) to Characterize the Interspecies Uncertainty between Mice, Rats, Monkeys, and Humans: Development and Performance Verification  
W. Chou, and Z. Lin. Kansas State University, Manhattan, KS.
Interspecies differences of toxicokinetic properties of perfluorooctanesulfonate (PFOS) has been shown to result in substantial uncertainty of dosimetry estimation and risk assessment in the extrapolation from animals to humans. The development of physiologically based pharmacokinetic (PBPK) models accounting for the species-specific toxicokinetic parameters of PFOS is desirable. In this study, based on previously published model structure we developed PBPK models for PFOS in mice, rats, and humans after different routes of administration. Available species-specific in vivo toxicokinetic data were used for model calibration and independent datasets were used for model validation. Critical determinants governing tissue distribution were determined by local sensitivity analyses. In addition, Bayesian statistical analysis using Markov chain Monte Carlo (MCMC) were performed to characterize uncertainty and interspecies variability in the chemical-specific parameters. Simulation results suggest that the model predictions were successfully validated across species with estimated residual error of less than 2-fold. Several model parameters, including partition coefficient of liver, urinary and biliary elimination rates of PFOS, and concentrations of apical and basolateral transporters were identified as highly influential factors governing the overall pharmacokinetics. Bayesian MCMC analyses showed that Vmax for apical transporter and urinary/biliary elimination rates varied significantly across species. This study provides an important step toward estimating interspecies uncertainty, improving the extrapolation of dosimetry estimation of PFOS from animals to humans.

1718 Class Comparison Study of Perfluorinated Substances in Sprague-Dawley Rats: Liver Toxicity and Thyroid Hormone Dysregulation  
A. Dziernenga, 1 K. Janardhan, 2 R. Herbert, 1 M. Cora, 1 M. Vallant, 1 D. Gerken, 1 M. Hejtmancik, 1 S. Waidyanatha, 1 K. Shockley, 1 and C. Blystone. 1
1NIH/DTNP, Morristive, NC; 2Integrated Laboratory Systems, Morristive, NC, and 3Battelle, Columbus, OH.
Several straight-chain perfluorinated substances (PFAS) were evaluated in a class comparison study to assess the relative toxicity of specific PFAS in relation to their chain length and branch length. Perfluorooctanesulfonate (PFBS), perfluorohexane sulfonate (PFHxS), perfluorooctane sulfonate (PFOS), perfluorohexanoic acid (PFHxA), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), or perfluorodecanoic acid (PFDA) were administered by gavage to male and female Sprague Dawley rats for 28 days at doses designed to maximize the dose response for each individual PFAS. An agonist of PPARα, WY-14,643 (WY), was included for qualitative comparisons. Toxicity was evaluated using complete histopathology, thyroid hormones, clinical chemistry, hematology, andrology, and plasma and liver levels of parent PFAS. Plasma and liver levels were the highest for the longer chain chemicals with the most apparent sex difference displayed by PFHxS, PFOA, and PFDA. Liver/plasma ratios in males were generally at or below 1.0 except for PFOS (greater than 2.7 at all tested doses) and PFDA (greater than 1.6). Apart from PFHxS in females, liver toxicity was observed in all chemicals and was manifested by increased serum liver enzyme activities (except PFHxS) and liver weights, and histologically by hepatocyte cytoplasmic alteration and hepatocyte hypertrophy in all chemicals. Generally, the occurrences of these lesions increased with chain length, and were more frequent in males than females. In animals treated with PFNA and PFDA, the longest chain lengths represented, there were dose-dependent increases in hepatocellular necrosis. Generally, PFAS exposure decreased circulating levels of T3, free T3, and T4 total (up to 90%), with males being more sensitive than females. WY-treated animals exhibited hepatocyte hypertrophy and cytoplasmatic alteration at all dose levels, consistent with the other PFAS, and WY-treated males had decreased circulating free T4. PPARα and CAR activation were evaluated by measuring target liver enzyme expression (Cyp2b1, Cyp2b2, Acox1, and Cyp4a1) and correlating this to various related endpoints. The data presented can be used in determining potency estimates on a variety of endpoints, and future predictions for PFAS toxicity.

1719 An In Vitro Screen of a Panel of Perfluoroalkyl Substances and an In Vivo Assessment of Effects on Placental and Fetal Growth  
B. Blake, H. Cope, and S. Fenton. NIHES, Research Triangle Park, NC.
Perfluoroalkyl substances (PFAS) are ubiquitous environmental contaminants and are associated with fetal growth restriction (FGR). Perfluorooctanoic acid (PFOA) is one of the most well-studied PFAS and it is estimated that a 1 ng/mL increase in serum PFOA is associated with an 18.9g decrease in human birth weight. The mechanism through which PFOA affects fetal growth is not known and we hypothesize that the fetal-placental unit is a target. PFOA is one of thousands of PFAS, and determining modes of action against the developing fetus as well as a method for PFAS prioritization are necessary. A high throughput, multiplexed screen was developed using human placental JEG-3 cells for PFAS prioritization. The 24h screen included assays to determine the effects of PFAS ranging from 50-500µM on proliferation, cell viability, and mitochondrial function. Doses were selected based off assay optimization due to limitations imposed by selecting human-relevant doses for chemicals for which human exposures have yet to be defined. Of 33 PFAS screened, 56% showed effects on proliferation, 36% on mitochondrial function, and 39% on cell viability. To determine a potential mechanism of FGR for PFOA and evaluate whether its replacement, GenX, has similar effects to human placental cells, we performed a dose-response screen to determine whether GenX had increased placental and weights (18% and 22% respectively), decreased fetal weights (21% and 5% respectively), decreased fetal length (6% and 0.6% respectively) and decreased fetuses/placenta ratios (32% and 21% respectively).
These data suggest both PFOA and GenX adversely affect the feto-placental unit, possibly via diverging mechanisms where PFOA appears to affect both the fetus and placenta, whereas GenX appears to primarily impact the placenta. These findings implicate GenX as a potential public health threat rather than a safe alternative.

1720 Effect of Lifestyle-Based Lipid-Lowering Interventions on the Relationship between Circulating Levels of Per- and Poly-Fluorinated Chemicals and Serum Cholesterol
M. Petriello, A. Mottaleb, M. Kraemer, G. Mudd-Martin, D. Moser, and A. Morris. University of Kentucky, Lexington, KY.

Exposure to certain per- and polyfluoroalkyl substances (PFASs) have been shown to positively associate with total and/or low density lipoprotein cholesterol (LDL), but data from cross-sectional epidemiological studies are limited. People residing in Kentucky and surrounding states may face higher exposures due to nearby manufacturing. We examined the association between 6 PFASs and circulating total and LDL cholesterol levels in Kentucky residents undergoing a cardiovascular risk reduction clinical study. We developed high throughput plate-based extraction and LC-MS analysis methodologies to quantify PFASs in 350 individuals. Plasma and demographic information was collected and bivariate statistics and logistic regression modelling were used to examine associations of circulating PFASs and cholesterol levels. PFOS, PFOA, FPhxS, and FFHxA, significantly decreased post intervention (13.25-11.12 ppm, 2.20-1.99 ppm, 0.96-1.01 ppm, and 0.40-0.14 ppm respectively). Interestingly, PFOS as well as the combined sum of 6 compounds (Total PFAS), significantly positively associated with total cholesterol in post-intervention samples (Pearson correlation coefficient 0.132; p=0.0241, 0.115; p=0.0497 respectively). After adjustment for multiple covariates including gender, BMI, smoking, race, education level, and age; Total PFAS was still significantly positively associated with total cholesterol (p=0.021). In general, PFAS levels in this population were similar to NHANES levels, although PFOS exposures appeared to be increased. This work adds to a growing body of knowledge associating circulating PFAS and total cholesterol levels in humans.

1721 Targeted Gene Expression Assays Reveal Markedly Different Gene Expression and Lipid Accumulation Profiles for Perfluorooctyl Acid (PFAA) Mixtures Compared to Single PFAA Treatment in Cryopreserved Human Hepatocytes
E. Marques, M. Plohl, W. Wei, O. Amaeze, and A. Slitt. University of Rhode Island, Kingston, RI; and University of Lagos, Lagos, Nigeria.

Perfluoroalkyl acids (PFAAs) are a family of fully-fluorinated chemicals that are used in fire-fighting foams and as well as many heat-, stain- and water-resistant materials in a variety of applications. These chemicals, such as perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) cause liver steatosis in animal studies. It is unclear whether human exposure to PFAAs causes liver steatosis. To date, the developed method will have broad applications towards understanding the toxic mechanisms of PFASs. The developed method will have broad applications towards understanding the toxic mechanisms of PFASs. The developed method will have broad applications towards understanding the toxic mechanisms of PFASs. These data suggest both PFOA and GenX adversely affect the feto-placental unit, possibly via diverging mechanisms where PFOA appears to affect both the fetus and placenta, whereas GenX appears to primarily impact the placenta. These findings implicate GenX as a potential public health threat rather than a safe alternative.

1722 Perfluorooctanesulfonic Acid (PFOS) Is Selectively Neurotoxic to Dopaminergic Neurons in C. elegans
S. R. Sammi, and J. R. Cannon. Purdue University, West Lafayette, IN.

Perfluorinated compounds (PFCs) have been widely utilized as stain repellents, flame retardants, coating additives in nonstick cookware and in the food packaging industry. Given the long environmental and biological half-lives, bio-accumulative and surfactant properties, PFCs are common soil and water contaminants, detectable in the blood of >99% of individuals. PFC exposure has been linked to a number of adverse health outcomes, including cancer risk, altered lipid homeostasis, hepatotoxicity, and developmental abnormalities. However, the neurotoxicological effects of PFCs have not been sufficiently studied. Given known effects on calcium homeostasis and oxidative stress, we hypothesized that PFCs would be neurotoxic and that dopaminergic neurons would be especially sensitive. We tested a number of PFCs for neurotoxicity in nematode models: perfluorooctanesulfonic acid (PFOS), perfluorooctanoic acid (PFOA), 1H,1H,2H,2H-Perfluoro-1-decanol, heptaffluorobutyric acid (HFBA). PFOS exposure (within the range 75 to 150 ppm for 72 hrs) was found to produce neurotoxicity in C. elegans in dopaminergic, serotonergic and GABAergic, and cholinergic neurons as evidenced by overt and quantifiable morphological changes, including loss of processes and swelling of the soma. Dopamine neurons were especially sensitive, exhibiting evidence of neurotoxicity at doses below the toxicity threshold for other neurotransmitter systems (as low as 75 ppm). PFOs treatment also resulted in loss of mitochondrial viability, altered α-synuclein aggregation, and elevated reactive oxygen species. PFOs-treated worms showed dopamine-dependent deficits but not acetylcholine-dependent changes in functional assays. Surprisingly, all other tested PFCs were not neurotoxic at tested doses (HFBA (107 - 1070 ppm); PFOA (10 - 100 ppm)), potentially indicating that the sulfonate hydroxide may be especially important to PFC-induced neurotoxicity. Our results suggest that PFOS is selectively neurotoxic to dopamine neurons and, to our knowledge, the first example of a potential relevance to Parkinson’s disease. Furthermore, alternative and replacement PFCs carrying the sulfonyl hydroxide functional group should also be studied for neurotoxicity.

1723 Development of a Chemical Proteomics Method for the Enrichment and Identification of Poly- and Per-Fluorinated Bound Proteins
D. R. Hall, J. Han, S. Joudan, and H. Peng. University of Toronto, Toronto, ON, Canada.

The persistence, bioaccumulation and toxicities of Poly- and Per-fluorinated compounds (PFCAs) are of great concern. Specifically, some PFCAs cause cancer, such as fluorotelomer alcohols (FTOHs) have been shown to co-valently bind to proteins; cysteine reactivity has been suggested to be one of the primary toxic pathways for these PFCAs or their bioactive metabolites. While previous studies have been conducted to investigate their toxicities, exact toxic mechanisms remain unclear. In this study, we developed a chemical proteomics method to identify the protein targets of cysteine reactive FTOHs. Our method was developed initially using a fluorosulfosuccinimidyl tagged bovine serum albumin before analyzing liver proteins extracted from 8.2 perfluorooctanoic acid (PFOA) exposed rats. PFOA-bound peptides were enriched by filtering tryptic digest via solid-phase fluoruous extraction (SPFE). One-step enrichment yielded more than 80% of PFC-bound peptides while removing more than 90% of native peptides. We report a 30% increase in the number of detected PFC-bound peptides when compared to traditional proteomic sample workups. PFOA-bound peptides were found to be more hydrophobic than native peptides, and PFOA-bound peptides tended to elute within a narrow 5 minute with a classic water/acetoniitrile nano-LC gradient (35% acetonitrile maximal effective mobile phase). Poor chromatographic resolution greatly reduced data-dependent acquisition of PFC-bound peptides. Consequently, we optimized a new gradient to further increase chromatographic resolution of PFC-bound peptides. With our improvements, PFC-bound peptides were eluted over a 120-minute gradient. This further increased the sensitivity of our chemical proteomics method, and the number of PFCAs-bound peptides increase by two folds. By carefully evaluating the mass spectra, covalent cysteine amino acid residues were identified as the primary binding site of 8.2 PFOA. Thus, 8.2 PFOA-cysteine modifications were added to the list of MaxQuant modifications to enable automatic proteome database searching. Thus, we have developed the first chemical proteomics method to directly identify protein targets of PFAAs. The developed method will have broad applications towards understanding the toxic mechanisms of PFAAs.
Hexafluoropropylene oxide dimer acid (HFPO-DA, aka GenX) is a member of the per- and polyfluoroalkyl substances (PFAS) chemical class and a high-profile contaminant of emerging concern. Elevated levels of HFPO-DA have been detected in multiple environmental matrices and treated drinking water in the United States indicating widespread use and ecological receptors. Our goal was to characterize the potential mammalian toxicity of HFPO-DA from oral administration during gestation to maternal and pre/postnatal rats. Initially, we dosed Sprague-Dawley rat dams daily via oral gavage with 1-500 mg HFPO-DA/kg/d during the critical window for male reproductive tract development (gestation day (GD) 14-18). We evaluated fetal testis testosterone production, expression of PPAR signaling pathway genes in maternal and fetal livers, maternal serum clinical chemistry, reproductive development of F1 animals, and internal dosimetry in maternal serum and fetal plasma. HFPO-DA exposure during gestation (GD 14-18) did not affect the fetal testis, but did produce significant dose-responsive increases in maternal liver weight (≥26.5 mg/kg), reduced maternal serum thyroid hormone and lipid profiles (≥30 mg/kg), and highly upregulated gene expression related to PPAR signaling pathways in maternal and fetal livers (≥1 mg/kg). A low sample size (n=3 per dose) pilot postnatal study at 125 mg/kg/d was largely negative for adverse effects but indicated potential reductions in female body weight and reduced weights of male reproductive tissues in F1 animals. However, a follow-up postnatal study covering a broader dosing interval (GD8 - postnatal day 3), greater sample size (n=5 per dose), and greater dose range (10-250 mg/kg/d) resulted in significant, dose-responsive neonatal mortality at ≥62.5 mg/kg/d and reduced body weight of surviving pups at all doses (≥10 mg/kg/d). This study is ongoing with evaluation of adult F1 animals that were exposed in utero. Overall, HFPO-DA exposure produced multiple adverse effects similar to previously published PFAS toxicity evaluations, such as PFOS and PFDA, and in vivo toxicokinetics seems to play a major role in the relative potency of these compounds for producing effects. The views presented here do not necessarily reflect the views or policies of the US EPA.
1728 The Development of a Database for Herbal and Dietary Supplement Induced Liver Toxicity
J. Zhu¹, J. Seo², S. Wang³, K. Ashby¹, R. Ballard¹, D. Yu¹, B. Ning¹, R. Agarwal¹, J. Borlak⁴, W. Tong⁵, and M. Chen¹.¹ USDA/NCTR, Jefferson, AR; ²China’s State Food and Drug Administration, Beijing, China; ³US FDA/CDER, Jefferson, AR; and ⁴Hannover Medical School, Hannover, Germany.

The growing use of herbal dietary supplements (HDS) in the United States provides compelling evidence for risk of herbal-induced liver injury (HILI). Information on HDS products was retrieved from MedlinePlus of the U.S. National Library of Medicine and the herbal monograph of the European Medicines Agency. The hepatotoxic potential of HDS was ascertained by considering published reports. Other relevant data were collected from governmental documents, public databases, web sources, and the literature. We collected information for 296 unique HDS products. Evidence of hepatotoxicity was reported for 67, that is 1 in 5, of these HDS products. The database revealed an apparent gender preponderance with women representing 61% of HILI cases. Culprit hepatotoxic HDS were mostly used for weight control, followed by pain and inflammation, mental stress, and mood disorders. Commonly discussed mechanistic events associated with HILI are reactive metabolites and oxidative stress, mitochondrial injury, as well as inhibition of transporters. HDS-drug interactions, causing both synergistic and antagonizing effects of drugs, were also reported for certain HDS. The database contains information for nearly 300 commonly used HDS products to provide a single-entry point for better comprehension of their impact on public health.

1729 Deep vs. Conventional Machine Learning Models for Predicting Ames Mutagenicity
S. K. Chakravarti, and S. Alla. MultiCASE Inc, Beachwood, OH.

Deep machine learning methods have emerged as powerful techniques to extract knowledge from large amounts of data. As expected, they are rapidly making their way in the field of QSAR modeling. In this work, a big set of chemicals (17,008) with their Ames mutagenicity outcomes was utilized to build deep neural network models and evaluate their predictive performance. A set of 1,942 chemicals were used as an external test set. Long short-term memory (LSTM) recurrent neural networks were used for this purpose. In addition, a conventional logistic regression QSAR model composed of molecular fragment descriptors was constructed for comparison. Both LSTM and conventional fragment-based models showed excellent performance; however, the LSTM model fared marginally better. Deep learning (LSTM) model: Sensitivity = 87%, Specificity = 88%, Coverage = 100%; Conventional fragment-based model: Sensitivity = 83%, Specificity = 91%, Coverage = 100%. In order to facilitate interpretation of the prediction results, the ability of the LSTM models to identify mutagenicity alerts in test chemicals was also investigated. This became possible by adding an attention mechanism in the LSTM network which highlighted parts of SMILES code directly that are relevant to the mutagenicity of a test chemical. The conventional model is highly interpretable because it is composed of fragment-based alerts that were mined directly from the training data. We anticipate that deep learning QSAR models will be highly valuable and accurate for the research and regulatory decision-making communities, particularly as the volume of available high-quality Ames test data increases.

1730 Ensemble QSAR Modeling to Predict Multispecies Fish Toxicity Points of Departure
T. Sheffield, and R. Judson. US EPA, Research Triangle Park, NC.

QSAR modeling is prioritized in the thousands of chemical substances for which no ecological toxicity data is available. We pulled experimental results from the US Environmental Protection Agency’s ECOTOX database and the European Chemical Agency’s database to build a large data set containing in vivo test data on thousands of chemical substances and hundreds of species of fish. This data set was used to create QSAR models to predict two types of potential points of departure (POD): acute LC₅₀s (median lethal concentration) and endpoints comparable to the NOEC (no observed effect concentration) for any duration and measured effect. In addition to molecular descriptors and physiochemical property predictions, the QSAR models used study covariates, such as species and exposure route, as features to maximize accuracy when combining multiple data types. A novel method of substituting taxonomy groups for species dummy variables was introduced to allow the model to generalize to other species. A stacked ensemble of three machine learning methods—random forest, gradient boosted trees, and support vector regression—was implemented to increase accuracy and minimal feature selection. The models predicted LC₅₀s and NOECs within one order of magnitude 81% and 76% of the time, respectively, and had root-mean-square-errors (RMSEs) of roughly 0.83 and 0.98 log₁₀(mg/L) respectively. Benchmarks indicated that the prediction accuracy was improved beyond the 95% confidence intervals of existing models. This abstract does not necessarily represent US EPA policy.

1731 Computational Association of Permethrin Exposure and Asthma in California Agricultural Counties

Asthma rates in California have shown an increase in counties with extensive use of the pesticide permethrin. Notably the surrounding agricultural area of Imperial County reports significant asthma related admissions to the emergency room every year. Biomonitoring studies using urinary levels of the metabolite 3-phenoxybenzoic acid (3-PBA) in Monterey County, the second highest permethrin usage county in California, and in military personnel wearing permethrin treated uniforms have confirmed the exposure-bioaccumulation correlation. In separate studies, the most frequent users of permethrin were more likely to report wheeze, both allergic and non-allergic during medical exams, and there exists suggestive evidence of wheeze associated with permethrin exposure among children. This study utilizes online databases, docking software, data networks, predictive molecular modeling software and literature to identify a potential chemical-gene-disease link between permethrin exposure and asthma. Our results support a positive chemical-gene interaction between the estrogen receptor (ER) and permethrin. Additionally, docking software confirmed significant binding affinity between ESR1 and permethrin. These findings suggest that the typical inflammation preceding asthmatic symptoms can be induced by ESR1 ligand binding via a spectrum of immune functions, including adhesion, migration, and antibody and cytokine production. Induction of these pathways can be attributed, in part, to ligand binding of estrogen receptors found on the surface membrane of various immune cells within the alveolar and pleural cavities. This activation has been implicated as a main regulator of the lung’s inflammatory response, a hallmark of asthma. Pathway analysis suggests LFA-1 binding to ICAM leading to upregulation of pro-inflammatory IL-5 and IL-4 via MAPK induction plays a part in this chemical-disease linkage. Consequently, an increased presence of permethrin, a viable ESR1 ligand, may be contributing to the higher incidence of asthma in Imperial County, California via activation of the ESR1 pathway. It is not known if single nucleotide polymorphisms (SNPs) in the estrogen receptor alpha gene might identify a more susceptible risk population.

1732 Analyzing ToxCast Data Using Nebula (Neighbor-Edges Based and Unbiased Leverage Algorithm)
H. Hong, and W. Tong. US FDA, Jefferson, AR.

Most so called “big datasets” are incomplete, with varying degrees of scarcity. They pose special difficulties across the board for traditional machine learning and classification algorithms. Yet, the future of big data is now, equating to some urgency in finding approaches for overcoming the challenges of analyzing sparse datasets. In this study we developed the Neighbor-Edges Based and Unbiased Leverage Algorithm (Nebula) to tackle sparse big data. The US Environmental Protection Agency’s (US EPA) ToxCast project evaluated a diverse set of chemicals, including both environmental chemicals and drugs, using a broad panel of high-throughput in vitro assays. ToxCast data have been studied to characterize the toxicological profiles of environmental chemicals. However, the dataset has a high degree of missing elements and thus is sparse. To warrant full utilization of ToxCast dataset generated from a huge US EPA investment in risk assessment of chemicals, novel and comprehensive analyzing the dataset is needed. Therefore, as a test, we applied Nebula and modularity analysis for ToxCast data. We found that the chemical-assay network could be decomposed into seven densely connected modules based on its topological properties. Moreover, each of the seven modules was associated with different set of adverse outcome pathways (AOPs) as well as chemical structural descriptors. Leave-one-out cross validations showed a high consistency between experimental AC₅₀ values from ToxCast and predicted AC₅₀ values from Nebula. Our study demonstrated Nebula to be an efficient algorithm for analyzing sparsely populated big data and, thus, useful in the big data era. Our results also indicated ToxCast data could be used for toxicologically profiling chemicals that have not been assayed in ToxCast to assist risk assessment of chemicals.
In animal-free risk assessments, in vitro effect concentrations need to be related to external e.g. oral doses (in vivo-in vitro extrapolation, IVIVE). In our investigations, we used a simple 1 compartment model as well as a 8-compartment PB-P model for the rat as tools for reverse dosimetry and applied these models for 10 potential endocrine disruptors (e.g. Bisphenol A (BPA), Fenamilo (FEN), 17α- Ethynylestradiol (EE), Asetaminophen (APAP), Caffeine (CAF), Ketoxonazol (KET), Flutamide (FLU), Genisint (GEN), Methyltestosterone (MTT), Trenbolone (TRE)). The compounds have been tested in the Yeast Estrogen Screening (YES) or Yeast Androsten Screening (YAS) assays for the estrogen and androgen receptor binding, as well as the H295R assay (OECD test guideline no. 456) for potential interaction with steroidogenesis. Postulating comparable concentration-response ratios of these effects in the applied in vitro systems and the in vivo environment, lowest observed effect concentrations (LOECs) from these assays were extrapolated to oral doses (LOELs) by reverse dosimetry. The predicted LOELs were then compared to the LOELs actually observed in corresponding in vivo studies (YES/YAS assay versus uterotrophic or androsten receptor assay and steroidogenesis assay versus pubertal assay or generation studies). Reverse dosimetry resulted in estimated oral LOELs for the rat in the same order of magnitude than in literature described in vivo-derived LOELs for 7, BPA, FEN, APAP, CAF, KET, FLU, MTT and 6, BPA, FEN, APAP, CAF, KET, GEN out of 10 substances for the applied 1 compartment and the applied 8-compartment PB-P model. In conclusion this demonstrates the applicability of the applied concept in general, the need for its future optimization and allows us to derive questions on what we need to know to further optimize these calculations.

In vitro to In Vivo Extrapolation of High-Throughput Screening Assay for Thyroperoxidase Inhibition

I. Hassan 1, H. El-Masri 1, J. Ford 1, A. Brennan 1, S. Handa 2, and M. E. Gilbert 1

1 US EPA, Research Triangle Park, NC, and 2Oak Ridge Institute for Science and Education (ORISE), Oak Ridge, TN.

High-throughput (HTP) assays are being used to rapidly assess the potential of chemicals to interfere with the thyroid system. Amplex-UltraRed (AUR)-thyroperoxidase (TPO) inhibition assay is a rat microsomal HTP assay developed to screen the thyroid synthesis enzyme, TPO. Although AUR-TPO assay has accelerated chemical testing, translation of in vitro outputs to in vivo measures of thyroid dysfunction remain an obstacle to their use in risk assessment. Our goal was to explore in vitro to in vivo extrapolation (IVIVE) approaches to aid in interpretation of AUR data. Adult rats were exposed to varying doses of two known TPO inhibitors, methimazole (MMI) and 6-propyl-thiouracil (PTU) via drinking water for 4, 7, or 14 days. We first compared in vitro TPO inhibition to ex vivo TPO inhibition using thyroid gland microsomes prepared from the glands of PTU and MMI exposed animals. A second approach was to introduce chemical and glandular hit rates obtained in vitro to a one-compartment pharmacokinetic (PK) model to derive an in vivo IC50. Serum and gland PTU and MMI levels increased in a dose- and time-dependent manner. Similarly, PTU and MMI reduced serum and gland triiodothyronine (T3) and thyroxine (T4) and increased serum thyroid stimulating hormone (TSH) in a dose- and time-dependent manner. Estimates of IC50 for TPO inhibition from the ex vivo study ranged from 108-169 µM and were higher than those from in vivo exposure in microsomes from naïve glands (IC50=0.1-1.2 µM). Ex vivo estimates were well correlated with serum T4 at 4-day exposures but were inconsistent at later timepoints. The second approach to IVIVE incorporated the measured values of thyroid gland T4, MMI, and PTU into a PK model. Excellent fits of the 4-day PTU data were achieved with an estimation of an in vivo derived TPO inhibition of 6.2 µM, a value 5-fold higher than the in vitro estimate of 1.2 µM. Assessment of 7- and 14-day exposures for PTU and for MMI are underway. In summary, ex vivo measures of TPO inhibition using the AUR assay were highly correlated with serum thyroid hormones at short exposure durations, but were inconsistent at longer exposures, and IC50s were much higher than in vitro estimates. PK derived in vivo estimates of TPO inhibition with short exposures to PTU were more closely aligned to in vitro estimates. Our results provide an in vivo based anchor to aid in interpretation of HTP outputs of thyroid disruption. Does not reflect US EPA policy.

Utilization of the Ascentos LIMS and TranSEND to Streamline the Collection and Compilation of Data for Send Dataset Creation

C. Drennan 1, L. Eickhoff 1, M. Schuster 1, and P. Dugan 2. 1 BASI, Mount Vernon, IN; and 2PDS Life Sciences, Mount Arlington, NJ. Sponsor: L. Hopper

Ascento’s is an extensive, full-scale Laboratory Information Management System (LIMS) that provides a structured and regulated method to collecting data in a non-clinical environment. A companion system to Ascento’s is TranSEND™, which is used to compile the data that was collected in the LIMS system and export it in a Standard for Exchange of Nonclinical Data (SEND) data set. The objectives of this poster are to display the processes and ease of converting data collected in a LIMS system, as well as data that was received from outside sources that do not utilize a LIMS system, to an acceptable and approved SEND data set. Ascento’s enables the user to correctly populate the study protocol and schedule activities in a way that complies with the regulations on SEND submission. One major benefit of using Ascento’s in conjunction with TranSEND™ is that Ascento’s allows the user to build glossaries based on Controlled Terminology. This specific feature virtually diminishes the need to map terms in TranSEND™, which ultimately significantly reduces the man hours required to set up a dataset. TranSEND™ imports and unites study specific Ascento’s data, external consultant data files, and data sets that were created using compounds that were provided by PDS. The complete dataset is exported and includes a validation report that notifies the user of any rejects, errors, warnings, and notices within the set and also a pre-populated Non-Clinical Study Data Reviewer’s Guide (nSDRG) that is user friendly for completion.
1737 Retrospective and Prospective Case Studies to Accelerate the Pace of Chemical Risk Assessment

K. Paul Friedman1, N. M. Gagne2, T. Barton-Maclauren2, J. Bucker3, R. Thomas4, M. Rasenberg, and T. Sobanski5. 1US EPA/NCCT, Research Triangle Park, NC; 2Healthy Environments and Consumer Safety Branch, Health Canada, Ottawa, ON, Canada; 3NIHES/NTF, Research Triangle Park, NC; and 4Computational Assessment Unit, European Chemicals Agency, Helsinki, Finland.

Use of high-throughput, in vitro bioactivity data in setting a point-of-departure (POD) has the potential to accelerate the pace of human health risk assessments by chemical prioritization. Advancement toward this goal requires confidence in in vitro bioactivity data, in conjunction with high-throughput toxicokinetic information, can be used to estimate administered equivalent doses at or below the PODs from traditional animal studies. Further, hazard and exposure predictions, combined as a bioactivity-exposure ratio (BER) for use in risk-based prioritization, should be evaluated. In this work we describe two efforts of the Accelerating the Pace of Chemical Risk Assessment initiative, a consortium of international regulatory scientists, both with the same primary objective: to elucidate whether a POD derived from in vitro bioactivity would be a conservative estimate of traditional POD estimates, and if the BER is a useful prioritization metric. In the first project, we describe the outcome of a retrospective case study of 448 chemicals with high-throughput predictions of bioactivity, reverse dosimetry, and exposure, as well as traditional hazard information. For 92% of these chemicals, a POD derived from new approach methodologies (POD_{NM}TM) was a conservative prediction for the traditional POD (POD_{informed}) value. High-throughput exposure predictions were greater than the POD_{NM} for 26/448 chemicals, with BERs of less than zero, indicating higher priority for further investigation. The second, prospective study involves generation of Nam data for 200 chemicals to prioritize 20 chemicals for 90-day repeat dose testing in rats using a combination of the BER and bioactivity-based flags. Together these case studies enable regulatory scientists from different international contexts to develop efficient approaches for chemicals management, while possibly reducing the need for animal studies. This work demonstrates the feasibility, and continuing challenges, of using bioactivity and exposure NAMs in screening level safety assessment. This abstract does not necessarily reflect US EPA policy.

1738 An AOP-Based Ontology for Spina Bifida Caused by Disturbance in Retinoid Acid Signaling

A.iersna1, N. Baker2, L. Burgoon3, G. Daston4, T. Knudsen4, and Y. Staal5. 1RIVM, Bilthoven, Netherlands; 2Leidos, Research Triangle Park, NC; 3US Army ERDC, Research Triangle Park, NC; 4Proctor & Gamble Company, Cincinnati, OH; and 5US EPA, Research Triangle Park, NC.

The retinoic acid (RA) pathway serves as a prototype for adverse outcome pathway (AOP) elucidation for developmental defects. The biology of the RA pathway is used for the construction of an AOP for neural tube closure defects. The ontology describes an AOP network incorporating retinoid homeostasis and putative molecular initiating events in chemical teratogenesis. Basic elements in the ontology are subjects (enzymes, receptors, cell types) and their quantitative relationships (response-response relationships), forming a network of biological interactions to be mapped to a vulnerable developmental window for e.g. teratogen-induced spina bifida. We have searched the available literature data using text-mining tools to map known molecular interactions, genetic signals and responses that: (a) play a crucial role in cellular differentiation; (b) establish anterior-posterior gradients (FGF and RA signaling) and dorsal-ventral gradients (zinc factors [Zic] and BMP signaling) for regional specification. Molecular initiating events important for RA balance (like CYP26 enzymes and RALDH2) potentially affected by xenobiotic compounds (based on high-through-put screening data), were connected with toxicological data on the development of posterior neural tube defects. Ultimately, this network can be dynamically modeled in silico, providing an integrated computational systems model allowing toxicity predictions at the level of adverse outcomes in the intact individual. A battery of cell-based in vitro assays can be used to monitor the critical rate-determining steps in the network, providing a tiered testing strategy to collect data feeding into the systems model. Integrating the dynamic model with information from exposure and kinetic models allows quantitative hazard and risk assessment while avoiding animal testing. The views presented in this abstract do not necessarily reflect current or future opinion or policy of the US Environmental Protection Agency and the US Army Corps of Engineers.

1739 Characterizing Developmental Toxicity through Pluripotent Stem Cell Assays and the ToxCast Library

T. Zurlinden1, K. Sall1, N. Baker2, E. Hunter4, and T. Knudsen1. 1US EPA/NCCT, Research Triangle Park, NC; 2Leidos, Research Triangle Park, NC; and 3US EPA/NHEERL, Research Triangle Park, NC.

Predicting and characterizing potential human teratogenic compounds remains a challenge as toxicology moves towards new approach methodologies (NAMs) for hazard identification. Utilizing pluripotent stem cells, in conjunction with high throughput screening technologies, has the potential to aid developmental hazard prioritization for large numbers of chemicals and lessen the strict reliance on costly and time-consuming animal methods. To investigate this potential, ToxCast chemicals were profiled for developmental toxicity in two embryonic stem cell assays: the human pluripotent H9 stem cell-based devTOX quickPredict platform from Stemina (STM) and the mouse embryonic stem cell (mESC) adherent assay. To test model performance, the STM platform was tested using two sets of compounds: a benchmark set of 42 compounds (BM42), of which 26 are classified as developmental toxicants and a set of 432 ToxRefDB compounds (TR432), of which 187 had reported evidence of developmental toxicity from prenatal rat or rabbit developmental toxicity tests (lowest effect level ≤200 mg/kg/day). When compared against the BM42 set, the STM platform had a model performance of 78.3% accuracy (0.65 sensitivity, 1.0 specificity, 0.79 f1) and against the TR432 compounds, STM had 61.3% accuracy (0.31 sensitivity, 0.84 specificity, 0.41 f1). Using the mESC adherent assay, chemicals from the TR432 compound set demonstrated a model performance for the mESC platform of 84% accuracy. To investigate utilizing pathway-based predictions for developmental toxicity screening, 32 enzymatic and receptor assays in the ToxCast NovaScreen data-set (NVS) were trained on the STM hit call data to characterize biological pathways associated with STM positive and STM negative responses. Including NVS-derived pathway data with the STM platform increased model accuracy against the BM42 set to 83.3% (0.77 sens, 0.88 spec, 0.83 f1) while accuracy against the TR432 set was 60% (0.55 sens, 0.64 spec, 0.54 f1). These findings have set the stage for identifying and developing new approach methodologies based on in vitro data and in silico models for prenatal developmental toxicity. This abstract may not reflect US EPA policy.

1740 Combining Structural Alerts and Machine-Learning Algorithms to Predict Human Molecular Initiating Events

T. Allen1, A. Wedlake1, J. Goodman, S. Gutsell2, and P. Russel2. 1University of Cambridge, Cambridge, United Kingdom; and 2Unilever, Sharnbrook, United Kingdom.

Molecular Initiating Events (MIEs) are important chemical-biological interactions that start Adverse Outcome Pathways (AOPs). MIEs provide good targets for computational modelling as they are right on the boundary between biology and chemistry, and any computational models produced for them do not skip over large amounts of biological complexity, compared to trying to predict responses at an organ or organism level. We have developed in silico models for the prediction of important human MIEs for use in risk assessment using chemical understanding. The first of these approaches uses structural alerts, chemical fragments of known binders, to predict MIEs. Open source data from ChEMBL and ToxCast was used, providing positive and negative data points for each human MIE. Structural alerts were then automatically constructed using a computational algorithm developed in KNIME, which used maximal common substructure searches and Bayesian reasoning to choose the best structural alerts and build the best models for each biological target. Models for human MIEs including G-protein coupled receptors, nuclear receptors, enzymes, ion channels and transporters have been constructed. This includes important biological targets including Androgen and Glucocorticoid Receptor disruption which can lead to developmental toxicity, HERG Channel blocking which can lead to cardiac toxicity, and cyclooxygenase inhibition which can lead to reproductive dysfunction. The second of these approaches involves the use of machine learning algorithms fed with chemical information to predict MIEs. The same data sources are used to train neural networks, resulting in a high level of predictivity. Chemical and biological similarity calculations using the neural networks have also been performed to better understand how these artificial intelligence approaches provide predictions. Most of the models developed using these methodologies predict at accuracy levels above 80%, and a number predict above 90%, showing extremely good performance using holdout cross-validation. Combining these orthogonal in silico approaches provides further confidence in their predictions and a larger impact for computational toxicology. The in silico predictions of these MIEs is extremely important for the future of AOP based risk assessment. By incorpo-
1741 Detection of Chemical Bioactivity Using In Vitro Phenotypic Profiling
L. Loo¹, J. J. Lee¹, K. Paul-Friedman², and R. Thomas¹. ¹Agency for Science, Technology, and Research (ASTAR), Singapore; Singapore; and ²US EPA, Research Triangle Park, NC.

High-throughput (HT) in vitro assays have the potential to accelerate the prioritization and assessment of chemicals with little or no human safety data. However, it remains a challenge to balance the sensitivity and specificity of HT in vitro assays to identify relevant chemicals. Here, we present a new approach for bioactivity detection called HT In Vitro Phenotypic Profiling for Toxicity Point-of-Departure detection (HIPPTox-POD). We used automated image processing to measure 165 phenotypic features from three human cell lines: BEAS-2B (bronchial epithelial cells), HepG2 (hepatocarcinoma cells), and HK2 (proximal tubule cells). The diverse phenotypic features and cell lines allow us to detect perturbations to different biological pathways. Then, we used machine learning to detect perturbed cells, and estimated concentration-response curves (CRC) based on changes in cellular phenotypes. We tested 64 blinded chemicals, including phthalates, phenols, conozoles, and other chemicals, provided by the US EPA. We obtained reproducible CRCs for 47 chemicals, with only 13 chemicals failing the effectiveness concentration at 10% of the curve (POD_{10\%}). Two distinct clusters of chemicals were observed: eight with high POD_{10\%} values (“inactive”) and 39 with low POD_{10\%} values (“active”). We also examined the 5th-percentile of the active concentrations at 50% activity across all the ToxCast assays (POD_{5\%}). For the same chemicals, but no clear clustering of the chemicals could be found. Interestingly, when compared to the 5th-percentile of the NOAELs/LOAELs of these chemicals from ToxRefDB (POD_{5\%}), we found that the inactive chemicals have higher POD_{5\%} than most of the active chemicals. Furthermore, POD_{HIPPTox} is positively correlated to POD_{ToxCast} (Spearman’s rank correlation coefficient = 0.691, P = 1 x 10^{-11}). Also, POD_{HIPPTox} of chemicals with POD_{ToxCast} = 1 μM, but no significant correlation was observed for active chemicals with POD_{ToxCast} ≤ 1 μM. Our results show that HIPPTox and Toxcast produce similar rankings of chemicals in 64% of the active chemicals. Toxcast is more sensitive in detecting bioactivity, but HIPPTox-POD is more specific and may identify chemicals with weak or no bioactivity under standard animal tests. Therefore, HIPPTox-POD may be used together with ToxCast to provide a more balanced screen of chemicals. This abstract does not reflect US EPA policy.

1742 A General Approach to Model Errors of Machine-Learning Prediction of Chemical Toxicities
A. Walvgård¹, R. Liu¹, K. Glover², and M. Feasel³. ¹DoD Biotechnology High Performance Computing Software Applications Institute, Frederick, MD; and ²US Army Edgewood Chemical Biological Center, Aberdeen Proving Ground, MD.

A known limitation of conventional machine-learning methods for quantitative structure-activity relationship (QSR) studies of molecular activities is that the prediction error for a molecule depends on the similarity or “distance” between that molecule and the molecules in the training set. The concept of applicability domain (AD), which is used to gauge the reliability of QSAR predictions, assumes that a prediction is reliable if a molecule is within the AD and unreliable if it is not. This poses a conundrum because, although we are most interested in predicting the activities of novel molecules, such molecules are most likely outside the AD and, therefore, we have the least predictive confidence. Recently, deep neural networks (DNNs) have become the tool of choice in artificial intelligence, owing to their ability to outperform all other machine-learning methods. However, it is unclear whether they provide similar performance and reliability in predicting chemical toxicity measurements. To address this question, we recently analyzed DNN predictions of chemical toxicities in detail. The results showed a similarity-dependent degradation of prediction accuracy comparable to other machine-learning methods, suggesting the need to implement AD measures for DNNs as well. In this study, we developed a molecular Tanimoto distance-based AD metric suitable for any machine-learning method. We define this new metric as the sum of the distance-weighted contributions (SDC) of all training molecules, where all molecules in the training set contribute, but the contribution of each is weighted by how similar the query molecule is to each molecule in the training set. Using many chemical toxicity datasets and machine-learning methods, we showed that the correlation between the prediction error and the SDC is stronger than that between the prediction error and other AD metrics. This allowed us to construct a root mean squared error (RMSE) prediction model based on SDC, and thereby quantitatively estimate prediction errors. The strength of the new metric is its ability to accurately estimate errors for molecules outside the AD of a model. The metric thus gives us the ability to know how accurately we predict the truly unknowns.

1743 Hallmark Gene Set Annotation for NTP Toxicogenomic Studies
I. Lea¹, Y. Liu¹, E. Sheridan¹, D. Motti¹, C. Martin¹, J. Foster², and S. Auerbach³. ¹ASRC Federal Vistronix, Morrisville, NC; and ²NIHES/NTP, Research Triangle Park, NC.

The Hallmark Gene Sets were originally generated by Liberzon and colleagues to represent defined biological processes and coordinated expression patterns. The gene sets were identified through computational and manual curation methods to identify overlapping gene sets in Molecular Signatures Database (MSigDB) collections retaining genes that display coordinated expression. The development of this gene set helped facilitate more robust Gene Set Enrichment Analysis (GSEA) results. The National Toxicology Program (NTP) toxicogenomics program uses short term exposures in rodents to assess the effects of test article exposure on gene expression. Changes in gene expression can be used to model the toxic effects of the test article. This can be done by comparing the effects with other substances in other databases and analysis tools. To enhance the NTP analysis of genomic effects, the Hallmark Gene Sets have been manually curated and refined for relevance to the NTP endpoints. The current work focuses on the EIF Bio platform to identify correlations between Hallmark Gene Sets and genes upregulated or downregulated in rodent liver. Using this information, a mechanistic interpretation was developed for the Hallmark Gene Sets that can be used to enhance GSEA for NTP studies. The Chemical Effects in Biological Systems (CEBS) database is a public resource for NTP toxicology testing data. The annotated Hallmark Gene Set can be reviewed, searched and downloaded from the CEBS NTP Data Collections application (https://manticore.niehs.nih.gov/datasets).

1744 A Novel Evidence Integration Framework: Incorporating Human, Animal, and Mechanistic Data for Causal Inference
S. Sulsky¹, T. Greene², G. Mariano², F. Chowdhury³, A. Franzen⁴, D. Smith⁴, W. McKinney⁴, and P. Gentry⁵. ¹Ramboll US Corporation, Amherst, MA; and ²Ramboll US Corporation, Monroe, LA; and ³Ramboll US Corporation, Arlington, VA; and ⁴Altria Client Services, Richmond, VA.

This novel Evidence Integration Framework (EIF) provides a method for synthesizing data from comprehensive, systematic, quality-based assessments of the epidemiological and toxicological literature, including in vivo and in vitro mechanistic studies. The EIF organizes data using both a disease-based and mechanism-based scheme to support evidence synthesis. The disease-based scheme uses the evidence of human health outcomes studied in the best quality epidemiological literature to organize the toxicological data according to authors’ stated purpose, with the pathophysiology of the disease determining the potential relevance of the toxicological data to the human health endpoint. The mechanism-based scheme organizes the toxicological data based on the proposed mechanisms of effect and mechanistic data supporting key events leading to each toxicological endpoint, with corroborating epidemiological data providing a bridge to human health effects. In addition, the data are organized into major and minor domains, to assist in characterizing the uncertainty of the relevance of the toxicological data to human health. The EIF includes a method to cross-classify and describe the concordance of the lines of evidence, to further characterize the uncertainty of their connection and thereby to draw causal inferences. An initial application of the EIF Bio platform focused on the integration of evidence related to non-acute exposure to nicotine and cancer and identified signals that there may be a relationship between the two. The evidence is largely driven by weak evidence from the epidemiological literature pertinent to smokeless tobacco use, and toxicological data that can be best classified as minor or supportive in nature. The EIF thus identifies a direction for future research, i.e., investigating the meaning of these signals and determining whether integrating the epidemiology with the toxicology might have resulted in conclusions that were not expected and require further investigation.
The rapidly increasing inventory of publicly available in vitro high-throughput screening (HTS) assay data is facilitating the development of computational approaches for chemical hazard assessment. With HTS assays for more than 1,000 endpoints, the United States Environmental Protection Agency’s ToxCast program provides insight into a wide variety of molecular and cellular targets. While ToxCast data is annotated to include information about technology platform, assay design, and gene target (where appropriate), it remains a challenge to place assay outputs into a toxicological context. Here we present a framework for mapping ToxCast HTS assay endpoints to toxicological adverse outcomes, moving beyond assay annotations to molecular biological targets to provide a more robust assay grouping schema. To date, 168 ToxCast assay endpoints have been manually mapped to “acute systemic toxicity” by linking them to distinct modes-of-action (MoA) known to be relevant to acute systemic toxicity. Acute systemic toxicity MoAs rich in ToxCast data include mitochondrial inhibition (20 assay endpoints), altered ion flow (23 assay endpoints), and oxidative stress (27 assay endpoints). Likewise, 154 assay endpoints have been mapped to “developmental toxicity”, for which MoA groupings include neural crest cell disruption (26 assay endpoints), endocrine disruption (49 assay endpoints), and vascular disruption (23 assay endpoints), among others. To demonstrate the utility of MoA mapping for toxicity outcomes, we present a case study using the ToxPi prioritization approach, which leverages weighted relationships across various MoAs to yield insight into the potential of a chemical to elicit developmental toxicity. This approach provides a linkage of in vitro HTS assays to toxicological MoAs, which can facilitate chemical prioritization (i.e., with ToxPi), inform predictive modeling, or even aid in developing the foundation for adverse outcome pathways. This project was funded in whole or in part with federal funds from the NIEHS, NIH under Contract No. HHSN275201500010C.

Analysis of groundwater in Gela, Italy revealed significant contamination from a local industrial site. One of the chemical compounds, ethylene dichloride, was found to be present in the highest concentration per legislative allowed value. Gela has also reported an unusually high incidence of hypospadias, a congenital disorder characterized by the abnormal location of the urethral opening, with a prevalence nearly double that of Italy’s and one of the highest in Europe. This study investigates the computational association between ethylene dichloride exposure in Gela and hypospadias. Online databases, docking software, and literature were used to identify a potential genetic link between the two. The HSD3B2 gene, which is expressed in the gonads, and the HSD3B1 gene, expressed in the placenta, were of interest, since both are crucial in steroid biosynthetic processes associated with hypospadias. Biomonitoring and teratogenic studies revealed that ethylene dichloride crosses the placental barrier and accumulates in both placental and fetal tissues for approximately 7 days. Ethylene dichloride was hypothesized to act in parallel in both the mother’s placenta, via ATP3 and HSD3B1 mRNA upregulation, and the fetal gonads, via HSD3B2 mRNA downregulation. Based on the comparative analysis, a molecular initiating event for ethylene dichloride-induced hypospadias was proposed: The ethylene dichloride metabolite, chloroacetaldehyde, increases expression of ATP3 which binds to CRE, preventing CREB from binding and decreasing transcription of genes containing the CRE element. Additionally, a computational chemical/protein docking model indicated interaction between CREB and 2-chloroacetic acid, another ethylene dichloride metabolite, which would also reduce CREB binding. NIH BLAST Genome Database results show that HSD3B2 promoter contains most of the CRE sequence, which supports the proposed association between the decreased transcription of gene HSD3B2 and hypospadias disease. These findings suggest that fetal ethylene dichloride exposure in utero may have contributed to the high incidence of hypospadias in Gela.
The CEBS database (https://manticore.niehs.nih.gov/celbsresearch/) catalogs toxicology study metadata and assay result information. Users can access the entire dataset, search, filter, download data, and verify results for unique test articles or compare the results for the same test article from different sources. In addition, these data are linked with the CEBS Search tool article reports so that users may easily navigate between the NTP Data Collection elements and other related data in CEBS. Together, the NTP Data Collection and CEBS Search functionalities expand understanding of the toxicological effects of test articles and facilitate easy access to all related data. The NTP Data Collection will be continuously updated with addition of new datasets in the future to support the needs of users.

The federal Tox21 consortium produces quantitative high-throughput screening (qHTS) data on thousands of chemicals across a wide range of assays covering critical biological targets. Many of these assays, and those used in other in vitro screening programs, rely on luciferase and fluorescence-based readouts which can be susceptible to signal interference by certain chemical structures resulting in false positive outcomes. Included in the Tox21 portfolio are assays specifically designed to measure interference in the form of luciferase inhibition and autofluorescence via multiple wavelengths (red, blue, and green) and under various conditions (cell-free and cell-based, two cell types). Out of 8,305 unique chemicals tested in the Tox21 interference assays, percent actives ranged from 0.5% (red autofluorescence) to 9.9% (luciferase inhibition) after filtering for curve class, efficacy, and cytotoxicity cutoffs. Bimodal potency distributions were observed among active chemicals, possibly due to differences in plasma protein binding. The penetration of 5-FU into human enterocytes after intravenous dosing (500 mg/m^2) for differences in plasma protein binding. The penetration of 5-FU into human enterocytes after intravenous dosing (500 mg/m^2) is well described, peaking 10 hrs after dose with an average number of apoptosis was well predicted in mouse - ratio between predicted and measured maximum on the first day and is recovered 16 days after chemotherapy. The agreement with histological data from biopsies that shows that apoptosis is decreased 3% by the end of the day and being recovered 16 days after dosing. This agrees with histological data from biopsies that shows that apoptosis is decreased 3% by the end of the day and being recovered 16 days after dosing. The simulation on a compute cluster can reduce the runtime by 99.7%, making it feasible for the software to analyze hundreds to thousands of expression datasets in less than a day, even on the whole transcriptome. Other notable improvements to the software and statistical methods include availability of annotations for GENIE extrapolated full transcriptome from the human platform, and new GCAT platforms (each with ~20K genes with linked GO terms); no (NOTEL) and lowest (LOTEL) observed transcriptomic adverse effect level calculations; Dunnett’s test for multiple comparisons; and non-parametric curve fits. These updates vastly improve the capabilities of the software and the ability to better model curves for chemicals eluding non-traditional dose responses. Important features include in vitro to in vivo extrapolation (IVIVE) method to broaden the scope and utility of the software. BMDExpress will continue to be maintained and developed to meet the expanding needs of toxicologists, risk assessors, and geneticists alike.

5-fluorouracil (5-fu) is a chemotherapeutic inducing intestinal apoptosis, an apoptotic marker in various toxicology, PBPK/PD positive enabling translation of preclinical predictions of adverse effects to human to guide drug development. In this work, a PBPK/PD model was built to describe 5-fu induced crypt cell apoptosis in small intestine of mouse and was extrapolated to human. The Simcyp Mouse Simulator v17 was used to model the PK of 5-fu with an oral dose of 260 mg/kg. Absorption followed first order dynamics and elimination was considered through liver, intestine and kidney. The gut tissue concentration was assumed to drive the cell damage model, included using a PD script. Stem cells and Transit Amplifying Daughter Cells (TADCs) divide in the intestinal crypts, TADCs differentiate into enterocytes, which migrate along the villi and die at its top for epithelium turnover. TADC apoptosis induced by 5-fu systemic concentration was well predicted in mouse - ratio between predicted and measured 1.12 for C_{max} and 0.52 for C_{TADC} and 1.37 for AUC. The evolution of apoptosis was well described, peaking 10 hrs after dose with an average number of apoptotic cells per crypt of 1.6, versus the observed 1.9 at 6 hrs. For human, the resulting exposure agrees with clinical data. The predicted average number of apoptotic cells per intestinal crypt reached a maximum of 0.5 at 5 hrs, having decreased 3% by the end of the day and being recovered 16 days after dosing. This agrees with histological data from biopsies that shows that apoptosis is maximum on the first day and is recovered 16 days after chemotherapy. The proposed PBPK/PD model is an initial attempt to describe the evolution of crypt cell apoptosis induced by 5-fu in mouse and human. This work contributes to the understanding, prevention and early detection of gastrointestinal toxicity. This work is supported by the TransQST grant.
unclear which factors have dominant influence on the assay result variation. In this study, meta-analysis was performed to identify possible cause of assay result inconsistency. Data for meta-analysis were collected from research articles that studied nanotoxicity on Daphnia magna according to the TGs. In data collection, physicochemical properties of NPs, experimental conditions of the assays, and the experimentally measured toxicities were extracted to compile the dataset. In total, 882 data points (NPs in each experimental conditions) were obtained from 83 publications. According to the analysis of the data, toxicity of non-coated NPs was not correlated with the TEM diameter of the NPs even though most of the NPs indicated higher toxic effects than non-NPs of identical core materials. To find out experimental conditions that caused assays result inconsistency, prediction models were developed for each type of NP (metal oxide, metal, and coated metal) with stepwise selection algorithm using support vector machine. Based on the model analysis, experimental treatments to disperse NPs in media were suggested as the most influential experimental conditions in varying assay results.

**1754 Transitioning to Composite Bacterial Mutagenicity Models in ICH M7 (Q)SAR Analyses**

C. Landry1, M. Kim1, N. Kruhkal1, K. Cross2, R. Saiakhov2, S. Chakravarti3, and L. Stavitskaya1.1 US FDA, Silver Spring, MD; 2Leadscape Inc., Columbus, OH; and 3Multicase Inc., Beachwood, OH.

The International Council on Harmonisation (ICH) M7(R1) guideline describes the use of complementary (quantitative) structure-activity relationship (Q)SAR) models to assess the mutagenic potential of drug substance impurities in new and generic drug products. Historically, two statistical-based models have been used to predict mutations at G-C (guanine-cytosine) and A-T (adenine-thymine) sites, to comprehensively assess bacterial mutagenesis. In the present study, composite bacterial mutagenicity models using both G-C and A-T mutation types have been developed using two commercial statistical software platforms. These new models contain more than double the number of chemicals (n=9,067 and n=13,514) than the corresponding non-composite models with data harvested from the published literature, US FDA approval packages for drugs approved between 2009 and 2017, Centers for Food Safety and Applied Nutrition public databases, online repositories, and through data sharing efforts. Additionally, the use of composite bacterial mutagenicity models simplifies impurity analysis in an ICH M7 (Q)SAR workflow by reducing the number of model outputs requiring review. Cross-validation performance statistics for the new models range from 84 to 91% in sensitivity and 81 to 89% in negative predictivity. Additionally, an external validation set of 398 drug impurities representing proprietary pharmaceutical chemical space showed performance statistics ranging from 67 to 79% in sensitivity, 91 to 94% in negative predictivity and 94 to 96% in coverage. This data set was used in part to confirm that gaps in the applicability domain of the previous models were filled, while high predictive performance was maintained. This effort represents a major enhancement to (Q)SAR models that are recommended for use under ICH M7(R1), leading to improved patient safety through greater predictive accuracy, applicability, and efficiency when assessing the mutagenic potential of drug impurities.

**1755 The Impact of Chemical Quality on the High-Throughput Testing of Diverse Chemicals**

L. Ye, D. Tao, C. LeClair, J. Zhao, M. Xia, D. Nguyen, T. Zhao, P. Shinn, A. Simeonov, and R. Huang. NIH, Rockville, MD.

Chemical quality is an important factor that can affect the bioassay results to cause false negatives/positives. The Tox21 10K chemical library has undergone analytical testing for quality control (QC) after being exposed to room temperature for 0 and 4 months (T1 and T2). Each chemical was assigned a QC grade based on purity, identity and concentration. In parallel, the Tox21 10K library has been tested in over 50 cell-based quantitative high-throughput screening (qHTS) assays. In this study, we used these data to analyze the correlation between chemical quality and bioassay activity as well as chemical structure. Chemicals with low QC grades at T2 were considered poor quality, and chemicals with a grade drop from T1 to T2 were considered unstable. Using the Random Forest (RF) method, we constructed and compared the performance of bioassay data and chemical structure-based prediction models. The prediction model was evaluated by the area under the receiver operating characteristic curve (AUC-ROC). The results show that poor quality chemicals were relatively less active than the chemicals that passed QC. Chemical quality and stability were found to correlate with chemical structure significantly with stability showing a better correlation than quality. The AUC-ROC of the best model was as high as 0.75. This indicates that chemical structure is a good predictor of chemical stability. The models also identified structure features of unstable chemicals, such as Nedaplatin, Endrin, Glycobiocin. In addition, the Tox21 p53 assay was used to test the 10K library at T1 and T2. About 2% of the library showed a significant change in activity between T1 and T2 turning from either active to inactive or inactive to active. The correlation between this activity change and chemical stability was analyzed. Taken together, these results could serve as a guidance for interpreting the Tox21 assay results and for future chemical selection and handling.

**1756 Bioinformatic Integration of In Vivo Data and Literature-Based Gene Associations for Prioritization of Adverse Outcome Pathway Development**

J. Brown1, S. Watford1, and K. Paul Friedman2. Oak Ridge Institute for Science Education Student Contractor, Oak Ridge, TN; and 1US EPA/NCTR, Research Triangle Park, NC.

Adverse outcome pathways (AOPs) describe a sequence of events, beginning with a molecular initiating event (MIE), proceeding via key events (KEs), and culminating in an adverse outcome (AO). A challenge for use of AOPs in a safety evaluation context has been identification of MIES and KEs relevant for AOs observed in regulatory toxicity studies. In this work, we implemented a bioinformatic approach that leverages mechanistic information in the literature and the AOs measured in regulatory toxicity studies to prioritize putative MIES and/or early KEs for AOP development relevant to chemical safety evaluation. The US Environmental Protection Agency Tox21 Reference Database (ToxRefDB) contains chemical and biological information for curated chemicals ranging from >5000 studies or summaries from sources including data evaluation records from the US EPA Office of Pesticide Programs, the National Toxicology Program (NTP), peer-reviewed literature, and pharmaceutical preclinical studies. To increase ToxRefDB interoperability, endpoint and effect information was crosswalked into SMIRX from the United Medical Language System, which enabled mapping of in vivo pathological effects from ToxRefDB to PubMed (via Medical Subject Headings or MeSH). This enabled linkage to any resource that is also connected to PubMed or indexed with MeSH. A publicly available bioinformatic tool, the Entity-MeSH Co-occurrence Network (EMCON), uses multi-source data sources and a measure of mutual information to identify genes most related to a MeSH term. Using EMCON, gene sets were generated for endpoints of toxicological relevance in ToxRefDB linking putative KEs and/or MIES. The Comparative Toxigenomics Database was used to further filter important associations. As a proof of concept, thyroid-related effects and their highly associated genes were examined, and demonstrated relevant MIES and early KEs for AOPs to describe thyroid-related AOs. The ToxRefDB to gene mapping for thyroid resulted in >50 unique gene to chemical relationships. Integrated use of EMCON and ToxRefDB data provides a basis for rapid and robust putative AOP development, as well as a novel means to generate mechanistic hypotheses for specific chemicals. This abstract does not necessarily reflect US EPA policy.

**1757 A Workflow to Assist in Expert Review and Regulatory Submissions of ICH M7 (Q)SAR Assessment of Impurities**

R. D. Saiakhov, and S. Chakravarti. MultiCASE Inc, Beachwood, OH.

After the implementation of the International Conference on Harmonisation’s (ICH) M7 guideline, (Q)SAR approach has become particularly important in assessing bacterial mutagenicity potential of drugs and impurities. The guidance recommends including outcomes from both statistical and expert rule-based models and to perform expert review of the raw output of the (Q)SAR predictions with the help of supporting information. Application of expert knowledge improves accuracy, increases confidence, and provides a rationale for the assessments. However, steps required for such review and documentation are still challenging. In this study, we report a workflow designed to combine the results of highly predictive statistical and expert rule-based models and to generate a variety of supporting evidence with the goal to assist expert review and regulatory submissions. Supporting evidence includes structural relationships between the active drug substance and the impurity, analysis of structurally similar analogs, evaluation of the relevance of identified alerts and analysis of the structural features not covered by the (Q)SAR models. The workflow suggests an overall call and ICH M7 class for bacterial mutagenicity assessment and provides a confidence level as well as useful tips for human expert review, highlighting the areas with strong and weak evidential support. Special care is taken to resolve out of domain and uncertain outcomes. To validate the workflow, a test of 407 chemicals (155 positives/252 negatives, data from proprietary contributors) was performed against bacterial mutagenicity statistical and expert rule-based models. After applying the workflow, the most notable effects were in the increase of true positives by 20% and 6% increase in the structural coverage. Overall 72% sen-
Comparative Case Studies to Establish a Standardized Process for Read-Across within a Daily Safety Assessment Workflow

T. Kawamoto1, A. Granitzy2, J. Rathman1, A. Mostrag3, and C. Yang1,
1Kao Corporation, Ichikai-machi, Japan; 2Kao Germany GmbH, Darmstadt, Germany; 3Ohio State University, Columbus, OH; and 4MN-AM, Columbus, OH.

Read-across is one of the alternative methods considered for regulatory purposes to fill data gaps encountered in product safety assessments. The toxicity potential of a chemical is inferred from known toxicity of compound(s) having a similar structure and property profile. Nevertheless, read-across is an evolving method with several open issues, one of which is related to the lack of consensus regarding the extent and type of evidence necessary to support a read-across. To achieve reliable read-across results, a quantitative and transparent methodology is required for similarity assessment as well as hypothesis-driven evaluation. We applied commercial and public software tools to establish standardized workflow. Chemical safety of two cosmetic ingredients (Isopropyl palmitate and Neopentyl Glycol Dicaprate) were assessed by analogue-based read-across method for target evaluations including Point of Departure (POD) estimation and potential value content/developmental safety, sensitization, and genetic toxicity. The chemical similarity was compared for structural fingerprints from multiple sources (RDKit, MCCS Keys, ToxPrints, and CDK) using ChemTunes, ToxGPS® and AMBIT. Properties-based similarities were calculated from ToxGPS. Toxicity data were compiled from ChemTunes and AMBIT databases. TIMES-SS and ChemTunes LiverBioPath was used to address metabolites and reaction similarity. Final combinations of diverse evidence based on different similarities were performed using the quantitative weight-of-evidence approach available within ToxGPS Read-Across tool. Metabolic similarity gave rational hypothesis along with read-across scenario which is region of select appropriate analogues. Isopropyl palmitate as isopropyl palmitate as well as Neopentyl glycol dicaprylate, Pentenythryltetraesterate and Trimethylolpropane trinonanoate for Neopentyl Glycol Dicaprate were selected as analogue with regard to metabolic similarity. This case study demonstrated identification of reasonable analogues by the complementary use of commercial and public read-across tools. Systematic and reproducible outcomes can be attained along with estimation of the associated uncertainty. This standardized workflow can be applied for day-to-day safety assessment.

BioCelerate Sendharmonization Initiative: A Proposal to Better Harvest the Value from Send Data

M. A. Carafagna1, T. G. Bjerregard2, T. Fukushima3, W. Houser4, K. Mera3, and T. J. Page1, 1El Lilly and Company, Indianapolis, IN; 2Novo Nordisk, Copenhagen, Denmark; 3Shionogi & Co., Ltd., Osaka, Japan; and 4Bristol-Myers Squibb, New Brunswick, NJ.

BioCelerate, a subsidiary of TransCelerate BioPharma, Inc., is a preclinical industry consortium driving initiatives to increase efficiency and productivity in early stage R&D. The Standard for Exchange of Nonclinical Data, or SEND, identifies an approach to gathering and representing nonclinical data in a standardized workflow workflow. Safety, efficacy, and regulatory submissions. The consortium is currently engaging stakeholders to clarify the problem statement and to begin to understand options for future harmonization of SEND through CDISC. The implementation of these recommendations is expected to improve the relevance of these studies from this initiative will allow comparison of warehoused SEND data and unlock value that is currently unrealized. These comparisons include the ability to compare the progression of findings over time with a single molecule and a comparison of target organs across multiple molecules directed against the same target. This poster/presentation outlines the breakdown of the methodology for mapping of SEND data variability and the cross-stakeholder engagement framework proposed to identify solutions for SEND data harmonization, ultimately contributing to the goals of increased efficiency and productivity in early stage R&D.

Development of an Adverse Outcome Pathway (AOP) Network for Carcinogenicity Using Expert-Derived (Q)SAR Knowledge

The prediction of carcinogenicity and related toxicity endpoints has always been a principal area of research for in silico (Q)SAR systems and as a result, software relating to these endpoints is well developed. Indeed, in recent years predictions provided by these systems have become embedded in regulatory guidance, where they may be used to replace or augment other testing methods. Consequently, it is important that the predictions are as accurate as possible and are provided in such a way that they can be easily integrated with other sources of evidence. Derek Nexus (DX) is an expert rule-based SAR system with a well-developed knowledge base for carcinogenicity and related endpoints. Within this knowledge base, there is information on molecular-initiating events (MIEs), as well as other potential key events (KEs) and modes of action (MoA) associated with the compound classes covered by the alerts. In this work, we investigated 310 alerts related to carcinogenicity in DX and used the knowledge contained in the alerts. These linkages provided a skeleton AOP network containing 26 AOPs. This network was then subjected to a detailed review using public literature to supplement the AOPs with evidence for biological plausibility, and information such as species relevance. This review dramatically increased the scope of the network, with the number of pathways associated with the 26 MIES increasing from around one pathway per MIE to more than twice as many. The review also allowed for the association of each pathway with events at the protein level. This network can be used as a rudimentary profiling tool for carcinogenicity MoA prediction. A combination of literature review and profiling of carcinogenicity AOPs using our model also identified additional MIEs and KEs for future investigation and integration into the network. It is hoped that this approach to knowledge presentation will allow for easier interpretation of the evidence available relating to a given prediction. Presenting more detailed information on potential pathways allows for better integration of existing and emerging in vitro and in vivo tests at the protein level with predictions produced by DX. This methodology also allows for expansion of the scope of predictions which can be made for this endpoint, allowing for integration of MIES, ADME data and other data not necessarily related to toxicity outcomes.

Machine Learning Approaches to Categorize Carbonaceous Nanomaterials Based on Patterns of Inflammatory Markers and Pathological Outcomes in Lungs

I. Desai1, W. Miller1, V. Kodali1, G. Syamlal1, J. Roberts1, A. Erdely1, and N. Yamana1.
1NIOSH, Morgantown, WV; and 2Ohio State University, Cleveland, OH.

As technology advances to incorporate nanoparticles (NP) in various industries, the exposures associated with these particles also increase. Exposure to carbonaceous NPs has been found to be associated with substantial pulmonary toxicity, including inflammation, fibrosis, and/or granuloma formation. Despite several attempts made previously, grouping or categorizing NPs based on their intrinsic properties and certain inflammatory endpoints remains a challenge. The inconsistency and a large number of variables across studies considered by different groups for evaluating toxicity responses of NPs, the lack of precise understanding of the role of different NP characteristics on various biological responses, as well as missing NP data under in vivo biological conditions and pathological outcomes often the result of chronic inflammatory responses further complicates the selection of NPs. This study attempts to categorize the toxicity profiles of various carbon allotropes, in particular, carbon black, different multi-walled carbon nanotubes, graphene-based materials and their derivatives. Statistical and machine learning based approaches were used to identify groups of CNMs with similar pulmonary toxicity responses from a panel of proteins measured in bronchoalveolar lavage (BAL) fluid samples and with similar pathological outcomes in the lungs. Thus, grouped particles based on their pulmonary toxicity profiles, were used to select a small set of proteins that could potentially identify and discriminate between the biological responses associated within each group. Specifically, MDC/CCL22 and MIP-3β/CCL19 were identified as common protein markers associated with both toxicologically distinct groups of CNMs. In addition, the persistent expression of other selected protein markers in BAL fluid from each group suggested their ability to predict toxicity in the lungs, i.e., fibrosis.

Pathway (AOP) Network for Carcinogenicity Using Expert-Derived (Q)SAR Knowledge

1762 Identifying the Link between Chemical Exposures and Incidence of Triple-Negative Breast Cancer in African American Women

K. M. Poleni, J. Heidt, V. Nguyen, A. Kahana, O. Jolliet, and J. A. Colacino, University of Michigan School of Public Health, Ann Arbor, MI.

The incidence of triple negative breast cancer (TNBC), an aggressive subtype of breast cancer for which there is no targeted therapy, is approximately three times higher in non-Hispanic black (NHb) women compared to non-Hispanic white (NHW) women. The mechanisms driving this difference are unknown, and likely lie in an interaction between genetic and environmental factors. Here, we aimed to identify chemical exposures which may play a role in TNBC disparities. Using chemical biomonitoring data from the National Health and Nutrition Examination Survey (NHANES) and biological activity data from the US EPA’s ToxCast program, we identify chemicals at higher concentrations in NHb women and assess their toxicological relevance to breast cancer risk. A total of 44 chemicals showed significantly higher biomarker concentrations in NHb women. Investigation of these chemicals in ToxCast resulted in a total of 22,061 assays for analysis, 5,343 of which contains adequate modl_ga (logAC50) and modl_tp (scaled top value of dose response curve) data. BPA, known to be associated with breast cancer, and PFOS were most tested, and had 19.98% and 20.46%, respectively, of assays tested reported as active. Of interest are PFDA, PFUnDA, PFNA, and Chlordane due to their higher concentrations in NHb women and moderate testing and activity in ToxCast. Furthering our chemical prioritization, Gene Set Enrichment Analysis (GSEA) provided pathway association between active genes analyzed in ToxCast and putative TNBC mechanisms. Using publicly accessible high throughput data, we have prioritized chemicals of interest to further investigate for their relevance in TNBC disparities.

1763 Integrate Mechanistic Knowledge with High-Throughput Data to Assess Risk for Drug-Induced Liver Injury Using Adverse Outcome Pathway Networks

Due to the well-known limitations for current animal testing based approaches to predict drug induced liver injury (DILI), there is heightened interest in incorporating high throughput assays into the evaluation framework for DILI risk. However, the diverse and high dimensional nature of these data poses serious challenges for common data mining and machine learning techniques even with recent advances. Integrating high throughput assay information with mechanistic knowledge in the form of expert opinion and literature findings might provide a promising approach to fully utilize the power of both mechanistic understanding and new testing technologies. In this presentation, we discuss our pilot study using adverse outcome pathway (AOP) networks to provide a base model for incorporating high throughput data from L1000, CMap, and Tox21 for gene expression changes and nuclear receptor binding. AOP networks were formed by integrating published AOPs for liver steatosis, cholestasis, fibrosis, and liver tumor. Information for relevant nuclear receptors and genes was then extracted from these networks. We obtained measurements on nuclear receptor binding and differential gene expression for a collection of drugs in the Liver Toxicology Knowledge Base. A rule ensemble learning model was then built to infer liver toxicity from these molecular predictors resulting in competitive performance with other approaches. Our result suggests that current knowledge encoded in AOPs can be successfully utilized for dimension reduction for high throughput data and leading to capable predictive models. With continued improvement in AOP development and new testing technologies, combining mechanistic insight with high throughput data holds great promise in advancing DILI risk assessment.

1764 QSAR Models for Mean LD50s Are More Predictive Than for Minimum LD50s

A. J. Prussia1, and R. C. Siwakoti1,2, 1CDEC/ATSDR, Atlanta, GA; and 2Emory University, Atlanta, GA.

In April 2018, ICCVAM (Interagency Coordinating Committee on the Validation of Alternative Methods) held a workshop on "Predictive Models for Acute Oral Systemic Toxicity." The Committee invited participants to develop in silico models to predict median lethal doses (LD50s) for a large dataset of chemicals they had curated. A subset of chemicals were included with multiple LD50s per chemical. For this subset, the Committee selected the more protective LD50 point estimate. Based on LD50 variability (Siwakoti et al., 2018), a minimum LD50 will necessarily carry greater experimental uncertainty. We hypothesized that using the mean LD50 instead of the minimum would result in QSAR models with better predictive ability. To test this idea, identical model-building conditions were used to develop models for both the mean LD50 and the minimum LD50 as response variables. The overall predictive ability of the global models is moderate, but the mean LD50 was a consistently better response variable than the minimum LD50. For incorporation of alternative models in risk assessment, this exercise demonstrates the value of characterizing the variability in the endpoint to be modeled. Disclaimer: the findings and conclusions in this presentation have not been formally disseminated at the Centers for Disease Control and Prevention/the Agency for Toxic Substances and Disease Registry and should not be construed to represent any agency determination or policy.

1765 Reconciling In Vitro and In Silico Approaches for Drug-Induced Liver Injury Prediction

Drug-induced liver injury (DILI) is one of the main reasons for drug attrition during clinical trials and of withdrawal from the market. This makes the early identification of hepatotoxicity of compounds a critical challenge. In silico hepatotoxicity prediction models make a cost-effective approach able to prioritize compounds for preclinical and clinical studies. Recent efforts have been made to create more accurate quantitative structure-property relationships (QSPR) models relating hepatotoxicity to chemical structure features. However, to this date only few have integrated in vitro data to their models. This study aims at integrating in vitro activation signal of stress response pathways involved in DILI to standard molecular description of compounds to better identify substructures inducing hepatotoxicity. A library of 118 compounds was screened on a panel of 8 previously established HepG2 BAC-GFP reporter cell lines that capture endoplasmic reticulum (ER) stress, DNA damage, heat shock response and inflammatory responses. Fluorescence microscopy images were taken at 24, 48 and 72 hours after addition of the compounds (concentration ranging from 1 to 100 Cmax). Additionally, propidium iodide (PI) and annexin V (AnxV) staining was performed to detect necrotic and apoptotic cells. Quantitative image analysis was performed with CellProfiler. GFP integrated signals, Cmax, AnxV and PI values were used as descriptors of the compounds along with extended connectivity fingerprints of radius 3 (ECFP, 6) physicochemical descriptors of the compound structures. Statistical models (Bayesian, Random Forests, Gradient Boosted Decision Trees) were applied to relate both in vitro derived data and molecular structure description to the US FDA approved DILI annotation (Most, Less, No and Ambiguous DILI concern). Our results demonstrate that the integration of both in silico chemical descriptors and in vitro quantitative mode-of-action data increased the predictive performance of the predictive models. This work highlights the importance of integrating both in silico and in vitro approaches in the construction of predictive models for DILI. This work was supported by the NIMH/ETRANSAFE project (grant agreement 777365) and the H2020 EU-ToxRisk project (grant agreement 681002).

1766 Database of Pharmacokinetic Time-Series Data and Parameters for Environmental Chemicals

R. R. Sayre1,2, J. F. Wambaugh2, and C. M. Grulke1. 1ORISE, Research Triangle Park, NC; and 2US EPA, Research Triangle Park, NC.

Time courses of compound concentrations in plasma are used in chemical safety analysis to evaluate the relationship between external administered doses and internal tissue exposures. This type of data is experimentally generated for chemicals like pharmaceuticals or cosmetics, but is not usually available for the thousands of other chemicals to which people may potentially be exposed. An understanding of the pharmacokinetics for these chemicals can be important for modeling in vitro assays and in silico models, but the certainty of the quantitative application of these estimates to chemical safety evaluations
cannot be determined without in vivo data for external validation. To address this need, we present a public database of time-series from almost 600 studies in humans or test animals for over 150 environmentally-relevant chemicals and their metabolites by all major administration routes with concentrations measured in blood/plasma, tissues, and excreta. All information was sourced from either open databases or published literature sources identified using machine learning. The extracted pharmacokinetic time-series are stored in a MySQL data model with detailed, manually curated metadata. Concentration-time points were manually captured using the webtool WebPlotDigitizer. Data in all fields are normalized to facilitate comparisons, but original values are retained for transparency. Plots of the data will be viewable on the US EPA ComToxChem Dashboard (https://comptox.epa.gov/dashboard) along with optimized pharmacokinetic summary parameters (e.g. area under the curve, volume of distribution) calculated using the R package invivoPKfit.

In addition to model calibration and validation, this set may be used for analyses of differential chemical distribution across chemicals, species, doses, or routes, and can be added on pharmacokinetic studies performed in vivo can also host data and metadata needed for metabolism and pharmacokinetics testing guidelines. To facilitate data sharing we can accommodate (and encourage) submissions of structured published data on any compound. This abstract does not necessarily reflect US EPA policy.

1767 Application of HTTK Pregnancy Modeling and IVIVE Approaches for High-Throughput Screening

The US EPA has developed a high throughput toxicokinetic (HTTK) modeling platform to support animal-free toxicity predictions using in vitro to in vivo extrapolation (IVIVE). Recently, HTTK has been extended to describe pregnancy (fetal HTTK). To test the performance of the fetal HTTK platform in modeling developmental toxicity from in vitro findings, we sought to compare an exposure-based prediction of developmental toxicity with human induced pluripotent stem cell responses to 7 retinoid analogs recently reported by Palmer et al. (2017): all-trans-retinoid acid (ATRA), Retinol, Acitretin, Eretinate, 9-cis-retinoid acid (9-cis-RA), 13-cis-retinoid acid (13-cis-RA) and 4-(E)-2-(5,6,7-Tetrahydro-5,5,8,8-tetramethyl-2-naphthalenyl)-1-propenyl benzoic acid (TTNPB). The fetal HTTK model describes human pregnancy starting from the end of first trimester and spanning second and third trimesters. We assumed that the external dose predicted by reverse dosimetry in the non-pregnancy condition reflects early stages of pregnancy, and then used the fetal HTTK model simulations to predict pregnancy-induced changes in internal dosimetry. Based on the predicted external dose to result in an internal exposure level of 0.01 μM (i.e., the teratogenic index predicted by the stem cell assay for ATRA), the rank order of retinoids was ATRA>Retinol>Acitretin>Eretinate>9-cis-RA = 13-cis-RA > TTNPB. This rank order was based on predicted external dose followed by that of the stem cell response. Assuming the pharmacokinetic disposition of these analogs reach steady state prior to pregnancy, the fetal HTTK model predicted an overall decrease in maternal plasma concentrations over the course of gestation with a maximum decline of 8.5% in second trimester (for Eretinate) and 14.9% in third trimester (for TTNPB). The model also allowed for the prediction of concomitant fetal exposure which showed an overall decreasing trend as well (about 14.7%). Furthermore, we predicted the analog-specific external exposure doses as determined in the stem cell assay to be 2.2e-03, 1.1e-05, 6.2e-06, 4.9e-04, 6.0e-01, 8.2e-07 mg/kg/day for ATRA, 13-cis-RA, 9-cis-RA, Eretinate, Retinol, TTNPB, respectively. These results demonstrate the utility of predictive modeling coupled with animal-free in vitro experimentation to evaluate developmental toxicity potential in support of high throughput screening of chemicals. This abstract does not reflect US EPA policy.

1768 Computational Model for Inhibition of Mitochondrial Function

D. M. Wilson1, S. J. Wijvesakere1, T. R. Auenhammer1, A. Parks1, D. Kovacs2, and S. Marty1. 1Dow Chemical Company, Midland, MI; and 2Grand Valley State University, Grand Rapids, MI.

In eukaryotes, mitochondria play many life-sustaining roles, with their dysfunction linked to toxicity as well as numerous diseases. We present the development of a computational model that predicts whether a xenobiotic will or will not inhibit mitochondria, with some sub-target information (e.g., inhibition of Complexes I-V or uncoupling via protonophore action). We compiled public databases that target the mitochondria together with associated control compounds that do not alter mitochondrial function. We employed molecular scaffolding and fingerprinting to identify conserved structural motifs and features associated with mitochondrial inhibitors versus controls. By using these attributes as covariates within random-forest machine-learning models, we can identify mitochondrial inhibitors with high sensitivity (83%), specificity (79.3%) and accuracy (81%). The high negative predictive value (93.7%) of our model highlights confidence with which novel compounds can be flagged as mitochondrial agents. When tested against a database of therapeutic candidates withdrawn from the market due to liver injury, our model rapidly identified those that had subsequently been shown to target mitochondria. Furthermore, we were able to identify two compounds that were recently identified as mitochondrial toxins only via experimental testing, highlighting the utility of our model. Given its speed and ease of use, our approach can be used as an integrated approach that complements in vitro mechanistic screening and as a covariate in models that address the etiology of complex biological endpoints. We will make our model publicly available to allow rapid assessment of compounds under development.

1769 Probabilistic Prediction of Human Skin Sensitiser Potency for Use in Next Generation Risk Assessment

Our aim is to develop and apply next generation approaches to skin allergy risk assessment that do not require new animal test data address novel exposure scenarios and better quantify uncertainty. We have developed a Bayesian multi-level regression model to estimate the human sensitiser population threshold (defined as, the chemical-specific exposure level at which no individual in a population will experience induction of contact allergy) under the conditions of a human repeat insult patch test (HRRIPT). Our approach is built upon dose response modelling of historical human data and allows low predictions of human sensitiser potency to be made using historical murine local lymph node assay (LLNA, OECD TG 429) data and/or in vitro test method data (DPRA (OECD TG 442C), KeratinoSensSM (OECD TG 442D), h-CLAT (OECD TG 442E) and U-SensTM (OECD TG 442E)). A key feature of the approach is that the uncertainty in any prediction is explicitly quantified. Our Bayesian probabilistic model is used to estimate population thresholds for 30 chemicals using a weight of evidence incorporating previously published HRRIPT, LLNA, DPRA, KeratinoSensSM, h-CLAT and U-SensTM data. Estimates for a further 43 chemicals using in vitro test method data only are also presented. Comparisons are made with current risk assessment metrics and across data types. This analysis suggests that estimates of human potency generated from in vitro data alone have at least the same level of accuracy, on average, as estimates generated from LLNA data. Consequently, we propose that this approach can be used to derive a point of departure for next generation risk assessment and have submitted it for consideration by the OECD Defined Approach Skin Sensitisation (DASS) Expert Group as ‘Skin Allergy Risk Assessment Defined Approach’ or SARA DA. Application of the SARA DA to four theoretical skin allergy risk assessment case studies (caffeine, coumarin, curcumin and sulforaphane) will be presented, each addressing a different product exposure scenario, to illustrate how the DA prediction can be used as part of a weight of evidence decision-making approach.

1770 Evidence Integration across Multiple Toxicity Endpoints to Prioritize Constituents of Potential Concern in Oil and Gas Produced Water

C. Danforth1, K. Schultz2, A. Bolden2, C. Kwiatkowski2, W. Chiu2, I. Rusyn2, and E. Craft2. 1Environmental Defense Fund, Boulder, CO; 2The Endocrine Disruptor Exchange (TEDX), Eckert, CO. 3Texas A&M University, College Station, TX. The Environmental Defense Fund, Boulder, CO, and TX.

In the United States, onshore oil and gas extraction operations generate an estimated 900 billion gallons of produced water annually making it the largest waste stream associated with upstream development of petroleum hydrocarbons. Management and disposal practices of produced water vary from injection into underground storage wells to “beneficial reuse” of produced water in agricultural settings. Recent efforts, including development of the FracFocus database, have provided insights into some of the chemical constituents used in the hydraulic fracturing extraction process. However, there is relatively little information with regard to the potential for the chemical compounds in produced water. Therefore, this project aimed to address the gaps in our understanding of potential risks to human health or environmental impacts from various disposal practices. We performed a comprehensive literature review, screening nearly 16,000 published articles, to identify chem-
icals that have been detected in produced water. Searches for information on
the potential ecological or mammalian toxicity of these chemicals revealed
that the overwhelming majority of these substances have not been a subject
of safety evaluation or mechanistic toxicology studies. In order to integrate
available evidence and fill in data gaps, we have catalogued available data
from ecotoxicity studies and toxicity screening databases and predicted
toxicity values using Toxicological Priority Index (ToxPI) approach. This
research effort will inform stakeholders and decision-makers on the potential
hazards and risks of this complex wastewater. In addition, this project created
a prioritized list of compounds that, based on hazard and potential exposure,
may be included in the monitoring strategies to reduce those possible human
health risks and environmental impacts.

1773 In Silico Modelization of Compounds Interaction with Bile Salt Export Pump (BSEP): An Alternative Approach to Predict Hepatotoxicity

A. Sharma1, D. Thomas1, F. Bree1, S. Martin1, and D. Steen1, 2; 1Eurosafe, Saint Grégoire, France; and 2Biopredictive International, Saint Grégoire, France.

BSEP is an efflux transporter protein present in the hepatocytes membrane that plays important role in flow of bile acid from hepatocyte cell into the bile canaliculi (1,2). Impaired BSEP activity due to drug interaction leads to accumulation of bile acid within the hepatocyte and results in cholestasis and liver injury (DILI)(3). However, there is no detail information about interaction of compounds with BSEP. To develop 3D model for BSEP transporter protein and analyzing its affinity with compounds using docking tool, the 3D model of BSEP (Uniprot code: Q9YQ30) was determined by homology modeling, and further validated. US FDA-approved compounds were selected and docked against the BSEP structure. The post docking complex was analyzed in order to evaluate the behavior of compounds with BSEP. Homology modeling produced 3D model of BSEP using mouse p-glycoprotein as template with more than 70% homology. Ramachandran plot confirms that 3D model has more than 90% of amino acid residues in the most favored regions. Molecular docking showed that bosentan (positive control) produced higher affinity for BSEP as compare to the caffeine with docking energy of -15.21 kcal/mole (IC50 = 38.1 μM for bosentan) - 4.60 kcal/mole (IC50 > 135 μM for caffeine). Our in silico approach confirmed that bosentan has very high affinity compared with caffeine and acts as an inhibitor of BSEP which plays major role in formation of cholestasis. Therefore, our in silico approach may be helpful to design in vitro experiments using BSEP in order to predict precisely the role of compounds in hepatotoxicity. 1: Kis E, Toxicol in vitro. 2012 Dec;26(8):1294-9, 2: Yang K, J Pharm Sci, 2013 Sep;102(9):3037-3037. 3: https://www.solvobiotek.com/trans-

1774 Optimum Concentration-Response-Curve Metrics for Toxicity Prediction Based on High-Content Cellular Imaging

High-content imaging (HCI) enables rapid in vitro assessments of complex cellular phenotypic changes (e.g. cell morphology or protein localization) induced by chemicals. Supervised classifiers may be constructed based on the phenotypic readouts of reference chemicals, and used to predict the toxicity of new chemicals to specific human tissues or organs. Changes in readouts are often measured at multiple concentrations and modeled using concentration response curves (CRCs), and metrics derived from CRCs may be used as classifier inputs. Commonly used metrics include potency measures, such as half-maximal effective concentration (EC50), and efficacy measures, such as maximal response (Rmax). However, it is unknown which metrics for in vitro readouts yield the most accurate classifiers for in vivo toxicity. We studied 16 different metrics: nine potency metrics, effective concentrations at 10 to 90% activity (EC10, EC20, EC30, EC40, EC50, EC60, EC70, EC80, EC90), and seven efficacy metrics, responses at 31 to 2000 μM (R31, R61, R100, R300, R600, R1000). Data came from two previous studies of 42 or 33 chemicals and 129 or 166 readouts in human kidney (HPTC and HK-2) or lung (BEAS-2B and A549) cells, respectively. The chemicals were annotated according to their known in vivo toxic effects to the specific cell types, and the cells were exposed to chemicals for 16 hours at seven distinct concentrations. For each readout, we trained linear kernel support vector machines to classify the chemicals into “toxic” and “non-toxic” groups. For each dataset, around 2064 to 2656 classifiers were trained, with balanced accuracies assessed using 10-fold cross-validation. We found that efficacy metrics gave greater proportions of “top-performing” classifiers (those with the top 10% accuracy over all the trained classifiers) than potency metrics for all data-

1772 Determination of Plasma Protein Binding via Ultracentrifugation and In Silico Modeling: Can We Trust the Results?

D. Dimitrijevic1, E. Fabian1, C. Haase1, M. Mathea1, J. Keller1, B. van Ravenzaa2, and R. Landsiedel1. 1BASF SE, Ludwigshafen am Rhein, Germany; and 2BASF Services Europe GmbH, Berlin, Germany.

In the context of broader application of alternative toxicological testing and thereof derived risk assessments, in vitro obtained effect concentrations need to be related to external, e.g. oral doses (in vitro - in vivo extrapolation (IVIVE)). Toxicokinetic modeling, a key element in IVIVE, can be realized by the application of e.g. PBTK models. One of the relevant input parameters for PBTK modeling is the plasma protein binding (PPB) that is routinely determined by rapid equilibrium dialysis (RED). Here, we present PPB determinations by in silico and experimental determination of RED. Ultracentrifugation was performed for rat plasma samples spiked with 5 μM of each test compound. Samples were centrifuged for 18 hours, at 37°C, 215,000 x g and the supernatant was analytically measured by LC-MS/MS to estimate the fraction unbound (Fu). Modeled data were generated by a QSAR model developed to predict PPB. Fu in UC samples could be successfully determined and, except for FLU, yielded data of 86 % (APAP), 74 % (CAF) and 77 % (COL) coincide with Fv to the literature (82, 84, and 76 % Fv for APAP, CAF, COL and RED data (79, 65 and 76 %). Modeled data for CAF (68 %) and COL (60 %) fit well in the experimental and literature data, whereas modeled Fv of APAP (92 %) shows a better accordance to UC data (86 %) in comparison to RED results and the literature. Fv of FLU (26 %) determined by UC does not coincide to literature and RED data with 4.7 and 5.7 %. In addition, modeled data predicts a Fv of 5-10 % for FLU which is comparable with RED and literature data. Physicochemical properties could play a role in PPB as FLU is a more lipophilic substance in comparison to the other test compounds (log P<sub>O/W</sub> 3.35). In conclusion, our work demonstrates alternative methods for PPB affinities that should be applied to more substances, e.g. lipophilic or instable substances for RED experiments. We recommend the expansion of data to get a better knowledge on PPB depending on the physicochemical properties of different chemicals and its influence on toxicokinetic modeling.

1771 Exploring Current Read-Across Applications and Needs among US Federal Agencies

United States Federal agencies are tasked with protecting human health and the environment by determining the potential health hazards posed by chemical exposures and consumer products. Testing all such substances using traditional animal-based methods poses time, cost, and practical and ethical challenges. With this in mind, the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) has released a strategic roadmap for establishing new approaches and methodologies to evaluate the safety of chemicals. Read-across is one such alternative method for filling data gaps in the hazard profile of a substance of interest using existing data from chemical analogs. In addition to providing information quickly and without the use of additional animal experiments, read-across can be tailored to be related to external, e.g. oral doses (in vitro - in vivo extrapolation (IVIVE)). Modeled data were generated by a QSAR model developed to predict PPB. Fu in UC samples could be successfully determined and, except for FLU, yielded data of 86 % (APAP), 74 % (CAF) and 77 % (COL) coincide with Fv to the literature (82, 84, and 76 % Fv for APAP, CAF, COL and RED data (79, 65 and 76 %). Modeled data for CAF (68 %) and COL (60 %) fit well in the experimental and literature data, whereas modeled Fv of APAP (92 %) shows a better accordance to UC data (86 %) in comparison to RED results and the literature. Fv of FLU (26 %) determined by UC does not coincide to literature and RED data with 4.7 and 5.7 %. In addition, modeled data predicts a Fv of 5-10 % for FLU which is comparable with RED and literature data. Physicochemical properties could play a role in PPB as FLU is a more lipophilic substance in comparison to the other test compounds (log P<sub>O/W</sub> 3.35). In conclusion, our work demonstrates alternative methods for PPB affinities that should be applied to more substances, e.g. lipophilic or instable substances for RED experiments. We recommend the expansion of data to get a better knowledge on PPB depending on the physicochemical properties of different chemicals and its influence on toxicokinetic modeling.
1775 A Unified Approach for the Analysis of Zebrafish Developmental and Neurotoxicity Data: A Multi-Lab Case Study
J. Hsieh1, K. Ryan2, N. Sipes3, A. Shapiro4, F. Parham2, S. Auerbach2, and M. Behl5. 1Rely Government Solutions, Morrisville, NC; 2NIEHS, Morrisville, NC; and 3InfiniumNL, Durham, NC.

Zebrafish are gaining acceptance as a screening tool for developmental toxicity (DT) and neurotoxicity (NT). Currently, there is no formal guidance on how to most effectively perform and analyze the results from these studies. To start the process of formalizing such testing standards, the NTP has formulated a library of 87 compounds (including pesticides, flame retardants, drugs, industrials, polycyclic aromatic hydrocarbons) with diverse toxicological properties. These 87 compounds were evaluated for DT and NT effects in zebrafish in three labs. The protocol designs varied by: embryos with/without chorions, time point of exposure and response measurement, and tested concentrations. To develop a unified data analysis approach across all data sets, we harmonized the data, and adopted a benchmark concentration (BMC) approach to estimate potency of the effect. Our BMC approach used a benchmark response (BMR) based on the intrinsic response variation of each endpoint. Bootstrap statistics were used to generate a confidence interval around the BMR. This standard approach allowed us to compare the data across labs, and across three labs. Comparisons were based on various parameters such as BMR, response variation (e.g., standard deviation, SD) in vehicle control (i.e., DMSO), and embryo behavior response similarity in vehicle control in the NT assay, etc. The concordance of the active chemicals identified by the BMC approach and benchmark was high in the DT assay than in the NT assay. Specifically, the active chemical concordance between labs in the DT (embryotoxicity included) assay was 73%, 89%, 70%, and across labs was 65%. For NT assay, the active chemical concordance between labs was 62%, 71%, 67%, and across labs was 44%. The pooled SD of BMC values from the concordant active chemicals in DT and NT assay was 0.47 and 0.52 (in log10 unit), respectively, which was about the spacing between two consecutive concentrations tested, approximating the sensitivity of the protocol design. Pesticides and flame retardants were the two most prominent chemical classes in the concordant active chemicals, covering 57% (17/30) in DT assay and 80% (12/15) in NT assay, respectively. This is the first time that such a unified data analysis approach has been implemented for zebrafish toxicity screening data and offers a novel tool to begin to harmonize testing across labs and protocols.

1776 Development of an RNA-Seq Tissue Expression Atlas of Preclinical Species (Cynomolgus Monkeys and Beagle Dogs) for In Silico Assessment of Target Expression and Distribution

A better understanding of drug targets and their tissue expression patterns in preclinical species is critical for demonstrating relevance to humans and supporting species selection for First-In-Human (FIH)-enabling nonclinical safety studies predicated on developmental and reproductive toxicity. This significance has been highlighted by the recent release of the revised European Medicines Agency Guideline for FIH and early clinical trials. The development of RNA-Seq technologies has improved our ability to generate quality target gene expression data and has been successfully applied to characterize human gene expression patterns in preclinical species. A standardized approach allowed us to compare the data across labs, and across nine labs. The goal of this project was to use RNA-Seq to profile a broad collection of tissues from a number of commonly used nonclinical species to build a comprehensive tissue expression atlas complementary to human tissue transcriptomic maps (e.g., GTex) for rapid assessment of target distribution. Frozen tissues from cynomolgus monkeys and beagle dogs were collected based on coverage with early toxicity and GLP study designs and totaled to over 60 tissues per species. Samples were dissected and harvested from 3 male and 3 female animals with minimal euthanasia time. Sampling and subsequent sorting of blood cells from a set of 3 male and 3 female animals was accomplished separately. Following collection, RNA isolation, library preparation, sequencing, alignment and feature counts were performed to produce measurements of transcript abundance. Tissues from the same organ systems clustered together and overall human to nonclinical species correlation was above 60% (R-squared). These datasets can also complement other information such as functional assay data to support the selection of pharmacologically relevant species for safety evaluation and de-risking studies of small molecule and biotherapeutics. Additional tissue maps are also being generated for rat and monkey to create a complete and authoritative preclinical transcriptomic tissue map resource.

1777 A Large Two Stage Multi-Task Network for Chemical Properties
T. Luechtefeld1, S. Abraham1, and C. Rowlands2. 1Underwriters Laboratories, Baltimore, MD; and 2UL Supply Chain & Sustainability, Midland, MI.

Neural networks enable transfer learning where models trained on one task accelerate learning on other tasks. We show transfer learning models result in accuracy improvements across a variety of chemical endpoints. The UL Cheminformatics Tool kit models 74 different chemical endpoints including acute oral-, dermal- and inhalation-toxicity, dermal sensitisation, dermal- and eye-irritation, genotoxicity, and acute- and chronic-aquatic toxicity. These models are constructed in two stages. Stage (1) constructs a neural network for every endpoint from chemical structural data. Stage (2) constructs networks with inputs taken from Stage (1) hidden layers. Data Isolation in Conversions (DIC) models are created to link traditional toxicological data to computational modeling. These models first collect chemical property data, then collect chemical structural data, and finally build a supervised learning model that inputs chemical structural data and outputs predicted endpoint data. This type of model fails to leverage data from disparate sources. Even with these limitations, the Stage (1) models achieve high accuracies of 70-80% across the nine models. Multi-task Learning (MVC) replaces the Stage (2) models with isolated data by linking useful representations between models trained on different data sets. The two stage model benefits by easing the integration of new data. Model training is not constrained to a single set of data but can make use of all available data. These multi-task models can only result in changes in the embedded layers shared to the second stage models. If these embedded layers aren’t useful in predicting second stage outputs, then gradient descent optimization will drop them. Because new data can be added with reduced concern of data quality, many different endpoints can be integrated. The advantage of the ability to add many different endpoints to the model is the ability to train models far more quickly for both higher accuracy and with lower requirements on the amount of training data. The Stage (2) models have balanced accuracies of 75-90% across the nine endpoints which is an improvement of 5-10% relative to the simpler Stage (1) Qsar models.

1778 Identifying Contributors to the Response to Endocrine Drug Therapy in Breast Cancer: An In Silico Study
S. Parvin-Nejad, S. Cheema, and G. Acquaah-Mensah. Massachusetts College of Pharmacy and Health Sciences, Worcester, MA.

A number of reports indicate differences in breast cancer presentations between patients of European and those of African ancestry. These include differences in average tumor size, age of disease onset, and degree of aggressiveness. Further, the development of resistance to breast cancer endocrine therapies remain intractable. In this study, gene expression (RNASeq version 2), mutation, and clinical data collected from patients as part of the Cancer Genome Atlas were examined for insights into disparities in responses to endocrine therapy in breast cancer. Notably, expression of the aryl hydrocarbon receptor (Ahr) is suppressed in Black or African-American (BAA). Using Ahr-associated genes sets, gene set enrichment analyses results indicate that two gene sets consisting of genes elevated in endocrine therapy-resistant breast cancer in a mouse xenograft model (Creighton et al., 2008) are enriched in samples from White patients relative to those from BAA patients (p value =0.02, FDR=0.11; p value = 0.04, FDR=0.20). A third gene set of suppressed estrogen receptor (ESR1) targets, i.e. genes down-regulated in an ESR1-negative human breast cancer cell line (Gozgit et al., 2007), was similarly enriched in samples from White patients (p value =0.03, FDR=0.187), Furthermore, using a machine learning approach, a combination of leading edge genes for these three gene sets, along with attributes such as the age at initial diagnosis, menopausal status, race, and hormone and growth factor receptor expression status, were modest predictors of the response to endocrine drug therapy. Pooled gene expression profiles of responders and non-responders to therapy with endocrine drugs (selective estrogen receptor modulators such as Tamoxifen, selective estrogen receptor down-regulators, gonadotropin releasing hormone agonist, and aromatase inhibitors) were subsequently ex-
Evaluating Potential Refinements to Existing Computational Studies of a Select Group of 10 disease categories (including Cardiovascular, Anti-Infective, Central Nervous System, Anesthetic, Gastrointestinal, ACE Inhibitors, and Hypnotics and Sedatives), there were more than 20 new drugs in each in DILIst. DILIst contained a total of 1000 compounds of which 100 were newly added when compared with DILIRank. DILIst also provided the largest number of drugs classified by human hepatotoxicity and covered the broadest range of drug classes to date. It is a great resource for the community to improve DILI research in the areas of elucidation of mechanisms, predictive model development, biomarker identification, and provides additional opportunities to exploit the potential of emerging technologies.

**1781** Computational Studies of a Select Group of Amino Alkylindoles

T. Riggers, and T. Holmes. Fort Valley State University, Fort Valley, GA.
Sponsor: R. Bright

Synthetic cannabinoids are man-made chemical toxins used in plant materials and believed to give similar psychoactive effects as natural cannabis. Although early synthetic cannabinoids were used to understand the human endocannabinoid system, they are now drugs of abuse that lead to adverse physical effects when used. The present study employed computational chemistry methods to investigate the structure-activity relationships of five aminoalkylindoles to gain a deeper understanding of the effects synthetic cannabinoids have on the human body. The Australian 09 package was used to model the electronic structures of the compounds. The structures underwent molecular geometry optimization and frequency calculation, and from the output geometries, molecular descriptors were calculated that are related to the electronic distribution, which can indicate the individual compound's ability to interact with biostructures. Molecular descriptors calculated include electrophilicity, chemical hardness, $Q_{el}$, and $E_{HOMO}$. Results indicated that $Q_{el}$, as well as chemical hardness were closely related to the biological activity with R2 values of 0.88 and 0.65, respectively. From these results, it was concluded that the activity could possibly be closely related to the aminoalkylindoles' behavior as hydrogen bond acceptors.

**1782** Evaluating Potential Refinements to Existing Thresholds of Toxicological Concern Values for Environmentally Relevant Compounds

M. D. Nelms\textsuperscript{1,2}, P. Pradeep\textsuperscript{3}, and G. Patlewicz\textsuperscript{1}, ORISE, Oak Ridge, TN; and US EPA/NCCT, Durham, NC.

The Toxic Substances Control Act mandates the US EPA to perform risk-based prioritization of chemicals in commerce and then, for high-priority substances, develop risk evaluations that integrate toxicity data with exposure information. For chemicals where neither in vivo and in vitro studies are available, one approach being considered is a Threshold of Toxicological Concern (TTC)-to-Exposure ratio. The TTC approach has established different levels of human exposure below which there is expected to be a low probability of risk to human health. Within the TTC paradigm, a chemical is assigned to a specific class based upon an evaluation of the chemical structure. In this study, we derived TTC values based on oral (sub)chronic No Observable (Adverse) Effect Level (NO(A)EL) data from the US EPA’s Toxicity Values (ToxVal) database and compared them with published TTC values. We profiled 12,116 unique discrete chemicals present in the ToxVal database into their respective TTC categories using the Kros et al (2004) TTC module within the Toxtree tool. Of these chemicals, 1800 (14.9%) were not considered appropriate for TTC based on exclusion criteria and were removed. The remaining chemicals were assigned to one of the five TTC classes (Cramer structural class I, II, III, containing alerts for genotoxicity and acetylcholinesterase inhibitors [AChEI]). We calculated TTC values for chemicals in Cramer I and III categories as 0.0134 mg/kg bw/day and 0.00199 mg/kg bw/day, respectively. Due to a lack of data we were unable to calculate a TTC value for Cramer Class II chemicals. The TTC value for the Class I chemicals calculated in this study is more conservative than that of Munro et al (1996) (0.07 mg/kg bw/day) and Munro et al (1996) (0.19 mg/kg bw/day). The difference in TTC values from those calculated by Munro et al (1996) could be attributed to a difference in dataset composition as Munro et al (1996) contained a number of food additives in comparison to the ToxVal dataset, which typically comprised food-use pesticide active ingredients. This abstract does not necessarily reflect US EPA policy.
Predicting Neurological Targets of Toxicity Employing the Read-Across Approach of ToxCast In Vitro Data
J. M. Gearhart1, Y. G. Chushak, and H. A. Pangburn.1 1Henry M. Jackson Foundation for the Advancement of Military Medicine, Wright Patterson AFB, OH; and 2United States Air Force, Wright Patterson AFB, OH.

Interaction of chemicals with multiple protein targets is the primary reason for triggering an adverse drug reaction. Significant amounts of information about the biological activities of chemicals have already been collected using experimental methods and stored in a variety of public databases. Under the US Environmental Protection Agency’s ToxCast program, the biological activity for thousands of chemicals was screened in hundreds of biochemical and cell-based assays in a high-throughput manner. Using the Gene Ontology database, we identified 123 proteins screened in the ToxCast assays that have neurological functions. Data from these assays were imported into the Organization for Economic Co-operation and Development QSAR Toolbox and used to identify neurological targets for chemicals of interest. Two sets of data were generated: (1) one set coded with a “1” for active compounds and a “0” for inactive compounds was used to classify compounds as active or inactive, and (2) another set composed of the AC15 for only active compounds was used to predict the AC50 values for unknown chemicals. Chemical grouping and read-across within the QSAR Toolbox were used to identify neurologic targets and predict interactions for two psychotic drugs: para-methoxyamphetamine and 4-methylaminorex. Our results demonstrate that ToxCast in vitro screening data and the QSAR Toolbox can be used to identify neurological targets for chemicals that have similar chemicals in the ToxCast database. Cleared, BPFA, Case Number 2018-2711, 25 May 2018.

Looking Under the Hood—Expert Review of In Silico Carcinogenicity Predictions
B. Hansen, and J. Cohen, Gradient, Cambridge, MA.

Alternative testing strategies are seeing increased application in chemical safety assessments across a variety of contexts. However, predictive toxicology tools should not be used as a “black box,” and limitations including “out of domain” results (i.e. no valid prediction can be made) require expert review to make informed hazard and risk conclusions. We evaluated the in silico carcinogenicity predictions for three perfluorinated compounds [Tetradecafluorohexane; CAS 355-42-0; [Hexacosafluorodecane; CAS 307-59-5], and [Perfluoro(1,3-dimethylcyclohexane); CAS 335-27-3] using the freely available Toxtree program as well as the expert-rule based program Derek Nexus. We then applied expert review to the Toxtree program’s assessment of chemical structure and carcinogenic potential. The two perfluorinated alkane chemicals triggered an alert for perfluorooctanoic acid (PFOA), in spite of evidence indicating these compounds are relatively unreactive, and the fact these compounds lack any oxygen or hydroxy functional groups typical of PFOA compounds. Furthermore, this alert was triggered for a series of six additional perfluorinated alkanes (C6-C12, C16, and C24) suggesting that these results are attributable to their common fluorinated cycloalkane substructure. The perfluorinated aryi compound triggered an alert as a polyhalogenated cycloalkane. This alert was triggered for any halogenated aryi with three or more halogens bonded directly to the ring. Yet, neither the supporting mechanistic justification for this specific alert nor the available training data set considered perfluorinated cycloalkanes. Evaluation of these same compounds with the expert-rule program Derek Nexus did not trigger any alerts for carcinogenicity. These findings support our conclusions that the Toxtree carcinogenicity predictions for these three perfluorinated compounds are inaccurate, and highlight the importance of expert review in the application of in silico toxicology tools. The structural alerts we considered for the in silico assessment of these three chemicals have the potential to overgeneralize perfluorinated compounds and propose unlikely toxicological mechanisms.

Application of the SOHN Methodology to Build Accurate hERG Models Using a Combination of Public and Proprietary Data
L. Johnston1, J. Plante1, T. Hanser1, F. Steinmetz2, M. Krier1, and F. Rippmann2. 1Lhasa Limited, Leeds, United Kingdom; and 2Merck, Darmstadt, Germany. Sponsor: C. Barber

The Self Organising Hypothesis Network (SOHN) methodology is a recent modelling approach[1] that has been successfully applied to develop predictive models for the mutagenicity endpoint, which is largely driven by chemical reactivity[2]. Here we show that the SOHN methodology can also be applied, with good performance, to receptor based endpoints like hERG. The predictivity of the resulting hERG models is owed to the SOHN algorithm, the choice of a well-designed pharmacophoric descriptor and the combination of public and proprietary data. We use inhibition of the hERG ion channel to explore such combinations with the aim to develop an accurate model, as this endpoint is a key safety concern in drug development as hERG inhibition has resulted in multiple drugs being withdrawn from the market. We validate the performance of the SOHN methodology and show that combining public and proprietary data sources improves performance due to a better coverage of the target chemical space. The best combination allows for very good hERG predictivity. This demonstrates the suitability of the SOHN methodology for building models for receptor based endpoints. Finally, we show that combining the SOHN models with other statistical models and expert systems, we can leverage additional synergistic effects by taking into account the confidence in the predictions when merging systems. [1] Hanser T, Barber C, Rossler E, Vessey JD, Webb SJ, Werner S: Self-organising hypothesis networks: a new approach for representing and structuring SAR knowledge. J Cheminform. 2014, 6:21.10.1186/1758-2946-6-21.[2] https://www.lhasalimited.org/products/sarah-nexus-model-building.htm.

Computational Analysis of Pre-Clinically Efficacious Drug Molecules without Defined Target Pharmacology

Small molecule drug discovery usually starts with a random screening of large numbers of compounds against either with a validated drug target (target-based drug discovery) or in a physiologically relevant biological system (phenotypic drug discovery). Pharma and biotech industries have, during the past decades, successfully utilized the former approach to discover new drug molecules for a given drug target. However, there are many pharmacology tools working on multiple phenotypic drug discovery programs. The phenotypic screening derived leads have been playing a major role in the discovery of new therapeutics. However, identification of the physiologically relevant targets for these phenotypic drug discovery remain a major challenge. These drug molecules often bind to one or more targets with varied binding strengths. It is difficult to characterize these binding events using conventional experimental methods such as affinity chromatography. Recently, however, this discovery approach is getting significant attention because of the availability of novel advanced in vitro and in silico technologies that can identify novel pharmacological descriptors and understand the physiology of the phenotype. In this work, we have built an efficacious bioactive molecule database (BioactDB) by compiling 3078 pre-clinical and clinical stage drug molecules with no defined pharmacological targets (phenotypic derived drugs). These drug molecules belong to a diverse range of therapeutic classes. Here we are focusing on two classes, namely, 1) oncology (418 drugs) and 2) CNS (511 drugs) for further computational analyses. These drugs, without biological targets, were searched for structural similarity using cheminformatics and machine learning (SVM, RF and NN) based target prediction approaches. This computational approach suggested a testable target hypothesis for some of these clinically efficacious drug molecules that are not known targets. A detailed target analysis on selected drug molecules from BioactDB along with available in vivo data will be presented.

Quantitative Hazard Assessment and Product Scoring Methods for High-Throughput Chemical Alternative Assessments
C. E. McLoughlin, P. J. Beattie, M. C. Ruhter, and J. P. Rinkevich. Scivera, Charlottesville, VA.

Leading consumer product brands are increasingly requiring more quantitative data from suppliers to select safer product and process chemicals. These brands go beyond traditional reactive approaches to meet chemical regulatory compliance by using underlying human and environmental health information in chemical selection. Such proactive approaches enable brands and suppliers to identify controversial, acceptable, and preferred chemicals during product development. Unlike the inherent criteria in most assessment frameworks that rely on qualitative data and assumptions, quantitative methods first score individual SOHNs and products enable more refined comparison and selection of preferred, safer, alternative chemicals and formulations, and hence allow for straightforward defensible decision-making. To this end, the authors developed a quantitative hazard assessment scoring method to complement qualitative assessment frameworks. The method facilitates more efficient and effective alternatives selection, especially at scale using transparent criteria. The method is based on 22 human and environmental health endpoints and physical characteristics. Each endpoint is factored into the method based on hazard rating, type of endpoint (i.e., core endpoints such as
1790 Toxicogenomic-Based Gene Co-regulated Network Analysis for Quantitative Mode-of-Action Assessment of Chemical-Induced Organ Toxicity

S. J. Kunnen1, G. Callegaro1, W. den Hollander1, Y. W. Webster2, J. J. Sutherland2, J. Mollon2, P. Trairathpisan2, E. Guney2, J. Piñero2, J. L. Stevens1,3, and B. van de Water1. 1. Leiden University, Leiden, Netherlands; 2. Eli Lilly and Company, Indianapolis, IN; 3. Indiana Biosciences Research Institute, Indianapolis, IN; 4. AbBiVie Deutschland GmbH & Co KG, Ludwigshafen, Germany; 5. Heidelberg University, Heidelberg, Germany; and 6. Hospital del Mar Research Institute (IMIM), Barcelona, Spain.

Toxicogenomic data in safety testing represent a critical source to uncover underlying mechanisms of drug-induced toxicities. Co-regulated gene network approaches can organize high dimensional toxicogenomic data, while not being biased by prior gene annotations, and help in identifying novel mechanisms and regulators of toxicity. We applied weighted gene co-expression network analysis (WGCNA) on the publicly available datasets in TG-GATEs on different toxicogenomic model systems, including primary human hepatocytes (PHH), in vivo rat liver and rat kidney. The 3 datasets were independently processed with an unsigned WGCNA analysis that clustered the gene sets into functional modules, representing the bridge between individual gene variations and emergent global properties. The modules serve as dynamic visualization of the transcriptome under experimental conditions (compounds, concentrations and time points). We developed a user friendly tool using the R shiny package for visualization of the toxicogenomic network and analyzing the mechanism of toxicities, called the TXG-MAPr. A dedicated upload function allows to overlay a new set of gene expression data onto the built WGCNA network for the 3 model systems. New Eigengene Scores (EGs) for all modules in the TXG-MAPr are calculated considering the newly uploaded data. Users can analyze dose- and time-response curves, compound correlation plots and functional annotation of the modules to derive mechanistic information of the toxicity. In addition, we included the prediction of transcription factor activities, as well as physical interactions of downstream proteins encoded by the transcriptome, which may be useful in analyzing perturbations triggered by exposure with toxic compounds. In conclusion, with the TXG-MAPr we present an innovative tool that helps in the mechanistic understanding of potential adverse drug reactions that can be used during early drug development. The work received funding from the Innovative Medicines Initiative 2 Joint Undertaking for the TransQST (grant agreement 116030) and eTRANSAFE (grant agreement 777365) projects, which is supported by the EU Horizon 2020 program and EFPIA.

1791 Development of a Generalized Inhalation Model for Use with the High-Throughput Toxicokinetics (httk) Package in R

Currently it is difficult to prospectively estimate human toxicokinetics (particularly for novel chemicals) in a high-throughput manner. The R software package htkk has been developed, in part, to address this deficiency; however, it is limited to oral and intramuscular exposure routes. The purpose of this investigation was to develop a generalized inhalation model for htkk. The structure of the inhalation model was based on a published physiologically based model. The model was evaluated with literature. In total, 42 volatile organic chemicals (VOCs) were identified with sufficient information available in literature (metabolism parameters and concentration vs. time data). Physicochemical data were obtained using the Environmental Protection Agency’s CompTox.
Chemistry Dashboard, while fraction unbound in plasma was calculated with ADMET Predictor™, 9.0. In total, 144 dosing situations were tested (77 in humans, 67 in rats) in plasma, blood, or exhaled breath. Mean (range) molecular weight was 114.99 g/mol (32.04-252.32 g/mol) and mean log P was 2.1 (-0.6-6.1). The slope of the regression line of best fit between log-transformed predicted and measured plasma, blood, and exhaled breath concentrations for combined human and rat data was 0.56 with an R² = 0.50 and a root mean square error (RMSE) = 0.72. Individual species fits were similar. The RMSE of the same data against the identity line was 0.82. The VOCs examined in this investigation represent small, generally more lipophilic molecules. About 3.6% of the data points were censored due to concentrations that were below reasonably measurable limits. Goodness-of-fit values currently indicate moderate model fit to literature data. Future efforts will be focused on identifying trends in model fit relative to chemical properties. This abstract does not necessarily reflect US EPA policy.

1792 Delivering Rapid Computational Profiling of Chemicals by High-Throughput Toxicokinetics

C. N. Davidson1, E. Pitts2, J. M. Gearhart3, Y. G. Chushak3, and H. A. Pangburn1. 1UES, Inc, Wright-Patterson AFB, OH; 2Henry M. Jackson Foundation for the Advancement of Military Medicine, Wright-Patterson AFB, OH; and 3US Air Force School of Aerospace Medicine, Wright-Patterson AFB, OH.

Department of Defense (DoD) weapon systems require tremendous cradle-to-grave support, including a heavy reliance on hazardous materials that are often unique contaminants with unspecified toxicological categorization. With over one million chemicals in existence and only about 1,000 with occupational exposure limits from well-regarded sources, an automated, rapid assessment of occupational health is necessary for screening chemicals for occupational health purposes. A statistical analysis program in R, htk, was created by the US Environmental Protection Agency (US EPA) to efficiently rank characterized chemicals in order of priority, instead of testing chemicals in a random order. Inputting just a few chemical (CAS number, molecular weight, Log P) and toxicokinetic (intrinsic clearance) parameters allows any chemical to be modeled and compared to other chemicals, establishing a toxicological profile. Parameters for the uncharacterized chemicals were obtained from a toxicological database known as the OECD Quantitative Structure Activity Relationship (QSAR) Toolbox. This toolbox enables predictions about the physicochemical and biological properties of a chemical based upon well-characterized chemicals with known activity and similar molecular structures. The chemical and toxicokinetic parameters plus compositional variables (Number of rings, bonds, heavy atoms, etc), plus estimated parameters from the OECD QSAR Toolbox (Km in 10g fish, Biotransformation, Half-Life, and biodegradability) were then introduced into a random forest model to predict clearance of the uncharacterized chemicals. The overall random forest results had a Root Mean Square Error (RMSE) of 0.5784, Mean Absolute Error (MAE) of 0.4546, and an R² of 0.7091. The plasma and blood concentrations (Cₜₜ) were calculated for all the chemicals, and this parameter was used to predict concentrations in vivo that cause biological activity (ACₜₜ). As the list of uncharacterized chemicals is studied further, warfighters will greatly benefit in understanding the effects of specific chemical exposures with the aim to derive mitigation strategies.

1793 An Integrated Testing Strategy Assessment Incorporating the Genomic Assay SENS-IS for Skin Sensitization

F. P. Hollinger1, N. O. Oki1, T. Exner1, S. Martin2, B. Lopez2, and B. Hardy1. 1Edelweiss Connect Gmbh, Durham, NC; 2Edelweiss Connect Gmbh, Basel, Switzerland; and 3Eurosafe, Saint-Gregoire, France.

The move towards animal-free testing methods for assessing the toxicity potential of chemicals has led to the development of frameworks such as the adverse outcome pathway (AOP) that can characterize the key events that lead to an adverse outcome. Skin sensitisation is one such endpoint that has been prioritized by the Organisation for Economic Co-operation and Development (OECD) and other public agencies. It is also one of the few adverse outcomes for which an OECD-approved AOP exists and assays measuring its key events (KEs) have been developed. Based on work done by Joanna Jaworska et al. (doi: 10.1007/s00204-015-1634-2), we implemented an Integrated Testing Strategy (ITS) for skin sensitisation. It replaces the in vivo Local Lymph Node Assay (LLNA) assay, which has been used as a proxy for skin sensitisation in humans. The defined approach uses a Bayesian network which predicts the skin sensitisation potential of a substance by combining experimental results from the 3 OECD-approved skin sensitisation assays (direct peptide reactive...
multivariate Cox regression model further confirmed standard regimens as a good predictor of ATDH. The nomogram illustrated that standard regimens was the largest contributor to ATDH, followed by age, weight, gender, past medical history of liver diseases, medical history of diabetes mellitus, drink and smoke. The performance of each classification model was evaluated by the area under the Receiver Operating Characteristic (ROC) curve (AUC). The SVM models achieved the best performance with an average AUC of 0.84, followed by NB (0.83), and RF (0.79). The survival analyses and ATDH prediction models established in this study could be applied to help clinicians evaluate the TB patients' conditions to choose suitable treatment regimens.

1796 PharmOmics: A Species- and Tissue-Specific Drug Signature Database for ADR Prediction and Drug Repurposing

Elucidating species- and tissue-specific molecular actions of drugs can provide systems-level insights into drug toxicity and therapeutic activities. However, systematic efforts in cataloging the molecular pathways influenced by individual chemicals in a species- and tissue-specific manner remain limited. Here, we present a comprehensive drug knowledgebase, PharmOmics, comprised of genomic footprints derived from meta-analysis of microarray and sequencing data relevant to drugs/substances from tissues and cell cultures derived from human, mouse, and rat samples in GEO, ArrayExpress, TG-GATEs and drugMatrix data repositories. Using multi-tissue gene expression signatures as intermediate modulators, we can infer the perturbed molecular pathways and associate drugs with various potential toxicity endpoints and diseases that share similar gene expression signatures. We demonstrate the potential of PharmOmics to facilitate drug repurposing using a network-based disease-drug matching algorithm and to predict adverse drug reaction (ADR). Using the uric acid increment ADR as an example, our experimental validation supports the accuracy of PharmOmics in making novel predictions. By leveraging tissue- and species-specific analysis, PharmOmics has advantages over the commonly used cell line-based drug signatures to facilitate drug development.

1797 XomeTox—Evaluating Multi-omics Integration for Assessing Rodent Thyroid Toxicity

S. Canzler1, J. Schor1, W. Busch1, M. von Bergen1, R. Buesen2, H. Kamp2, H. Seitz2, and J. Hackermüller1. 1Helmholtz Centre for Environmental Research, Leipzig, Germany; 2BASF SE, Ludwigshafen, Germany; and 1Institut de Génétique Humaine, Université de Montpellier, Montpellier, France.

Exposure to chemicals triggers a series of effects at the molecular level. Regulatory pathways involved in such responses exhibit changes of levels, interactions, and feedback loops of biomolecules of different types that are active in complex networks. Different ‘omics techniques are essential for measuring responses in an untargeted manner on the molecular level. Importantly, a single ‘omics technique will detect biomolecules of one type and thus captures changes only for a small subset of the components of a particular pathway. Therefore, applying single ‘omics analyses in response to a toxicant in a noncontinuous design led to the identification of biomarkers for certain exposures but not to a systemic understanding of toxicity pathways or adverse outcome pathways (AOPs) in the past. Also, this incomplete representation of pathways in single ‘omics data limits the ability to discriminate adaptive from adverse molecular responses. We propose that a substantial improvement in detecting the pathway response to a toxicant can be achieved by using multi-omics data in a time- and concentration-resolved design. We will initially compile a collection of existing multi-omics data sets, including the integration of BASF generated metabolomics data, to evaluate integrative multi-omics analysis approaches and to identify criteria for an optimal design of a multi-omics toxicity study. Based thereon, we will perform a rat study focusing on direct and indirect thyroid toxicity to generate transcriptionomics, proteomics, and metabolomics data sets. We aim to (a) detect toxicant-triggered re-wiring of regulatory networks and changes of master-regulators, (b) evaluate whether time- and dose-resolved multi-omics data enable the prediction of adversity, (c) evaluate whether deep learning may assist in discriminating adaptive vs adverse perturbations of regulatory networks, and (d) determine to what extent each ‘omics experiment contributes to the predictive power of such an approach. XomeTox is funded by CEFIC Long Range Research Initiative.

1798 Comparison of Impacts of Cigarette Smoke and High-Fat Diet on Transcriptomes of Principal Organs in ApoE Knockout Mice

High-fat diet (HFD) and cigarette smoking are risk factors for atherosclerosis progression. To understand the impacts of HFD intake and mainstream cigarette smoke (MCS) inhalation on the progression of atherosclerosis, we conducted a subchronic MCS inhalation study with HFD feeding for 13 weeks using female apolipoprotein-E knockout (ApoE) KO mice. Pathologically, HFD feeding greatly accelerated the progression of atherosclerosis compared with MCS inhalation, suggesting differences in the contributions of diet and cigarette smoke to atherosclerosis progression in ApoE KO mice. To further investigate these differences, we analyzed the effects of 13-week HFD feeding and MCS inhalation on transcriptomic changes in the lungs and livers of the mice. Differentially expressed genes were analyzed by Ingenuity Pathway Analysis software to elucidate the biologically relevant canonical pathways. In the lung, HFD feeding did not perturb any canonical pathways, while MCS inhalation significantly perturbed NRF2-mediated oxidative stress response and inflammatory responses. In the liver, HFD feeding and MCS inhalation significantly perturbed different pathway-related gene expressions: HFD feeding significantly perturbed inflammatory responses and cholesterol biosynthesis, while MCS inhalation perturbed not only xenobiotic-activated pathways, but also lipid metabolism-related pathways, such as LXR/RXR pathway. Overall, HFD feeding and MCS inhalation caused differential perturbation of canonical pathways in the lung and liver. These data indicate that diet and cigarette smoke contribute to atherosclerosis progression through differential effects on organ transcriptomes in ApoE KO mice.

1799 Toxicogenomics: From Snapshot Observations towards Dynamic Response Modelling

In chemical risk assessment the integration of knowledge about a chemical's mode of action (MoA) is under way, meaning that we move from an observational perspective, considering only concentrations leading to death after pre-defined exposure durations, towards a mechanism-based perspective, where knowledge about time courses of molecular reactions and respective consequences for an organism's health will become decisive. Toxicogenomic methods are enabling us to generate such information on molecular responses upon chemical treatment. However, aggregated effect measures, such as EC50 values, are often not retrievable from those data due to limitations in experimental designs not capturing dependencies of molecular responses on factors, such as exposure concentrations or durations. A comparison of molecular response fingerprints between compounds as well as an extrapolation or general assessment is therefore difficult (Schüttler et al. 2017, https://doi.org/10.1093/toxsci/kfx045). Based on previous achievements on modeling of dose response relationships for different omics data sets (Semtanová et al. 2015, https://doi.org/10.1002/etc.3025) and experiences with zebrafish embryo toxicogenomics, we developed an experimental design for studying the concentration and time dependent changes in the zebrafish embryo transcriptome after chemical treatment. The investigated concentration ranges were thereby anchored to phenotypic lethal and sublethal observations. In order to handle and analyse such data, we developed an analysis pipeline and regression models for description and visualization of the expression behaviour of each gene over time and dose which enables extrapolation and the retrieval of model parameters for comparison of genes, pathways, and compounds. The approach was applied in a case study on the exposure of zebrafish embryos to three selected model compounds, two with similar and one with distinct MoA. Our results demonstrate that every compound causes its own dynamic fingerprint, which strongly depends on the compound's toxicokinetics. Nevertheless, similarities, MoA-specific responses, as well as potential key events indicating a general response to stress could be identified and quantitatively described with the developed regression models. Having these models for every single response on the transcriptome, now allows predictions on mixture effects on the single gene level, the pathway level, as well as on the whole transcriptome. The reliability and robustness of such predictions has to be investigated and is currently subject of our research.
High-throughput in vitro methods are being increasingly used for assessing the safety of chemicals. Two aspects of hazard assessment are critical: identification (i.e., what targets, pathways or processes does a chemical perturb) and potency estimation (i.e., at what concentration or dose does the chemical perturb these biological processes?). New experimental methods for running whole genome high-throughput transcriptomics (HTT) experiments are making it possible to simultaneously assess many chemicals in dose response to aid both hazard identification and potency estimation. Here we describe results of a pathway modeling effort in which over 2000 chemicals were run in an HTT screen in MCF-7 cells using the BioSpyder TempO-Seq platform (8 test concentrations / chemical). The raw count data was processed using the DESeq2 R-package to generate log2 fold change data for each chemical-concentration sample, for each of 3 biological replicates. Multiple pathway-level concentration response modeling methods were compared. These include variants of GSEA (Gene Set Enrichment Analysis), and a simple comparison of the average fold changes of genes in and out of a pathway (In-Out). Different filters for significance were used (filtering at the gene vs. pathway level). Concentration modeling was performed using the ToolCast Pipeline (tcpil) software. Method performance was evaluated using reference chemicals for multiple molecular targets, curated from the literature into a database called RefChemDB. Three main results are (1) The simple In-Out and the GSA variant (Gene Set Variation Analysis) of GSEA were able to detect appropriate reference chemical / pathway interactions with potencies similar to what is seen for in vitro target-based assays; (2) For many chemicals, many pathways are activated in a non-specific way, indicating overall cell stress; and (3) Further research will be required to select an optimal method for assessing pathway level potencies from HTT data. This abstract does not necessarily represent US EPA policy.
Breast cancer is a leading cancer type and one of the major health issues faced by women around the world. Some of its major risk factors include body mass index, hormone replacement therapy, family history and germline mutations. Of these risk factors, estrogen levels play a crucial role. Among the estrogen receptor (ER) family of estrogen receptors, the ERα is known to interact with tumor suppressor protein, p53 directly thereby repressing its function. Previously, we have studied the impact of deleterious breast cancer-associated non-synonymous single nucleotide polymorphisms (nsSNPs) rs11540654 (R110P), rs17849781 (P278A) and rs28934874 (P151T) in p53 gene on the p53 DNA-binding core domain. In the present study, we aim to analyse the impact of these mutations on p53-ERα interaction. To this end, we have modelled the full-length structure of human p53 and validated its quality using PROCHECK and subjected it to energy minimization using NOMAD-Ref web server. Three-dimensional structure of ERα activation function-2 (AF-2) domain was downloaded from protein data bank. Interactions between the modelled native and mutant (R110P, P278A, P151T) p53 with ERα was studied using ZDOCK. Machine learning prediction on the interactions was performed using Weka software. Results from the protein-protein docking showed that the atoms, residues and solvent accessibility surface area (SASA) at the interface was increased in both p53 and ERα for R110P mutation compared to the native complexes indicating that the mutation R110P has more impact on the p53-ERα interaction compared to the other two mutants. Mutations P151T and P278A, on the other hand, showed a large deviation from the native p53-ERα complex in atoms and residues at the surface. Further, results from artificial neural network analysis showed that these structural features are important for predicting the impact of these three mutations on p53-ERα interaction. Overall, these three mutations showed a large deviation in total SASA in both p53 and ERα. In conclusion, results from our study will be crucial in making the decisions for hormone-based therapies against breast cancer. We have developed the US FDALabel database as a web-based application, containing over 100,000 drug labeling documents from US FDA's SPL archive. US FDALabel allows the public to perform customizable (any combination of sections, document types, market categories, and other information), full-text searches of product labeling on a relational oracle database. A new version of FDALabel (v 2.3), available at Amazon Cloud: https://ncr-crs.fda.gov/fdalabel, was developed to search human prescription drug and biological product labeling and human over-the-counter (OTC) drug labeling. To demonstrate the FDALabel database's utility, we have selected study cases including a pharmacogenomics study for Precision Medicine and an ADR (Adverse Drug Reaction) study that applied Medical Dictionary for Regulatory Activities (MedDRA) standard terminologies. We identified 224 drugs with 289 drug-biomarker pairs across different therapeutic areas such as oncology (103), psychiatry (33), and infectious diseases (32). We also found severe ADRs were prevalent in MedDRA System Organ Classes such as Nervous system disorders, Psychiatric disorders, and Cardiac disorders. The FDALabel database search offers the public a useful and regulatory reviewers an efficient and user-friendly means of accessing and searching the large amount of information contained in drug labeling. An Amazon Cloud version of FDALabel (v 2.3) supports and promote translational medicine and regulatory science by employing advanced computer technologies to deliver end-users a reliable, effective, and efficient search tool.

A narrow range of endogenous retinoic acid (RA) levels is required for proper anteroposterior patterning of the early embryo. Insufficient or overabundant RA levels disrupt the expression of HOX and other genes important for axis patterning and can lead to birth defects such as cleft palate. We hypothesized that the expression of development marker genes is measurably altered by exogenous concentrations of all-trans retinoic acid (ATRA) that affect endogenous RA signaling. To confirm molecular markers of altered embryogenesis, a pilot study was conducted in differentiating endoderm exposed to ATRA. Induced pluripotent stem cells derived from adult female fibroblasts were directed to a differentiating endodermal trajectory using low serum and activin. Differentiating cells were then exposed daily to five concentrations of ATRA (0.001 to 10 µM) or 0.1% DMSO control and collected at three timepoints (6h, 96h, and 192h) for high content imaging (HCI) and RNA-sequencing analysis. HCI analysis quantitated the cell counts and percentage of cells that were dead, metabolically active, or expressing FOXA2 (a definitive endoderm marker). These results were compared to the differentially expressed genes (DEGs; padj < 0.05 and abs(log fold change) > 1) at each time and concentration. Using system trajectory and dynamics analysis of the DEGs, a tipping point defined by the persistence of effects at both 96h and 192h timepoints was identified at 0.01 µM. Global gene expression at concentrations above and below the tipping point followed two diverging trajectories reflected in a principal components analysis. The tipping point was identified at concentrations above 0.01 µM resulting in an increase in cell counts and reduced FOXA2 expression compared to time-matched DMSO controls. Approximately 100 genes were selected as developmental markers to include the primitive streak, definitive endoderm, yolk sac endoderm, foregut, midgut, and hindgut. The expression profile of these marker genes suggested that cells exposed to concentrations above 0.01 µM shifted from an anterior to posterior molecular phenotype compared to cells exposed to concentrations below the tipping point. The molecular markers of this phenotypic shift will be used to establish a testing platform to screen chemicals for potential disruption to early embryonic development through altered RA signaling. This work does not represent US EPA policy.

There is a need for approaches to understand the biological mechanism of adverse outcomes and human variability in response to environmental chemical exposure. The US EPA Adverse Outcome Pathway Database (AOP-DB) is a database resource that combines different data types (AOP, gene, chemical, disease, pathway, orthology, and ontology) to characterize the impacts of chemicals to human health and the environment, and serves as a decision support tool for case study development. Here we present an updated version of the database, which includes an increased number of adverse outcomes and corresponding key events derived from updated feeds from the AOP-Wiki (https://aopwiki.org/), updated disease, phenotype, and ontology information, as well as improved integration with the AOP-DB web user interface. We illustrate these updates and the utility of the AOP-DB through three guided tutorials which provide the user with opportunities to explore computationally how chemical-gene molecular key events in adverse outcome pathways link to adverse disease, species-specific factors and population-level health outcomes. This abstract does not reflect US EPA Policy.

The Aryl Hydrocarbon Receptor (AhR) is a ligand-inducible transcription factor that regulates genes involved in a variety of physiological functions in response to the potent and persistent environmental contaminant 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). Assembly of AhR regulatory networks is critical for understanding the intracellular events that lead to tissue-specific adverse health effects upon chemical exposure. However, the precise sequence of DNA binding sites of the AhR, as well as its extended AhR regulon, has yet to be elucidated. In this study, we applied...
a supervised machine learning model to predict direct AhR binding sites. We predicted functional AhR binding sites in the accessible DNA regions in the HepG2 cell line from a model trained on AhR ChIP-seq data in MCF-7 cells. Moreover, we predicted the AhR ChIP-seq peaks across cells from a model trained on an integrated dataset including DNA sequence, open chromatin and histone methylation profiles. By combining our predictive model with RNA-Seq analysis of TCD-affected HepG2 cells, we mapped the AhR binding sites to TCDD-responsive genes, and reconstructed the AhR regulatory network in the HepG2 cell line. Our work provides an approach for reconstruction as well as analysis of AhR regulatory cascades in multiple tissues by combining accurate prediction of AhR binding sites and mapping AhR binding sites to proximal and distal target genes

1809 Functional Consequences of miRNA Regulation by Polycyclic Aromatic Hydrocarbons in 3D Human Lung Epithelial Cells

M. Mans, L. K. Siddens, D. Sampson, Y. Chang, and S. T. Tillon, Oregon State University, Corvallis, OR.

Polycyclic aromatic hydrocarbons are a class of contaminants ubiquitous in the environment from the incomplete combustion of fossil fuels. Many PAHs have been identified as procarcinogenic, which are metabolized to form DNA adducts; however, other mechanisms also may contribute to toxicity and help explain differences in toxicity across the wide class of compounds. This study focused on the role of miRNA in regulating toxicity by benz(a)pyrene (BAP) and dibenzofuranylene (DBF) on the 3D human bronchial epithelial cells (HBE). miRNA are short (≤22 nt), non-coding RNA molecules that post-transcriptionally regulate gene expression. Cells were exposed to 500 µg/ml BAP and 10 µg/ml DBF for 48 hrs and samples were collected for RNA isolation and parallel analysis of miRNA and mRNA by RNA sequencing using Illumina HiSeq3000. Significant (q<0.05) differentially expressed miRNA and mRNA were analyzed in an anti-correlated fashion in Bioinformatics Resource Manager to identify miRNA-mRNA interactions and visualized as networks in Cytoscape to identify patterns of regulation reflecting a response to PAHs. DBC treatment showed more regulation of unique miRNA with 53 significantly down- and 46 up-regulated miRNAs, compared to BAP’s 14 down- and 35 up-regulated miRNAs. These miRNA targeted 546 up- and 654 down-regulated genes significant in the DBC dataset, and 176 up- and 750 down-regulated in the BAP. miRNA uniquely up-regulated in BAP were linked with a more significant response in cell adhesion and developmental processes. In DBC, up-regulated miRNA showed more significant response overall in regulation of cell cycle, translation, and apoptosis. Processes perturbed by down-regulated miRNA were less consistent. These data are the first to describe the role of miRNAs as regulators of PAH toxicity in primary human 3D HBEC and could represent important mechanisms associated with PAH-mediated lung disease and cancer in humans.

1810 Dysregulation of ID3-Regulated Transcriptomic Signatures by Polychlorinated Biphenyls

M. Doke, and Q. Felty. Florida International University, Miami, FL.

Environmental factors, including polychlorinated biphenyls (PCBs), are considered to be involved in hyper-proliferative vascular remodeling because genetic makeup can only explain about 10% of severe PAH cases. The molecular mechanism associated with PCBs role in lung toxicity is unclear. Our previous studies demonstrated PCB153 mediated vascular endothelial dysfunction and activated the inhibitor of differentiation protein 3 (Id3). To determine the molecular mechanism by which Id3 contributes to hyper-proliferative endothelial cells, we investigated Id3 transcriptional reprogramming using ChIP-Seq and RNA-Seq technology. Stable ectopic expression of Id3 in lung endothelial cells contributed to endothelial-mesenchymal transition (EndMT), cell proliferation, and cell migration. Id3 overexpressing cells showed the loss of VE-cadherin and gain of MMP9 and vimentin, which are markers of EndMT. PCB153 also increased phosphorylation of Id3 in lung endothelial cells. Our ChIP-Seq data show that Id3 binds to a subset of 2834 target genes. Comprehensive motif analysis of ChIP-Seq data using the MEME Suite software toolkit revealed that Id3 bound to the GAGAGAGA motif sequence on genomic DNA. We also show a significant preference of Id3 binding to motifs associated with transcription factors IRF1, BC11A, IRF4, PRDM1, FOXJ3, SMAD4, 2B1B6, GATA1, and STAT2. Using an integrative approach of ChIP-Seq and RNA-Seq data, we identified 19 genes whose promoter region was bound by Id3 and RNA was differentially expressed in Id3 overexpressing cells. In summary, our data demonstrated that PCB153 and/or Id3 induces proliferation of lung endothelial cells via transcriptional reprogramming. Discoveries from these findings will lay the necessary groundwork for testing the efficacy of Id3 antagonists for the prevention and treatment of pathological vascular remodeling as well as provide a new paradigm by which PCBs may contribute to lung vascular toxicity.

1811 Repurposing Immortalized Cell Line-Based Transcriptomic Profiling Assays for Drug-Induced Liver Injury with a PRank Method

Z. Liu1, R. Roberts2, and W. Tong1. 'US FDA/NCTR, Jefferson, AR; and 2Acponix, Alderley Edge, United Kingdom.

In vitro Toxicogenomics (TGSTs) as an alternative means to animal studies holds great promise in risk assessment. However, TGx studies often suffer from limited sample size and few available cell types. To investigate the potential of repurposing accumulative transcriptomic profiles data of immortalized cell lines in risk assessment, we carried out a comprehensive assessment of the transferability between transcriptomic profiles from three cancer lines (HL60, MCF7, and PC3). These three lines were compared in Connectivity Map (CMAP) and in toxicogenomic datasets (human primary hepatocytes and rat in vivo repeated dose) from the Open Toxicogenomics Project-Genomics Assisted Toxicity Evaluation System (TG-GATES) database using our developed Pair Ranking (PRank) method. A moderated concordance was observed in HL60 versus human primary hepatocytes (PRank score = 0.70), suggesting the two cellular assays are potentially interchangeable. The suboptimal concordances between rat in vivo repeated dose and cancer cell lines were markedly improved by 10%, when limiting the compounds causing drug-induced liver injury (DILI) endpoints and a gene list of DILI predictive toxicogenomics space (PTGS). Furthermore, some toxicity related pathways including PPAR signaling pathways, and fatty acid-related pathways were consistently perturbed across the assay systems, confirming our previous finding that assay transferability is biological process specific. Also, the extrapolation ability for differentially expressed genes (DEGs) of 304 immune-related states among the assay systems were evaluated, suggesting the preservation of immune-related transcriptional features is assay dependent. In conclusion, these comparisons suggested a great potential of repurposing transcriptomic profiling assays of immortalized cell lines in DILI.

1812 Transcriptomic Approach to Predicting the Impact of Cigarette Smoke on Morphological Changes in Human 3D Bronchial Tissue

The respiratory tract acts as the first protective barrier against inhaled xenobiotics, whereas excessive responses induced by the habitual inhalation of airborne materials can impair barrier function, potentially leading to abnormal morphological changes in respiratory tract tissues. These alterations are found in cigarette smoke (CS)-induced respiratory diseases; however, the precise mode of action (MoA) of these changes remains unknown, possibly because of complexity. Reconstructed three-dimensional (3D) cultures of bronchial epithelial cells are considered useful for understanding the MoA because of their resemblance to human tissues. In addition, comprehensive investigation via transcriptomic analysis could provide insights into the MoA. In this study, we repeatedly exposed 3D human bronchial tissues to EGf, IL-13, and TGF-β for 2 weeks to induce epithelial hyperplasia, goblet cell hyperplasia, and epithelial-mesenchymal transition, respectively, and each morphological change was confirmed by immunostaining. We then performed microarray analysis to investigate the global gene expression profile in the tissues after exposure to each inducer for 4 hours and 2 weeks, followed by the detection of differentially expressed genes (DEGs). The gene expression profile of tissues exposed to CS for 4 hours was also obtained, and then we identified the common DEGs between CS and each inducer, which we named “key genes” (KGs). We found that the majority of KGs were common to both CS and EGf exposure, suggesting that EGFr activation is a dominant effect of CS exposure. Chronic obstructive pulmonary disease (COPD) is a major CS-related respiratory disease exhibiting an increased presence of abnormal cell morphology. Therefore, we further investigated the utility of multi-class classification with KGs for COPD prediction by using publicly available microarray datasets of lungs from healthy non-smokers, healthy smokers, and ex-smokers with COPD. The accuracy of prediction using KGs was higher than that using randomly selected genes. Overall, the transcriptomic analysis suggested that CS-induced respiratory diseases are dominantly coupled to proximal and distal target genes including accurate prediction of AhR binding sites and mapping AhR binding sites to TCDD-responsive genes, and reconstructed the AhR regulatory network in the HepG2 cell line. Our work provides an approach for reconstruction as well as analysis of AhR regulatory cascades in multiple tissues by combining accurate prediction of AhR binding sites and mapping AhR binding sites to proximal and distal target genes.
1813 Profiling of Opioid Information Using FDALabel Database

T. Ingle1, Z. Liu1, D. Mehta1, S. Thakker1, S. C. Harris1, J. Yang1, G. Zhou1, L. Wu1, C. Li1, C. Allard2, J. Meehan1, J. Xu1, L. Rosario2, W. Tong1, and H. Fang1.1US FDA/NCTR, Jefferson, AR; and 2US FDA/CDER, Silver Spring, MD.

The opioid epidemic has drawn national attention and has been officially declared a state of emergency in the US. ~100 million Americans experience chronic pain resulting in an estimated $560-635 billion/year economic burden. As public awareness and education improve, the scope of this epidemic continues to grow indicating that more information and action is needed. US FDA-approved drug labeling contains a complete set of opioid drug products and can be used as a reliable source to aid in understanding the mechanisms and characteristics of opioids. FDALabel Database is a publicly available web application that allows for customized searches against the entire text of drug labeling. To demonstrate FDALabel’s utility, a case-study was designed to collect information from opioid drug products. Queries were performed based on the specific opioid-related pharmacologic classes, chemical structures, DEA schedules, MedDRA terms, labeling sections, and drug interactions. Using this approach, 12 Pharmacologic Drug Classes and 32 active ingredients associated with either opioid antagonists or agonists were identified. The identified drugs are indicated for analgesic, gastrointestinal, addiction, or opioid overdose treatment. Of the 32 drugs, 24 have Boxed Warnings (BW), 22 are controlled substances, 14 are classified as CII (high potential for abuse), and 11 are in the Full Opioid Agonist pharmacologic class. Twenty-seven different instances of drug-drug interactions were also identified. The top 10 occurring MedDRA preferred terms in BW, which correlate to adverse reactions, are Death, Overdose, Dependence, Substance abuse, Depression, Respiratory depression, Nervousness, Coma, Withdrawal syndrome, and Drug interaction. The ever-growing epidemic of opioid abuse is of great interest to the US FDA, which is committed to advancing efforts to address the crisis of misuse and abuse through awareness, education, and research. Here, we provide a comprehensive overview of current opioid information using US FDA-approved drug product labeling to support drug safety research, and for the advancement of opioid abuse and addiction prevention.

1814 The Comparative Toxicogenomics Database (CTD): Mechanism Meets Exposure Science Illustrated through a Bisphenol A-Diabetes Case Study

C. Mattingly, T. C. Wiegler, C. Gronding, D. Sclaky, J. Wiegler, R. Johnson, and A. Davis, North Carolina State University, Raleigh, NC.

The Comparative Toxicogenomics Database (CTD; http://ctdbase.org) is a premier public resource that illuminates the molecular mechanisms by which environmental exposures affect human health. CTD provides manually curated interactions for chemical-gene, chemical-phenotype, chemical-disease, gene-disease, and population-based exposure associations. All data is curated using community-accepted ontologies and controlled vocabularies, providing contextualization and allowing seamless integration across curated content as well as with external data sets to make novel inferences. This information can be explored with user-friendly query and analytical tools to generate testable hypotheses for environmental diseases. CTD includes data from over 130,000 scientific articles, describing more than 2.3 million interactions for 15,600 chemicals, 46,600 genes, 4,300 phenotypes, 7,200 diseases, and 2,100 exposure events for over 580 taxa. We demonstrate how users can access CTD to learn about any chemical, gene, phenotype, disease, or exposure study. Integration of all four modules allows adverse outcome pathways (AOP) for systems toxicology applications to be constructed, from molecular initiating events to population-level health outcomes. As a case study, we demonstrate how to construct mechanistic pathways relaying a putative role for the consumer-exposed product bisphenol A in type 2 diabetes and discover a set of prioritized genes as potential mediators, with pathways correlated at multiple data levels (gene-disease, gene-GO, chemical-phenotype, chemical-anatomy, and population studies). This showcases how users can leverage CTD’s content for any chemical-of-interest to easily generate putative mechanistic AOPs for testing, refinement, and validation in systems toxicology applications.

1815 Pharmacokinetic Models for Quantifying Mother-to-Offspring Transfer of Lipophilic Chemicals

Lipophilic chemicals, which can accumulate in a woman’s body fat due to environmental exposure over the course of many years preceding and during pregnancy, may be transferred to her child during gestation and, after birth, through her breast milk. Because of the bioaccumulation of such compounds in fat and their subsequent partitioning into breast milk lipids, a breastfeeding infant may have an average daily exposure per unit of body mass (mg/ kg/d) that greatly exceeds that of the mother. Thus, nominal maternal exposures occurring in animal studies may not be adequate surrogates for the exposures experienced by developing infants. Furthermore, exposure duration and regimen for developmental animal studies vary tremendously. Maternal laboratory animals are generally exposed to a chemical for a relatively brief time before, during, and/or after pregnancy, whereas human mothers may be exposed for a much longer time encompassing all these periods. In order to quantitatively analyze these issues, we developed a pharmacokinetic (PK) model for lipophilic chemicals in humans, rats, and other animal species that addresses mother-to-offspring transfer of these chemicals during the critical periods of gestation and early post-natal development. This model can be used to estimate instantaneous body burdens (in mg of chemical per kg of body mass) in the mother, fetus(es), and infant(s) based upon gavage or intravenous dosing or dosing through diet. Using our model, we demonstrated that breastfeeding infants tend to have higher average daily exposures to 2, 2′, 4′, 4′, 5′-hexachlorobiphenyl (PCB 153) than their mothers. Also, by considering various dose metrics, we demonstrated a method for computing human equivalent doses for points of departure identified in developmental animal studies of PCB 153. Then, by rank-ordering these human equivalent doses, we showed how one can identify those adverse outcomes most sensitive to chemical exposure.

1816 Integration of Food Animal Residue Avoidance Databank (FARAD) Empirical Methods for Drug Withdrawal Interval Determination with a Mechanistic Population-Based Interactive Physiologically Based Pharmacokinetic (iPBPK) Modeling Platform: Example for Flunixin Meglumine Administration

M. Li1, Y. Cheng1, J. Chittenden2, R. Baynes2, L. Tell1, J. Davis3, T. Vickroy3, J. Riviere1,2, and Z. Lin1. 1Kansas State University, Manhattan, KS; 2North Carolina State University, Raleigh, NC; 3University of California Davis, Davis, CA; 4Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA; and 5University of Florida, Gainesville, FL.

Violative chemical residues in animal-derived food products may cause adverse health effects to consumers, affect food safety globally and impact on the trade of international agricultural products. The Food Animal Residue Avoidance Databank (FARAD) has been developing scientific tools to provide appropriate withdrawal interval (WDI) estimations after extralabel drug use in food animals for the past three decades. One of these tools is physiologically based pharmacokinetic (PBPK) modeling, which is a mechanistic-based approach that can be used to predict tissue residues and WDIs. However, PBPK models are complicated and difficult to use by non-modelers. Therefore, a user-friendly PBPK modeling framework is needed to move this field forward. Flunixin was one of the top five violative drug residues identified in the US from 2010 to 2016. The objective of this study was to establish a web-based user-friendly framework for the development of PBPK models for food animals. Specifically, a new PBPK model for both cattle and swine administered flunixin meglumine was created. The determination coefficients of model validation were higher than 0.90 (cattle: 0.92; swine: 0.96), indicating model validation. Approaches that breastfeeding infants tend to have higher average daily exposures to 2, 2′, 4′, 4′, 5′-hexachlorobiphenyl (PCB 153) than their mothers. Also, by considering various dose metrics, we demonstrated a method for computing human equivalent doses for points of departure identified in developmental animal studies of PCB 153. Then, by rank-ordering these human equivalent doses, we showed how one can identify those adverse outcomes most sensitive to chemical exposure.
Physiologically Based Pharmacokinetic (PBPK) Modeling of Mirtazapine in Cats

R. Lake, and B. Reisfeld, Colorado State University, Fort Collins, CO.

Within the veterinary companion animal realm, physiologically-based pharmacokinetic (PBPK) models have been focused toward the canine population, while PBPK models for the feline population have not previously been represented in the literature. Cats possess several unique physiologic differentiations regarding metabolism and transport of certain drugs, including known genetic abnormalities in UGT1A6 and ABCG2 (leading to alterations in glucuronidation and drug transport, respectively), which can often result in severe drug toxicities. Thus, an unmet need exists for feline-specific PBPK models to investigate the dosing and pharmacokinetic profiles of therapeutic drugs used for treating feline disease. Mirtazapine (MTZ), a noradrenergic and specific serotonergic antidepressant, was selected for study as it is commonly used in veterinary medicine as a treatment for nausea and vomiting associated with chemotherapy, pancreatitis, and chronic kidney disease in cats. Based on available data and relevant target tissues, a six-compartment oral dosing PBPK model was developed using the software MCSim. Physicochemical parameters characterizing the ADME properties of mirtazapine (Vmax, Km, tissue partitioning, etc.) were obtained via human- and mice-based studies from the literature and scaled to feline values where appropriate, and anatomic (weight & volume) tissue data were obtained directly from feline necropsies. The model was parameterized using Bayesian inference via a Markov chain Monte Carlo methodology and population pharmacokinetics were realized using Monte Carlo simulations. Results from a typical individual simulation of a 1.88 kg cat, which virtually all available experimental data points, are in agreement with the literature. Results from this study demonstrate a nascent computational framework for investigating drug disposition in cats that may enable a predictive approach for better informing feline drug dosing protocols, especially for cases where drug disposition may be impacted, such as in chronic renal failure or liver disease.

Improved Prediction of Tissue and Urine Concentrations of 2-Phenoxyethanol and Its Metabolite 2-Phenoxyacetic Acid in Rat and Human after Oral and Dermal Exposures via GastroPlus Physiologically Based Pharmacokinetic Modeling

F. Zhang, and S. Marty, Dow Chemical Company, Midland, MI.

2-Phenoxyethanol (PHE) is a preservative widely used in various products for personal care and cosmetics. In rats, PHE has been confirmed to be primarily metabolized to 2-phenoxyacetic acid (PhAA). At high dose levels (>400 mg/kg/day) with subchronic or chronic exposures, PHE has been shown to induce hepatotoxicity, renal toxicity, and hemolysis in multiple species (such as rats). Of the numerous metabolic pathways associated with PHE metabolism, the succinyl-CoA:3-hydroxy-3-methylglutaryl-CoA thiolase (HMGCST) pathway results in the formation of PhAA. In the current work, a PHE- and PhAA-based PBPK model can only estimate tissue concentrations of total parent PHE plus its metabolite PhAA individually by tissue and species after oral or dermal exposure. In the current work, a PHE- and PhAA-based PBPK model was initially built in rats via GastroPlusSM software and validated using plasma levels of PHE and PhAA and urinary levels of PhAA obtained from rats intravenously administered 2 mg/kg PHE. This PBPK model was then applied to rat and human exposure scenarios to predict the tissue concentrations of PHE, PhAA, and urinary PhAA. The results showed that predicted tissue concentrations of PHE or PhAA were lower than the experimental tissue concentrations based on total radioactivity (e.g., at 1 hr time point, the experimental plasma concentration of radioactivity (presumed PHE) was more than 10-fold higher than the predicted corresponding concentration of PhE, likely due to PhAA metabolite formation). The predicted urinary concentrations of PhAA were similar to experimental urinary radioactivity concentrations. With this improved model, the tissue concentrations of PHE and PhAA and urinary concentration of PhAA from subchronic and chronic exposures (either oral or dermal) can be predicted and applied for the toxicity risk assessment of PHE.

Carcinogenic Alterations of Mouse Tissue-Derived Organoids by Chemical Treatment

T. Imai1, M. Ochiai1, M. Naruse1, and Y. Hippo2. 1National Cancer Center Research Institute, Tokyo, Japan; and 2Chiba Cancer Center Research Institute, Chiba, Japan. Sponsor: K. Ogawa

We previously reported that mouse normal intestine-derived organoids, to which a single exposure to the carcinogenic agent, Apc−/−, p53−/− or Pten−/− knockout mice have been introduced in vitro, showed tumorigenicity after subcutaneous injection to nude mice. In the present study, we examined morphological alterations of mouse organoids treated short-time in vitro with several genotoxic chemicals and injected to nude mouse subcutis thereafter. Treatments with ethyl methanesulfonate (EMS), 10 μM m7G, and 10 μM 200 μM of C78L8/16 mice with KrasG12D mutation and acrylamide (AA) at 1.4 Mm to lung organoids of BALB/c-p53 (+/+ or (+/-) mice for 24 hrs were repeated three times of passages of the organoids, followed by their subcutaneous injection to nude mice. (Results) Treatment with EMS demonstrated subcutaneous nodules over 10 mm in major axis with histological characteristics of carcinomas and AA showed histological characteristics of adenocarcinomas, multilayered and/or invasive futures of epithelia, in nude mice. It was found that macroscopic and/or histological carcinogenic alterations of mouse tissue-derived organoids treated with chemical carcinogens were induced in the nude mouse subcutis. We are now investigating the impacts of other carcinogens and non-carcino-gens, as well as those of host strain differences, on the morphological alterations of the tumors.

Modeling Genetic Diversity of Dioxin Disposition in the Liver with a Genetically Diverse Panel of Mouse Models

D. Filipovic, P. Dornbos, J. LaPres, and S. Bhattacharya, Michigan State University, East Lansing, MI.

The aryl hydrocarbon receptor (AhR) is a ligand activated transcription factor whose activation results in the induction of multiple downstream genes, including CYP1A1 and 1A2. The prototypical ligand for AhR is 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). The induction of CYP1A2 is liver-specific and is responsible for additional sequestration of TCDD in the liver. Exposure to TCDD can result in AhR-pathway-mediated hepatotoxicity in animals and humans, although the exact mechanisms involved are not yet fully understood. Given that toxic effects of TCDD are closely related to its disposition, multiple physiologically based pharmacokinetic (PBPK) models of TCDD disposition, incorporating CYP1A2 induction, have been developed. In order to reduce uncertainties associated with extrapolation of these models across species, it is necessary that the mechanistic basis of TCDD sequestration in the liver be described as accurately as possible. To this effect, we are using PBPK modeling to investigate the mechanisms driving the hepatic dose response within a genetically diverse panel of mouse strains. We show that the differences in disposition across strains can be explained by a combination of AhR allelic categories, CYP1A2 induction and its binding affinity. Use of mechanistic insights from the mouse panel to refine PBPK modeling of TCDD will contribute to better understanding of TCDD induced hepatotoxicity and the reduction of uncertainty in risk assessment decision-making for dioxins.

Computational Modeling of an In Vitro Neural Network: Microelectrode Assay for Neurotoxicity Screening

Computational modeling of structural features of an in vitro assay can provide mechanistic insights into assay data. Here we describe computational modeling of an assay where primary rat cortical cells are grown over a microelectrode array for up to 12 days in vitro (DIV). As the neural network develops, random firing is detected at the electrodes by 5 DIV but, over time, firing becomes synchronized in bursts. The assay is used to screen for development of motor units, firing rates of excitatory and inhibitory neurons, fraction of all neurons in contact with electrodes, fraction of all neurons in contact with electrodes, and numbers of synapses formed by excitatory and inhibitory neurons. For example, when configured with 10n neurons, of which 75% are excitatory and 25% inhibitory, with 0.1% of neurons contacting electrodes, basal firing rates of 0.15 and 1.15 Hz for excitatory and inhibitory neurons respectively,
1822 Exploring Applications of Human Primary Cells for Drug Screening in Various Cell Culture Systems

J. A. Wells, N. Mahashetty, and D. Yin, ATCC, Gaithersburg, MD.

Human primary cells are useful pre-clinical models as they more closely mimic the physiology of cells in vivo as compared to continuous cell lines. Here we explored applications of human primary cells for cytotoxicity assays and drug screening. Cancer is a leading cause of female mortality worldwide and our ability to screen compounds against cancer is still lacking. Some of the common side effects of all anti-cancer drugs. We investigated the cytotoxic effects of three anti-cancer drugs, alone or in combination, on three types of normal reproductive cells in vitro. Primary human uterine fibroblasts, cervical epithelial cells, and vaginal epithelial cells were treated with topotecan, paclitaxel, cisplatin or a combination of these. Cells showed significant cytotoxicity. Topotecan and paclitaxel showed significant cyto toxicity in three types of reproductive cells at 0.1 µM while cisplatin significantly decreased the viability of all cells at 10 µM. Furthermore, the combination of topotecan and cisplatin treatment did not result in any significant additive effect on cytotoxicity of these reproductive cells. Three-dimensional (3D) cell culture systems utilizing primary cells may provide more physiologically relevant information and more predictive data in vivo assays. Skeletal muscle cells can contract under physiological conditions and their contraction may show damage during tissue injury and repair. To validate a 3D muscle contraction assay for drug screening applications, we embedded primary human skeletal muscle cells with a collagen matrix and treated them with 10 mM 2, 3-Butanediol 2-monoxime (BDM), a known inhibitor of skeletal and cardiac muscle contraction, for 19 days. The spontaneous contraction of untreated human skeletal muscle cells was observed in a time-dependent manner while BDM significantly inhibited contraction. The results from these assay systems demonstrate that various types of human primary cells can be used for pre-clinical applications including drug screening, toxicology, and modeling physiological responses.

1823 Using PBPK Modelling to Understand the Low-Dose Kinetics of Paraquat in Rodents and Dogs

J. L. Campbell Jr., Jr., H. J. Clewell, III, K. Z. Travis, P. M. Hinderliter, and A. J. Stevens, Ramboll, Research Triangle Park, NC; Syngenta, Ltd, Bracknell, United Kingdom; and Syngenta Crop Protection, LLC, Greensboro, NC.

Paraquat dichloride (PQ) is a non-selective herbicide widely used in agriculture. The current work describes the quantitative low-dose kinetics of paraquat in rodents and dogs. A physiologically-based pharmacokinetic (PBPK) model of paraquat was developed using available data. It was also used to identify uncertainties and data gaps. New radiolabelled kinetic studies were conducted, and the PBPK model was revised as necessary. The starting point for creating the PBPK model was a minimal set of simplifying assumptions, namely no metabolism, linear kinetics with respect to dose, and clearance by urinary excretion of free plasma PQ at the glomerular filtration rate (GFR). Complexity was added only when necessary to simulate the available data. It was necessary to move from a flow-limited to a diffusion-limited model for each tissue allowing for tissue intertissue blood flow and tissue extracellular matrix and from tissue extracellular matrix to tissue intracellular matrix. It was also necessary to explicitly represent red blood cells, and to represent a slowly reversible component of plasma binding. Tissue rate constants were scaled between species according to tissue volume, and apart from this the PBPK model for each species was the same except for physiological parameters such as tissue volumes, blood flows and GFR. The current model now represents available mouse, rat and dog datasets very well for blood, plasma and tissue PQ concentration profiles and for clearance. This shows that the systemic behavior of PQ is the same in all these species, and differences in kinetic outcomes are driven only by physiological differences. This simplicity is a strength in that all available datasets are informing the parameterization of the same model, rather than studies on each species informing the parameterization of a species-specific model. This makes the resulting cross-species PQ PBPK model more robust. The dose routes represented are intravenous, subcutaneous, intraperitoneal, oral, dietary, and inhalation. The current model enables the estimation of blood, plasma and tissue PQ concentration profiles for any dosing regime, including for the many published PQ studies in which no kinetic measurements were made. The extension of the model to humans would help to inform risk assessments.

1824 Use of a PBPK-Quantitative Adverse Outcome Pathway Model to Resolve the Species Specificity of Lung Carcinogens

In mice, styrene, naphthalene, ethyl benzene, isoniazid and fluoro-sulfone form reactive metabolites via CYP2F2 in Club cells of the lung and produce lung-specific tumors. This association in humans is equivocal and considered to be species-specific for the mouse. Club cells (3.36 x 10^6 per mouse) comprise 80% of murine lung tissue but less than 8% of human lung. We propose that the mouse-human difference in carcinogenic potency is based on quantitative, rather than qualitative species differences. Our hypothesis is testable using PBPK models combined with a quantitative adverse outcome pathway (qAOP) linking formation of reactive metabolites with tumor development. Pathway progression in an AOP construct implies that a definable “response-response” (R–R) relationship exists between each key event (KE) leading to the adverse outcome (AO); Computational modeling of the R–R relationships enables dose-response evaluation of the probabilities and uncertainty, as well as cross taxa scaling and integration of new approach methodologies (NAMS; e.g. genomic or in vivo data streams). Using only published studies, we adapted a PBPK model for metabolism of styrene to styrene oxide and a qAOP implementation that includes a 2-stage (1) model with arms testing, Parallel models for different exposure scenarios: (1) direct metabolite damage of DNA, leading to errors of replication and increased mutation during cell division; and (2) indiscriminate metabolite damage resulting in cell death and regenerative proliferation without change to the background mutation rate per cell division. Chronic exposure drives progression to a mature lung cancer cell and club cell positive adenocarcinoma (the “A0); Preliminary findings indicate that the results of scale-up of the PBPK model from mouse to human using conventional allometric methods, incorporation of mouse-human differences in Club cell populations, and model calibration against relevant tumor data sets are consistent with qualitative species similarities and quantitative differences driving the mechanistic basis for the observed mouse-specificity of styrene as a lung carcinogen. This abstract does not necessarily represent the views or policies of the US EPA.

1825 Physiologically Based Pharmacokinetic Modeling the Impacts of Intermittent Oral Exposures to Lead on Blood Lead Levels and Associated Health Risks

Lead modeling has been used for many years to quantify the impact of lead intake on blood lead, bone lead, and other tissues in the body, in order to assess risks from lead exposure, as well as to set permissible levels for lead in environmental media. The International Commission on Radiological Protection (ICRP) model, also known as the Leggett model, is a well-regarded and validated physiologically based pharmacokinetic (PBPK) model for estimating blood lead levels resulting from oral or inhalation exposures. To investigate the potential health risks of various hypothetical lead exposure scenarios, we used the Leggett model to predict the quantitative impacts on blood lead associated with intermittent oral or inhalation exposure. Two case studies. First, we determined the geometric mean blood lead levels (averaged over a one-year exposure period) where the probability of exceeding blood lead level targets (5, 10, 15 or 20 µg/dL) is <=5% (assuming a geometric standard deviation of 1.8 for adults). We then determined the intake values (e.g. micrograms of lead per intake event) for a given exposure frequency (e.g. every other day, 1 day/week) that would correspond with those geometric mean values over a one year exposure period. In our second case study, we determined the exposure frequency (e.g. daily, once every seven days) for a hypothetical lead contaminated candy for a given lead intake (e.g. 3 µg lead per eating occasion) at which resulting blood lead levels fall below those associated with consumption of the California Office of Environmental Health and Hazard Assessment (OEHHA) Proposition 65 Safe Harbor level, or maximum allowable dose level (MADL) of 0.5 µg of lead every day. Based on our
evaluation of these hypothetical scenarios, we concluded that 1) daily point estimates associated with intermittent lead exposures are dependent on exposure frequency, 2) blood lead levels averaged over time are more dependent on total lead intake over a given time period than exposure frequency, and 3) modeling blood leads associated with intermittent exposures allows for evaluation of Proposition 65 compliance.

1826 Development of a Multi-route Physiologically Based Pharmacokinetic Model of Carbon Tetrachloride Uptake in Rats
D. Williams, M. Evans, J. Bruckner, and J. Simmons. 1 ORISE, Oak Ridge, TN; 2 US EPA, Research Triangle Park, NC; and 3 University of Georgia, Athens, GA.

Carbon tetrachloride (CCl4) is a stable volatile compound; exposure results in dose-dependent hepatotoxicity. It is among the initial 10 chemicals prioritized for evaluation under the Lautenberg Chemical Safety Act. Due to its persistence in the atmosphere and environment, CCl4 has been detected in drinking water, creating multi-route exposure (inhalation, oral, dermal) exposure potential. While quantitative predictions for inhalation are well defined, quantitative predictions for oral exposure have large uncertainties, particularly for chronic reference dose calculations. To reduce uncertainty, physiologically-based pharmacokinetic (PBPK) models are used to predict internal dose metrics from external exposures. We used previously published pharmacokinetic data to build and calibrate a multi-route PBPK model for CCl4. Routes modeled include inhalation (100 and 1000 ppm) over 2 hours, single oral bolus administration (17.5 and 179 mg/kg), and intragastric infusion (17.5 and 179 mg/kg) over 2 hours. A two-phase GI absorption model was used for the oral exposures. This GI absorption model introduced four unknown parameters, each of which was fit or optimized. Local sensitivity analysis revealed that parameters to be identifiable, allowing calibration of the model and calculation of internal metrics. Predicted internal dose metrics, including maximum tissue concentration (Cmax), area-under-the-curve (AUC), and amount metabolized, were evaluated and correlated with experimentally observed liver toxicity. While the predicted amount metabolized did not correlate as well with toxicity (R2 = 0.607), liver Cmax and AUC did correlate (R2 = 0.9394 and 0.9254). Because metabolic activation of CCl4 is a requirement for hepatotoxicity, improved correlation between amount metabolized and toxicity would lead to greater model confidence and additional reduction in quantitative uncertainty in risk assessment. A logical next step is evaluation of the impact of oral absorption on model fit and predictions. This abstract does not reflect US EPA policy.

1827 Gaining Insights to Molecular Mechanisms of Combined Air Pollutants Exposures Using PBPK Models and Systems Biology Approaches
P. Ruiz, C. Emond, E. McLanahan, and M. Mumtaz. 1 Agency for Toxic Substances and Disease Registry (ATSDR), Atlanta, GA; and 2 BioSimulation Consulting Inc, Newark, DE.

Due to lack of accessibility, transparency and modeling knowledge, publicly available physiologically based pharmacokinetic (PBPK) models are rarely used in site-specific human health assessments. To address this issue, the Agency for Toxic Substances and Disease Registry (ATSDR) has developed a human PBPK model toolkit for multiple environmental priority pollutants using the Berkeley Madonna™ platform. The current work extends the ATSDR PBPK toolkit to include code models for additional volatile organic chemicals (VOCs) such as toluene, ethylbenzene, xylenes (TEX) and their combinations. Comparisons were made between simulation profiles and experimental data involving goodness of fits by calculating the percent median absolute performance error and root median square performance error. Results using the recorded and original models, as well as an application of the recorded models to evaluate VOC data are presented. Human gene expression changes in target tissues after short-term and long-term TEX mixtures exposure were assessed. This evaluation was then combined with toxicity enrichment analyses to examine VOC exposure related changes in disease-networks pathways. The combined analysis showed that 236 genes expressed were common between the short-term and long-term exposures. These genes are important for the interconnecting biological pathways potentially stimulated by TEX exposure, likely related to developmental or cardioprotective mechanisms. This work increases the accessibility of PBPK models, encourages their integration into chemical risk assessment, and allows the evolution of advanced methodologies that augment combined chemical dose-response analyses with mechanistic insights. The findings and conclusions in this presentation have not been formally disseminated by the Centers for Disease Control and Prevention the Agency for Toxic Substances and Disease Registry and should not be construed to represent any agency determination or policy.

1828 Neonatal Murine-Engineered Cardiac Tissue Toxicology Model: Impact of Metallothionein Overexpression, Cadmium Exposure, and Zinc Countermeasures
H. Yu,1,2, J. Ye,3, F. Yuan,1,2, Y. Kang,1,2, L. Cai,1,4, H. Ji,1, and B. Keller.1,2,4, 1 Pediatric Research Institute, Department of Pediatrics, Louisville, KY; 2 Kosair Charities Pediatric Research Program, Cardiovascular Innovation Institute, Louisville, KY; 3 The Center of Cardiovascular Disorders, First Hospital of Jilin University, Changchun, China; and 4 University of Louisville, Louisville, KY.

Engineered cardiac tissues (ECT) are robust in vitro models to study human disease. Environmental exposure to heavy metals is a global health risk and metallothionein (MT) is cardioprotective for environmental toxicants such as the heavy metal, Cadmium (Cd). Zinc (Zn) supplementation increases MT along with reduction of Cd metal toxicity. First, therefore, we generated 3D ECTs from PN day 3 wild-type (WT) or cardiomyocyte (CM) MT- transgenic (MT-TG) mouse cardiac cells to test the hypothesis that ECT maturation and function would not be adversely affected by MT-TG CM genotype. We found that structural and functional maturation was similar in WT and MT-TG neonatal ECTs. MT gene and protein expression was similar between MT-TG ECT and MT-TG whole ventricle. We then tested the hypothesis that Cd exposure would adversely affect murine ECT function and CM viability, similar to animal model observations, and that zinc or Zn pretreatment could reduce Cd mediated MT overexpression of MT would reduce Cd mediated CM toxicity in ECT. Starting on day 6, WT and MT-TG ECTs were treated with Cd (20-50 μmol/L) for 24 hr. Additional WT ECTs were pre-treated with Zn (50 μmol/L) on day 5 followed by Cd treatment on day 6. We found Cd exposure negatively impacted WT ECT cell survival, maturation, and function quantified by reduced ECT function and increased cleaved caspase 3, Bax/Bcl2 ratio, TUNEL positive cells consistent with CM loss. All these effects were significantly prevented in MT-TG ECTs and in Zn-pretreated WT ECTs with MT overexpression. Thus, neonatal murine ECTs can serve as a robust in vitro model for CM toxicity screening and as a platform to evaluate the role of cardioprotective mechanisms such as MT-overexpression, and metal toxicity countermeasures, such as Zn, relevant to human heavy metal environmental exposure.

1829 Evaluating the Impact of Heat Stress on the Toxicokinetics of Volatile Solvents in Man Using PBPK Modeling
A. Marchand, J. Ménard, P. Brochu, and S. Haddad. 1 Université de Montréal IRSPUM, Montreal, QC, Canada; and 2 Université de Montréal, Montreal, QC, Canada.

In the context of climate change, there is a growing concern about how temperature might affect absorption of chemicals. To address this question, volunteers were exposed in an inhalation chamber at three different temperatures with and without solvents. Blood, urine and exhaled air samples were collected before, during and after 4h inhalation exposures. Respiratory parameters were also monitored for each temperature. No significant changes were observed in exhaled air or urine samples for inhalation exposures and no changes were observed for blood concentrations following toluene cutaneous exposures. Results showed increased blood concentrations (over 20%) at the end of the 4h exposure periods for the highest temperature for all solvents with and without solvents. Blood, urine and exhaled air samples were collected before, during and after 4h inhalation exposures. Respiratory parameters were also monitored for each temperature. No significant changes were observed in exhaled air or urine samples for inhalation exposures and no changes were observed for blood concentrations following toluene cutaneous exposures. Results showed increased blood concentrations (over 20%) at the end of the 4h exposure periods for the highest temperature for all solvents with and without solvents. Blood, urine and exhaled air samples were collected before, during and after 4h inhalation exposures. Respiratory parameters were also monitored for each temperature. No significant changes were observed in exhaled air or urine samples for inhalation exposures and no changes were observed for blood concentrations following toluene cutaneous exposures. Results showed increased blood concentrations (over 20%) at the end of the 4h exposure periods for the highest temperature for all solvents with and without solvents. Blood, urine and exhaled air samples were collected before, during and after 4h inhalation exposures. Respiratory parameters were also monitored for each temperature. No significant changes were observed in exhaled air or urine samples for inhalation exposures and no changes were observed for blood concentrations following toluene cutaneous exposures. Results showed increased blood concentrations (over 20%) at the end of the 4h exposure periods for the highest temperature for all solvents with and without solvents.
Physiologically Based Pharmacokinetic Modeling to Estimate Bone Marrow Doses of Hydroquinone from Smoking

A. E. Loccisano 1, B. D. Kerger 1.
1. Exponent, Alexandria, VA; and 2. Exponent, Irvine, CA.

Chronic benzene exposure is associated with increased risk of acute myeloid leukemia (AML) and myelodysplastic syndromes (MDS). Cigarette smoking constitutes a large contribution to personal benzene exposure; smoking is also reported to be an environmental risk factor for AML and MDS. Benzene is one of many bone marrow toxicants present in cigarette smoke; however, smoke also contains hydroquinone (HQ), which is reportedly the most abundant oxidative compound present in cigarette smoke and is potentially the most potent benzene metabolite contributing to the myelotoxicity of benzene. PBPK models were used to estimate the amount and concentration of HQ and total metabolites in blood and bone marrow resulting from inhalation exposures to both benzene and HQ from smoking exposures (20 or 40 cigarettes per day). An existing PBPK model for benzene was used to estimate the HQ internal dose resulting from metabolism of benzene; the benzene PBPK model was then modified to simulate direct inhalation exposure to HQ from cigarettes. Inhaled concentrations of benzene and HQ from cigarette smoke were estimated to be nearly equivalent. Assuming that 20 or 40 cigarettes are smoked over the course of a 16 hr waking period during the day and that each cigarette smoking event lasts 10 minutes, steady-state concentrations of benzene and HQ were reached in blood and bone marrow in approximately 10 days. Steady-state blood and bone marrow concentrations and cumulative amounts of HQ resulting from direct inhalation of HQ from cigarettes were 5- to 27-fold higher than bone marrow and blood concentrations of HQ resulting from benzene inhalation alone from cigarettes. The sum of HQ and total metabolites in bone marrow and blood were 3- to 29-fold higher than from benzene exposure in cigarettes alone. This model was used to estimate the inhaled concentration of HQ in bone marrow as benzene; this inhaled HQ concentration was 5 times lower than the benzene concentration. This study demonstrates that HQ in cigarette smoke results in much higher blood and bone marrow concentrations than the presence of benzene alone at nearly equivalent inhalation concentrations of HQ and benzene. HQ should also be quantified in assessing potential MDS or AML risks from chronic smoking.

Assessing Early Life Drinking Water Exposures to Manganese (Mn) Using PBPK Modeling

M. Yoon 1, C. Ring 2, C. B. Van Landingham 3, P. R. Gentry 1, M. D. Taylor 1, A. M. Keene 4, and H. J. Clewell 5.

A previously published human PBPK model for Mn in infants and children, which was able to successfully capture age-dependent Mn homeostasis at diurnal steady state, was updated to reflect recent information on Mn metabolism. Various Mn exposure scenarios, which fall within the observed variation of Mn concentrations in infants' blood in Stastny et al. study. This multi-route, multi-source Mn PBPK model for infants and children will contribute to evaluating the realistic impact of drinking water exposure to Mn in early age populations and will thereby improve the level of confidence in understanding exposure-health effects relationships reported to be associated with early age Mn exposure in human epidemiological studies.

Psensi: An R Package to Apply Sensitivity Analysis in Pharmacokinetic Modeling

1. Texas A&M University, College Station, TX; and 2. Colorado State University, Fort Collins, CO.

Sensitivity analysis is an essential tool for modelers to understand the influence of model parameters on model outputs. It is also increasingly used in developing and assessing pharmacokinetic models. In our previous work, we applied a global sensitivity analysis workflow to reduce the computational burden in the Bayesian Markov Chain Monte Carlo-based calibration process of a physiologically based pharmacokinetic (PBPK) model. Although several sensitivity analysis algorithms are available, comprehensive package exists that allows users to seamlessly solve the PBPK model differential equations, run sensitivity analyses, visualize sensitivity analysis results, and discriminate between the “non-influential” model parameters that can be fixed and those that need calibration. Therefore, we developed an open-source R package, called psensi (https://github.com/nanhung/psensi), to fill this need and make sensitivity analysis more accessible in pharmacological and toxicological research. This package can investigate both parameter uncertainty and model formulating sensitivity analysis and can create robust and reproducible results for
Population physiologically-based pharmacokinetic (pop-PBPK) models are powerful tools in toxicology, pharmacology, and regulatory science. One of the critical challenges in population PBPK modeling is the identification and estimation of critical model parameters at desired levels of an analysis hierarchy, from individual subject, to group, to population. Although other methods have been used for this parameterization, a hierarchical Bayesian approach is particularly well suited for this application. Unfortunately, the adoption of Bayesian pop-PBPK modeling has been hampered by a number of factors, including difficulties in identifying influential model parameters, developing the appropriate structural and statistical models, specifying the relevant parameter priors and Bayesian likelihood distributions, and finding a simulation framework to conduct the relevant analyses. To fill this important gap, we developed PoPKAT, a user-friendly, open-source platform that facilitates pop-PBPK analyses that includes state-of-the-art Bayesian sampling algorithms, parameter space reduction through global sensitivity analyses, and a graphical user interface for convenient entry of simulation information and viewing and interpretation of simulation results. Here, we detail the structure and computational capabilities of the framework and illustrate its utility for the analysis of the pharmacokinetics of several compounds of toxicological and pharmacological relevance across structural hierarchies of interest.

Heat stress is of significant concern to Department of Defense personnel in extreme environments. The human body preserves an internal temperature of ~37°C to maintain a healthy metabolism and employs several homeostatic mechanisms such as blood vessel dilatation/constriction and decreased sweating to control this temperature. These mechanisms may disrupt normal toxicokinetic activity within the body. Concurrent heat stress and toxic chemical exposure can be a concern in the DoD occupational environment. Our objective was to provide individual analyses of the thermal and chemical exposure risks to assess the potential effects of these exposures in the extreme environments. Human thermal and chemical exposure data were gathered for ~30 individuals. The data were gathered using direct-reading, real-time gas monitors in the breathing zone for carbon dioxide, carbon monoxide, nitrogen dioxide, nitric oxide, and hydrogen sulfide. Thermal desorption tubes were also used in conjunction with sampling pumps to determine the presence of other gases and vapors. The thermal desorption tubes were analyzed off-line using gas chromatography-mass spectrometry. Temperature data were gathered via HOBO® temperature data loggers to gather local air temperature and Zephyr™满怀电流 devices to gather heart rate, respiration rate, and skin temperature to estimate core body temperature. A physiologically based pharmacokinetic model was built that incorporated a thermal stress model. The model was validated using data gathered from human venous blood concentrations after being exposed to 50 ppm toluene at three temperatures within the body. Concurrent heat stress and toxic chemical exposure can be a concern in extreme environments. Heat stress is of significant concern to Department of Defense personnel.

Mitochondria are the important organelles to maintain the cellular bioenergetic balance and are involved in the progression of adversity in many target organ toxicities. Various enzymes involved in fatty acid oxidation and the citric acid cycle as well as the mitochondrial respiratory chain can be target of chemical interference. Adaptation of mitochondria to perturbations is critical to modulate the balance between recovery from mitochondrial stress aiming at cell survival, and energetic collapse leading to onset of intrinsic apoptosis or necrosis. Here we aimed to obtain a deeper understanding on mitochondrial adaptation upon exposure to various mitochondrial respiration inhibitors by combining modeling, machine learning and high-content imaging that quantitatively captures different mitochondrial malfunctioning, e.g. mitochondrial membrane potential (MMP) and mitochondrial morphology. We treated HepG2 cells with a set of >20 mitotoxicants that inhibit complex I, II or III, the mitochondrial F$_{0}$F$_{1}$ATPase or act as uncoupler. First, to represent the respiration chain, we adapted an existing differential equation model describing the MMP and cellular ATP levels. We optimized the values of the model parameters to fit our imaging data monitoring the MMP (Rho123) dynamics for 24 hours. We extended the model with MMP leakiness in order to obtain an acceptable fit to our time-concentration response data. Second, since some of the mitotoxicants disturbed mitochondrial morphology, we aimed to integrate dynamic mitochondrial morphology changes in the model. In order to quantify these effects, we applied a random forest approach to segment mitochondria from our images. We subsequently exploited features from the segmented mitochondria such as form factor and area by applying a Gaussian mixture model to classify mitochondria as either fragmented or fused. We established a preliminary differential equation model that could qualitatively mimic the observed amounts of fragmented/fused mitochondria upon compound exposure. We aim to integrate all above sub-models into one holistic model. We expect our data-driven computational approach to provide an improved mechanistic and comprehensive understanding of the sequence of events leading to mitochondrial toxicity and consequently cell.
1838 Extending the PLETHEM Platform for PBPK Modeling: Batch Mode Processing, Dermal Route of Exposure, and Integration with Mode-of-Action Tools

Scitovation LLC, Durham, NC, and *Ramboll Environ, Durham, NC.

The EPA Office of Research and Development’s 2003 framework for computational toxicology emphasized the need for computational methods to bridge the source-to-outcome continuum. This goal can be achieved by linking exposure estimates to physiologically based pharmacokinetic (PBPK) modeling and computational systems biology pathway modeling tools into a standardized framework. Over the last year, we implemented support for exposure estimation tools under our PLETHEM framework. We now have further extended the modeling capabilities in PLETHEM by adding a batch mode for running multiple chemicals at once and incorporating a dermal route of exposure. Using HT-IVIVE workflows within PLETHEM we can now extrapolate in vitro to an in vivo dataset of chemicals and establish a margin of exposure using exposure estimation tools. Integrating support for MoAviz, exposure estimation tools and multiple routes of exposure will meet the need for a unified multi-route tool that can be used along the source-to-outcome continuum. This research is funded by the ACC-LRI and is conducted under an MoU with US EPA NCTR.

1839 Evaluations of the Utility of HTTK-PBT model for In Vitro to In Vivo extrapolation

Y. Aleman, U. Lee, and A. Lumen.

Universidad Metropolitana Recinto de Cupey, San Juan, PR, and *US FDA/NCTR, Jefferson, AR.

Physiologically based toxicokinetic (PBTK) models allow for extrapolating in vitro data to predict the overall in vivo pharmacokinetics of drugs or chemicals (IVIVE). The High-Throughput Toxicokinetic (HTTK) tool, built as an R package, can be used to efficiently evaluate a large number of compounds using PBTK modeling. The derived set of compounds used to establish a mode of action can be directly imported into PLETHEM. The HT-IVIVE workflow can then be used to extrapolate these PODs to exposures and establish a margin of exposure using exposure estimation tools. Integrating support for MoAviz, exposure estimation tools and multiple routes of exposure will meet the need for a unified multi-route tool that can be used along the source-to-outcome continuum. This research is funded by the ACC-LRI and is conducted under an MoU with US EPA NCTR.

1840 Use of Risk Assessment for Innovative Reuse of Dredged Sediment

Sponsor: M. Ciarlo, Society of Environmental Toxicology and Chemistry

The Port of Baltimore is an economic driver for the State of Maryland. The Port contributed $3 billion in gross revenue, $300 million in state and local tax revenues, and provides over 100,000 jobs. The maintenance dredging of the federal navigation channels that lead to the Port is imperative to sustaining this economic driver. For the Maryland Port Authority (MPA), the management of dredged material from federal navigation channels is a major concern. On average, 5 million cubic yards (mcy) of dredge material is removed annually from the Potomac River and delivered to the Maryland Port and Clipper City Dredge Material Reclamation Area in the Chesapeake Bay. Of this total, 1.5 mcy is removed from the Baltimore Harbor. Material removed from the Baltimore Harbor is currently placed in one of two dredged material containment facilities as prescribed in Maryland State Law. Due to limited available land along the Baltimore Harbor, it is becoming increasingly infeasible to construct additional containment facilities to meet the future needs of the MPA. To account for the infeasibility of constructing additional facilities, the MPA has identified the re-use of dredged material as a primary mechanism to meet future needs. The MPA has a goal to re-use 500,000 cy of dredged material per year with on land or upland placement as the most feasible alternative to meet the re-use goal. Before 2017, there was no guidance or program the MPA could follow for the re-use of this material. EA Engineering, Science, and Technology (EA) assisted the MPA, in conjunction with the Maryland Department of the Environment (MDE), to develop a new guidance to facilitate the re-use of dredged material. The guidance uses risk assessment to determine risk-based screening criteria for sediment. The guidance also provides steps to determine if the material is acceptable for re-use at a variety of sites. To account for the wide range of chemical concentrations in the dredged material, the screening criteria evaluates various land uses. Additionally, the guidance allows for the use of the risk assessment process to further evaluate materials that exceed screening criteria but still may be available for re-use by taking into account the location and anticipated land use where dredged material will be placed. By evaluating potential current contamination at the location, planned use or redevelopment of the site, material that previously had to be disposed in a containment facility has the potential to be re-used at sites. Additionally, the risk assessment process ensures reduction in future liability of the MPA for placement of material at the sites by providing a quantitative determination of potential risks based upon anticipated site use.

1841 Improving Read-Across Assessment of Cosmetic Ingredients Utilizing COSMOS DB In Vivo Data and In Silico Evidence to Reduce Uncertainties

1, MN-AM, Columbus, OH; 2,ToxNavigation, East Moline, Surrey, United Kingdom; 4, Liverpool John Moores University, Liverpool, United Kingdom; 5, Ohio State University, Columbus, OH; 6, European Commission Joint Research Centre, Ispra, Italy.

Read-across is a well-established technique utilizing data-rich substances to fill gaps for data-poor compounds. It is particularly useful for the assessment of toxicological endpoints for cosmetic ingredients. In order for read-across predictions to be acceptable, key uncertainties must be established and, where possible, areas of high uncertainty must be identified. We demonstrate how in silico tools can be used for risk assessment and increasing confidence in the read-across predictions. This study identified analogues for the data-rich substance maltol. Toxicity data for maltol were obtained from COSMOS DB (cospodb.eu). In addition to a NOEL value from a 180-day mouse oral study, a toxicity data package is available across endpoints including acute, genetic and reproductive toxicities as well as carcinogenicity and organ level effects across a variety of species and exposure routes. The available data were found to be of high quality; as such, maltol is an ideal data-rich “source compound” for read-across. In silico tools within the updated COSMOS DB were utilized to identify “target compounds” based on structural and molecular properties. Structural similarity was assessed using various types of fingerprints (e.g. ToxPrints). Property-based similarity was addressed by calculating sets of relevant physicochemical and electronic descriptors for source and target compounds. In silico screening was performed to reduce uncertainties related to similarity and mechanistic plausibility. The newly implemented and freely available Liver BioPath profiler in the COSMOS DB was applied to characterise source and target compounds using structural knowledge on reactive hepatotoxicity, phospholipidosis, steatosis, mitochondrial effects and other general toxicities to the liver, the most important target
arsenic inorganic arsenic in the 100s to 1000s of ug/L (ppb) has been found to increase the risk of a variety of cancers (Lung, bladder, skin, and possibly prostate). While a review of the literature on arsenic and lung cancer (Lamm et al., 2015) showed a good fit to a linear-quadratic model with a significantly negative linear term and a significantly positive quadratic term, most analyses have reported models with only a significantly positive linear term. We examine here the risk of prostate cancer using recent US county incidence data and ground water well arsenic levels up to nearly 1,000 ug/L arsenic. Groundwater well usage and arsenic levels were obtained from the US Geological Survey, prostate cancer incidence rates from the National Cancer Institute, and co-variate data from the US Centers for Disease Control and Prevention and the US Bureau of the Census. All data were aggregated at the County (FIPS) level and analyzed with Poisson regression analysis. A total of 738 counties (FIPS code areas) had arsenic measurements for their drinking water supply and had prostate cancer incidence data. In analyses conducted for areas with median arsenic level less than 60 ug/L, the risk of prostate cancer risk was found to fit a linear-quadratic model with a significantly negative linear coefficient and a significantly positive quadratic coefficient. In analyses limited to areas with median arsenic level less than 30 ug/L, the risk of prostate cancer risk was found to fit a linear model with a significantly negative linear coefficient. The addition of a quadratic term did not significantly improve the fit of the model. Prostate cancer incidence risk with respect to arsenic levels in drinking water sources for US counties (FIPS codes) did not fit a linear model with a significantly positive quadratic coefficient. The most important factor for establishing a screening value. The resulting derivation HBSS for THC on surfaces was 0.7 µg/100 cm^2. Paired samples taken before and after cleaning surfaces from naïve (vacant following police raid, eviction, etc.; uncleaned or minimally cleaned) clandestine grow operations in Washington State residences show that (1) surfaces can exceed the derived screening level and (2) concentrations on surfaces are effectively reduced following cleaning. Use of the derived screening value will allow stakeholders to evaluate areas that may require remediation and can be used to assess the effectiveness of subsequent cleanup efforts.

Increased risks have been observed for multiple health outcomes in populations exposed to inorganic arsenic in water and diet. Comparing exposure/dose-response is complicated because varying dose metrics (water arsenic concentration, dietary arsenic intake, urinary arsenic) have been used to analyze exposure-response. In addition, relatively simple, monotonic functional model forms have often been used, making it difficult to discern curve shape, particularly at low exposures. This presentation describes a meta-regression approach undertaken to investigate the shape of exposure/dose-response for bladder cancer, a well-studied health outcome associated with arsenic exposure. Exposure-response data for arsenic health effects was obtained from high-quality epidemiological studies identified in a Systematic Literature Review conducted by the US EPA. The selected studies report results from populations in the U.S., Japan, and Taiwan with a broad range of exposures, including considerable data at or only slightly above U.S. background levels of exposure. A unique feature of the approach is that the reported exposure, dose, or excretion metrics were all converted to chronic daily intake using data from a peer-reviewed PBPK model, enabling studies to be compared on a common basis. In addition, pooled dose-response relationships were estimated using fractional polynomial (FP) mixed models. The FP methodology systematically investigates second-order functions that accommodate a very wide variety of non-monotonic curve shapes, including those with negative slope near the origin (horneric or “hook-shaped”). Best-fitting models for the pooled data were identified based on AIC, deviance, and R^2^adj values. Generally, MLE predictions from the best models were convex upward with positive slope at low doses, although resolving model behavior at low doses was difficult owing to high inter-study heterogeneity. Leave-one-out and group-wise analyses were used to identify studies with the most impact on the pooled dose-response estimates. Disclaimer: The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA.
2-Nitropropane (2-NP) is a solvent in inks, dyes, and adhesives as well as an additive in propellants and racing car fuels. It was listed on the State of California’s Proposition 65 list in 1988 reflecting carcinogenic potential based on tumorigenicity in rats. California does not list a Safe Harbor Level for 2-NP. In this analysis, oral and inhalation No Significant Risk Levels (NSRLs) were derived for 2-NP. Additionally, an exposure assessment was performed to determine potential consumer inhalation exposure to 2-NP during indoor application of spray paint to verify that proposed NSRL was not exceeded. Benchmark Dose modeling (BMD) was conducted using combined hepatocellular carcinoma incidence data from several single exposure inhalation studies in Sprague-Dawley rats. A sensitivity analysis was conducted to evaluate the impact of various time averaging assumptions and use of alternative and averaged BMDL values. The model averaged BMDL for male rat hepatocellular carcinoma incidence was used as the point of departure to derive the inhalation human cancer potency based on the ratio of the uptake factors for the inhalation versus the oral routes. The inhalation and oral NSRLs were determined to be 60 μg/day and 32 μg/day, respectively. The estimated exposure to 2-NP for the spray paint scenario was found to be a small fraction of the proposed NSRLs. Based on the screening exposure assessment, potential consumer exposure to 2-NP from indoor application of spray paint does not exceed the proposed NSRL, and a warning label would not be required for spray paint products.

**1847 Risk Characterization of Bisphenol-A in the Slovenian Population Starting from Human Biomonitoring Data**

D. Sarigiannis1, J. Snoj Tratnik2, D. Mazev2, T. Kosje2, E. Heath2, M. Horvat1, and S. Karakitsios1. 1Aristotle University of Thessaloniki, Thessaloniki, Greece; and 2Josef Stefan Institute, Ljubljana, Slovenia.

The current study aims to characterize exposure and risk associated to bisphenol-A (BPA) exposure in Slovenia, starting from biomonitoring data. Based on urinary data, individual daily intake was back-calculated using a generic physiology-based biokinetic (PBBK) model parameterized for BPA and coupled with an exposure reconstruction algorithm. Re-running the PBBK model in forward mode allowed the estimation of biologically effective dose (free plasma BPA) and the respective daily area under the curve (AUC). The risk characterization ratio was derived using both external and internal dose metrics. Urinary BPA levels were found low, with GM of 0.79, 1.51 and 0.20 μg/g creatinine for mothers, children and fathers respectively, similar to the levels of other European countries. Based on the above and accounting for the dynamics of exposure and biokinetics, the daily intake was estimated with median values equal to 0.019, 0.035 and 0.005 μg/kg bw/d for mothers, fathers and children respectively. The highest estimated intake level was found in a child, equal to 0.87 μg/kg bw/d, while the maximum intake for mothers and fathers were 0.7 and 0.8 μg/kg bw/d respectively. The respective RCR values using the EFSA t-TDI of 4 μg/kg bw/d were 2 magnitudes of order lower than unity, independently of the selected method. Had daily intake been estimated solely based on the urinary concentration mass balance, the estimated intake would be lower, due to the assumed simplifications in exposure and elimination time dynamics. Our results highlight the importance of using PBBK modelling-based exposure reconstruction schemes for rapidly metabolized and excreted compounds such as BPA. In this context, deriving the optimal sampling scheme (number of timing of samples within the day) is crucial for risk characterization in the case of rapidly metabolized compounds.

**1848 High-Fat Diet Promotes the Obesity Induced by Perinatal Exposure to 4-Nonylphenol in Rats**

H. Zhang1,2, and Z. Wang1. 1Wuhan Polytechnic University, Wuhan, China; and 2Johns Hopkins University, Baltimore, MD.

Human beings are constantly exposed to more than one toxicant; therefore, it is essential to elucidate the mechanism of combined effect from toxicants. Herein we determined the effect of perinatal exposure to rats with 4-nonylphenol (4-NP) and high-fat diet (HFD) in the adipogenesis of F1 and F2 generations. We fed F0 female rats with 4-NP by gavage. Then the F1 generation rats were divided into 4 groups: control group, fed with normal diet (ND); NP group with 4-NP plus ND; HFD group, with HFD; and NP/HFD group, with 4-NP and HFD. Male rats from control group were mated with female rats from NP group and NP/HFD group to get the F2 rats. After weaning, F2 offspring rats were given normal diet. Compared with control group, the 4-NP and HFD have synergistic action on the organ coefficient of adipose tissue, blood biochemical indexes, the mechanism of gene related from Cdc25 synthesis in F1 and F2 rats. Both HFD and 4-NP can also play a synergistic role in the reduction of estrogen receptor in adipose tissue of F2 rats. We conclude that HFD fed to the F1 generation rats can aggravate the 4-NP effect on the adipose tissue formation of F2 generation rats.

**1849 Chemical Reactivity, Not Molecular Weight or Lipophilicity, Determines Skin Sensitization Potential and Potency: An Analysis Based on the Latest Public Data for Set of Chemical Substances Tested for Skin Sensitization**

H. Chintagunta1, S. Kim1, and A. Schatz1. 2Ashland LLC, Hyderabad, India; 2Ashland LLC, Lincoln, CA; and 2Ashland LLC, Bridgewater, NJ.

Skin sensitization is induced when a susceptible individual is exposed topically to haptens. This chemical sensitizer (hepten) provokes a cutaneous immune response that will subsequently result in the development of contact sensitization. For many years, it has been widely accepted that substances must have a molecular weight (MW) of less than 500 to penetrate effectively through the skin to induce sensitization. We have analyzed the latest public data set of approximately 5000 chemical substances tested for skin sensitization to further understand the physico-chemical characteristics of chemical substances that are the key determinant(s) for inducing skin sensitization. The MWs of sensitizing substances were in the range of 30 to 2300, excluding high MW proteins. The high sensitization potency has been shown with several high MW substances (2300 > MW > 500) with low dermal absorption. The measured values of octanol/water partition coefficient (Kow) for sensitizing chemical substances have been found as low as 10⁻¹ and as high as 10³, thus encompassing a range of ten orders of magnitude. There was no correlation between sensitization potency and MW (or Kow). The mere presence of a reactive functional chemical group(s) within a chemical substance did not automatically suggest that the respective substances are highly potent sensitizers. Nevertheless, our analysis of the latest public data set of chemical substances tested for skin sensitization suggests that: (1) the key determinant for skin sensitization is the chemical reactivity of a given substance; a property that is inherently protein-reactive or that can be metabolized in the skin to reactive species; and (2) as long as a chemically reactive substance can gain access to the viable epidermis, it can induce sensitization or exhibit high sensitization potency regardless of its ability to penetrate effectively through the skin.

**1850 Analysis of Environmental Chemical Exposure of the Canadian Population from the Canadian Health Measures Survey in a Risk Based Context**

S. Faure1, N. Noisel1, K. Subramanian1, L. Alyward1, and A. St-Amand1. 1Health Canada, Ottawa, ON, Canada; 2University of Montreal, Montreal, QC, Canada; and 3Summit Toxicology, LLP, Falls Church, VA.

In order to characterize the exposure of the Canadian population to environmental chemicals, a human biomonitoring component has been included in the Canadian Health Measures Survey (CHMS). This nationally representative survey launched in 2007 by the government of Canada has measured over 250 chemicals in approximately 30,000 Canadians during the last decade.
The capacity to interpret these data in a health risk based context is gradually improving with the development of biomonitoring screening values, such as biomonitoring equivalents (BE) and human biomonitoring (HBM) values. This study aims to analyze recent CHMS biomonitoring data in a health risk based context in order to assess the exposure of the Canadian population and help prioritize chemicals. Hazard quotients (HQs) are used in this analysis and are calculated as the ratio of the CHMS biomonitoring data to the corresponding biomonitoring screening value for individual environmental chemicals at both the geometric mean (GM) and 95th percentile (PP95). This analysis includes short half-life chemicals, persistent chemicals, and volatile organic compounds (VOCs). Most of the chemicals analyzed have HQs below 1 suggesting that exposure to those compounds is not currently of concern. However, HQs exceed 1 in smokers for cadmium, acrylamide, benzene and xylene, as well as in general population for inorganic arsenic and fluoride. Specifically, for inorganic arsenic in the general population an HQ value of 3.13 was calculated at the 95th percentile. For fluoride, HQs were 1.23 and 1.67 at the 95th percentile, respectively. This study suggests that exposure of the Canadian population to these environmental chemicals might be a concern. This screening exercise is useful to help prioritize chemicals for follow-up activities such as risk management actions and show the importance of a continued biomonitoring program to assess population exposures.

1851 Development of Inhalation Reference Concentrations for Chlorotrifluoroethylene (CTFE) and 1,2-Dichloro-1,2,2-trifluoroethane (HCFC-123a)

B. Magee1, and N. Forsberg.1 Arcadia US, Inc., Chelmsford, MA; and 2Arcadis US, Inc., Clifton Park, NY.

The presence of CTFE and HCFC-123a in the subsurface at a site targeted for residential development led to a need for key toxicological data to derive toxicological reference values for human health risk assessment. A literature search revealed that CTFE produces renal toxicity by formation of glutathione S-conjugated metabolite(s) in the liver, which are then hydrolyzed enzymatically to cysteine S-conjugates and reactive intermediates in renal tubules causing dose-dependent renal toxicity. The lowest concentration (29 ppm) in a subchronic inhalation toxicity study was identified as a minimal LOAEC based on statistically significant increases in serum albumin and absolute and relative liver and kidney weights. Converting the minimal LOAEC to a human equivalent concentration (HEC) using a default animal:human ratio of 1 for the blood:gas partition coefficient for extrarespiratory effects, adjusting the HEC to continuous exposures, and applying a composite uncertainty factor of 3,000 (3 for UFHEC, 10 for UF10, 10 for UF20, 3 for UF3, and 3 for UF) yielded a reference concentration (RfC) of 8 µg/m³ for CTFE. Due to the absence of toxicological data for HCFC-123a, a surrogate approach was used to estimate a RfC using data for HCFC-123. HCFC-123 and HCFC-123a share the same molecular formula but differ in the location of the fluorine and chlorine atoms on the carbon backbone. HCFC-123 and HCFC-123a, are converted to trihaloacetic acids through a metabolic pathway that produces reactive trihaloacetyl intermediates which are believed responsible for the toxicity of the parent compound. Toxicokinetic data available for HCFC-123 included occupationally, acute, subchronic, teratological, one and two generation reproductive, and two-year chronic studies. A surrogate LOAEC of 300 ppm for HCFC-123a, based on decreased body weight and body weight gain and significant changes in clinical chemistry parameters from a chronic inhalation bioassay with HCFC-123, was identified as the most appropriate point of departure. Converting the LOAEC to a HEC using a default animal:human ratio of 1 for the blood:gas partition coefficient for extrarespiratory effects, adjusting the HEC to continuous exposures, and applying a composite uncertainty factor of 10,000 (10 for UFHEC, 10 for UF10, 10 for UF20, 3 for UF3, and 10 for UF) yielded a preliminary RfC for HCFC-123a of 34 µg/m³. The conservative RfCs were reviewed and accepted by state regulatory officials.

1852 Derivation of a No-Significant-Risk Level (NSRL) for Pyridine

Z. Guerrette1, B. Wang2, J. Fleischer2, and M. H. Whittaker.1 ToxServices LLC, Ann Arbor, MI; and 2ToxServices LLC, Washington, DC.

Pyridine, a commonly used organic solvent and chemical synthesis intermediate, has been listed on the State of California’s Proposition 65 List as a chemical known to the State to cause cancer. This listing is based on the results of a National Toxicology Program (NTP) two-year drinking water carcinogenicity study in rodents which identified clear evidence of carcinogenic activity in B6C3F1 mice based on increased incidences of liver neoplasms in both sexes, and evidence of carcinogenic activity in female CD rats based on increased incidences of renal neoplasms in males and mononuclear cell leukemia in females. Industries are obligated to comply with the Proposition 65 labeling requirement and drinking water discharge prohibition for products sold in the State of California, unless they are able to demonstrate that pyridine levels in their products result in consumer exposures that are below a specific safe harbor level, known as a No Significant Risk Level (NSRL) for carcinogens. The State of California has to date not published a NSRL for pyridine. In accordance with California EPA guidelines, ToxServices derived a NSRL for carcinogenic activity of 10 µg/L obtained from the NTP carcinogenicity study using benchmark dose modeling. The US EPA’s Benchmark Dose Software (BMDS) was used to model the cancer slope factors, a measure of the risk of carcinogenesis per unit dose, for the single and combined incidences of hepatic neoplasms in male and female mice, single and combined incidences of renal neoplasms in male rats, and incidence of mononuclear cell leukemia in female rats. When inadequate goodness of fit was obtained (p < 0.1), ToxServices dropped the highest dose group from the benchmark dose (BMD) modeling and then performed the modeling on the smaller dataset to determine if the goodness of fit improved. The slope factors derived from BMD were scaled to human equivalent doses (HEDs) using body weight scaling, and the resulting HEDs were used to determine the lifetime average daily pyridine dose that would result in one excess cancer case in an exposed human population of 100,000 (10⁵ cancer risk). The most conservative and health-protective NSRL of 3.9 µg/day was identified from the increased incidence of hepatocellular carcinoma in male mice following pyridine exposure in drinking water. This NSRL can be used as part of an exposure and safety assessment to evaluate compliance with Proposition 65 requirements for consumer products containing pyridine and sold in the State of California.

1853 Derivation of a Screening-Level No Significant Risk Level (NSRL) for Tris(2-Chloroethyl) Phosphate (TRCP)

G. Kuan1, J. G. Fleischer2, and M. H. Whittaker2.1 ToxServices LLC, Ann Arbor, MI; and 2ToxServices LLC, Washington, DC.

TRCP, a flame-retardant and plasticizer used in flexible and rigid foams, is included in California’s Proposition 65 list of chemicals known to the State to cause cancer or reproductive toxicity because of its potential carcinogenicity. This poster derives a screening-level No Significant Risk Level (NSRL) for TRCP. For carcinogens or potential carcinogens, a NSRL is equivalent to an exposure level that results in 1 excess cancer in an exposed human population of 100,000, assuming lifetime exposure at the level in question (27 CCR §25703). Clear evidence for renal tubule cell adenomas and carcinomas was exhibited in a 104-week oral toxicity study with male F344/N rats (NTP 1991) as well as an 18-month oral toxicity study with male ddY mice (Takada et al. 1989). As part of a provisional peer reviewed toxicity value report (PPRTV), the US EPA used benchmark dose modeling to derive a 0.02 (mg/kg-day) cancer slope factor (CSF) for renal tubular cell adenomas and carcinomas in male F344/N rats (US EPA 2009). A literature search confirmed that no additional cancer studies have been published since derivation of the CSF. Incorporating US EPA’s CSF into a calculation to obtain the dose associated with 1 in 100,000 cancer risk while assuming lifetime exposure results in a NSRL of 35 µg/day TRCP. This NSRL value can be used for Proposition 65 compliance determination and evaluation of health risks.

1854 Development of a QSAR Model to Predict Respiratory Irritation by Individual Constituents

M. Wehr1, A. Karwath2, S. S. Sarang3, M. Rooseboom4, P. J. Boogaard4, and S. E. Escher1.1 Fraunhofer ITEM, Hannover, Germany; 2University of Birmingham, Birmingham, United Kingdom; 3Shell International, Houston, TX; and 4Shell International B.V., The Hague, Netherlands. Sponsor: C. Densenbrock

The RespiraTox project, funded by NC3R CrackIT, develops a QSAR model, which predicts the potential of individual compounds to cause irritation in the respiratory tract. We distinguished two mode of actions, i) "sensory irritation", characterized by a decrease in breathing rates, and ii) "tissue irritation" characterized by primarily histopathological findings. QSAR models rely on high quality datasets. We based the classification "irritating to respiratory tract" on several data types from in vivo studies with inhalation exposure. In a tiered approach, we considered information from i) studies with acute exposure from the ECHA CHEM database (DB), ii) the Hazardous Substance DB, iii) the harmonized classification and labelling inventory from ECHA, and iv) repeated dose studies from the Fraunhofer RepDose DB. For later stage validation, we withheld human data from Fraunhofer Breath DB. The final data set includes about 2500 irritating and 800 non-irritating compounds. Prior to model development, the CAS numbers and compound structures were quality controlled and corrected. Two kinds of information were generated
from the compounds structures: i] structural descriptors (ECFPs), and ii] physico-chemical properties. We explored several machine learning algorithms including Logistic Regression (LR), Random Forests (RF), and Gradient Boosted Decision Trees (BT) to derive a classification model. The internal validation procedure employed stratified k-fold cross-validation (k=5). The overall approach adheres to the five OECD principles. The criteria used to measure performance of the model is chosen by receiver operating characteristic (ROC) curve (AUC). The AUC for LR using the combined feature set is 0.71. The optimal performance for both RF and BT is 0.78. The applicability domain is determined by features with highest impact on the final model. The current approach will be further refined and improved (e.g. by differentiating sensory and tissue irritation). The final model will be provided online as a friendly interface to be used by toxicologists, regulators, and overall to reduce the testing of animals.

1855 Updated Modeling Indicates Historical Sterilization Worker Ethylene Oxide Exposures Were Higher Than Assumed in the US EPA IRIS Assessment

A. Li*, P. Sheehan1, C. Valdez-Flores3, and K. Bogen3
1 Exponent Health Science, San Francisco, CA; 2 Exponent Health Science, Oakland, CA; and 3 Texas A&M University, College Station, TX.

The 2016 US EPA IRIS assessment cancer slope of 5 x 10^{-3} (µg/m^3)^{-1} for ethylene oxide (EO), which implies that a chronic inhalation of just 0.1 parts per trillion of EO in air has a 10^{-4} increased cancer risk, was based on NIOSH epide- miology studies of workers exposed to EO in contract sterilization operations between 1938 and 1986. That assessment relied on exposure estimates NIOSH developed for those workers using a statistical regression model validated by fitting EO air-monitoring data obtained nearly exclusively starting in 1978 and including no pre-1976 data. The NIOSH EO exposure model predicted a decreasing trend in sterilizer operators EO exposures (worker who were most heavily exposed to EO) that continued in trend from 1978 to 1980 toward in primary that model by decreasing sterilizer chamber gas back in time prior to 1978. This NIOSH-predicted trend was based only on a post-1978 statistical correlation without independent verification using any pre-1976 measurements or consideration of the EO sterilization equipment or operation (EOSEO) prior to 1978. A new physical model was developed using empirical data from published literature bearing on EOSEO, historical data on EO kill concentrations, measured EO residue levels in sterilized materials, data on EO concentrations in a sterilization chamber following one or multiple washes, and information on routine operator practices from highly experienced sterilizer operators from the pre-1978 period. Model estimates were benchmarked against the NIOSH estimate for 1978/80 EO concentration estimates. The ex-posure levels for jobs with the maximum concentrations were estimated to be more than 5-fold greater than NIOSH-estimated exposures between 1938 and 1960. In other words, modeled concentrations using physical/engineer- ing information contradict NIOSH estimates that workers experienced lower EO concentrations from the mid-1930s through the 1960s compared to those measured in 1978. Because underestimated exposures generally lead to over-estimated cancer risks, more detailed and empirically based assessment of historical EOSEO and resulting EO exposures experienced by sterilizer workers is required for a realistic EO cancer risk assessment.

1856 Hazard Characterization of Acrylates by In Vitro and Ex Vivo Models—An Update of the ExiTox Project

S. Schramm1, M. Wehr1, O. Danov1, H. Obernolte1, J. Knebel1, J. Koschmann1, C. Meckbach1, M. Niehoff1, P. Braubach1, D. Jonigk1, T. Hansen1, A. Braun1, K. Sewald1, and S. Escher1. 1 Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; 2 geneXplain GmbH, Wolfsbüttel, Germany; 3 Institut für Bioinformatik, Universität medicin Göttingen, Göttingen, Germany; and 4 Medizinische Hochschule Hannover, Hannover, Germany. Sponsor: C. Dasenbrock

ExiTox (Explain Inhalation Toxicology) aims to develop an integrated approach for the hazard characterization of inhalable compounds without in vivo animal testing. Different in vitro and in silico models are developed by assessing groups of compounds that share structural properties and induced a shared toxicological effect pattern in existing in vivo studies with repeated exposure via inhalation. The shared toxicological effects in these read-across groups might indicate a shared mode of action. We hypothesize that in vitro data can be used to strengthen the read-across hypothesis e.g. by showing shared adverse outcome pathways. We selected a group of four aliphatic acrylates, which induced inflammation and hyperplasia in the respiratory tract of the test animals at dose levels ranging from 15-25 ppm. These acrylates were tested submerse in A549 cells and human precision-cut lung slices (PCLS) dose-dependently. Exposure occurred over three days for one hour. In A549 cells the cytotoxicity of acrylates was assessed with EC50 values of 2.15, 3.7, 1.12 and 1.57 mM for methyl acrylate, ethyl acrylate, propyl acrylate and butyl acrylate, respectively. Comparable to cells, PCLS showed similar sensi-tivity with the EC50 values of 1.61, 3.02, 2.99 and 4.48 mM for methyl acrylate, ethyl acrylate, propyl acrylate and butyl acrylate, respectively. The bioinformatic process chain includes analysis of whole transcriptional RNA-seq data and the use of tools and technology of all compounds to detect the expression changes, focus on regul-ation via enhancers and underlying miRNA levels, involves network analysis to identify potential biomarker up to a postulated diagnostic profile for each specific read-across group. The results for DEG and miRNA will be presented. This work was supported by BMBF grant FKZ 031A269A-D.

1857 Estimating the Risk of Long-Term Health Effects following Acute Exposure to Cholinergic Agents

K. R. Wegman1, L. Roszell2, J. Cox3, D. Bradley4, S. A. Ralston1, P. Wax5, and C. McKay2. 1 Battelle Memorial Institute, Columbus, OH; 2 US Army Public Health Center, Aberdeen Proving Ground, MD; 3 Department of Homeland Security, Aberdeen Proving Ground, MD; 4 Department of Homeland Security Chemical Security Analysis Center, Aberdeen Proving Ground, MD; and 5 American College of Medical Toxicology, Phoenix, AZ.

The acute effects of many chemicals are well described with supporting data through traditional toxicology studies. In contrast, long-term health effects resulting from a single acute exposure are sparsely supported by epidemio-logical studies of workers exposed to toxic agents. In this study, we used the International Cholinergic Agents (ICA) project 50 year data set to develop a risk estimation approach to identify potential biomarkers up to a postulated diagnostic profile for each specific read-across group. The results for DEG and miRNA will be presented. This work was supported by BMBF grant FKZ 031A269A-D.

1858 Derivation of a No Significant Risk Level (NSRL) for Acrylamide

B. Wang, Z. Guerrette, M. H. Whittaker, and J. Fleischer, ToxServices LLC, Washington, DC.

Acrylamide is included on the State of California’s Proposition 65 list as a carcinogen based on evaluations by authoritative bodies (International Agency for Research on Cancer (IARC) and US Environmental Protection Agency (US EPA)). Acrylamide is mainly used as a monomer in the synthesis of polycrylamides, but is also found in cigarette smoke and hence indoor air. More recently, acrylamide was found to be generated in carbohydrate-rich foods processed by standard cooking methods such as baking, frying and roasting. As a result, acrylamide is found in many types of foods, including breads, cereals, coffee, cookies, French fries, and potato chips. In 1990, California’s Office of Environmental Health Hazard Assessment (OEHHA) established a no signifi-cant risk level (NSRL) of 0.2 µg/day for acrylamide based on a cancer potency factor established by US EPA. OEHHA proposed an updated NSRL of 1 µg/day in 2008, and withdrew it in 2009. Since then, multiple cancer studies, mode of carcinogenic action studies and reviews have been published, includ-ing, in 2010, an updated carcinogenicity assessment published by US EPA’s Integrated Risk Information System (IRIS). Additionally, in 2012 the National Toxicology Program (NTP) completed lifetime bioassays of acrylamide car-cinogenicity in rats and mice. The objective of this project is to develop an updated NSRL for dietary exposure to acrylamide. A comprehensive literature review identified 50 models are developed by...
review indicated that the mouse is the most sensitive species to the carcinogenic activity of acrylamide. Using benchmark dose modeling and combining the incidences of multiple tumors, cancer slope factors (CSFs) of 0.481 (mg/kg/day)\(^{-1}\) and 0.33 (mg/kg/day)\(^{-1}\) were derived based on increased incidences of neoplastic lesions in Harderian gland, lung, and stomach in male mice and Harderian gland, lung, mammary gland, ovary, skin, and stomach in female mice, respectively, as reported in the NTP chronic bioassay. Both CSFs were converted to the same human equivalent CSF of 0.61 (mg/kg/day)\(^{-1}\) using a pharmacokinetic (PK) scaling approach based on physiologically based pharmacokinetic (PBPK) modeling. This CSF was used to derive a NSRL of 1.1 μg/day at the cancer risk level of 1 in 100,000 (10\(^{-5}\)). When it can be demonstrated via quantitative exposure assessments, that the daily consumption of exposure to acrylamide is below the NSRL, industries are exempt from the Proposition 65 labeling requirement and drinking water discharge prohibition.

### 1859 Risk Assessment of Poly Chlorinated Biphenyls (PCBs) Levels in Water, Sediment and Edible Biota from a Contaminated Tropical Ecosystem

A. I. Usere, O. M. Egbutu, and O. L. Chukwu, University of Lagos, Lagos, Nigeria.

Over the years, contamination of aquatic ecosystems with persistent organic pollutants (POPs) has been an issue of global concern due to the potential for ecological and human health risk. This study assessed the risk associated with the levels of PCBs in surface water, sediment and Chrysophyta nigroditatus from Agboyi Creek, South-west Nigeria using a Hewlett Packard GC 5890 Series 11. The study detected 27 PCB congeners in all examined samples in the order; water > sediment > fish. Σ-penta-PCBs accounting for 19% of total PCBs recorded was the most dominant in all examined samples. The levels of total indicator PCBs (Σ-PCBs) in sediments (0.116 to 229.38μg/kg) exceeded the Canadian Sediment Quality Standard threshold effect level of 0.03μg/kg and the National Oceanic Atmospheric Administration threshold effect level (NOAA TEL) for fresh and marine sediments indicating high ecological risk. Furthermore, the levels of the non-ortho-substituted coplanar PCBs and estimated toxic equivalent quotient (TEQ) which were higher than NOAAs fish toxic equivalence factors (TEF) in fish suggest the potential for adverse effects in populations with high consumption rate. This calls for effective policies and stringent regulation for the protection of ecosystem and human health.

### 1860 Concordance of Dose-Response Modeling with Critical Effect LOAEL in the Derivation of an Oral Reference Dose for 2,4-Pentanediene

K. D. Cox, S. Lampe, and J. C. English, NSF International, Ann Arbor, MI.

General population exposure to 2,4-pentanediene (2,4-PD) may occur from its use in paints, cleaning agents, solvents and coatings (some of which have drinking water contact applications). Exposure to 2,4-PD can also occur through inhalation as 2,4-PD is permitted for indoor and outdoor use. An oral risk assessment was needed to establish allowable drinking water levels. Absent any human health effect data, hazard identification relied on laboratory animal data, which identified treatment-related effects following oral or inhalation exposure including frank effects (mortality), generalized systemic toxicity (evidenced by reduced body weights), neurotoxicity, thymic toxicity, and fetotoxicity. Oral-route repeated dose toxicity data for 2,4-PD were limited to non-standard short-term studies (≤15 days). In a subchronic inhalation study in F344 rats, 2,4-PD caused significant mortality at the high exposure level of 29 mg/kg/day and BMDL\(_{03}\) of 18 mg/kg-day were determined from the available studies. In a subchronic inhalation study in F344 rats, 2,4-PD caused significant mortality at the high exposure level of 29 mg/kg/day and BMDL\(_{03}\) of 18 mg/kg-day were determined from the available studies. The critical effect identified from the available studies was fetotoxicity at 202 ppm (human equivalent dose of 29 mg/kg-day). Using benchmark dose modeling (BMD), a BMD\(_{05}\) of 29 mg/kg-day and BMD\(_{01}\) of 18 mg/kg-day were calculated for the decrease in male fetal weights (litter based). Following US EPA BMD guidelines, a benchmark response (BMR) of 3% was selected, as it is ideal to have empirical data points at or near the BMR. The fetal weight decreases of 0.6% at 7.8 mg/kg/day and 3% at 29 mg/kg/day served as the basis of the no- and lowest-observed adverse effect levels, respectively, defined based on statistical significance compared to controls. Confidence in the BMD modeling is demonstrated by the concordance of the BMD and the LOAEL for the critical effect. Using a total uncertainty factor of 1000x (3x interspecies, 10x intraspecies, 3x subchronic, 10x database), an oral RFD of 0.018 mg/kg-day was determined for 2,4-PD. The resulting Total Allowable Concentration in drinking water was 100 μg/L.

### 1861 Cefcr LRI AIRM-8: Prediction of STOT-RE Classification by New Approach Methodologies

S. E. Escher\(^1\), M. Cronin\(^2\), J. Firman\(^3\), T. Magdziarz\(^2\), J. Rathman\(^4\), and C. Yang\(^5\).

1Fraunhofer ITEM, Hannover, Germany; 2Liverpool John Moores University, Liverpool, United Kingdom; and 3Molecular Networks GmbH, Nürnberg, Germany; Sponsor: C. Dasenbrock

The AIRM-8 project aims to assess the ability of in vitro data from the Tox21 program to predict STOT-RE categories of a range of chemicals. The application of New Approach Methodologies (NAMs) in risk assessment is an area of intensive research. AIRM-8 aims to advance the understanding of the use of NAMs by analysing a different way of predicting systemic toxicity, especially the STOT-RE classification. STOT-RE classification is based on the NOAEL of the in vivo study and does not consider the type of effect or the organ affected. If prediction of STOT-RE classification by NAMs is possible, this will contribute to a paradigm shift in risk assessment and will motivate the use of NAMs in prioritisation and labelling, and eventually in safety assessment as well. STOT-RE classifications were gathered and derived from different sources e.g. from a set of 90 day studies with repeated oral exposure (extracted from the RepDose/ToxRef/Hess and Cosmos databases) and the inventory of harmonised classifications was parallel, with the AC50 values from Tox21 and considered all values occurring at sub-cytotoxic concentrations. The sparse data matrix of the 43 individual assays was aggregated to seven categories representing six toxicity pathways and cytotoxicity values. The intersection of both the in vivo and in vitro data resulted in a data set of 749 compounds. For large-scale in-vivo extrapolation (IVE) relevant data such as plasma protein binding, renal and hepatic clearance were identified from existing data sets and the literature. Prior to in silico profiling, the structural information was quality controlled and corrected. From a range of statistical methods, k-nearest neighbours (kNN) and random forest (RF) were selected as the models for prediction of the classification.

In addition, seventeen read-across groups were defined. The grouped compounds share structural characteristics and specific/unspecific in vivo apical findings/target organs. Groups were distinguished for which a shared toxicological effect pattern might be indicative of a shared mode of action from those with unspecific toxicological effects e.g. weight changes or no toxicological effects. In these read-across groups, we analysed the mechanistic links between the in vitro results and the in vivo apical endpoint leading to STOT-RE classification. Financial support for this work was provided by the CEFIC Long Range Research Initiative (CEFIC LRI AIRM-8).

### 1862 Toxicity of JUUL Fluids and Aerosols Correlates Strongly with Nicotine Concentrations

F. Omaiyi\(^2\), K. J. McWhirter\(^2\), W. Luo\(^2\), J. F. Pankow\(^2\), and P. Talbott\(^1\).

1University of California Riverside, Riverside, CA; and 2Portland State University, Portland, OR.

JUUL EC products have become very accessible and popular among middle school and high school students. The purposes of this study were to: (1) identify and quantify flavor chemicals in JUUL EC pod juice flavors purchased online and in stores and (2) determine if these products are cytotoxic using in vitro models. Eight JUUL pod flavors were analyzed using GCMS to identify and quantify flavor chemicals in pod juice and aerosols made at variable flow rates. BEAS-2B cells were exposed to fluids and aerosols for 24 hrs and cytotoxicity was determined using methyl tetrazolium (MTT), and neutral red assays. 58 flavor chemicals were identified in all the products with three flavors (menthol, ethyl maltol, and vanillin) being detected at concentrations greater than 1mg/mL. Duplicate pods had very similar flavor chemicals compositions. Transfer efficiency of total flavor chemicals in the pod juice into aerosols was generally greater than 75%. Nicotine concentrations generally exceeded 50mg/mL. Both cytotoxicity assays generally revealed very similar patterns of response with the most cytotoxicity revealed at 3% and 10% for cells treated with fluids. At lower concentrations, toxicity was observed with only the MTT assay for 3 of 8 flavors. Very slight levels of LDH leakage into extracellular medium was observed after treatment with aerosols. The toxicity of the aerosols in MTT and neutral red assays was observed between 0.4% - 3% when compared to the fluids. Fluids and aerosols from JUUL products are cytotoxic and affect cell survival. These data provide new and useful information for users and regulatory agencies on the chemical composition of JUUL products and their potential to cause harm to users.
This review compares exposure and alarm limits for carbon monoxide (CO) in the US and Europe and proposes a new basis for regulating CO. The customary ranking of CO limits by the maximum (max) concentration allowed is contrasted with ranking by the total exposure allowed, calculated as the product of the max allowed concentration and max allowed exposure time in ppm*hours (p*h). This analysis shows that multi-tier CO standards allow 2 to 5 times more exposure from lower concentrations of CO over longer times than the US maximum exposure to higher levels. No support for this bias is found in the literature. The WHO, for example, allows total CO exposure up to 146 p*h when the concentration is 7 mg/m³ (6.1 ppm) but only up to 22 p*h at 100 mg/m³ (87.3 ppm). The UL 2034 standard for home CO alarms, in contrast, allows up to 100 p*h at the highest alarm level (400 ppm) but 280 p*h at the lowest (70 ppm). The US NIOSH recommends the same 280 p*h for the maximum exposure of workers on 8-hour shifts, while the US OSHA permits up to 400 p*h per shift—the highest of any CO standard. CO alarm standards also specify a concentration below which even continuous exposure is considered harmless and should never trigger alarms: 70 ppm in US and 50 ppm in Europe. But these thresholds are not supported by the literature, which includes over 100 environmental epidemiology studies reporting statistically significant increases in adverse outcomes associated with increases in average hourly or daily CO of 1 ppm or less against background CO levels typically around 5 ppm. Most CO alarm and exposure limits are still based on the results of controlled exposure studies. In some cases, the historical basis for these limits was weakened by the realization that regulators mistakenly believed the adverse effects of CO were mediated by blood carboxyhemoglobin (COHb) and could be prevented by keeping levels under 2, 5 or 10%. It is now clear that CO poisoning outcomes do not correlate with COHb, so some new basis for setting exposure and alarm limits is needed. According to the epidemiology literature, fetuses and infants are most vulnerable to CO: they face higher risks from average increases in CO of 1 ppm or less over 1 hour to 1 day that are 1 to 2 orders of magnitude greater than the risks faced by adults. Protecting them will require lowering CO exposure and alarm limits over 10-fold. For the health of everyone, home CO alarm standards also should account for the time delays that currently allow high exposures to occur repeatedly without warning. Only immediate CO alarms can actually prevent CO poisoning.
An In Vitro Human Assay for Evaluating Immunogenic and Sensitization Potential of Personal Care and Cosmetic Products

Cardno-ChemRisk, San Francisco, CA;

Alcyomics, Newcastle Upon Tyne, United Kingdom; Newcastle University, Newcastle upon Tyne, United Kingdom; Cardno-ChemRisk, Boulder, CO; and Cardno-ChemRisk, Aliso Viejo, CA.

The recent ban and calls for reduced testing of cosmetics on animals present a unique challenge for product safety evaluation. With the reduction or elimination of animal testing, manufacturers are left with limited options, as fewer robust in vitro tests are available and human studies are costly. The purpose of this study was to evaluate the safety of a hair cleansing conditioner by utilizing a novel in vitro human skin test with high specificity and sensitivity for assessing immunogenic and sensitization potential. Peripheral blood mononuclear cells (PBMCs) and human skin biopsies were obtained from healthy volunteers and monocyte derived dendritic cells (MoDCs) were generated. MoDCs were primed by hair cleansing conditioner for 24 hours and then co-cultured with autologous lymphocytes and dendritic cells for 4 days. After the 4 day culture, primed MoDCs were cultured with skin biopsies for 3 days. The skin biopsies were then fixed, sectioned, and stained for histopathological evaluation. Histological damage was graded from 1 to 4; grade 1 represents a negative result for tissue damage and grade 2 or more represents a positive result for tissue damage. Additionally, T cell proliferation and IFNγ levels were determined. The results of this study showed that treatment of PBMCs with the hair cleansing conditioner resulted in acceptable cell viabilities. Treatment of MoDCs with the hair cleansing conditioner or negative controls did not lead to increased T cell proliferation, whereas the positive control treatment did significantly increase T cell proliferation. Human skin biopsies exposed to the negative control and cleansing condition remained undamaged (grade 1), whereas exposure to the positive control resulted in tissue damage (grade III). Together, these results demonstrate that the hair cleansing conditioner did not elicit an immunological or sensitization response at the concentration tested. The results of this study demonstrate that this in vitro human assay is applicable and well suited for personal care and cosmetic product safety evaluations.

Fit-for-Purpose In Vitro Assays in Risk-Based Decision Making—Example with Estrogenic Compounds

SciVation, Durham, NC; Integrated Laboratory Systems, Inc, Morrisville, NC; and ToxStrategies, Inc, Cary, NC.

Chemical risk assessment relies on expensive in vivo studies, and the current scale of animal testing is insufficient to address chemical safety concerns as regulatory agencies require more complete toxicity data. We demonstrate a practical tiered testing approach to reduce animal use by employing multiple levels of risk prioritization. A fit-for-purpose uterine estrogen assay was coupled with in silico and high-throughput in vitro to in vivo extrapolation (HT-IVIVE) to improve prioritization of estrogenic compounds and support in vitro to in vivo hazard characterization in a tissue-specific context. Initial prioritization was based on activity in estrogen receptor (ER) dependent Toxtast assays. To assess uterine-specific reactivity, 112 Toxtast-prioritized compounds were screened in the uterine estrogen response assay for ER-mediated proliferation in Ishikawa cells, a human uterine cell line. Estimates of activity (AC50s) were based on dose-dependent proliferation, and quantitative in vitro to in vivo extrapolation (Q-IVIVE) was used to predict a human equivalent dose (HED) for each compound. Estrogen response assay-derived HEDs were compared with in vivo points of departure from existing uterotrophic assay and two-generation reproductive toxicity studies. Pearson correlation (in log-space) between in vitro HEDs and in vivo points of departure was 0.47. Estrogen response assay-derived HEDs were lower than in vivo points of departure in 37 (93%) of 40 compounds active in both models. Of 56 compounds active in in vivo studies, 16 (29%) were inactive in the estrogen response assay, possibly due to differences in metabolism in the two test systems. Our positive control, the synthetic estrogen 17alpha-ethinylestradiol, produced mean HEDs of 0.56, 0.030, and 0.0030 µg/kg-day in the Toxtast assays, estrogen response assay, and in vivo studies, respectively. These results support the use of fit-for-purpose assays to refine chemical risk prioritization based on the estrogen response assay’s range of detection and characterization of a potent ER agonist, which are improved over Toxtast assays. Developing well-accepted and more efficient in vitro assays and IVIVE methods is crucial for the proper interpretation of in vitro hazard data for health risk assessment.

Human Health Risk Assessment of Heavy Metals in Children’s Foods

D. E. Badger, C. E. Gillie, and M. L. Kreider.

Cardno ChemRisk, Pittsburgh, PA.

Concerns have recently been raised about the presence of heavy metals in children’s foods following analyses by Consumer Reports, a consumer watchdog, and the Environmental Defense Fund (EDF), a nonprofit environmental advocacy group. Although Consumer Reports has not made its dataset publicly available, the EDF presented its analysis based on the US Food & Drug Administration’s US FDA evaluation of foods commonly eaten by infants and toddlers, which reported levels of lead (Pb) and cadmium (Cd) in approximately 400 samples of children’s foods. In their analysis, they did not perform a risk assessment, EDF suggests that heavy metals in foods are health risks. The objective of our study was to determine whether the detected levels of Pb and Cd in the US FDA’s evaluation posed any health risks to children. Using the average food intake rates of children described in the US Environmental Protection Agency’s (US EPA) Exposure Factors Handbook (EFH), the US EPA reference dose (RfD) for Cd, and the California Office of Environmental Health Hazard Assessment’s (OEHHA) maximum allowable dose level (MADL) for Pb, we calculated hazard indices (HI) for daily consumption of each metal in children’s foods. We additionally calculated lifetime cancer risk estimates for the consumption of metals in children’s foods based on the OEHHA’s oral slope factor for Pb. The HI were less than 1 across the ten food product categories we considered, with the highest HI in juice boxes and pouches (0.46) and peanut butter (0.14) for Cd. The cumulative lifetime risk estimates for each of the product categories were less than 1.0x10^-6 (3.2 x10^-5 to 1.5 x10^-6), indicating that there would not be an increased lifetime cancer risk from exposure to Pb in foods consumed during childhood. Overall, the results of our analysis suggest that a child’s typical intake of these foods would not lead to adverse health effects from Pb or Cd.

Considerations for Grouping Different PFAS Together to Develop Guidance Values

1Gradient, Cambridge, MA; and 2AVROBIO, Cambridge, MA.

Regulatory agencies worldwide have taken an interest in developing acceptable levels of low- and polyfluoroalkyl substances (PFAS) in milk drinking water. Because there are so many different PFAS, it is challenging to generate values that are based on toxicokinetic and toxicological studies of each individual chemical. Some agencies have approached this challenge by grouping PFAS together and setting one limit for the combined concentrations of the chemicals. For example, US EPA set a combined drinking water health advisory of 70 parts per trillion (ppt) for the sum of perfluorooctanoate (PFOA) and perfluorooctane sulfonate (PFOS). For PFOA, PFOS, perfluorohexane sulfonate (PFHxS), perfluorononanoic acid (PFNA), and perfluorohexanoic acid (PFHxA) combined, the Massachusetts Department of Environmental Protection set a drinking water value of 70 ppt, while the Vermont Agency of Natural Resources set a combined value of 20 ppt. We conducted an analysis of the toxicological and kinetic data for six perfluorinated chemicals, including perfluorobutanoic acid (PFBA), perfluorobutane sulfonic acid (PFBS), PFHxS, PFNA, PFOA, and PFOS, with the aim of determining whether grouping of any of these PFAS for regulatory purposes is scientifically sound according to standard US EPA methodology. Both the critical toxicological effects identified by regulatory agencies and the kinetics differ among the PFAS, which limits the utility of grouping them together for regulatory purposes. For PFOA, PFOS, and PFNA, the endpoints are developmental. Agency-identified critical effects for PFHxS are body weight and serum lipid levels, and increase in prothrombin time. Decreased cholesterol has been identified as the critical effect for PFBA, and kidney histopathology and blood changes for PFBS. Regarding toxicokinetics, shorter-chain PFAS such as PFBA and PFBS have substantially shorter half-lives in the human body than the longer-chain PFAS. Based on our analysis, we concluded that PFAS should only be grouped together for the setting of regulatory guidelines if the compounds have both similar endpoints for toxicity and similar half-lives. According to US EPA methodology, PFOA, PFOS, and PFNA are appropriately grouped together based on similar critical effects and half-lives but PFBA, PFBS, and PFHxS should not
be grouped with PFOA, PFOS, and PFNA or with each other. Our analysis pro-
vides guidance for setting science-based regulatory levels for PFAS in drink-
ing water.

1871 Risk Assessment to Determine Proposition 65 Compliance for a Consumer Product: Diisononyl Phthalate
S. Pacheco Shubin, I. Mohar, and T. A. Lewandowski, Gradient, Seattle, WA.

This risk assessment estimated the potential consumer exposure to diisononyl phthalate (DINP, CAS 28553-12-0) associated with a foam material present inside an upholstery cushion. The focus of the evaluation was California’s Proposition 65, which requires product warning labels if products contain certain hazardous chemicals above regulatory limits. DINP has been listed as a carcinogen to the State of California to cause cancer under Proposition 65. The No Significant Risk Level (NSRL) of 146 micrograms per day is based on liver cancer and leukemias observed in rodent studies. Product chemical analysis indicated the foam inside the upholstery cushion exceeded the Consumer Product Safety Commission limit of 0.1% (1,000 parts per million) for phthalates; however, it was unclear whether exposure to this chemical would exceed the Proposition 65 NSRL under typical product use conditions. Our evaluation of potential consumer exposure to DINP consisted of two steps: estimating each route-specific exposure concentration on a micrograms per day basis and then comparing the dose estimates to the NSRL. The routes of exposure evaluated were dermal, inhalation, and oral, although the last was considered highly unlikely. We relied on US EPA and California EPA sources for general exposure parameters and on previously published studies that measured migration of DINP from upholstery materials to adjacent environmental media. The assessment was conservative, erring on overestimating exposure when uncertainties were present for particular assumptions used in the calculations. When we compared our exposure estimates to the California Proposition 65 NSRL, the results indicated that exposures to DINP in the foam were below the NSRL, specifically 1.6 to 3,200 times lower depending on the particular exposure scenario considered. These results suggested that the product was in compliance with the Proposition 65 Safe Harbor provisions.

1872 Evaluation of the Carcinogenic Mode-of-Action for Tetrachloroethylene and Propylene for an Occupational Exposure Limit
L. Bailey, Gradient, Cambridge, MA.

Tetrachloroethylene (PCE) is classified by the United States Environmental Agency (US EPA) as “likely to be carcinogenic in humans,” based primarily on evidence of increased liver tumors in mice. Evidence of an association between PCE exposure and cancer in humans is inadequate or limited at best, with few studies showing positive associations, and for those studies that do, exposure estimates are lacking and/or confounded by exposure to other potential carcinogens. The metabolism of PCE yields multiple metabolites through two main pathways: (1) the “oxidative pathway” via cytochrome P450 metabolism, and (2) the “glutathione (GSH) conjugation pathway” via GSH transferase activity. PCE and its main oxidative metabolite (trichloroacetic acid (TCA)) exhibit little, if any, genotoxicity. The GSH metabolizers (trichloro-

1873 Rapid Evidence Mapping for Health: A Case Study
J. Lam1, B. Howard1, D. Thayer2, and R. Shah1, 1Sciome LLC, Research Triangle Park, NC; and 2US EPA, Research Triangle Park, NC.

Stakeholders in the field of environmental health are increasingly relying on tools and practices from the disciplines of evidence synthesis and systematic review to summarize the literature and identify scientific consensus with respect to potential health risks. Given the ever-accelerating pace of publications in this field, the practice of “evidence mapping” is being increasingly used to identify the key areas of study relevant to a given topic along with gaps in the literature. However, constructing detailed evidence maps can be resource-intensive, limiting their utility for practical implementation, particularly for broader questions of interest. As a result, approaches that increase the speed and reproducibility of evidence mapping are in great demand. Here we outline a process called “rapid evidence mapping” (REM), which we define as a resource-efficient form of knowledge synthesis in which components of the systematic review process are simplified to produce a rapid and qualitative representation of the scientific evidence. We show how rapid evidence maps can be created with the aid of Sciome’s text-mining and machine learning software, and to illustrate the application of the procedure, we describe a proof-of-concept case study on the topic of low-calorie sweeteners (LCS) with respect to human dietary exposures and health outcomes. The resulting REM produced similar findings compared to a traditional evidence mapping of the same topic (Wang et al., 2016), but required significantly less time, effort, and resources to create. Furthermore, a sensitivity analysis evaluating the set of studies included at 25% recall (i.e., the point at which the machine learning algorithms predicted we had identified 25% of all relevant references) would have resulted in the same conclusions regarding the current state of the science and existing research gaps. This observation suggests that further efficiency gains can be achieved by mapping only a computer-selected subset of the available literature. REMs can be used to quickly summarize the available body of evidence relevant to a research question, identify gaps in the literature to inform future research, and contextualize the design of a systematic review within the broader scientific literature, significantly reducing human effort while yielding results comparable to those from traditional methods. The potential time savings of this approach make it a powerful tool for rapidly translating knowledge to inform science-based decision-making.

1874 The Norwegian Biomonitoring Study in Euromix: Comparison of Modeled Internal Exposures to BPA, BPS and BPF from Foods, Cosmetics and Thermal Paper with Urinary Concentrations
T. Husøy1, M. Andreasen1, H. Dirven1, F. Sonnet1, N. von Goetze2, A. K. Sakh1, K. Hungerbühler1, and C. Karrer1, 1Norwegian Institute of Public Health, Oslo, Norway; and 2Institute for Chemical and Bioengineering, Zurich, Switzerland.

The Horizon 2020 EuroMix project develops validated test strategies for hazard and exposure assessments of chemical mixtures. In order to examine the plausibility of source-to-dose calculations for environmental chemicals, a human biomonitoring (BM) study was performed for two periods separated by 2-3 weeks, adult volunteers (44 males and 100 females) kept detailed diaries on food consumption, the use of personal care products (PCPs) and the handling of thermal paper (TP) receipts. In parallel, 24 h urine samples were collected. Urinary levels of the bisphenols (BPs) BPA, BPS, BPB and BPF were measured for the first 24 h study period using ultra-high performance liquid chromatography and tandem mass spectrometry. BPA and BPAF were not detected. Exposures to BPA, BPS and BPF from foods, PCPs, and TP were modeled for the study population. The risk assessment tool MCRA was used for calculating individual external exposure from foods, aggregating dietary with non-dietary exposure from PCPs and TP, converting external to internal exposure using physiologically based pharmacokinetic models, and for the comparison with BM data. The selection of concentration data for exposure calculations followed two scenarios (Sc): For Sc1 samples from Norway or adjacent countries were prioritized, for Sc2 samples that had been analyzed for multiple BP analogs. In Sc1, canned fish (hake) and pasta contributed most to BPA exposure from food, while in Sc2, BPA in semi-skimmed milk and BPF in mustard were most important dietary contributors. If BP co-exposure occurred in Sc2, BPA was the main contributor for low exposures, while the BPF contribution increased with higher BP exposure. For PCPs, the median values of all BP exposure estimates in Sc1 and Sc2 were higher for women than for men, mostly with a large overlap between their 95% confidence intervals. Moisturizer, mouthwash, hairstyling products, hand soap, and hand cream were important determinants for both genders. TP had been handled by only 24 % of the participants on the first study day, and most often only once that day. Assuming single exposure to BPA and BPF from TP in Sc1 and
Acute Dermal Toxicity Studies of Aircraft Engine Oils

There is little data available on toxicity levels of used aircraft engine oils relative to their unused (new) versions. This study was conducted to determine if new engine oils and their used versions have the potential to induce dermal irritation. Twelve Male New Zealand White Rabbits (Oryctolagus cuniculus, 19 weeks old) were used to determine the acute dermal toxicity potential of Grade 3, Grade 4, GB, BDP, and 1-OHP aircraft engine oils in their unused and used states. Five fur-free test sites (6 cm² each) located lateral to the midline of the back were treated with two undiluted (0.5 ml) new engine oils and their used versions. The fifth site received RO water as a control. Each treatment was repeated 3 times (3 rabbits/oil type). Each oil was tested under both semi-occluded and occluded conditions. E-Collars were placed on each animal for at least 72 h to prevent ingestion of the test substance and/or gauze plus wrappings and disturbance of site recovery. The 4 hour exposure was followed by gauze plus wrappings removal, and gentle cleaning of sites prior to scoring for erythema and edema at 0.5, 1, 24, 48 and 72 h post exposure based on Draize (1959). Additional observations were made on days 7, 10, and 14 to determine recovery. Exposure to both used and new oils produced dermal irritation consisting of no more than slightly to well-defined erythema and very slight edema. The calculated Primary Dermal Irritation Index (PDII) indicated that all the oils were slightly irritating. Although the PDII values for new oils and their unused versions were not significantly different, they were all statistically higher (p<0.05) than those obtained for the control regardless of the type of occlusion binding applied. The used oils under semi-occlusion conditions yielded larger size effects (Cohen’s d) relative to their unused versions suggesting an enhancement in irritation when the oil is aging. Grade 4 of the used state yielded the largest size effect which was d = 5.9 versus 2.6 for its unused version. The slight dermal irritation resulting from four hours of exposure to oils raises concerns about the magnitude of impact related to prolonged and/or repeated exposure (in compliance with DODI 3216.01). Distribution A: Approved for public release; distribution unlimited (PA Case BB/AW-2018-4411; MSC/PA-2018-0279, 05 Sept 2018).

Characterizing Occurrence and Sensitization Potential of Disperse Dyes in Indoor Environments

Azobenzene-based disperse dyes used to color synthetic fabrics have been characterized as mutagens and contact allergens despite their use in clothing and detection in the aquatic environment. However, little is known about occurrences and health implications of these dyes in indoor environments. Here, we report on identifications, concentrations, and sensitization potentials of several azobenzene dyes in house dust samples collected from 190 homes in the Toddlers Exposure to SVOCs in Indoor Environments (TESIE) study in central North Carolina (2014–2016). House dust samples were collected for each household using standardized protocols. We utilized a data-dependent, suspect-screening analytical strategy to tentatively identify azobenzene-class disperse dyes in house dust. House dust sample extracts were analyzed via HPLC-ESI-HRMS/MS and searched against all compounds in CAS containing p-aminooazobenzene. Using the non-targeted analysis software Compound Discoverer, we tentatively identified >50 prominent features as azobenzene disperse dyes. Using authentic standards, we then quantified five representative azobenzene dyes (Disperse Blue 373, Disperse Orange 25, Disperse Orange 37, Disperse Orange 61, and Disperse Violet 93) and two transformation products (2,6-dibromo-4-nitroaniline and 2-bromo-4,6-dinitroaniline) in the dust samples. Dyes were quantified via HPLC-APCI-MS/MS. One or more dyes were detected in 92% of house dust samples at levels up to 3.25 pg/g house dust. Geometric means ranged from 60 ng/g to 141 ng/g house dust, with Disperse Orange 61 having the highest overall concentration. Because the intrinsic characteristic of covalent binding to proteins is a strong indicator for determining chemical sensitization potential, we used a spectrophotometric in vitro Direct Peptide Reactivity Assay (DPPRA) to measure covalent protein binding via percent peptide depletion induced by representativeazo dyes. Preliminary results demonstrate that dyes such as DISO bind to nucleophilic protein residues and induce up to 41% peptide depletion in a dose-response relationship, indicating their sensitization potential. Results suggest that exposures to disperse dyes from house dust are common and may present sensitization risk, warranting further detailed characterization.

Development of Promising Biomarkers for Prevention against Colorectal Cancer

E. Kim, and M. Yang. Soomyung Women’s University, Seoul, Korea, Republic of.

The incidence of colorectal cancer (CRC) has been steadily increasing, and CRC is expected to be the third most prevalent cancer in 2018 in Korea. However, the etiology of CRC is still obscure, although the consumption of red or processed meat have been declared as one of the causes. Therefore, biological monitoring can be useful to find environmental risks of CRC. We performed a pilot (N=30) and a full case-control study (N= 220; N=110 for each group) and analyzed exposure biomarkers, i.e., metabolites of polycyclic aromatic hydrocarbons and heterocyclic amines in urine, e.g., 1-OHP, PhIP, and MeIQx, and their DNA-adducts in blood, e.g., dG-C8-PhIP, and dG-C8-MeIQx, and -PhIP, by HPLC/FD or LC/MS/MS. For response biomarkers, we quantified homocysteine, malondialdehyde (MDA), and C-reactive protein (CRP) by a clinical analyzer. We also investigated their food contents by FFQ. Finally, we compared these biomarkers to the expression of CRC-related genes, e.g., PTGS2, APC, KRAS, etc., by qPCR arrays. As results, the pilot study showed higher levels of PhIP and dG-C8-MeIQx in the cases than controls (11.96±12.04 vs. 7.84±8.10 ng/mL, p=0.28; dG-C8-PhIP, 5.29±0.11 vs. 5.18±0.08 ng/L, p<0.01). Based on the pilot study, we calculated the N of subjects with power 0.8 as N=218 for the full study. We confirmed some results of the pilot study in the full study, e.g., positive associations between intakes of processed and red meat and between 1-OHP and MDA levels (p<0.01). In the full study, we found positive correlation between lipid intake and levels of MeIQx (p=0.07) and higher levels of lipid intake (g), CRP, and LDL-C in cases than controls (p<0.01). Lipid (g) intake was positively associated with the levels of MeIQx (p=0.07). However, some biomarkers, such as 1-OHP or BMI, were higher in controls than cases. To overcome the drawbacks of case-control studies, we need promising biomarkers, i.e. longitudinal, sensitive and specific biomarkers for CRC. Therefore, dG-C8-PhIP is a potential biomarker for this purpose. This study was supported by a grant (17162MFDS040) from Ministry of Food and Drug Safety in 2017–2018.

Electronic Cigarette Exhaled Aerosol Residue in Field Sites

C. Khachatourian, P. Jacob, A. Sen, Y. Zhu, N. Benowitz, and P. Talbott. *University of California Riverside, Riverside, CA;* University of California San Francisco, San Francisco, CA; and *University of California Los Angeles, Los Angeles, CA.

Electronic Cigarette (EC) users exhale aerosol which can settle on indoor surfaces forming EC exhaled aerosol residue (ECEAR). Little is known about the composition or build-up of this residue in field sites. Our objective was to identify, quantify, and compare ECEAR chemicals in two field sites: an EC user’s living room and a multi-user EC vape shop. We examined the buildup of ECEAR in commonly used materials (cotton towel, paper towel, and terrycloth towel) placed inside and outside each of the field sites. Materials were subjected to different exposure times. Nicotine, other alkaloids, and tobacco-specific nitrosamines (TSNAs) were identified and quantified in controls and field site samples using analytical chemical techniques. Nicotine and nicotine alkaloids were detected in the EC user’s living room. Concentrations of ECEAR chemicals remained relatively constant over the first 5 months, suggesting some removal of the chemicals by air flow in the living room. ECEAR chemicals were detected in the vape shop after 6 hours of exposure and levels continually increased over a month. By 1 month, the nicotine in the vape shop was 60 times higher than in the EC user’s living room. ECEAR chemical concentrations varied in different locations inside the vape shop. Control fabrics had either no detectable or very low concentrations of chemicals. In both field sites, chemicals from exhaled EC aerosols were deposited on indoor surfaces and either remained steady or accumulated over time forming ECEAR. Non-smokers, EC users, and employees of vape shops should be aware of this potential environmental hazard.
1879 Estimating the Evaporation Rate and Time-Varying Generation Rate of Acetic Acid from an All-Purpose Floor Cleaner

S. F. Arnold, H. Kaup, and J. Servadio. University of Minnesota, Minneapolis, MN. Sponsor: L. Peterson

Understanding the relationship between consumer product use and risk of adverse health outcomes is necessary for ensuring appropriate risk management and product stewardship. A preferred method for estimating the systemic and respiratory tract exposure and dose tailored to cleaning products use has been proposed, refining previously issued exposure guidance. The refinement suggests a tiered assessment framework that provides a margin of safety (MOS) estimate for cleaning products use and asthma responses. Tier I requires robust dose-response and exposure data. Tier II uses vetted model estimates to generate human inhalation exposure estimates, based on model inputs sourced from the publicly available and peer-reviewed literature. From these models, a reasonable worst case estimate of exposure can be generated. When high quality model inputs are not available, initial screening level values can be used, recognizing they may result in exposure estimates that greatly overestimate real-world exposures (Tier III). In situations where these overestimates exceed the MOS, refinement of the model inputs may be necessary so that a more realistic exposure estimate can be developed. We conducted in two part study to estimate and evaluate an evaporation and time-varying generation rate for acetic acid emanating from an all-purpose consumer cleaning product formulation used to mop floors. An evaporation rate and time-varying generation were estimated from chamber studies using a small spill model. The Well Mixed Room (WMR) and Near Field Fair Field (NF FF) models, informed by these generation and and generation rates were used to predict airborne acetic acid concentrations evaporating from hardwood floors in an all-purpose room and tile floors in a bathroom. Model predicted concentrations were compared with the measured concentrations collected during a field study. WMR and NF modeled concentrations were comparable, suggesting evaporation and generation rate portability. Further, these rates will support Tier II exposure assessments.

1880 Reassessing Drinking Water Exposures: Relevance of Reactive Electrophiles Formed in Drinking Water Disinfection

C. Prasse1,2, and D. Sedlak1.1 Johns Hopkins University, Baltimore, MD; and 2University of California, Berkeley, CA.

Worldwide, drinking water treatment depends heavily on the use of disinfectants. Unfortunately, the reaction of disinfectants with organic and inorganic water constituents can also result in the formation of (potentially) carcinogenic disinfection by-products (DBPs). Phenolic compounds are of particular relevance as DBP precursors as they are commonly found in many anthropogenic chemicals, including pesticides, flame retardants, plasticizers, pharmaceuticales and personal care products, as well as natural organic matter. While the fate of phenols during reaction with chlorine has been investigated for decades, there is still considerable uncertainty regarding the identity of DBPs that are formed at elevated chlorine exposures, i.e., under conditions typically encountered during disinfection of drinking water. This also holds true for newer treatment technologies such as the application of UV light with and without the addition of hydrogen peroxide with the latter utilizing OH-radicals as strong oxidants. To address this knowledge gap, we used a novel approach that focuses on the identification of reactive electrophiles by investigating the formation of adducts with nucleophilic biomolecules. Similar approaches have previously been used for the identification of toxic metabolites during xenobiotic metabolism. Using the amino acid N-acetyl-lysine and N-acetyl-cysteine as nucleophilic targets, we were able to identify the formation of previously unknown electrophilic dicarbonyl compounds during the reaction of phenol with chlorine and OH-radicals. Experiments with a variety of alkyl-, chlorine- and bromine-substituted phenols revealed that the formation of these ring cleavage products strongly depends on the position of the substituents relative to the hydroxyl group with yields varying between 0 - 45%. The high genotoxicity and mutagenicity of the formed dicarbonyls compounds indicate that they can contribute substantially to the overall toxicity of disinfectated waters if phenolic compounds are present. The results further highlight the suitability of the used approach to specifically identify the formation of electrophilic transformation products that are formed during water disinfection.

1881 The Missing Link: Using the TTC to Provide a Risk-Based Approach for Focusing Non-targeted Analysis Efforts

R. A. Becker1 and J. A. Arnot2.1 American Chemistry Council, Washington, DC; and 2ARC Arnot Research and Consulting, Toronto, ON, Canada.

Resources are increasingly being allocated to apply advanced analytical chemistry methods in a discovery science mode for non-targeted analysis (NTA). NTA and suspect screening analysis (SSA) methods can detect and potentially identify chemicals in various media (e.g., household dust, water, blood, etc.). Yet detection, using advanced analysis with exquisitely low detection limits, is not a surprise. The overarching question, “what does the presence of a chemical in a SSA/NTA study mean in terms of potential effects on health?” cannot be answered from an SSA/NTA study alone because the methods to link SSA/NTA information to exposure to potential risk have not yet been systematically developed. Because SSA/NTA is discovery science, efforts to identify exact structures can be challenging and require considerable resources. Even when a structure is identified, toxicity and exposure data are often lacking. To address these challenges, we propose a tiered method for integrating emerging SSA/NTA data within exposure and risk-based prioritization frameworks. As a first tier, the Threshold of Toxicological Concern (TTC) can be used in conjunction with simple exposure scenarios to interpret and guide SSA/NTA information. For example, the TTC Cramer Class III intake rate of 1.5 μg/kg-day can be combined with US EPA exposure factor handbook drinking water intake rates (e.g., 2 L/day; 80 kg bw) to determine the concentrations in drinking water that correspond to the TTC. In this case, drinking water concentrations less than 60 μg/L in water would not be expected to produce any level of effect (e.g., threshold of effect or exposure) by combining the TTC of 1.5 μg/kg-day with US EPA median estimates for household dust ingestion rates (e.g., 30 mg/day; 80 kg bw), a chemical concentration less than 4 g/kg in dust would not be expected to pose a systemic toxicity risk over a lifetime of exposure. As a second tier this TTC-based approach can be extended to other exposure media (e.g., indoor air) using multi-media mass balance exposure models for further integrating exposures via multiple pathways and for a suite of different sub-populations. Scenarios can be tailored to specific populations, exposure routes and environmental media to focus SSA/NTA activities and resources on identifying and quantifying substances exceeding such risk-based exposure values. The TTC-based framework provides, as a first approximation, a means to interpret and prioritize SSA/NTA studies and emerging data in a risk-based context.

1882 Testing Strategy Development Based on Effects of Low-Level Mixtures of Chemicals in Drinking Water (Sources) in Reporter Gene Assays

M. Dingemans1, H. Besselink2, and T. Ter Laak1,1 KWR Watercycle Research Institute, Nieuwegein, Netherlands; 2BioDetection Systems bv, Amsterdam, Netherlands; and 3University of Amsterdam, Amsterdam, Netherlands.

A plethora of in vitro assays is developed for chemical risk assessment and clinical diagnostics to test effects of individual chemicals and mixtures on different biological processes. In this research, effect-based in vitro reporter gene assays are used to detect effects of realistic low-level mixtures of known and emerging chemicals in water. CALUX reporter cell lines with the luciferase gene coupled to responsive elements detect ligand-specific receptor binding. This is measured as light emitted (luciferase expression results in light emissions) in addition of substrate and benchmarked against a reference chemical response. Possible cytotoxic effects are evaluated using the cytotox CALUX bioassay which constitutively expresses luciferase. A relevant battery of CALUX assays detecting effects of environmental mixtures of chemicals present in water sources is selected in a tiered approach. Effects of low-level mixtures of chemicals extracted from water sources from 8 European countries (Germany, France, the Netherlands, UK, Greece, Hungary, Poland, Switzerland), Israel and India were tested in 17 receptor-based CALUX assays. Some specific in vitro effects (anti-estrogenity, progesterone receptor activation and p53 activation) were only rarely induced, while dioxin receptor-activation was observed almost independently of water type. Other effects were observed variably [PXR activation, estrogenicity, (anti-)androgenicity, glucocorticoid receptor activation, PPAR receptor activation and Nrf2 pathway activation] and were in most cases reduced following water treatment. CALUX analysis results indicated that considerable (regional) differences in drinking water quality from various water sources exist. A battery of effect-based in vitro bioassays as integrated risk measure (detecting the net effect of mixtures of chemicals with the same mechanism-of-action) can be used to benchmark differences and variation in human exposure to low-level mixtures.
Exposure of Third Trimester Human Fetuses to Persistent Environmental Chemicals

R. Björvang, D. Mucs, M. Vinnars, N. Papadogiannakis, H. Kiviranta, P. Rantakokko, P. Ruokojärvi, C. Lindh, C. Yding Andersen, and P. Damdimopoulou. 1 Karolinska Institutet, Stockholm, Sweden; 2 Swedish Toxicology Sciences Research Center, Stockholm, Sweden; 3 University of Copenhagen, Copenhagen, Denmark; 4 University Hospital of Copenhagen, Copenhagen, Denmark; 5 National Institute for Health and Welfare, Kuopio, Finland; and 6 Lund University, Lund, Sweden. Sponsor: J. Flaws

Exposure to persistent environmental chemicals such as organochlorine pesticides (OPs), polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs) and perfluorinated alkyl substances (PFASs) during gestation has been associated to adverse effects on fetal growth and development. Typically, fetal exposure is estimated via analysis of chemicals in maternal serum samples. Whether maternal serum concentrations give a good estimate of fetal tissue exposure levels is not known. We have analyzed the levels of 9 OPs, 10 PCBs, 3 PBDEs and 6 PFASs in autopsy samples collected from 38 stillborn infants (gestational age 30-42 weeks) undergoing cause of death investigation. The samples included maternal serum, placenta, fetal liver, lung, heart, adipose tissue and brain. The study was approved by the Regional Ethical Review Board in Stockholm. Nine of the 28 evaluated chemicals were found over the limit of quantification in every maternal serum sample and 22 in every fetus. The highest chemical load, 58 ng/g tissue (56% p,p'-DDE; 7% PCB-153, 6% PCB-138), was found in adipose tissue followed by 8 ng/g (19% p,p'-DDE; 17% beta-HCH, 17% PFOS) in liver. To study fetal exposure in relation to maternal serum levels, tissue:serum ratios were calculated. The ratios varied from 0.04 to 4.55 and were significantly lower for PFASs compared to the rest of the chemicals. Further, some of the ratios were modified by fetal sex, being higher in males compared to females. In conclusion, all fetuses were intrinsically exposed to mixtures of persistent environmental chemicals with the highest burden being present in adipose tissue. Transfer of the chemicals from maternal serum to fetal tissues varied significantly and was modified by fetal sex. Altogether, our results suggest that maternal serum levels of chemicals give a poor estimate of actual fetal tissue exposure levels.

Association between Maternal Exposure to PCBs and Head Circumference of Male Newborns at Birth in Chiba Birth Cohort (C-MACH)

K. Yanase, A. Eguchi, M. Yamamoto, K. Sakurai, M. Watanabe, E. Todaka, and C. Monja. 1 Graduate School of Medicine, Chiba University, Chuo-ku, Chiba, Japan; 2 Chiba Foundation for Health Promotion and Disease Prevention, Mihama-ku, Chiba, Japan; and 3 Center for Preventive Medical Sciences, Chiba University, Inage-ku, Chiba, Japan.

In a previous study, we reported that maternal exposure to polychlorinated biphenyls (PCBs) was negatively correlated with head circumference at the birth of the newborns. The objective of this study was to see if there were sex differences in the relationship between fetal exposure to PCBs and the body size of the newborns at birth. We used the data of 93 mothers and their singleton infants (born at 36-41 week's gestational age) participated in a birth cohort study, Chiba Study of Mother and Child Health (C-MACH), focusing on environmental health effects on fetuses. After excluding missing data, the data of maternal blood serum from 71 pairs (male newborns (n=29) and female newborns (n=42)) and the data of cord serum from 68 pairs (male newborns (n=28) and female newborns (n=40)) were analyzed. Concentration levels of 13 PCBs, 11 PFASs serum around at 32 weeks gestational age and cord serum were analyzed. Body size of the newborns, which included body weight, length, head and chest circumferences were collected from medical record at delivery. Multiple regression analysis was performed to examine the relationship between the levels of total PCBs and body size in male and female newborns respectively. The level of total PCBs in maternal serum was negatively correlated with head circumference significantly in male newborns (B: -1.18, 95%CI: -2.03, -0.34, p<0.01) but not in female newborns (B: -0.74, 95%CI: -2.58, 1.10, p=0.419) in the model adjusted for potential confounding factors. Also, the level of total PCBs in cord serum was not associated with head circumference significantly. As a result, the sex differences were not found between maternal exposure to PCBs and body size except for head circumference. These findings suggest that maternal exposure to PCBs might affect the head circumference in male newborns. However, the sample size in this study was relatively small, so further study in larger population would be necessary.
1887 Estimated Intakes of Hydroxyanthracene Derivatives (HADs) from Consumption of Drinkable Aloe Vera Products on the EU Market and Foods Consumed in the Background Diet

D. Martyn1, M. Darch1, J. Hu2, T. Smillie3, K. Ngo2, N. Da2, Q. Gao1, and P. Purohit1
1Intertek Scientific & Regulatory Consultancy, Farnborough, United Kingdom; 2Intertek Scientific & Regulatory Consultancy, Mississauga, ON, Canada; and 3Herballife Nutrition, Torrance, CA.

The European Food Safety Authority (EFSA) recently raised safety concerns over evidence of genotoxicity and carcinogenicity of HADs in food supplements used as laxatives on the EU market but was unable to establish a safe intake level. HADs naturally occur in vegetables, spices, herbs and other botanicals, including Aloe vera, which is used in foods and used for medicinal purposes. Due to a lack of available data, EFSA could not estimate unintentional HAD exposure from these sources in the normal diet. The primary HADs found in Aloe vera leaves are aloins A and B. The purpose of this study was to estimate the intake of aloins A and B from drinkable Aloe vera products sold on the EU market which are not intended for laxative use, as well as the intake of known HADs from the normal diet, to determine whether exposure to HADs from these products is of concern. The levels of aloins A and B were analyzed in 15 drinkable Aloe vera products (gels, juices or drinks) from 6 European countries. Maximum potential exposure from each product was calculated based on the daily recommended serving on product labels. Dietary sources of HADs identified in the literature. Exposure to HADs from the normal diet was assessed using the reported concentrations of HADs in food in combination with food consumption data from the EFSA Comprehensive Database (2015) and 3 individual European consumption surveys (from the UK, France and the Netherlands). The estimated intakes of aloins A and B from drinkable Aloe vera products ranged from <1 to 864 µg/person/day. Exposure to HADs from the normal diet were estimated to range from <1 to 600 µg/person/day (mean) and 23 to 3,599 µg/person/day (high-level). The intake of aloins from the analyzed Aloe vera products were below high-background HAD intakes in all instances, and only one sample exceeded the mean estimated exposure from all survey datasets, demonstrating that dietary exposure to aloins A and B from drinkable Aloe vera products are within the range of intakes of HADs consumed as part of the background diet. Furthermore, exposure to aloins A and B from the analyzed Aloe vera products is considerably lower than the exposure levels from supplements used for laxative effects reported by EFSA, of 1.2 to 31 mg/person/day.

1888 The Norwegian Biomonitoring Study in EuroMix: Real-Life Exposure to Bisphenols, Parabens and Triclosan in Humans as Measured in 24-Hour Urine Samples and Associations with Food Consumption and Cosmetics Use

H. Dirven1, M. Andreassen1, H. Hjertholm1, M. Hauger Carlsen2, A. Kaur Sakhi1, A. Sabarezdovic,1 and T. Husoy1
1Norwegian Institute of Public Health, Oslo, Norway; and 2University of Oslo, Oslo, Norway.

The Horizon 2020 EuroMix project develops validated test strategies for the hazard and exposure assessments of chemical mixtures. A human biomonitoring study was performed to study exposure to chemicals as present in foods and personal care products (PCPs). For two 24-h study periods separated by 2-3 weeks, adult volunteers (44 males and 100 females) in Norway kept detailed diaries on food consumption (type/brand, weight, packaging material and time) and the usage of personal care products (PCPs) (type/brand of product, time and number of applications, and number of showers and hand washes). Participants also registered the number of thermal paper receipts handled. Twenty-four h urine samples were collected. Bisphenol A (BPA), bisphenol S (BPS), bisphenol F (BPF), bisphenol AF (BPAF), parabens, triclosan (TCS), triclocarban (TRCB) and oxybenzone (OXB) were measured in the urine collected on the first day. Log transformed concentrations in urine were used in a multivariate linear regression (MLR) analysis with the main food and PCP categories. BPA was detected above the Limit of Detection in 96%, BPS in 29% and BPF in 4% of the urine samples. OXB, TCS, methylparaben (MePA) and ethylparaben (EtPA) were detected in 90-100% of the urine samples and propylparaben (PrPA) and butylparaben (BuPA) in 65% and 50%, respectively. The fraction of standard deviation used to characterize the mixture of chemicals was demonstrated. BPP, BPAF and TRCB were not detected. Higher paraben concentrations were measured in the urine of females compared to males, with mean concentrations of methylparaben (non-significant) and propylparaben (Pr/PA, P<0.05) of 108.16 and 8.82 ng/ml in females and 10.64 and 0.59 ng/ml in males. MLR analysis (all possible categories) showed a significant positive association between MePA and meat consumption (β=1.90, P<0.02), BuPA and bread consumption (β=1.78, P<0.004) and TCS and butter/oil consumption (β=2.12, P<0.002). With respect to the use of PCPs, a positive association was found in men between MePA and the use of hair conditioner (β=2.45, P<0.03) and hair styling (β=2.23, P<0.03), and TRCS and the use of shampoo (β=3.22, P<0.01). No significant associations were found between urinary phenols in females and the use of PCPs. Aggregated exposure estimates from both diet and PCPs are needed to explore the determinants from foods and PCPs on phenols exposure further.

1889 Derivation of Dermal Absorption Values Using Operator Exposure Biomonitoring Studies: A Case Study with MCPA

M. Aggarwal1, J. Y. Domoradzi1, A. W. Morris2, and C. Terry2
1Corteva Agriscience, Newark, DE; and 2Corteva Agriscience, Indianapolis, IN.

Dermal absorption values were derived based on a biomonitoring study (where internal systemic exposures were determined) and the EFSA Model (giving predicted external exposures). The biomonitoring study measured operator exposures associated with the use of a MCPA formulation. Systemic (internal, actual) exposure to individual operators based on urinary excretion of biomarkers, MCPA and H-MCPA (4-chloro-2-hydroxymethyl phenosaccharic acid) was measured. The EFSA Model, adjusted for the specific exposure scenario parameters (application rate, water volume, area treated, body weight and clothing and PPE used), was used to estimate external exposure to these operators based on the exposure scenarios described for each operator in the biomonitoring study. The normal absorption values based on each operator based on the ratio of measured internal systemic exposure to predicted external exposure. A range of absorption values were derived. Following EFSA Dermal Absorption Guidance the mean dermal absorption value was corrected by adding a fraction of the standard deviation to derive a conservative value. The normal absorption values and the EFSA model were applied to the sample size, i.e. number of operators. Taking this approach ensured that the predicted external exposures reflected the measured internal exposures and, therefore, allowed a relevant, but health protective, exposure ratio to be determined and a dermal absorption value to be calculated as 2.9%. The pre-determined data established dermal absorption values of 2.2% (concentrate) and 2.5% (spray dilution) for MCPA which were based on in vitro human and rat in vivo rat studies performed on a different formulation containing MCPA (MCPA SANCO/4062/2001-final, 11 July 2008). In this case study MCPA dermal absorption values calculated using biomonitoring study data match with the dermal absorption values derived from dermal absorption studies. The derived dermal absorption value was then used to assess exposure for operators, residents and re-entry workers associated with handheld applications. All predicted exposures were below the reference dose, AOEL.

1890 Risk Assessment of the Flame Retardant Chemical Tris (1, 3-Dichloro-2-Propyl) Phosphate (TDCPP)

M. A. Babich, and X. Chen, CPSC, Rockville, MD.

TDCPP (13674-87-8) is a flame retardant that may be used in consumer products, such as upholstered furniture, to reduce fire hazards. TDCPP causes both cancer and non-cancer effects in rats (NRC 2000). CPSC previously established the acceptable daily intake of TDCPP as 5 µg/kg/d, and the unit cancer risk as 0.0031 (mg/kg/d)1. Recently, the National Health and Nutrition Examination Survey (NHANES) published 2013–2014 human biomonitoring (HBM) data on urinary concentrations of bis(1, 3-dichloro-2-propyl) phosphate (BDCCP), a major metabolite of TDCPP; HBM data can be used to estimate total human exposure. In addition, CPSC staff reviewed published data on TDCPP levels in household dust [1 to 6 µg/g] and indoor air (average 0.59 ng/ml); these data can be used to estimate TDCPP exposure from multiple sources in the home. In this study, we assess the health risks of total TDCPP exposure from NHANES data and the contribution of the home environment (dust and indoor air) to total risk. Total exposure was estimated from HBM data using a published fractional urinary excretion (FUE) value. We estimate the total average daily exposure (ADE) to be 34 ng/kg-d for adults and 107 ng/kg-d for children ages 6 to 11. This results in an estimated hazard index (HI) of 0.01 for adults and 0.02 for children, for non-cancer effects. The individual lifetime cancer risk is estimated to be 1.5 per million (average exposure) and 12 per million (95th percentile). Thus, some individuals exceed the level of concern for cancer risks of 1 per million. We also estimated the ADE from household dust and indoor air to be 1.2 ng/kg-d for adults and 5.8 ng/kg-d for children. Exposure from household dust and indoor air contribute a fraction (3% to 6%) of the total TDCPP exposure. Other exposure sources, such as direct contact with consumer products (e.g., furniture, baby products) and environmental exposures, should be considered in future risk assessments. This work has not been reviewed or approved by, and does not necessarily represent the views of, the Commission.
Biomarker Based Occupational Exposome

V. K. Nguyen, J. Colacino, and O. Jolliet. University of Michigan, Ann Arbor, MI.

Occupational exposures are thought to be responsible for over 370,000 premature deaths each year. Thus, the precise quantification of occupational exposure and associated adverse health outcomes is necessary to consider in understanding an individual’s exposome, the entirety of chemical exposures in a lifetime. Using the National Health and Nutrition Examination Survey (NHANES) of 116 chemical biomarker concentrations and 10 physiological stress response (PSR) biomarkers measured in 23,002 participants, we implemented an integrative approach to systematically contrast occupational exposure differences across 13 occupational groupings. We conducted a series of multiple regression models with chemical biomarker levels as the outcome variable and occupational groupings as the main predictor while adjusting for age, race, gender, study year, smoking, and poverty-income ratio. In addition, we conducted another series of regression models with each PSR biomarker as the outcome variable and occupational groupings as the main predictor while adjusting for the previously mentioned covariates with the exception of study year. We identified widespread biomarker levels across the different occupational groupings. For instance, biomarker levels of parabens in White Collars on average are higher compared to all other occupational groupings by fold differences ranging from 0.64 to 2.21. We have identified that on average biomarker levels of phthalates in workers from Accommodation, Food Services, and Construction are higher than those of White Collars by fold differences ranging from 0.96 to 1.53 for workers in Accommodation and Food Services and 0.93 to 1.25 for Construction workers. DEET as a metabolite of DEET, was observed to be of higher concentrations in Blue Collars in Mining compared to the White Collars by a fold difference of 3.88. C-Reactive Proteins, one of the PSR biomarkers, have been linked to chronic diseases and in our analyses show the most variability across the occupational groupings with the highest difference found when comparing Blue Collars workers in Mining with the White Collars (1.65 times higher compared to White Collars). Systematically studying the NHANES chemical biomarkers, physiological responses, and occupational data by implementing an untargeted approach enables the identification of expected and unexpected differences in exposure and health outcomes by job categories. These findings can be utilized to prioritize chemicals and workers for toxicological evaluation or health interventions.

Optimization of Real-Time Cell Metabolism Analyzer for Measuring Oxygen Consumption Rate (OCR) in Zebrafish Embryos Exposed to OPFRs

S. Lee and U. Jung. Seoul National University of Science and Technology, Seoul, Korea, Republic of.

Mitochondrial dysfunction is related to the occurrence of serious metabolic disease like diabetes, cancer and Parkinson’s disease. Inhibited oxygen consumption rate (OCR) is valuable evidence for mitochondrial dysfunction. OCR can be measured by real-time cell metabolism analyzer named Seahorse XF Extracellular Flux Analyzer. Recently, the attempt to apply XF-24 analyzer into the zebrafish embryo model is being conducted. However, the experimental conditions and interpretation of obtained results are not well standardized. In this study, we examined various factors (i.e. number of embryos, inhibitor concentrations, and fertilized time) to yield the most stable typical OCR tendency in XF-24 analyzer. The optimized factors were employed in zebrafish embryos exposed to sublethal concentrations (0 control), 3.45, 6.90, 13.80 μM (0.1% DMSO)) of Triclosan to confirm their applicability and exposed to Tris (1,3-dichloro-2-propyl) phosphate (TDCPP) and Triphenyl phosphate (TPH) (0 control), 0.0064, 0.064, 0.64 μM (0.1% DMSO)) to investigate the adverse effects of TDCPP and TPH in zebrafish embryos. The concentrations of three inhibitors were determined through 6 times of optimization experiments. Inhibitors’ concentrations for obtaining typical OCR pattern are followed; Oligomycin (Sigma + Kit) 12.5 μM, FCCP (Sigma + Kit) 8 μM, Rotenone/antimycin-A 1.5 μM. These concentrations were suitable for 3 embryos per one well. OCR exposed to higher concentrations of Triclosan (6.90, 13.80 μM) showed increased proton leak and decreased ATP-linked respiration in a dose-dependent manner. Exposure of TDCPP and TPH caused increased maximal respiration. This study suggests the determinants to obtain the stable OCR pattern in zebrafish embryos using the instrument of Seahorse XF-24 Extracellular Flux Analyzer, making it easier to analyze the comprehensive mitochondrial dysfunction in zebrafish embryos exposed to toxic chemicals of interest.

In Vivo to In Vitro Translation of Salivary Concentrations for Non-invasive Biomonitoring of 2,4-Dichlorophenoxyacetic Acid (2,4-D)

A. Han1, Z. A. Carver2, C. Timchalk1, T. J. Weber1, and J. N. Smith1.
1Pacific Northwest National Laboratory, Richland, WA; and 2Columbia Basin College, Pasco, WA.

Biomonitoring practices generally examine blood and urine to acquire insight regarding chemical exposures. Saliva has become a favorable sample matrix due to its non-invasive attributes and overall flexibility in collection. Relating concentrations measured in saliva to concentrations in blood or urine can be challenging due to gaps in knowledge of mechanisms driving salivary transport. We employed a Transwell in vitro system under physiological conditions to monitor and measure salivary chemical transport of a commonly applied herbicide, 2,4-dichlorophenoxyacetic acid (2,4-D). High levels of protein binding (> 92%) were observed, resulting in transport (primarily via passive diffusion) to the salivary compartment limited by formation of free unbound species, predicting a saliva/plasma ratio of 0.034. Comparatively, a saliva/plasma ratio of 0.0079 was produced from an in vivo study, orally dosing male Sprague-Dawley rats with 30-150 mg/kg 2,4-D and collecting plasma and saliva 1 hour post-exposure. A physiologically based pharmacokinetic (PBPK) model was developed to translate observations from the cell culture model to those in animal models. The PBPK model notably incorporated descriptions of protein binding, salivary/plasma partitioning, and permeation. While apparent differences in in vitro and in vivo saliva/plasma ratios (0.034 and 0.0079, respectively) were observed, simulations with the PBPK model demonstrated dynamic saliva/plasma ratios over time and concordance between in vitro and in vivo experiments. This indicated that 2,4-D exhibits diffusion limited transport to saliva in vivo, with saliva/plasma ratios requiring longer time after exposure to reach equilibrium, compared to other small organic chemicals like trichloropyridinol. Sampling time after exposures is then a critical component for interpreting salivary 2,4-D biomonitoring data. This work demonstrates the potential of PBPK modeling and linking observations made with in vitro and in vivo approaches and additionally allows for further extrapolation of salivary concentrations for human biomonitoring. Supported by CDC/NIOSH grant R01 OH011023.

Exposure Assessment of Milk Protein in Non-dairy or Vegan Ice Cream Substitutes: Are Non-dairy or Vegan Products Safe to Populations with Milk Allergy?

Milk is recognized as one of the eight most common food allergens in humans in the United States, and is one of the most common causes of fatal or near-fatal food-induced anaphylactic reactions in adults and young children globally. Undeclared allergens in food products are the leading cause of US FDA requests for food recalls, with undeclared milk as the most frequently cited allergen. For example, a recent study by the US FDA found that dark chocolate bars frequently contained undeclared milk. The purpose of this study was to evaluate products marketed as non-dairy to investigate this problem and understand potential risk to allergic individuals consuming these products. In this study, milk allergen contamination in ice cream substitutes labeled as “non-dairy,” “dairy free,” and/or “vegan” was measured, including plain ice creams and those containing swirls and/or solid additives. Results from this analysis are used to determine if consumers of the ice cream substitutes poses a risk to allergic individuals by comparing the measured allergen concentrations to published threshold doses for a reaction to milk protein. More than 30 flavors of non-dairy and/or vegan ice cream substitutes, including plain flavors and flavors with swirl and/or solid additives, from 16 different brands were tested for total milk protein using enzyme-linked immunosorbent assay. Milk protein was detected in three of the tested flavors; two contained solid additives and one was a plain flavor. One of the three products with detectable milk allergen was labeled that it was manufactured on equipment or in a facility that processed milk. Based on the package serving size, one serving of some of the tested non-dairy ice cream substitutes could have several milligrams of milk allergen. There is no consensus on the minimal dose of milk protein that will elicit an adverse effect in a milk-sensitized individual, as the eliciting dose has variable estimates, depending on the population and metrics used. The US FDA reported that the lowest dose of milk protein associated with an observable adverse effect among milk-allergic individuals is approximately 0.3-3.6 mg. These results suggest that a single serving of some ice cream substitutes has the potential for an allergic response in a highly milk-sensitive individual.
1895 Chemical Characterization of Cigarette Smoke and Aerosol of the Candidate-Modified Risk Tobacco Product, Tobacco Heating System 2.2, Trapped in Biocompatible Solvent Using a Non-targeted Screening Approach

It is estimated that there are more than 6,000 chemicals in cigarette smoke (CS), many of which have been classified as harmful and potentially harmful constituents (HPHC) and are associated with smoking-related diseases. The Tobacco Heating System (THS 2.2) is a smoke-free product designed to heat tobacco rather than burn it. As a result, its aerosol is mainly composed of water, glycercin, and nicotine, with significantly lower levels of HPHCs compared with CS. Aqueous extracts (AE) are biocompatible fractions usually tested in vitro for product assessment. In this study, the chemical composition of both CS and THS 2.2 aerosol trapped fractions were investigated using a non-targeted screening (NTS) approach. AEs were generated by bubbling CS or THS 2.2 aerosol through an impinger containing phosphate-buffered saline. The applied NTS approach combining liquid chromatography and 2D gas chromatography coupled to mass spectrometry to comprehensively cover the chemical space of both AEs. The trapped constituents were identified according to a confidence match factor substantiated by complementary parameters, such as retention time, mass spectrum similarity, and library proposal. Their concentrations were measured as semi-quantitative values using stable isotopically labelled internal standard and with a 100 ng/item cut-off. In both aqueous fractions, 108 compounds were found with significantly lower concentrations in the THS 2.2 fraction compared with CS. About 70% of them were identified and confirmed by reference standards. The remaining portion of constituents were identified with either high or medium confidence, and only 3% were given as not identified with concentrations lower than 100 ng/stick. In conclusion, we found different chemical composition profiles between AEs derived from CS and THS 2.2 aerosol. Most of the constituents were identified and either confirmed by reference standards or providing high confidence in the proposed structures. Therefore, a good understanding of exposed system for in vitro product assessment was provided by the characterization of biocompatible fractions.

1896 Evaluation of Lead Exposure by Hand Wipes: Efficacy of Personal Hygiene on Industrial Sites

K. Guth, M. Bourgeois, G. Johnson, and R. Harbison. College of Public Health, University of South Florida, Tampa, FL.

It has been 25 years since the passage of the OSHA lead in construction standard (29 CFR 1926.62) meant to control both inhalation and ingestion exposures. Despite advances in engineering controls and work practices, elevated blood lead levels persist in the industrial painting industry. The purpose of this study was to evaluate the effectiveness of worker’s personal hygiene practices at removing lead from their hands at industrial sites (n=30). Hand wipe samples collected from three bridge painting projects were analyzed for total lead by method ASTM E-1979-17/EPA SW846 7000B. Exposures resulted from the removal of lead-based paint from the structure and trace elements were evaluated (n=6). Sixty unique hand wipe samples were evaluated. Thirty samples were collected during and after the work shift. These data will be useful in raising awareness in the industrial painting industry that personal hygiene practices must be improved to prevent the uptake of lead during the removal of lead-based paint.

1897 Biomonitoring of Polycyclic Aromatic Hydrocarbons in Breast Milk of Texas Women

N. Acharya1, B. Gautam2, S. Subbiah1, M. M. Rogge2, T. A. Anderson1, and W. Gao1.1 Institute of Environmental and Human Health, Lubbock, TX; 2 Texas Tech University Health Sciences Center, Lubbock, TX; and 3 West Virginia University, Morgantown, WV.

Biomonitoring of human breast milk is one of the best ways to identify body burdens of contaminants and associated risk estimation. The objectives of the current study were to evaluate milk concentrations of persistent organic pollutants, mainly polycyclic aromatic hydrocarbons (PAHs), associated exposure estimation, and the role of body mass index (BMI) in their bioaccumulation. A total of 45 breast milk samples were collected from 24 women with BMI ≥ 30 (obese) and 21 women with BMI < 25 (18.5-24.9, normal) from different counties in West Texas; age ranged from 18-34 years. Samples were analyzed using high resolution gas chromatography coupled with mass spectrometry (GC-MS). A total of 69% of samples tested positive for PAHs. Phenanthrene was the most frequently detected PAH following by pyrene and fluoranthene. The mean of individual PAH concentration for all samples ranged from 0.02 to 5.01 ng/mL; the sum of all means of individual PAHs was 29.38 ng/mL. The mean concentration of total PAHs in the BMI ≥ 30 group was 44.95 ng/mL, which was approximately 4 times the mean of total PAHs in the BMI < 25 group (11.58 ng/mL). None of the samples from the BMI < 25 group contained higher molecular weight (5-6 rings) PAHs, while in the BMI ≥ 30 group, a total of 11 PAHs listed as US EPA priority pollutants were observed. In this study, benzo[a]fluoranthene was found to contribute the highest percentage of carcinogenic PAHs (32%), yet it was not detected in any samples from the BMI < 25 group. These findings suggest that breastfeeding babies from obese mothers of West Texas are at higher risk of exposure to carcinogenic/obesogenic PAHs. However, babies fed with breast milk from lean body weight women are at relatively less risk of exposure to carcinogenic/obesogenic PAHs.
Human-impacted surface, ground and drinking water can contain a complex mixture of micropollutants, such as pharmaceuticals, pesticides, and industrial compounds. In vitro bioassays based on various cellular response pathways have been applied to detect and quantify the presence of micropollutants in water samples. These bioassays allow for sensitive, rapid and inexpensive detection of bioactivity while considering complex mixtures of compounds and potential toxicity. However, the current approach where single response pathways are examined sequentially limits its usefulness since it requires dozens of different cell lines and reporter systems and often does not cover a wide range of activities. In these studies, we developed a work-flow to maximize the number of receptors and pathways examined with enhanced throughput and toxicologic information. First, the water sample extract is examined in mixtures of optimized reporter assays that are grouped based on biological niche including: Xenobiotic and Bile Acid Metabolism (XM Panel; CAR2, CAR3, PXR, FXR, VDR, AhR), Lipid and Energy Metabolism (LEM Panel; THRB, PPARA, PPARB, RXRA, RXR, LXR), Reproductive and Developmental Effects (EDC Panel; AR, ERA, ERB, PGR, GR, TRH); Central Nervous System and Basal Metabolism (BM Panel; LRX, RXRB, RXRG, MR, RARG) and Toxicology and Inflammatory Pathways (TOX Panel; NFKB, NFR2, AP1, p33, MTP). Extracts that exhibit positive activity in one of these five panels (representing 28 pathways), can be examined in a dose-response to determine Bioanalytical Equivalents (BAEs) for that pathway. In addition, each receptor in the impacted panel can be explored individually to determine its contribution to overall activity. Several environmental and waste water samples and known contaminants of concern (CECs) have been examined in this manner.

**Assessing External Exposure to Chemical Mixtures Starting from Human Biomonitoring Data with the INTEGRA Computational Platform**

D. Sarigiannis, S. Karakitsios, and A. Gotti. Aristotle University of Thessaloniki, Thessaloniki, Greece.

The current study aimed at the estimation of external and target tissue exposure to a mixture of 15 different chemicals commonly found in human biomonitoring (HBM) samples, including both rapidly (BPA, DEHP, triclosan) and non-rapidly (PCBs, BDEs, HCB, DDT) metabolized compounds, starting from HBM data. The simulations were carried out on INTEGRA, a computational platform that provides exposure assessment coupled with a genomic physiology-based bio-kinetic (PBBK) model and numerical “reverse dosimetry” techniques (based on Markov chain Monte Carlo and dynamic evolution Monte Carlo techniques) for exposure reconstruction. The process starts from ancillary exposure-related data that are fed into the exposure model. The results are evaluated against the HBM data distributions, aiming at the reduction of uncertainty in back-calculating doses, by minimizing the error between the predicted and the actual HBM data. Parameterization of the model for a large number of receptors and pathways are examined sequentially limits its usefulness since it cover a wide range of activities. In these studies, we developed a work-flow to maximize the number of receptors and pathways examined with enhanced throughput and toxicologic information. First, the water sample extract is examined in mixtures of optimized reporter assays that are grouped based on biological niche including: Xenobiotic and Bile Acid Metabolism (XM Panel; CAR2, CAR3, PXR, FXR, VDR, AhR), Lipid and Energy Metabolism (LEM Panel; THRB, PPARA, PPARB, RXRA, RXR, LXR), Reproductive and Developmental Effects (EDC Panel; AR, ERA, ERB, PGR, GR, TRH); Central Nervous System and Basal Metabolism (BM Panel; LRX, RXRB, RXRG, MR, RARG) and Toxicology and Inflammatory Pathways (TOX Panel; NFKB, NFR2, AP1, p33, MTP). Extracts that exhibit positive activity in one of these five panels (representing 28 pathways), can be examined in a dose-response to determine Bioanalytical Equivalents (BAEs) for that pathway. In addition, each receptor in the impacted panel can be explored individually to determine its contribu
1903 Improving Agrochemical Risk Assessment: Building Confidence in Estimating Chronic Dietary Exposure at Early Stages

C. Lohr1, P. Geurs2, Y. Li2, Z. Yan2, and C. Terry1. 1Michigan State University, East Lansing, MI; and 2Corveta Agriscience, Indianapolis, IN.

Within the human health assessment paradigm, exposure assessment is a core component for assessing and preventing potential adverse human health outcomes. In current agrochemical risk assessment, extensive and multiple-year residue trial studies are required but usually not available for estimating human chronic exposures until later stages of new agrochemical development. This is a problem in the new era of problem formulation, human exposure-based toxicity testing and Risk21-like approaches. Therefore, a platform was established to predict chronic exposures at early stage by integrating modified DynamICROP model (for predicting residue levels in various crops) and Dietary Exposure Evaluation Model (DEEM, for predicting human dietary exposure) using very limited residue trials. A case study demonstrated that the predicted exposures were within 5% relative to that from measured residues for all subpopulations. However, for all active substances, following initial product registrations, many changes (such as type and number of formulations, application rates, application methods as well as expanded crops) can be made resulting in changes in potential human exposure. To understand the exposure change patterns during the course of post-launching and implication of the predicted exposure from the Platform, a retrospective study on human chronic dietary exposures to 37 active substances across 30 years was conducted by comparing the first and last available exposure data obtained from public available risk assessment documents. For substances with no drinking-water assessment, DEEM was conducted. To calculate water exposure based on maximum estimated concentrations in drinking-water which was then combined with exposure from food. In general, the results indicate that 97% of active substances including herbicides, fungicides and insecticides have less than 10-fold (1-8-fold) change to general and the most sensitive populations over this period on the market. Based on these results, in the absence of future product use pattern changes, chronic exposures can be reasonably predicted using the Platform and an extrapolation factor of 10 to represent possible future worst case human exposures. The confidence in exposure estimates at the early stages can provide a basis for exposure-driven toxicity testing as well as tiered toxicity acquisition to inform internal and potentially regulatory decision-making.

1904 Post-Hurricane Harvey Sediments: PAH Distributions and Relative Sources

K. M. Camargo1, A. Knapp2, J. L. Sericano3, T. M. Dellenapenja3, J. Horney4, T. J. McDonald4, and W. A. Chiu1. 1Texas A&M University Department of Veterinary Integrative Biosciences, College Station, TX; 2Texas A&M University Geochemical Environmental Research Group (GERG), College Station, TX; 3Texas A&M University Galveston, Galveston, TX; and 4Texas A&M University School of Public Health, College Station, TX.

In the fall of 2017, Hurricane Harvey was responsible for severe flooding all over Houston, TX and there is a need to understand the distribution of contaminants within the impacted region. The first analyte class to be extensively covered for most of the sediment samples collected post-Harvey are polymeric aromatic hydrocarbons (PAHs). They are ubiquitous compounds in the environment, originating from petroleum as well as incomplete combustion and the pyrolysis of organic matter. What is unique for Houston, is the diverse source inputs for these compounds and the ever changing dynamics of the region. As a result of the severe flooding, sediment beds in the northern parts of the Houston estuary were shifted and moved into Galveston Bay (GB). Therefore, we hypothesized there is a new baseline for any contaminants present in soil and sediment samples. As a part of collaborative efforts with the School of Public Health and TAMU Galveston, soils and sediment samples were collected over the course of Fall 2018 where they have been analyzed for a detailed suite of analytes; which include: PAHs, Organochlorine Pesticides, Polychlorinated Biphenyls, and Dioxins/Furans. For the sediment samples, PAHs were the first analyte analyzed, where appropriate ratios indicate most of the sources are pyrogenic in nature; such as vehicular emissions. PAH totals range from 152.3 µg/kg to 4291.5 µg/kg with initial spatial analysis indicating high spatial dependence amongst the samples collected. Based on these results, we are in the process of developing a geospatial sampling map for future analyses utilizing statistical predictive methods. From these the initial PAH maps, local and regional stakeholders will be equipped with an understanding of potential exposure routes of any detected PAHs. This research was funded by P42 ES027704 and T32 ES026568.

1905 Perfluoroalkyl Acid Mixtures—Data Analysis Steps to Uncover Clues Hidden in Biomonitoring Data

P. Goodrum1, J. Anderson1, and A. Luz3. 1Integral Consulting Inc., Fayetteville, NY; 2Integral Consulting Inc., San Antonio, TX; and 3Integral Consulting Inc., Annapolis, MD.

Biomonitoring programs serve a critical role in guiding strategies to identify and manage chemical exposures that may present a risk to public health. Well-designed biomonitoring programs can provide critical information to address questions about the relationships between exposures, toxicokinetics, and health outcomes, particularly in the case of classes of chemicals that tend to occur as mixtures. Using data reported on populations exposed to perfluoroalkyl acids (PFAs) in drinking water, we demonstrated a bio- kinetic slope factor that properly accounts for background exposure, which can be estimated from the National Health and Nutrition Examination Survey (NHANES). Using perfluorooctanoic acid (PFOA) and perfluoromonoamino acid (PFNA) as a case study, we illustrate how current approaches based on ratios of concentrations in drinking water and serum yield estimates of the biokinetic slope factor that are biased high by a factor of 2 to 5 because they reflect the combination of baseline and drinking water, rather than drinking water alone. We provide a side-by-side assessment of key studies that inform current kinetic models, and highlight examples of how variability in species-specific kinetics and exposure sources impact interpretations of biomonitoring data. Specifically, we use first-order kinetics models to quantify the inherent interindividual-variability in volume of distribution, and corresponding estimates of serum elimination half-life and clearance, and we explain how this informs the interpretation of the observed range in serum levels for a community exposed to a range of drinking water concentrations. Furthermore, we show how uncertainty in estimates of the relative serum half-lives of PFOA and PFNA can be resolved by examining the PFAA mixtures paired at the individual level. Applying these data analysis steps to biomonitoring data in communities with known drinking water contamination can improve estimates of the time course of changes in PFAS both before and after intervention.

1906 Indirect Dietary Exposure Assessment of Surface Cleaner Residues (ADBAC) and Refinement Using a Novel Analytical Residue Method

J. Vaughan, Q. Wei, M. Miller, D. Boessenberg, J. Rubino, J. Rowland, and B. Lew. RB, Montvale, NJ.

Alkyl dimethyl benzyl ammonium chlorides (ADBAC) encompass a cluster of 24 structurally-related quaternary ammonium compounds (QAC). Typically, these organic salts only differ with regard to alkyl chain lengths and are often commercially available in biocidal disinfectants/antiseptic products. Moreover, ADBAC has a ubiquitous presence in consumer goods: ranging from personal care to surface cleaners. In the evaluation of product safety, exposure-based risk assessment is a necessity - not only as it pertains to product use but also in regard to the unseen residues on residential food-contact surfaces. Generally, in the absence of data, worst-case exposure assessment is conducted. However, the result is often an overly conservative, unrealis- tic estimation of surface residues. Therefore, a novel analytical method was developed and validated which allows for a near-complete collection and accurate quantification of residues using a variety of real-world product-types (wipe, aerosol, trigger spray), cleaning substrates (paper towels, sponges, cloths), and cleaning surface (stainless steel, formica, ceramic). Collectively, these potential variables were evaluated in a number of experiments spanning several Latin-square matrices to decipher the most influential factors which contribute to ADBAC surface residues. Ultimately, we found that both product and surface type were significant in dictating total residual ADBAC concentrations and relative percentages respectively; whereas cleaning material was an insignificant determinant. Honing-in on these two factors, tier-based exposure assessment in line with US EPA practice, comprised of Tier 1 (A-Default assumptions of FDA EDI methodologies, B-refined based on transfer general efficiency, C-refined using measured surface residues), Tier 2 (IDREAM - food consumption model using default parameters); and Tier 3 approaches (IDREAM - refined using chemical-specific residue values). Ultimately, we found that even at Tier 1 (worst-case scenario), the corresponding ADBAC exposures were below US EPA established Chronic Population Adjusted Doses. However, refinement from Tier 1 to Tier 3 exposure assessment resulted in a significant reduction of estimated doses, more interestingly we found that these de- clines were disproportionate and dependent on product type (Reductions: Aerosol >7-fold; Trigger >27-fold; Wipe >100-fold). The findings of the study are important in both claims substantiation and safety evaluation of cleaning products positioned for use on food contact surfaces.
In commercial and academic facilities, various additive and subtractive manufacturing technologies such as 3D printing and laser cutting are used. These processes are associated with emission of volatile organic compounds (VOCs) and particle pollution depending on the specific activity. The sampling site selected in this study was a Makerspace facility with a variety of machines including 3D printers (Enclosed and Open) and Laser Cutters. The emission of ultrafine particles (UFPs) and VOCs, from each type of these machines, was quantified and the input/contribution of each machine in the indoor air quality was estimated. Ultrafine particles were measured using a TSI P-trak. VOCs were measured with a real time monitor with a PID sensor (MOCON Inc.) and grab samples were taken using evacuated canisters and analyzed by GC-MS. For an enclosed 3D printer using ABS filament feedstock, a comparison of the front and rear emissions showed higher UFPs at the rear (3000-5000 pt/cm³) at the beginning of printing and going down to a background level of 1383 pt/cm³, while VOC emissions were higher at the front with the real time moni- tor peaking at 700 ppb in the middle of printing. Canister samples showed increases in acetone, ethanol, methyl methacrylate, and styrene during the 3D printing process. With an open 3D printer using PLA filament, VOC and UFP emissions surprisingly remained at the same levels as the background concentrations. Sampling at a laser cutting acrylic plastic showed higher total VOC emissions in front of the machine when the lid was opened right after the job completion, with a peak reading of 2251 ppb. In the grab sample, the concentration of methyl methacrylate and methylene chloride went up to 51.7 and 3.4 ppb compared to a background of 0 ppb. Interestingly, sampling at the exhaust assembly for the laser cutter showed a maximum increase of these two analytes 4.4 and 5.1 times greater than the concentrations observed in the front of the machine. UFP numbers peaked at 16000 pt/cm³ when the laser cutter lid was opened after completion of cutting with a mean (SD) concentration over the entire period of cutting of 2376±591.8 pt/cm³. In conclusion, emissions from burgeoning manufacturing technologies contributed to the airborne concentrations of volatile gases and particle in the Makerspace facility, but the levels observed in this study appeared to remain within recommended occupational exposure limits.

Flumetralin, a substance with plant growth regulating activity, is applied as a topical treatment for the control of sucker growth on various types of tobacco. The dissipation and residues of flumetralin in tobacco were investigated by modified QuEChERS method combined with gas chromatography tandem mass (GC-MS/MS). The average recoveries were in the range of 78-96% with relative standard deviations (RSD) less than 15%. The limit of detection (LOD) and limit of quantification (LOQ) of flumetralin was 0.9 and 3 µg/kg at the signal-to-noise ratio (S/N) of 3 and 10, respectively. Field experiments including residue dynamic experiment and final residue experiment were conducted in Enshi, Linyi, Qujing and Zunyi during the year of 2016. The dissipation of flumetralin appeared to follow the first-order kinetic reaction with half-lives of 3.5-5.8 days at four geographical experimental plots, which suggested that the dissipation of flumetralin in the field might be affected by some physical and chemical factors like rainfall, light, heat and moisture in addition to growth dilution factor. Tobacco flue-curing experiments were carried out after the field trials following the three-stage curing technology. Tobacco leaves collected from final residue experiments were processed. About 56.7-96.3% of the residues had degraded after tobacco flue-curing, it suggested that high temperature during tobacco processing seemed to be the most important factor affecting degradation. The terminal residues of flumetralin at two dosage were less than 4.62 mg/kg in any locations, which never exceed the guidance residue level (GRL) established by CORESTA (5 mg/kg). This study could provide guidance for the safe use of flumetralin and serve as a reference for the establishment of maximum residue limit (MRL) in China.

Effects of Glyphosate and Its Formulations on DNA Damage in HepaRG and HaCat Cell Lines

J. Rice, P. Dunlap, S. Ramajaghari, S. Fergusson, S. Smith-Roe, and M. DeVito, NIEHS, Durham, NC.

Glyphosate (GLY) is an active ingredient found in herbicide formulations around the world. It affects the shikimate pathway in plants, blocking the activity of 5-enolpyruvylshikimic-3-phosphate synthase (EPSPS). First reported in the late 1970s, but intensive use of GLY began with the introduction of GLY-resistant crops in the late 1990s. Conflicting reports exist as to whether GLY poses a cancer risk to humans, though it has a low toxicity profile for humans and mammals. Both European regulatory agencies and the US EPA have described GLY as unlikely to pose a carcinogenic hazard to humans, but the
International Agency for Research on Cancer (IARC) and the California EPA have classified GLY as “probably carcinogenic to humans” and “known to the State of California to cause cancer,” respectively. It has been proposed that oxidative stress may be a mechanism by which GLY could potentially cause cancer. To address this hypothesis, we tested GLY in two human cell lines, HepaRG (metabolically competent hepatocytes) and HaCaT (human keratinocytes) using the γ-H2AX assay which detects DNA double strand damage. Thirteen formulations with high concentrations ranging from 3 mM to 103 mM and 5 actives including GLY, GLY salts, and other active ingredients in the formulations were tested at ten different concentrations post 1- and 24-hour exposure. The results were then compared with the effects of glyphosate and its formulations on cytotoxicity (CellTiter-Glo assay) to determine whether GLY induces oxidative stress and DNA damage. While the positive controls etoposide and diquat elicited a markedly increase in γ-H2AX phosphorylation at concentrations lower than those that reduced cell viability, glyphosate and its formulations showed no or minimal γ-H2AX phosphorylation, and then only at cytotoxic concentrations that induced significant cell viability. In fact, the only formulation to show some DNA damage contains diquat as an active ingredient. This data suggests that GLY does not induce double strand DNA damage in HaCaT and HepaRG cells. It should be noted that the formulations marginally increased oxidative stress only after significant loss of cell viability. The results were very similar in both the HepaRGS and HaCaT cells, suggesting that xenobiotic metabolism has negligible impact on toxicity.

**1912 Role of the Organic Backbone and Metal Moeities in Alteration of Essential Metal Levels after Oral Mancozeb Exposure in Sprague-Dawley Rats**

B. Kistinger, and D. Hardej. St. John's University, Queens, NY.

Mancozeb (MZ) is a broad-spectrum fungicide of the ethylene bisdithiocarbamate (EBDC) class. Use in agriculture raises questions about the effects of oral exposure of MZ on consumers, pesticide manufacturers, and applicators. Previous studies have shown that oral exposure to MZ in rats results in increased Gl tract Mn and increased renal Cu levels, raising concern due to altered metal homeostasis. MZ is comprised of an EBDC backbone complexed to Mn and Zn metals. It is suggested that MZ dissociates to its components in the body. The aim of the present study compared the altered metal profiles of MZ-dosed rats with rats dosed with namb (NB) (sodium salt of EBDC backbone) or with metal moieties (Mn and Zn) alone. MZ by weight is 77.5% EBDC, 20% Mn, and 2.5% Zn. To give equivalent doses of the components in 100 mg/kg MZ the EBDC group was dosed with 95 mg/kg NB and the Mn/Zn group was given a combined dose of 46 mg/kg MnCl₂ and 5 mg/kg ZnCl₂ (to give 20 mg/kg Mn and 2.5 mg/kg Zn doses, respectively). Sprague-Dawley rats (n=32) were divided into 4 groups: 25% PEG400 (vehicle), NB (EBDC), Mn/ Zn (Mozieb), and MZ and dosed for 28 days. After the 28th dose, rats were fasted overnight. On 29th day organs were harvested from euthanized animals and frozen until analysis. Analyses of Mn, Zn, and Cu were obtained using Inductively Coupled Plasma-Optical Emission Spectroscopy (ICP-OES) and results were expressed as ppm metal per g dry organ weight (ppm/g). In kidney, NB and MZ treatment resulted in Cu increase (76.69 and 78.39 ppm/g) compared to controls (9.696 ppm/g). Livers of MZ rats showed a decrease in Mn levels (2.114 ppm/g) compared to control (0.3637 ppm/g). A significant increase in Cu (3.742 ppm/g) relative to control (4.132 ppm/g) was observed in myocardium of NB and MZ treatment rats. DS treated rats showed a significant increase in Cu levels (10.23 ± 0.55 ppm/g dw) vs control (5.44 ± 0.06 ppm/g dw) in the myocardium. No significant changes in metal levels were observed in the vatsus medialis of MZ or DS treated rats as compared to control. This study has shown that DTGs alter metal levels in only myocardium of Long-Evans rats, and may not have a direct influence on skeletal muscle damage. Additional research is being conducted to determine the mechanism of toxicity that DTGs cause on both myocardium and skeletal muscle.

**1914 Determination of Offspring NOAEL for Zeta-Cypermethrin from Developmental Neurotoxicity Studies in Rats Using Internal Exposure Data**

Z. Liu, A. Chandrasekaran, and J. Becker. FMC Corporation, Newark, DE.

Zeta-cypermethrin is an enriched isomer of cypermethrin, a synthetic pyrethroid. Range-finding and definitive dietary developmental neurotoxicity (DNT) studies have been conducted in the 1990s. A pharmacokinetic (PK) study in PND 11, 21 and 90 female rats was recently conducted to obtain data that would allow for a more accurate calculation of offspring NOAEL. In the definitive DNT study (dosages: 0, 50, 125 and 300 ppm; 0.3, 6.0, 9.0 and 21.1 mg/kg/day for dams during gestation; 0.8, 7.1, 41.4 and 45.7 mg/kg/day for dams during lactation), maternal body weight and food consumption, offspring body weight were reduced significantly at 300 ppm. Zeta-cypermethrin was not considered to be developmentally neurotoxic from the results showing no CNS domain-, age- or test article-related adverse pattern of DNT in the offspring. The NOAEL for maternal and offspring systemic toxicity was determined to be 125 ppm. Plasma concentrations were determined at a single time point, approximately 1 hour after the dark period which corresponded to expected peak concentrations following dietary consumption. The maternal/offspring plasma concentrations of zeta-cypermethrin were 0.535/0.245 mg/L (mean value on LDS and 21) during PNDs, 21. In the single gavage dose PK study, after 0.25 mg/kg, the C₀ values were 0.094, 0.140 and 0.037 mg/L, respectively; the AUCs were 0.804, 0.180 and 0.229 mg·h/mL, respectively, in PND11, 21 and 90 rats. At 0.75 mg/kg, the C₀ values were 0.344, 0.158 and 0.108 mg/L, respectively; the AUCs were 2.329, 1.210 and 0.779 mg·h/mL, respectively, in PND01, 21 and 30 rats. These data suggest that tₕ½ values in the PND 11 and 21 are about 3X and 2X higher than those in the PND0 rats at the same dose, and it required about 1/3 and 1/2 doses in the PND11 and 21 to produce the same levels of C₀ and AUC in PND0 rats. The dose normalized C₀ (the slope factor of the linear PK curve) is 3X and 2X higher in the PND1 and 21 than that in the PND90 rats. Therefore, by using the mean maternal/offspring plasma concentrations (0.535/0.245 mg/L), a more conservative 3X relative PK factor and the equation 35/20 mg=r2456 mg/kg of intracellular NOAEL (Cu) with the group is calculated to be 3.3 mg/kg which should be protective of all human populations including children.

**1915 An Investigation of the Antifungal Activity of Forty Ebselen Analogs in Candida albicans**

S. M. Menon, M. Pietka-Ottlik, and B. Billack. St. John’s University, Queens, NY; and Wroclaw University of Technology, Wroclaw, Poland.

The growing emergence of fluconazole as well as multidrug-resistant strains in immunocompromised patients justifies the need for novel antifungal targets. Our lab has previously described the antifungal mechanism of ebselen.
EB, an organoselenium compound showing growth inhibitory activity (IC50 ~15 µM) for various C. albicans strains. In view of the current interest in organoselenium inhibitors of the plasma membrane H+ -ATPase, the present study was undertaken to investigate the antifungal activity of forty novel EB analogs in S1 (fluconazole sensitive) and S2 (fluconazole resistant) strains. Cells of both strains were prepared in RPMI 1640 medium using the microliduction method and were incubated for 48 hr with each EB analog. Amongst the test compounds, three of them (G-4, G-13, and G-30) surpassed the antifungal activity of EB in both strains. To confirm the growth inhibitory effect in living yeast cells, we determined the minimum inhibitory concentration (MIC) for the three most active test compounds along with EB and fluconazole using a colorimetric assay based on conversion of resazurin dye in 96-well plates displayed a MIC of 25 µM in both S1 and S2 whereas fluconazole-treated wells reduced the dye to pink color at all concentrations (MIC >100 µM) confirming that it is a fungistatic agent. G-4 and G-13 exhibited MIC values of 25 µM and 12.5 µM, respectively, in the S1 strain and 25 µM for both compounds in the S2 strain; whereas G-30 demonstrated a MIC of 6.25 µM in S1 and 12.5 µM in S2. In addition, medium acidification assays were performed for 30 min with each of the three most active compounds along with EB and fluconazole. As anticipated, fluconazole showed no effect on medium acidification, whereas EB inhibited medium acidification (IC50 ~ 5 µM) in both strains. G-4 and G-13 showed a similar inhibitory effect as EB in a time- and concentration-dependent manner (IC50: 3.6 µM and 4.7 µM, respectively, in S1 yeast and 5.6 µM and 5.2 µM, respectively, in S2 yeast). Compound G-30 displayed no inhibitory effect for the first 15 min; however, inhibition of medium acidification was observed thereafter. We hypothesize that this late inhibitory effect on medium acidification may be due to the bulky nature of the test compound. Taken together, the present results indicate that modified EB analogs should be investigated further for use as antifungal agents in fluconazole-resistant as well as other C. albicans strains.

1919 Carboxylesterase Isoform-Selective Inactivation in Lung following Oral Chlorpyrifos Exposures of Neonatal and Adult Mice

B. N. Szafrań, A. Borazjani, R. L. Carr, M. K. Ross, and B. L. Kaplan, Mississippi State University, Starkville, MS.

Chlorpyrifos (CPF) is an organophosphate (OP) pesticide known to exhibit toxicity via inhibition of acetylcholinesterase (AChE) in the nervous system. We previously showed that endocannabinoid (eCB) metabolizing enzymes were even more sensitive than AChE to inhibition by OP pesticides in neonatal rats, leading to increased levels of eCBs in brain. Because eCBs are known to be immunomodulatory molecules, we are investigating a link between eCB metabolism and immunity in adults and neonates exposed to CPF. We hypothesized that neonatal mice would be more sensitive than adult mice to the effects of CPF on eCB metabolism. Adult mice (≥ 8 weeks old) and neonatal mice (post-natal day 10) were treated with CPF (2.5 mg/kg oral) or vehicle daily for 7 days. Tissues were harvested 4 hr after final treatment. Lung microsomes from both age groups demonstrated marked inhibition of carboxylesterase (Ces) activity, one of the known eCB metabolizing enzymes. Lung Ces activity in neonates was more sensitive to CPF than adults. Activity-based protein profiling (ABPP) and immunoblotting of lung microsomes confirmed that Ces1 was present in both age groups, and the activity was inhibited by CPF. ABPP-mass spectrometry of lung microsomes identified 31 serine hydrolases in the neonatal lung and 32 serine hydrolases in the adult lung. Ces1d was selectively inactivated by CPF in neonatal lungs and Ces1c was selectively inactivated by CPF in adult lungs, indicating an age-related difference in sensitivity to CPF. In follow-up experiments in adult mice, treatment with WWL229, a selective Ces1d small-molecule inhibitor, potentiated lung IL-6, TNF-α, and IL-1β mRNA expression in response to lipopolysaccharide. Further studies will determine if treatment with CPF and LPS yield similar results, as this could indicate a mechanism by which low-dose CPF is immunotoxic to neonates. Moving forward, the overall goal of this project will be to explore age-related Ces1 sensitivities and the role of inhibition of Ces1d by CPF in pulmonary inflammation. Supported by MSU-CVM and R15GM128206.

1917 Genetics of the Effect of Paraquat on Iron, Copper, and Zinc in Mouse Midbrain

B. C. Jones1, E. Adamova1, L. Lu1, C. Torres-Rojas1, and P. Jimenez2.
1University of Tennessee Health Sciences Center, Memphis, TN; and
2University of Memphis, Memphis, TN.

Paraquat is an herbicide used widely in many countries, including the USA. It has also been implicated as a risk factor for development of sporadic Parkinson’s disease, especially in those living in agricultural areas and drinking well water. Although there is evidence for risk, not all epidemiological studies are consistent. The reason is likely genetically-based differential susceptibility to paraquat neurotoxicity in sub-populations. To address this issue, we have tested the effects of paraquat in a genetic reference population of mice (the BXD recombinant inbred strain family). In our earlier work, we showed that in genetically susceptible mice, paraquat increases iron in the ventral midbrain, the area containing the substantia nigra. Our hypothesis then is that the iron increase contains loosely-bound or unbound iron that in turn causes neuron toxicity by producing free oxygen radicals. To test the hypothesis more fully, we treated male mice from 28 of the BXD recombinant strains with 3 doses of paraquat, 1, 5 and 10 mg/kg three times on a weekly basis. At the end of the treatment period, we euthanized the animals and analyzed the ventral midbrain for concentrations of iron by total reflection x-ray fluorescence. Because our instrument (Bruker PicoFox) analyzes most elements, we also measured copper and zinc. The results showed that at 1 mg/kg compared to control, 2 strains showed a decrease in [Fe] and 7 showed an increase. For [Cu] 5 strains showed a decrease and 13 an increase. We also observed a significant association between a Ce marker and a genetic marker on chromosome 7 at 90 Mb. The search for a candidate gene at that location produced Picalcim, phosphatidylinositol binding clathrin assembly protein; intron 1. This gene is involved in iron regulation and is a one of the candidates for Alzheimer’s disease. At 5 and 10 mg/kg of paraquat, we also observed differential responses in increases and decreases of all three metals, at 1 and 5 mg/kg the concentrations of copper and zinc were correlated and at 10 mg/kg, iron and copper and copper and zinc were correlated. These results show that paraquat can affect the regulation of all three metals in the ventral midbrain and therefore one means of producing neurotoxicity.

1918 Cancer Risk Assessment for Agrochemicals: Are Non-cancer Endpoints Protective of Tumor Endpoints?

Z. Yan, Y. Li, and C. Terry. Corteva Agriscience, Indianapolis, IN.

Human health assessment of agrochemicals requires a comprehensive battery of toxicological studies covering different life stages and exposure durations. The carcinogenicity studies in both rats and mice are designed to assess tumorigenic potential of substances and have been implemented in the toxicity testing program for the past 5 decades. Given the significant animal use, it is important to consider, for non-genotoxic carcinogens (NGTxCs), if tumorigenicity must to be known in animals to protect again tumors for human health protection. A retrospective analysis on one hundred and twenty-eight (128) non-genotoxic agrochemicals was conducted to investigate (1) if tumor thresholds exist based on chronic NOAELs from the same study, (2) whether nonchronic non-cancer NOAELs with certain extrapolation factors (Efs) can be protective of cancer, and (3) if NOAELs from non-carcinogenicity studies (e.g. developmental or reproductive studies) being used to derive Acceptable Daily Intakes (ADIs) are more sensitive than tumor NOAELs. The results indicate that the tumor NOAELs are uniformly less or equally sensitive to chronic non-cancer NOAELs in both rodent species, indicating threshold effect for tumor endpoints. Based on the established correlation between rodent chronic and chronic NOAELs, when Efs of 6 and 5 are used to the rat and mouse subchronic NOAELs respectively, the predicted chronic NOAELs are protective of tumors except for 2 substances (sulfosulfuron in rats and forchlorfenuron in mice). Further investigations showed that sulfosulfuron induced tumors are due to irritations resulting from calcul and are generally not considered relevant for human risk assessment and the forchlorfenuron result is due to unusual dose spacing (tumor NOAEL and LOAEL are 4.3 and 500 mg/kg bw per day, respectively). For more than 30% (38/128) of ADIs derived from non-carcinogenicity studies, their NOAELs were exclusively lower than tumor NOAELs. Taken together, the results indicate that NGTxCs caused tumors in rodent thresholds do not exceed the accepted range of carcinogenicity studies, systemic rodent subchronic NOAELs with defined Efs or other more sensitive NOAELs are protective of tumor endpoints. These findings coupled with convincing evidence that non-cancer hazard can be adequately identified and protective points of departure can be established from other studies demonstrate limited utility of cancer bioassays in risk assessment.

1919 The Integrated 90-Day Rat Study Design: A Decade of Experience and Regulatory Acceptance

C. Terry, L. Murphy, M. Aggarwal, S. Papineni, J. Domoradzki, and S. Gehin. Corteva Agriscience, Indianapolis, IN.

The 90-day rat study is a fundamental toxicity study conducted within the package of studies defining the toxicity profile for agrochemical active ingredients. For a decade, it has been possible to integrate additional endpoints and obviate need for separate studies. Experience from 8 integrated 90-day rat studies, including study design, the need (or not) for additional studies.
examining the same endpoints and an overview of regulatory acceptance of this study type is presented. The study designs for eight 90-day rat studies with agrochemicals (sulfoxaflor, halaluxifen-methyl, halaluxifen-acid, florpyn-ixufen-benzyl, fenpicoxamid, XDE-469, XDE-607 and experimental fungicide) were compared. The base guideline was OECD 408, adapted to include OPPTS 870.7800 (immunotoxicity), OPPTS 870.6200 (neurotoxicity), and OECD 474 (mucinocular test). Integrated toxicokinetics (TK) measurements (blood/urine) were included with no additional animal use. Mode-of-action tissue samples were stored for potential toxicogenomic analysis. Results show 100% of these studies that were submitted to global Regulatory agencies (including EU, US, Canada, Australia, New Zealand, Brazil, China, India, and others) were accepted. The improved study design uses 130 animals in 12-232 as support for the separate studies. An analysis of each chemical was conducted to investigate which separate studies were not necessary using the integrated design. In 100% of these studies submitted, separate immunotoxicity and neurotoxicity studies have never been conducted or requested by any Regulatory agency. In 88% of cases, a separate OECD 474 was conducted as complementary to the data package. In 38% of cases, integrated TK data contributed to a kinetically-derived maximum dose (KMD) approach in follow-up studies. In 50% of cases, integrated MoA data was critical to the overall toxicity profile and avoided separate studies. In summary, in a 90-day rat study it’s possible to include immunotoxicity, neurotoxicity, genotoxicity, mode-of-action and TK endpoints whilst adhering to the guideline requirements. A recent example is the required in vivo MNT with recent guidance for demonstration of systemic exposure of the test compound such that integration in the 90-day study along with TK aids in the justification for dose selection and validity of the MNT results alongside assessment of systemic toxicity. These studies have been accepted in all geographies for new agrochemical registrations. This study design should be standard for agrochemicals and represent a significant 3Rs improvement.

1920 Evaluation of the Application of an AEP/AOP Framework to an Agrochemical, Sulfoxaflor
L. Murphy, and C. Terry, Dow AgroSciences, Indianapolis, IN.

The application of a combined Adverse Outcome Pathway (AOP) and Aggregate Exposure Pathway (AEP) framework to an insecticide was investigated. AOPs describe the Key Events (KEs) that follow a molecular initiating event (MIE, i.e. a binding to a receptor) and result in an adverse outcome. Sulfoxaflor (“Slocast”) is a sulfoximine insecticidal acetylcholinesterase (AChE) inhibitor. In rats, it induces developmental toxicity, mediated by the binding (MIE) and prolonged agonism (KE1) of the foetal-type muscle nAChR, leading to sustained muscle contraction (KE2), limb contracture (forelimb flexure and hindlimb rotation), clavicle abnormalities (from shoulder girdle contracture) and decreased neonatal survival (from diaphragm contracture, causing breathing abnormalities). In the application of the AOP approach, the critical doses causing effects, and/or the highest doses not causing effects, were identified for each of the KEs. The AEP framework allows for comparison and integration of exposure data to the specific AOP, in this case, sulfoxaflor mediated developmental toxicity, and considers available toxicokinetic (TK) data while potentially informing exposure and human health risk assessments. TK data were available for most of the key in vivo studies, enabling a qualitative comparison of effect levels between in vitro, ex vivo and in vivo studies in different species. This data enabled the AEP approach to be applied to sulfoxaflor at two levels: predicted external exposure of the test compound such that integration in the 90-day study design should be standard for agrochemicals and represent a significant 3Rs improvement.

1921 Hemp-Based Formulation Disrupts Development and Increases Mortality in Houseflies (Musca domestica)
M. Better, and S. Chao, Fayetteville State University, Fayetteville, NC.

Musca domestica, otherwise known as the housefly, serves as a vector for over 100 human and animal diseases. Flies carry disease-carrying organisms in their mouthparts, body surfaces, feces, and vomit. The problem has been exacerbated by over spraying with toxic insecticides resulting in the development of insecticide resistance. As a strategy to control these pests without harming nontarget organisms, Fayetteville State University has developed a hemp-based formulation to specifically target flies. Previous studies found hemp to disrupt development in fruit flies; therefore, it was hypothesized that the hemp formulation would disrupt development in houseflies. Three main feeding assays were conducted: one to determine toxicity in the larvae, one to determine development, and one to determine developmental effects on the flies as they developed from egg to adult. The flies were subacutely exposed to the hemp formulation for up to nine days at the following concentrations: 0, 25, 50 and 100%. Findings showed significant increases in mortality for all stages tested. In the development assay, the larvae exposed to the hemp formulation died 2 days after the control group. Once the adults emerged, those exposed to the formulation convulsed and died within 2-3 days of emergence. In the adult toxicity assay all adults in the 100% concentration died within a 2-day exposure. It was concluded that the hemp formulation was effective in controlling adult flies and larvae. While adult flies exposed to the 100% concentration died within 2 days of exposure, development of larvae was disrupted with an exposure concentration of 50%. Future studies will include biochemical analyses to test acetylcholinesterase (AChE) levels in the flies at all stages. This enzyme could be a target site for the formulation and would explain convulsions in the adults. Analyzing hormone levels in the larvae may explain the occurrence of developmental defects since AChE may regulate ecysone or juvenile hormone levels, both of which control molting and metamorphosis in the larvae.

1922 Efficacy of Hemp Seed Formulations for the Control of Darkling Beetles (Alphitobius diaperinus) with No Observed Toxicity in Hens Following Surface Treatment of Bedding
A. Grant, E. Kang, M. Targaszewski, and S. Cho, Fayetteville State University, Fayetteville, NC.

The darkling beetle (Alphitobius diaperinus) is one of the major pests of poultry houses causing millions of dollars of structural damage each year. In addition, darkling beetles also transmit disease in poultry. While synthetic pesticides such as imidacloprid and pyrethroids have been applied primarily to control this problem, concerns about toxic residues have prompted the need for safer control alternatives. The present study examined the efficacy of a patented hemp seed formulation for the control of darkling beetles after surface treatment of poultry bedding. In addition, the safety of hemp formulations on hens was determined and results were expressed as adverse effect levels of hemp formulations on their bedding for six weeks. Following exposure to the hemp seed formulation, darkling beetles laid significantly fewer eggs. Increased mortality was also observed in adult beetles following exposure to hemp seed formulations. However, no toxicity was observed in hens exposed to surface treatments. Specifically, no changes in body weight and number of eggs produced by hens were observed. In addition, no changes in liver toxicity indicators, such as aspartate aminotransferase and alanine aminotransferase, were observed. Findings suggest that the patented hemp seed formulation is an effective and safe alternative to control poultry pests.

1923 Detecting Toxic Effects of Roundup Concentrate Plus with the DEL Assay
V. Jung, and D. Paiz, California State University Northridge, Northridge, CA.

Sponsor: R. Schiestl

Pesticides have become a worldwide source of pollution and its ever-increasing use has attributed to detrimental health effects over the past decade. About 1 billion pounds of pesticides are used each year in the United States and among human health risks, exposure to a group of pesticides have been associated with many cancers. As of 2014, over 250 million pounds of glyphosate, an active ingredient in the popularized herbicide product, Roundup® (RU), has been used across the United States. Although pesticides are known to come with benefits for agriculture, such as pest control and increased food production, in contrast it has been proven to be a human health concern. While studies have shown multiple toxic effects in increased correlation between diseases with RU and glyphosate exposure, the full extent of its hazard is still being researched. According to the US Environmental Protection Agency (US EPA), the legal limit of glyphosate is 140 mg/kg. This does not take into consideration the risk of RU at low doses. Thus, this study aims to examine a broad range of dose responses, below what is considered the safe limit or threshold of RU, using the deletion (DEL) assay. The DEL assay model is a eukaryotic (yeast strain RS112) in vitro model that examines a double stranded break in the yeast when exposed to a toxic substance. This model is inexpensive, easy to apply, and a single assay that looks at the Shikimate pathway to study genotoxic and cytotoxic effects. By exposing RS112 to RU concentrations between 100mg/mL to 0.001pg/ml we have observed a nonmonotonic
Pesticide use in Thailand has increased annually and many of these pesticides are potentially immuno- or neurotoxic in humans. For this project, hospital staff and health volunteers were assisted with recruitment: contacting farms, collecting samples, and conducting medical examinations. All study participants—conventional farmworkers (n=70) and age and sex-matched comparison workers (n=70)—were enrolled in this study. Conventional farmworkers were selected based on the previous study, and comparison workers were selected from the general population. The study was approved by the Institutional Review Board at both the University of Michigan and the University of New Orleans. Serum samples were collected from all participants at baseline and at the end of the 10-day study period. Blood and urine samples were collected from all participants at baseline, at the end of the study period, and at the follow-up visit. The samples were analyzed for a wide range of pesticides using high-performance liquid chromatography and tandem mass spectrometry. The results showed that conventional farmworkers had significantly higher levels of exposure to pesticides than comparison workers. This study highlights the importance of pesticide exposure studies in developing countries and the need for effective public health interventions to reduce pesticide exposure.

**Pesticide Use in Thailand**

Myclobutanil, a conazole class fungicide is heavily used to control fungi and fungal diseases associated with perennial and annual crops, turf, fruit trees, and vines by inhibiting ergosterol synthesis. Conozoles are known to have hepatotoxic effects in mice through induction of hepatic cell proliferation and altered cholesterol levels. Myclobutanil is non-tumorigenic in mice and is considered to have low acute toxicity in humans. However, the mechanisms of the hepatotoxic effects of the fungicide are poorly understood. Most recently, myclobutanil has been associated with increased lipid deposition in hepatocytes and cell death in an in vitro model, suggesting the environmental contaminant can impact hepatocellular diseases. In this study, myclobutanil exposure was assessed as a potential contributor to non-alcoholic fatty disease (NAFLD), specifically subacute changes in genes associated with NAFLD in the liver and white adipose tissue were assessed. C57BL/6J mice at 18 weeks of age were dosed with vehicle, 20 ppm, 100 ppm, or 500 ppm of myclobutanil (CAS Number : 88671-89-0) via oral gavage for 10-days and sacrificed 3 hours following the last dose. In agreement with previous studies, there was a trend for a dose-dependent increase in liver to body weight percentage that achieved significance compared to vehicle at 70.2 mg/kg/day (53%, p=0.005) and a trend for increased alanine aminotransferase (ALT) serum levels with increasing dose, with ALT levels of 63±28 IU/L at 500 ppm compared to vehicle levels of 33.2±8 IU/L. Key genes of the bile acid synthesis pathway, Cyp7a1 and Cyp8b1, were up-regulated with myclobutanil exposure. Cyp8b1 was significantly increased for vehicle at all doses, and Cyp7a1 was significantly increased 14.5 and 17-fold at 100 and 500 ppm doses, respectively. In white adipose tissue, a trend for increased mRNA levels of Pparγ2, Adiponectin, and aP2 at the highest exposure was noted. The changes in mRNA levels following a subacute oral exposure to myclobutanil suggest that the nuclear receptor FXR or the disruption of bile acid homeostasis may contribute to the hepatotoxicity in mice. Further, myclobutanil modulation of metabolic pathways within adipose tissue may favor adipogenesis contributing to altered lipid regulation. Therefore, the characterization of whether myclobutanil contributes to the enhancement of NAFLD disease progression is paramount.

**Cigarette Smoke Exposure in a Three-Dimensional Model of Human Bronchial Epithelial Cells**

Cigarette smoke (CS) is a complex mixture of chemicals and interacts with various physiological processes. We previously reported that nuclear factor erythroid 2-related factor 2 (NRF2) was the most sensitive transcription factor to aqueous cigarette smoke extract (AqCSE) exposure in monolayer cultured human bronchial epithelial cell lines. Recently, in vitro three-dimensional (3D) culture models have been used to supplement pharmacological and toxicological assessments. Bronchial epithelium models in particular are useful for the evaluation of substances that directly contact the respiratory tract, such as CS. In the present study, we used 3D-cultured human bronchial epithelial cells (HBEc3) to assess activation of transcription factors and relevant gene expression in response to AqCSE, primarily focusing on NRF2 and nuclear factor-kappa B (NF-kB) pathways. The 3D-cultured HBEc3 exposed to AqCSE showed expression of NRF2 and its nuclear translocation in addition to upregulation of genes related to oxidative stress. Our results suggest that the NRF2 pathway was the dominant pathway when 3D-cultured HBEc3 were exposed to AqCSE at a low dose, supporting our previous findings that NRF2 was the most sensitive transcription factor in response to AqCSE. Expression and nu...
clear translocation of NF-κB were not increased, although pro-inflammatory genes were upregulated. However, another inflammation-related transcription factor, activation protein 1 (AP-1), was induced by AqCSE. Gene classification analysis suggested that induction of the inflammatory response by AqCSE was dependent on NQO1 and AP-1 rather than NF-κB.

1928 Developing a Versatile Exposure System for the Analysis of the Effects of Electronic Cigarettes

Use of electronic cigarettes (e-cigs), particularly among youth, has proliferated in recent years. However, there remains little consensus on e-cigs’ health effects. With the plethora of devices, e-liquids, and flavorings available on the US market, there is a need for a controlled yet flexible in vitro exposure system which can accommodate the versatility of devices. This standardized exposure system will allow for more meaningful comparison between e-cig devices, e-liquid components, and devices operated at varying settings. The goal of this study was to develop and optimize a versatile in vitro e-cig exposure system and perform initial experiments to determine biological effects. Our exposure chamber is composed of a 3 L Plexiglas cube with an inlet for e-cig operation, an outlet attached to a vacuum line, and a fan for aerosol distribution. A series of mock exposures using a third-generation e-cig device at a rate of 2.5 LPM (Fig. 1) was performed to determine chamber parameters which yield even aerosol deposition while minimizing gas loss and disruption of aerosol nucleation. Average aerosol deposition across the 12 well plate was found to be 1.634 mg/cm² for propylene glycol (PG), 1.600 mg/cm² for glycerin (GLY), and 1.707 mg/cm² for a 55:45 PG/GLY mixture with no significant difference in deposition between the wells of the plate. Initial application of the exposure chamber included exposure of human bronchial epithelial cells to vaporized PG and GLY at ratios of 100% PG, 55:45 PG/GLY, and 100% GLY. PG and GLY are universal components of e-liquids, with 55:45 being a commonly used ratio among e-cig users. IL-6 and IL-8 transcript levels were analyzed in the exposed cells at varying time points. Our results indicate that exposure to PG aerosols increased IL-6 and IL-8 transcript levels at 2 hours post-exposure, suggesting an inflammatory response. Liquid Chromatography interfaced to Electrospray Ionization Mass Spectrometry is used to analyze the aerosol composition. The results of this study describe a novel and versatile in vitro e-cig exposure system that will allow for a controlled, replicable exposure to a variety of different e-cig aerosols, thus producing meaningful in vitro assessment of e-cig toxicity.

1929 Analyzing the Cellular Stress Response in Airway Epithelial Cells to Vaporized Propylene Glycol and Glycerol

In the United States the use of electronic cigarettes (e-cigs) has surged since its introduction to the market in 2007. Despite previous claims that e-cig use is ‘safer’ than traditional cigarette use, there is insufficient data to determine if e-cig generated aerosol itself is safe. To further compound the problem of determining the safety of e-cigs is the sheer number of variations in e-cig use: e-cig device type, wattage or temperature settings, flavorings and nicotine concentrations. However, one standard component of e-cigs, is its use of the humectants propylene glycol (PG) and glycerol (GLY). All e-cig devices heat the humectants to the point of vaporization, which can cause the formation of aldehydes and free radicals. The goal of this study is to determine the health effects of vaporized PG and GLY on airway epithelial cells. We exposed airway epithelial cells (16HBE cells) at air liquid interface to the vaporized humectants: 100% PG, 100% GLY, and 100% PG increased the expression of NAD(P)H Quinone Dehydrogenase 1 (NQO1) and the corresponding protein. These responses were not observed in 16HBE cells exposed to the aerosol generated at the 45W setting of the e-cig device. Additionally, we repeated the 80W exposure with primary airway epithelial cells from non-smokers and smokers. The 100% GLY exposure caused an upregulation of HMOX-1 in the cells from non-smokers but not smokers. Furthermore the PG/GLY exposure caused an upregulation of glutamate-cysteine ligase catalytic (GCLC), which is the rate limiting step of glutathione synthesis, in non-smokers but not smokers. These data suggest that aerosols generated from e-cig devices at high temperatures, regardless of flavoring content, are likely to cause cellular stress responses. Additionally non-smokers are likely to experience more cellular stress from e-cig use than smokers.

1930 Effects of E-cigarette Flavoring Chemicals on Human Macrophages and Bronchial Epithelial Cells

A. Morris1, M. Olguin1, K. Attfield1, J. Fowles2, and S. Leonard1. 1. NIOSH, Morgantown, WV; 2. West Virginia University Health Sciences Center, Morgantown, WV; and 3. California Department of Public Health, Richmond, CA.

E-cigarettes are a relatively new and popular alternative to tobacco cigarettes used by many young adults and teens. Due to their novelty, the respiratory health effects of e-cigarette flavoring components are not well understood. There are thousands of e-cigarette flavoring chemicals available on the market, many of which have the potential for toxicity. The majority of e-cigarette flavoring chemicals (ECFCs) have not been tested for inhalation safety. In this study, we used pulmonary-associated cell lines to assess the in vitro effects of thirty ECFCs to determine their potential cytotoxicity at various concentrations. The ECFC vehicles, propylene glycol (PG) and vegetable glycerin (VG), were tested individually and as mixtures that mirrored common ratios found in e-liquids (50:50 and 30:70 PG/VG, respectively). Cultured human monocytes (THP-1) were differentiated into a macrophage phenotype with vitamin D3 before treatment. Cultured human bronchial epithelial cells (BEAS-2B) and human monocyte-derived macrophages (HMMs) were treated with 10, 100, and 1000 μM of ECFC and analyzed for cytotoxicity and inflammatory markers, including changes in viability, cell membrane damage, reactive oxygen species (ROS) production, and inflammatory cytokine release. The ECFCs that caused the most cell death in both cell types (eugenol, linalool, and nonanol) were primarily classified as hydroxyls. A number of aldehydes (cinnamaldehyde, decanal, and trans-2-hexen-1-al) also caused significant cell death. Cell membrane damage, as measured by lactate dehydrogenase release, was elevated in both cell lines after treatment with eugenol, linalool, and nonanol. Decanal also caused membrane damage to BEAS-2B cells, while vanillen was damaging to THP-1 cells. Vanillien elicited high amounts of ROS from both cell lines, with the BEAS-2B also producing ROS after exposure to diketones (2,3-pentanedione, 2,3-heptanedione, and 2,3-hexanediol). These findings provide insight into the potential tissue damage that e-cigarette users are at risk for and provide a basis for future experiments with ECFC exposures.

1931 Systems Toxicology Assessment of a Representative E-liquid Formulation Using Human Primary Bronchial Epithelial Cells

Cigarette smoke (CS) is a risk factor for respiratory and systemic diseases, smoking cessation remains the most effective approach for risk reduction. Innovative products with the potential to reduce the risk of smoking related diseases are being developed with the aim to provide a better alternative to smokers who would otherwise continue to smoke. Literature suggests that e-vapor products likely have a significantly lower risk profile than cigarettes. E-vapor products that are novel in their notified high amounts of ROS from both cell lines, with the BEAS-2B also producing ROS after exposure to diketones (2,3-pentanedione, 2,3-heptanediol, and 2,3-hexanediol). These findings provide insight into the potential tissue damage that e-cigarette users are at risk for and provide a basis for future experiments with ECFC exposures.
and alpha-pinene (0.049%) were found to exhibit the highest cytotoxicity. A decrease in cytotoxicity was observed only when D-L-citronellol was removed, suggesting that D-L-citronellol was accountable for most of the mixture's overall cytotoxicity.

1932 Differential Regulation of Ion Channel Function from Exposures to Cigarette Smoke and ENDS Preparations

R. E. Rayner1, P. Makena2, G. L. Prasad3, and E. Corney-Boyaka1. 1Ohio State University, Columbus, OH; and 2RAM Services Company, Winston Salem, NC.

Cigarette smoking is known to disrupt the normal mucociliary function of the lungs, whereas the effect of Electronic Nicotine Delivery Systems (ENDS) is incompletely understood. This study aimed to compare the effects of acute exposure of primary normal human bronchial epithelial (NHBE) 3D cultures at air-liquid interface to combustible cigarette and ENDS preparations on mucociliary function including ion channel function, ciliary beat frequency (CBF) and airway surface liquid (ASL) height. Differentiated NHBE cultures were exposed to whole smoke conditioned media (WS-CM) or total particulate matter (TPM) prepared from 3R4F reference cigarettes, whole aerosol conditioned media (ACM) or e-TPM generated from a marketed ENDS product, or nicotine alone. We found that a dose of 7μg/ml equi-nicotine units of cigarette TPM and WS-CM significantly decreased Cystic Fibrosis Transmembrane conductance Regulator (CFTR) and the epithelial sodium channel (ENaC) function which regulate fluid homeostasis in the lung. Conversely, higher (5μg/ml) equi-nicotine units of ENDS preparations or nicotine alone had no effect on CFTR and ENaC function. Despite a significant decrease in ion channel function, cigarette smoke preparations did not alter CBF and ASL. Similarly, ENDS preparations and nicotine alone had no effect on ASL and CBF. This study demonstrates that acute exposures of cigarette smoke preparations exert a notable inhibitory effect on the CFTR and ENaC function compared to ENDS preparations. In summary, the functional assays described herein are useful for tobacco product evaluations.

1933 In Vitro Toxicity Induced by JUUL and E-cigarette Aerosol Extracts in Human Bronchial Epithelial Cells

R. Pinkston1,2, H. M. Zaman3, P. Perveen1, E. Hosseini1, A. L. Penn2, and A. Noel1. 1Southern University and A&M College, Baton Rouge, LA; and 2Louisiana State University, Baton Rouge, LA.

While electronic-cigarettes (e-cigs) are open system devices with user-adjustable operational conditions, JUUL devices are closed system with no modifiable settings. These devices of different design are the most commonly used form of tobacco products by youth in the US; however, scientific evidence related to the effects of e-cig or JUUL aerosols on lung toxicity is limited. The aim of this study was to evaluate the in vitro toxicity of two commonly used JUUL and e-cig flavors: cool mint, a simple flavor mixture, and crème brûlée, a more complex flavor mixture, on human bronchial epithelial (BEAS-2B) cells. JUUL and e-cig aerosol extracts displayed a concentration-dependent decrease in lactate dehydrogenase (LDH) activity (≥25%), a marker of cytotoxicity, for cool mint and crème brûlée JUUL and e-cig aerosol extracts vs. control. Moreover, gene expression (qRT-PCR) were assessed. Cool mint and crème brûlée JUUL flavors composed of a mixture of catechol, a polyphenol, a natural pharmaceutical ingredient, and IL-10, an anti-inflammatory cytokine, were increased ≥4 fold by JUUL and e-cig aerosols compared to control. While the adaptation of existing cigarette smoker-based testing puffing regimes to alternative nicotine delivery devices are an attempt at controlling variability, these fail to address variables unique to the devices themselves such as wattage or flow rate. Furthermore, it is vital to match puff regime to user behavior for realistic exposure assessment. The study investigated variability of aerosol mass generation in two dissimilar devices: the JUUL, a popular electronic cigarette, and a Vaporeoso custom tank aimed at vaping enthusiasts, with the ultimate goal of examining toxicity in 2D and 3D cell culture systems. Both e-cigarette devices were coupled with an electronic cigarette aerosol generator (eAerols) for the generation of an aerosol which was captured on in-line 44nm Cambridge filter pads and weighed. The JUUL device was driven according to the CORESTA puffing regime. JUUL aerosol generation was found to vary considerably with increasing puff count on a single fluid filled pod (1.69mg at puff Number 1 to 3.18mg by puff Number 160), between puffs on the same pod (5D from 0.14 to 1.87mg), and between pods (range 2.17mg to 4.10mg). Such variability only becomes apparent when flow rate and puff timing are strictly controlled. The Vaporeoso tank was subjected to both the CORESTA regime (3s coil activation, 55ml puff volume, 30s interval) and a more realistic profile based upon user observation (4s coil activation, 500ml puff volume, 30s interval) while varying total power output from 60 to 110W. The CORESTA regime revealed an initial increase of aerosol generation with increase in power leveling off between 80 and 110W (17mg initial, leveling at 23mg). The more realistic puff profile demonstrated much higher mass production and a linear increase with no plateau effect (47mg to 92mg). Consequently, applying the CORESTA method to this device appears to underestimate user exposure. Thus, toxicologists must validate e-cigarette aerosol generation methodologies for reproducible toxicity testing.

1934 The Importance of Controlling Exposure Generation Parameters for In Vitro Electronic Cigarette Toxicity Testing

J. Adragna, R. Uhl, K. Corbett, R. Jaeger, and T. Gordon. 1NYU Langone Medical Center, New York, NY; 2Aerols, LLC, Central Valley, NY; and 3ICH Technologies, Westwood, NJ.

Electronic cigarette use increases annually with now soaring rates seen among underage demographics. The current number of studies are insufficient to address health concerns arising from widespread use. Inter-study variability creates doubt about the validity or inter-comparability of study results. Meaningful design requires reliable and replicable control of all parameters influencing exposure generation to study the effects of e-cigarette aerosol on cell culture models. While the adaptation of existing cigarette smoker-based testing puffing regimes to alternative nicotine delivery devices are an attempt at controlling variability, these fail to address variables unique to the devices themselves such as wattage or flow rate. Furthermore, it is vital to match puff regime to user behavior for realistic exposure assessment. The study investigated variability of aerosol mass generation in two dissimilar devices: the JUUL, a popular electronic cigarette, and a Vaporeoso custom tank aimed at vaping enthusiasts, with the ultimate goal of examining toxicity in 2D and 3D cell culture systems. Both e-cigarette devices were coupled with an electronic cigarette aerosol generator (eAerols) for the generation of an aerosol which was captured on in-line 44nm Cambridge filter pads and weighed. The JUUL device was driven according to the CORESTA puffing regime. JUUL aerosol generation was found to vary considerably with increasing puff count on a single fluid filled pod (1.69mg at puff Number 1 to 3.18mg by puff Number 160), between puffs on the same pod (5D from 0.14 to 1.87mg), and between pods (range 2.17mg to 4.10mg). Such variability only becomes apparent when flow rate and puff timing are strictly controlled. The Vaporeoso tank was subjected to both the CORESTA regime (3s coil activation, 55ml puff volume, 30s interval) and a more realistic profile based upon user observation (4s coil activation, 500ml puff volume, 30s interval) while varying total power output from 60 to 110W. The CORESTA regime revealed an initial increase of aerosol generation with increase in power leveling off between 80 and 110W (17mg initial, leveling at 23mg). The more realistic puff profile demonstrated much higher mass production and a linear increase with no plateau effect (47mg to 92mg). Consequently, applying the CORESTA method to this device appears to underestimate user exposure. Thus, toxicologists must validate e-cigarette aerosol generation methodologies for reproducible toxicity testing.

1935 A 7-Month Inhalation Study in C57Bl/6 Mice to Investigate Potential Toxicity of E-vapor Aerosols Compared to Cigarette Smoke Using Cessation and Switching Study Design

A. Kumar1, S. Harbo2, E. Benson1, M. Oldham1, B. Gardner1, J. Hoeng1, W. McKinney1, and K. M. Lee1. 1Altria Client Services LLC, Richmond, VA; 2Battelle, West Jefferson, OH; and 3Philip Morris International R&D, Neuchatel, Switzerland.

Chronic exposure to cigarette smoke is a risk factor for the development of various diseases. Smoking cessation remains the most effective approach to minimize smoking related diseases, however only a small percentage of smokers succeed in quitting. It is generally regarded that switching from combustible cigarette to e-cigarettes (e-vapors), can offer a potential alternative for tobacco-related harm reduction. Though various e-vapor products are available, studies evaluating long-term toxicity and biological implications of e-vapors alone and in the context of switching from cigarettes to e-vapors are not available. We designed a 7-month nose only inhalation (4 hours/day, 5 days/week, for 7 months) study to evaluate chronic toxicity of MarkTen® e-vapor aerosols and compared it to responses from exposure to the 3R4F reference cigarette (CS). Additional groups of mice were added to explore the impact of switching or cessation after first 3 months of exposure to CS. Over the 7 months of exposure, there were no notable in-life observations from the e-vapor groups. Their body weights were comparable to the sham control, whereas the CS group showed consistently lower body weight. In contrast to e-vapor, the 3R4F group showed transient clinical signs of distress post-exposure, and, in part because of reduced respiratory volume during exposure, they had lower plasma nicotine and cotinine levels compared to the e-vapor group. In addition, the CS exposure induced significant changes in organ weights. Following 7 months of exposure, e-vapor resulted in no or minimal increase in inflammatory cellular responses in BALF, while the CS group showed consistently elevated responses (activated macrophages, CD4+ T cells, neutrophils and eosinophils). Also, the extent of changes observed in switching group was overall similar to changes observed in the cessation group. Altogether, the pathophysiological changes induced by e-vapor exposures were significantly lower than changes induced by CS expo-
1936 Toxic Effects of Waterpipe Tobacco Smoking: Revealing the Mechanism Using Bioinformatics Approach

D. Mitic Potkrajac1, T. Krsmanovic1, K. Jankovic1, G. Apic1, and R. B. Russell1. 1Metisox Ltd, Cambridge, United Kingdom; and 2Cell Networks, University of Heidelberg, Heidelberg, Germany.

Waterpipe tobacco smoking (WTS), in Middle East commonly called shisha or narghile, is becoming more popular in Western societies, especially among young people as an alternative form of tobacco use other than traditional cigarettes. Although waterpipe tobacco use is associated with greater carbon monoxide, similar nicotine, dramatically more smoke exposure and some of the same toxins as cigarette smoking, the health risk associated with WTS is highly underestimated. The aim of this study was to investigate toxicities induced by light-use WTS. We analysed gene expression data (Walters M et al, 2017) from small airway epithelium of waterpipe tobacco smokers and WTS impact on pathological changes and affected pathways. From the whole genome analysis, 282 signature genes (p<0.05, FC=1.5) were detected as significantly dysregulated after exposure to WTS. We created a computational model of biological pathways describing cellular processes in human respiratory tissues, by manually annotating and processing molecular information from the published data (PubMed articles and UDA reports) and making the information computable. WTS exposure induced genes involved in immune responses, G-protein coupled receptor signalling, oxidative stress and mRNA regulation of translation. Furthermore, we annotated data about WTS toxic components (such as the ones from Hoffmann’s list, Hoffmann D et al, 1998) and generated a comprehensive database of known side effects and protein targets of these toxicants. By applying bioinformatics analysis tools to gene expression data and combining with toxicants data, we have identified several pathologies that affect respiratory and circulatory system. For each of these pathologies we generated the hypothesis of mechanism of action that is supported by current knowledge. These data imply that even light-use waterpipe tobacco smoking is as much harmful as traditional cigarette smoking, and may lead to damaging respiratory system.

1937 Prenatal Waterpipe Tobacco Smoke Exposure Alters Lung Immune Responses to House Dust Mite Allergen in Adult Offspring Mice

H. L. Hammond, D. B. Paulsen, A. Noel, and A. L. Penn, Louisiana State University School of Veterinary Medicine, Baton Rouge, LA.

The rate of waterpipe (hookah) use is as high as 40% among young adults of reproductive age. There is limited amount of research evaluating potential adverse health effects resulting from maternal hookah use during pregnancy. This study was designed to test the hypothesis that in utero exposures to waterpipe tobacco smoke (WTS) aggravate adult lung immune responses to house dust mite (HDM) allergen. Pregnant BALB/c mice were exposed to either air or WTS with average CO levels of 633 ppm for 2 hours per day during gestational days 6 to 19. Starting at 14 and 15 weeks of age, male and female offspring, respectively, were given an intranasal instillation of saline or HDM (males = 50 μg, females = 25 μg) once a week for 3 weeks. At 17 and 18 weeks of age, lung function (plethysmography), bronchoalveolar lavage fluid (BALF), and lung tissue were examined. In utero exposure status did not alter lung function or structure. Of 84 allergy- and inflammation-related genes examined in the lungs via qPCR array, in utero WTS exposure alone resulted in a significant down-regulation of 24 genes in adult males and 11 in adult females. The 9 genes common to both males and females (Adam33, Alox5, Bcl6, C1r/c2, Il-3ra, Il-4ra, Stat6, Tbx1, and Trnfsf4) are cytokine receptors and transcription factors involved in Th1/Th2 activation and Jak1/Jak3 cytokine signaling pathways, indicating early downstream immunosuppression. In males, histopathological assessment of both HDM challenged groups revealed phenotypic changes associated with allergic asthma. Compared to its in utero air + HDM controls, in utero WTS + HDM males had significantly higher levels of BALF neutrophils and increased gene expression of Il-13 and Il-21 (> 5-fold), and Cc4 and Cc11 (> 3-fold), suggesting an exacerbation of HDM-induced neutrophilic inflammation due to in utero WTS exposure. In the lungs of in utero WTS + HDM females, Cc256, Cc2f, Il-17a, and Il-25 were up-regulated (> 3-fold) compared to the in utero air + HDM females, yet only the latter displayed phenotypic asthmatic responses. No significant cellular or tissue changes were observed in the in utero WTS + HDM females, suggesting a sex-specific response of males to WTS plus HDM allergen. Overall, our data suggest that prenatal exposure to WTS modifies the adult immune response to a common respiratory allergen and that in utero WTS exposures alone may have immunosuppressive effects in the lungs that persist into adulthood.

1938 Exposure of Cells of the Airways to Cigarette Smoke Extract or Acrolein Disrupts the Molecular Regulation of Mitochondrial Metabolism

C. B. Tulen1, C. H. Schiffer1, N. L. Reynaert1, M. A. Dentener1, S. J. Snow1, U. P. Kodavanti2, X. Liu2, P. M. Sivasankar2, F. J. van Schooten1, A. Oppelhozen1, and A. L. Penn1. 1Moscow State University Medical Center, Maastricht, Netherlands; 2US EPA, Durham, NC; 3University of North Carolina at Chapel Hill, Chapel Hill, NC; 4Purdue University, West Lafayette, IN; and 5Netherlands Food and Consumer Product Safety Authority, Utrecht, Netherlands.

Chronic Obstructive Pulmonary Disease (COPD) is a devastating, highly prevalent and incurable lung disease mainly caused by smoking. During pyrolysis and combustion of tobacco, various types of aldehydes are generated of which, due to its unsaturated structure, acrolein is considered the most reactive. From in vitro studies it is known that acrolein can induce cellular processes considered to be central to COPD pathogenesis including inflammation, oxidative stress, cell death and tissue remodelling. Interestingly, mitochondria, traditionally viewed as the cell’s powerhouse, are now known to play an important regulatory role in all of these processes. Moreover, mitochondrial morphology was found to be abnormal in airway epithelial cells of COPD patients. Based on this, we hypothesized that cigarette smoke-induced mitochondrial dysfunction, driven by aldehydes, is the central mechanism underlying COPD airway pathogenesis. This was addressed by investigating the expression of genes involved in the regulation of mitochondrial metabolism, assessment of activity of mitochondrial metabolic enzymes and abundance of mtDNA copy number in primary human bronchial epithelial cells (PBECs), provided by PLUC facility MUMC+, exposed to cigarette smoke extract (CSE: 0-1-2-4%) as well as in lung tissue of rats exposed acutely (1-2 days) or sub-acutely (4 weeks) to acrolein (0-4 ppm). CSE dose- and time-dependently affected gene expression of key constituents and regulators of mitochondrial metabolism in PBECs. Moreover, both acute and sub-acute in vivo exposure of rat lungs to acrolein dose- and time-dependently decreased the activity of Hydroxacyl-Coenzyme A dehydrogenase (rate-limiting enzyme in the mitochondrial fatty acid β-oxidation), upregulated mtDNA copy number and affected mRNA levels of genes involved in the molecular regulation of mitochondrial metabolism. These results show that CSE as well as acrolein disturb the molecular regulation of mitochondrial metabolism in cells of the airways. Disclaimer: This work does not reflect US EPA policy.

1939 Acute Exposure to Thirdhand Smoke Produces Rapid Changes in the Human Nasal Epithelial Transcriptome

G. L. Pozuelos1, M. Kagda1, S. Schick2, T. Girke1, D. C. Volz3, and P. Talbott4. 1University of California Riverside, Riverside, CA; and 4University of California San Francisco, San Francisco, CA.

Thirdhand smoke (THS) is the residue that builds up on indoor surfaces after smoking has occurred. These chemicals remain for months or years and non-smokers can be exposed unknowingly. Prior studies on the toxicity of THS have been done with cultured cells and animal models. The purpose of this study was to evaluate the effects of acute THS exposure on the transcriptome of the human nasal epithelium. Non-smoker females were exposed for a total of ~3 hours in controlled laboratory conditions, first to clean air and later to THS. Nasal scrapes taken before and after exposure were analyzed for differential gene expression using RNA-seq. Clean air exposure only affected the expression of two genes. In contrast, in THS exposed nasal epithelium, 389 genes were differentially expressed, some of which are associated with increased mitochondrial activity, oxidative stress, DNA repair activity, cell survival, and inhibition of cell death. Activation of some of these processes may be due to residual nicotine in THS. Several of these responses are similar to those demonstrated previously using in vitro cultured cells, such as stress-induced mitochondrial hyperfusion. In conclusion, our translational study is the first to show that a 3 hour exposure to THS affects gene expression in humans. Our data are consistent with the idea that short exposure induces cell stress leading to the activation of various survival pathways and that nicotine may be involved in promoting survival. These data will be valuable in formulating regulations for the remediation of THS contaminated environments.
**1940** Cigarette Smoke Induced Pathophysiological Changes in the Extracellular Matrix but not Inflammation as Early Events in Fresh Human Lung Tissue

H. Obernolte1,2, D. Ritter1,2, J. Knebel1,2, M. Niehoff2,2, P. Braubach1,2, D. Jonigk1,2, G. Warnecke1,2, P. Zardo1,2, H. Fieguth1, O. Pfennig1, A. Braun1,2, and K. Sewald1,2. 1Fraunhofer Institute for Toxicology and Experimental Medicine ITEM, Hannover, Germany; 2Member of the German Center for Lung Research (DZL), Biomedical Research in Endstage and Obstructive Lung Disease (BREATHE) Research Network, Member of the Cluster of Excellence Regenerative Biology to Reconstructive Therapy (REBIRTH), Hannover, Germany; 3Medical School Hannover, Hannover, Germany; and 4KRH Clinics, Hannover, Germany. Sponsor: C. Dasenbrock

Cigarette smoke (Cs) inhalation is a main reason to develop chronic obstructive pulmonary disease (COPD), characterised by degradation of alveoli, mucus hypersecretion, emphysema development and inflammation [1]. The pathophysiology of COPD is not well understood so the mechanisms that underlie various components of COPD need to be modelled in vitro, specifically using Cs. We assessed the pathophysiological effects of Cs and Csc on fresh human lung tissue. Human Precision Cut Lung Slices (PCLS) were exposed to Cs or Csc to determine whether their toxicological effect on the lungs. Mitochondria maintain the cellular homeostasis by balancing metabolic activities. We determined the molecular events in the process of Cs-induced mitochondrial dysfunctions and mitochondrial function and dynamics leads to the disruption of cellular function. This study emphasizes the crucial role of mitochondrial proteins and bioenergetics in Cs-induced lung epithelial cellular stress and senescence. Supported by the NIH grants HL137738-01, HL135613, HL085613, ES028006, and EB023595.

**1941** Mitochondrial Stress and Dysfunction by Tobacco Smoke, Leading to Cellular Senescence in Lung Epithelial Cells

Tobacco smoking remains one of the major causes of COPD, which is debilitating and the current treatment is palliative. Cigarette smoke (CS) contains several chemical and physical toxins that are responsible for their toxicological effect on the lungs. Mitochondria maintain the cellular homeostasis by balancing the cellular respiration and energy demand. Any pathological insults to the mitochondrial function and dynamics leads to the disruption of cellular functions. We hypothesized that Cs induces mitochondrial dysfunction in several lung epithelial cells leading to cellular abnormalities. We determined the molecular events in the process of Cs-induced mitochondrial dysfunctions and mitostress by the Seahorse technique. Methods: Human pulmonary epithelial cells like SAEC, NHBEAC, BEAS2B, and mouse MLE15 were exposed to Cs or Csc (CSE) at varying lengths of time (from 24hrs to 15days) and concentrations (0.25% to 2%) and observed various parameters for several endpoints. A minimum of three samples from each group were analyzed for all the estimations. Results: CSE treatment significantly decreased several mitochondrial parameters like non-mitochondrial oxygen consumption (P<0.01), basal respiration (P<0.05), ATP production (P<0.05), and spare respiratory capacity (P<0.05) in these cell lines. OXPHOS blot analysis showed decrease in several of the mitochondrial protein complexes exposed to CSE. Experimental analysis using mitochondrial specific dyes showed decrease in mitochondrial mass, membrane potential, along with the increase in mitochondrial ROS production leading to cellular senescence at day 15. Western blot analysis showed the involvement of important mitochondrial proteins, such as Rho TPase (Miro1), mitofusin2, and parkin in mitochondrial dysfunction caused by CSE (24hrs and 15days). Further studies employing RHO zero cells determined the precise role of mitochondrial disruptions/transfers in these cells. Seahorse data for mitostress and phenotype characterization indicated that cells are under stress at different doses and duration of Cs exposure (P<0.05).

**1942** Vaping during Pregnancy Impairs Cerebrovascular Function in Offspring

E. N. Burrage, E. A. Aboaziza, M. C. Parsley, K. Marshall, J. Moore, A. Johnson, J. O’Reilly, L. Hare, S. Dangott, A. Tice, P. D. Chantler, and L. Oliert. West Virginia University School of Medicine, Morgantown, WV.

Electronic cigarettes (Ecigs) have gained popularity amongst the young, and even is being promoted as a safe or ‘safer’ option than smoking tobacco cigarettes during pregnancy. However, it is unknown if Ecigs are a safer option during pregnancy. We examined the effects of maternal Ecig exposure (Joyetech eGrip OLED using 5-sec puffs @17.5 W) on cerebrovascular function in offspring from rat dams that had been exposed ambient air (Sham, n=6), Ecig with 18 mg/ml nicotine (Ecig+18, n=5) and without nicotine (Ecig+0, n=5). Exposure consisted of 30 puffs over 1-hour each day, 5 days/week, and resulted in an average daily TPM of ~120 mg/m². Maternal exposure was started on gestational day 2 and continued until pups were wean. Pups were never directly exposed. The middle cerebral arteries (MCA) were obtained from 1-month old pups, isolated and positioned in a pressurized in myobath, and exposed to increasing concentrations of acetylcholine (Ach; 10⁻⁴ M to 10⁻² M), serotonin (5-HT; 10⁻⁴ M to 10⁻² M), and sodium nitroprusside (SNP; 10⁻⁴ M to 10⁻³ M) in the presence or absence of Tempol (a superoxide dismutase mimetic). The MCA dilation to Ach was impaired in Ecig+0 and Ecig+18 vs sham pups (14±2%, 10±1%, 30±2%, p<0.05, respectively). Tempol did not affect MCA dilation to Ach in either sham or Ecig+0 pups, but restored MCA dilatory response to Sham levels in Ecig+18 pups, suggesting that vascular dysfunction associated with exposure to Ecig with nicotine involves the superoxide pathway. The MCA constriction to 5-HT was similar between all groups. Minor changes were evident with endothelium-independent dilation to SNP between groups. Examination of posterior cerebral arteries incubated in diaminofluorescein-(DAF)-FM showed a lower nitric oxide bioavailability in the Ecig+0 and Ecig+18 vs pups exposed to nicotine (3.0±2.3, 1.3±0.3 vs 17.3±6.1 au, respectively, ANOVA p<0.05). These data suggest offspring born to mothers who vape during pregnancy (with or without nicotine) have impaired cerebrovascular function suggesting it may not be safe. Our data also suggest the pathway(s) involved may be different with vs without nicotine. **1943** In Utero Exposure to Electronic Cigarettes Results in Aortic Dysfunction

E. A. Aboaziza, E. N. Burrage, J. Moore, J. O’Reilly, M. C. Parsley, K. Marshall, A. Johnson, L. Hare, S. Dangott, A. Tice, P. D. Chantler, and I. M. Oliert. West Virginia University School of Medicine, Morgantown, WV.

Electronic cigarettes (Ecigs) are touted as effective smoking cessation tools and are popular among women of child-bearing age, despite recent evidence of cardiovascular harm. Pregnant women smokers alarmingly turn to Ecigs during pregnancy, although risks to their offspring (even when using nicotine-free e-liquid) are largely unknown. Rat dams were exposed to either nicotine-free Ecig vapor (Ecig+0), Joyetech eGrip OLED using 5-sec puffs @17.5 W or ambient air. Exposure consisted of 30 puffs over 1-hour each day, 5 days/week, and resulted in an average daily TPM of ~120 mg/m². Maternal exposure started on gestational day 2 and continued until pups were weaned (postnatal day 21). Pups were never directly exposed. 2mm segments of thoracic aorta were obtained from 3-month old pups (Ecig+0, n=8; Sham, n=8), dissected out, and mounted on a wire myograph system (DAM, AD Instruments) containing warmed aerated Krebs-Henseleit buffer solution. Vessels were pre-constricted with U46619 (10⁻⁴ M) and exposed to increasing concentrations of methacholine (Mch;10⁻⁵ M to 10⁻³ M) to assess endothelial-dependent relaxation. Pre-constricted vessels were challenged with sodium nitroprusside (SNP;10⁻⁴ M to 10⁻³ M) for endothelial-independent relaxation. Additionally, the rings were subjected to increasing doses of U46619 (U46;10⁻⁴ M to 10⁻³ M) for a constriction-dose response (reported as a % of maximum constriction to KCl). Significant impairment in thoracic dilation to Mch was observed in Ecig pups vs Sham pups (78.6±4.6% vs 86.6±6.0%, p<0.05). No difference in constriction to U46619 nor change in SNP endothelial-independent dilation were different between groups. Examination of aortic rings incubated in diaminofluorescein-(DAF)-FM showed a lower nitric oxide bioavailability in the Ecig+0 pups vs air exposed pups (3.0±2.3, 1.3±0.3 vs 17.3±6.1 au, respectively, ANOVA p<0.05). These data suggest offspring born to mothers who vape during pregnancy (with or without nicotine) have impaired cerebrovascular function suggesting it may not be safe. Our data also suggest the pathway(s) involved may be different with vs without nicotine. In vitro studies have supported the toxicological evaluation of chemicals and complex mixtures including cigarette smoke and next generation tobacco and nicotine products (NGP) which include electronic-cigarettes and tobacco heating products (THP). The NGP environment is fast-paced requiring higher throughput and more advanced in vitro studies, to meet the growing requirement for product innovation and the duty of care assessments. These products are believed to be less risky compared to conventional cigarette smoking, but more work is required to understand this new and continually evolving category. In this study, total particulate matter (TPM) from two commercially available THPs (termed THP1.0 and THS) and a Kentucky reference (3R4F) cigarette were assessed using the in vitro micronucleus assay under various conditions and cell types (V79, TK6 and CHO-K1). V79 and TK6 cells were assessed under short +/- 59 and long +/- 59 conditions using standard manual scoring techniques. CHO-K1 cells were assessed under short +59 conditions and long -59 conditions using automated cell imagine high content screening approaches (Cellomics ArrayScan VTI). The response to reference cigarette smoke varied between cell types. V79 cells gave the most consistent response with all three treatment conditions producing a clear positive response. Human TK6 cells only produced a weak-positive response under one condition (3hr+59) and CHO-K1 cells produced a positive response under long -59 conditions, with automated scoring. However, all three cell lines equally demonstrated a negative response with THPs up to 500 µg/mL. In many cases toxicity of the test article indicated that treatment conditions could be pushed even further. In conclusion, the THPs assessed did not increase the micronucleus formation above control levels at TPM doses far exceeding that of cigarette smoke and up to 500 µg/mL. Cigarette smoke responses were observed in the 0-70 µg/mL range depending on cell type used. This study further supports the growing consensus that THPs are potentially less risky than conventional cigarettes and that innovative screening technologies like HCS can be employed for NGP product assessment. This will become especially important where increasing product innovations require higher throughput duty of care in vitro assessments.

In this study, traditional in vitro toxicological approaches such as in vitro mutagenicity, cytotoxicity and tumour-promoting activity assays were employed across total particulate matter (TPM) and whole aerosol text matrices, to assess cigarette smoke (Kentucky Reference 3R4F) against a prototype electronic cigarette (e-cigarette) that has a unique aerosolisation technology. The Ames bacterial mutation assay was employed using Salmonella typhimurium tester strains TA98, TA100, TA1535, TA1537 and TA102 +/- metabolic activation (59). The mouse lymphoma assay (MLA) was assessed +/- metabolic activation with short 3 h exposures and longer 24 h -59 exposures. The Bhas 42 cell transformation assay supplemented traditional approaches and was incorporated as an in vitro alternative for detecting tumour promoters and the neutral red uptake (NRU) cell viability assay provided an acute measure of cytotoxicity. The in vitro micronucleus assay was employed +/- 59 with short and long exposures. To complement this testing strategy, the Ames assay was also employed with S. typhimurium strains TA98, TA100, TA1535, TA97 and TA102 using a scaled down 35 mm whole aerosol methodology. This methodology utilised a unique set of undiluted exposure parameters. Cigarette smoke from TPM test matrices was deemed positive under almost all test conditions in all assays. For NRU, Ames, MLA, Bhas 42 and IVMN assays, responses were observed at 60 µg/mL, 240 µg/plate, 60 µg/mL, 50 µg/mL and 30 µg/mL respectively. In contrast, THP TPM failed to elicit a response in each of the assays up to 500 µg/mL. In a complementary approach undiluted e-cigarette aerosol was assessed using 90%Bufs. Despite delivering a more concentrated aerosol stream under extreme exposure conditions, e-cigarette aerosol was deemed negative under all conditions and strains, confirming the results obtained in TPM assessments. These data demonstrate that the e-cigarette assessed was negative at doses equivalent and exceeding those of cigarette smoke where positive responses are observed in all assays assessed. This study further supports the growing consensus that e-cigarettes are significantly less toxic than cigarette smoke and that a novel technological development in this case did not adversely affect the genotoxicological outcome.
E-cigarettes (e-cigarettes) are often marketed as safer than tobacco products and are gaining popularity as an alternative to smoking traditional cigarettes. E-cigarettes heat and vaporize e-liquids, which typically contain humectants, nicotine, and flavorings. The flavorings found in e-liquids are generally recognized as safe (GRAS) for oral consumption by the United States Food and Drug Administration (US FDA) but have not been evaluated for inhalational toxicity. Our lab has previously shown that the flavoring chemical cinnamaldehyde, an aromatic aldehyde that is component of spicy and cinnamon-flavored e-liquids, can impair key functions in human neutrophils, macrophages, and natural killer cells. In this study, we isolated peripheral blood neutrophils from healthy human subjects and investigated the effects of two other aromatic aldehyde flavoring chemicals found in e-liquids - ethyl vanillin and benzaldehyde - and one non-aromatic aldehyde flavoring - isoamyl acetate. We challenged the isolated neutrophils with up to 5 mM of each flavoring compound and then assessed changes in phagocytosis, oxidative burst, and cytotoxicity.

Materials and Methods:

Neutrophils were isolated from whole blood samples using a density gradient centrifugation method. The isolated neutrophils were then challenged with 5 mM of each flavoring compound and the effects on phagocytosis with pHrodo Red-labeled Staphylococcus aureus particles, oxidative burst, and cytotoxicity were assessed.

Results:

1. Phagocytosis: The percentage of neutrophils that phagocytosed pHrodo Red-labeled S. aureus particles was significantly decreased in the presence of ethyl vanillin and benzaldehyde compared to control, while isoamyl acetate did not significantly affect phagocytosis.

2. Oxidative Burst: The ROS production measured by dihydroethidium (DHE) was significantly decreased in the presence of ethyl vanillin, benzaldehyde, and isoamyl acetate compared to control.

3. Cytotoxicity: The lactate dehydrogenase (LDH) release was significantly increased in the presence of ethyl vanillin, benzaldehyde, and isoamyl acetate compared to control.

Conclusion:

The study findings suggest that the aromatic aldehydes found in e-liquids can significantly impair phagocytosis and oxidative burst, and cytotoxicity of neutrophils. These findings highlight the potential respiratory health risks associated with e-cigarette use and underscore the need for further research to better understand the health impacts of e-cigarette flavorings.
1952 The Role of PI3K Pathway and MAPK Pathway in Cigarette Smoke-Induced Autophagy and Inflammation in BEAS-2B Cells

Smoking, as an individual consumption habit and cigarette smoke being environmental pollutant, involves a variety of related diseases. Exposure of cigarette smoke was reported to induce autophagy and inflammation in humans, experimental animals and different cell lines. However, the exact toxicological mechanisms of cigarette smoke in organisms have not been fully explored. In the present study, our goals were to explore the autophagy and inflammatory responses induced by cigarette smoke in human bronchial epithelial cells (BEAS-2B), and the role of the phosphatidylinositol 3-kinase (PI3K) pathway and the mitogen-activated protein kinase (MAPK) pathways in autophagy and inflammation. The alterations of autophagy-related proteins and inflammation-related proteins were detected by western blot assays, and the release of inflammatory cytokines was detected by enzyme-linked immunosorbent assays. The results showed that in BEAS-2B cells exposed to 10 µg/mL cigarette smoke particle matter (TPM), the activities of autophagy-related protein LC3B-II increased in time-dependent manner, and obtained its maximum at 24 h. The release level of IL-1β, IL-6 and IL-8 were increased with the exposure time. The alterations of autophagy classical pathway PI3K/Akt/mTOR were inhibited and inflammatory pathway MAPKs were activated in time-dependent manner. These results suggested that cigarette smoke-induced autophagy and inflammation, and the PI3K/Akt/mTOR pathway might be involved in the activation of autophagy induced by cigarette smoke, as well as the MAPK pathway might be involved in the inflammation induced by cigarette smoke. These results might help to understanding the adverse outcome pathway underlying cigarette smoke exposure and provide the information for the health risk assessment of tobacco products.

1954 Assessment of Anti-Cancer Potential of Nanogold Conjugated Toxin GNP-NN-32 from Naja Venom in Human Breast Cancer Cell Lines
S. Pandit, and S. Attarde. Savitribai Phule Pune University, Pune, India. Sponsor: P. Deshmukh

Cancer, despite the all-out efforts from developed countries still causes one in five deaths. Surgery, chemotherapy and radiotherapy provide inadequate protection and instead affect normal cells along with cancer cells. The present study aims at exploring the conjugation of protein toxin (NN-32) on GNP surface, characterization and comparative study of toxicity profile of NN-32 and GNP-NN-32. The present study was planned to evaluate in vitro toxicity of NN-32 and GNP-NN-32. The outline of study describes procurement of snake venom, purification of protein NN-32, the synthesis of gold nanoparticles (GNP), conjugation of NN-32 with GNP to synthesise GNP-NN-32 and characterization of GNP-NN-32 by various analytical methods. The study protocol was approved by the Institutional Bio-safety Committee (IBSC) and Institutional Animal Ethics Committee (IAEC) of Savitribai Phule Pune University, Pune, India. We have performed MTT assay, Neutral red uptake assay, Anti-proliferation assay and Detection of apoptosis by flow cytometric analysis on human breast cancer cell lines (MCF-7 & MDA-MB-231) after treatment with NN-32 and GNP-NN-32. IC50 values of NN-32 toxin and GNP-NN-32 toxin after 48 hrs treatment ranged between 2.5 and 6.7 µg/ml and 1.5 and 5.0 µg/ml for MCF-7 and MDA-MB-231 cell lines respectively, as compared to IC50 value 25µg/ml and 19 µg/ml respectively for the normal MCF-10A cells.

1955 Nicotine Induces Malignant Transformation through Oxidative Stress in Human Renal Epithelial Cells
Y. Chang, and K. Singh. Texas Tech University, Lubbock, TX.

Kidney cancer is one of the most common and lethal urologic malignancy. Nicotine is a component of cigarette smoke and mounting evidence implicates tobacco smoking in kidney cancer development. Whether nicotine itself can cause kidney cancer and the underlying molecular mechanisms is still not well understood. Hence, the objective of this study was to determine the chronic effects of nicotine exposure in malignant transformation of HK-2 kidney epithelial cells. In order to understand the molecular mechanism, the effect of nicotine exposure on the expression of genes for cellular reprogramming, redox status, and growth signaling pathways were also evaluated. Results revealed that chronic exposure to nicotine induced growth and malignant transformation in HK-2 cells. Interestingly, the nicotine-exposed cells had inherently (even after withdrawal of nicotine exposure) increased levels of intracellular ROS, acquired stem cell-like sphere formation, and epitheliomesenchymal-transition (EMT) changes. The analysis of gene expression further confirmed the results. Treatment with antioxidant NAC resulted in abrogation of EMT and stem cell-like sphere in HK-2 cells thereby suggesting the role of nicotine-induced ROS in these morphological changes. The results also suggest that nicotine-induced ROS, through regulation of AKT pathway, control the EMT and stemness during early stages of carcinogenesis. In summary, to our knowledge, this is the first report showing that chronic exposure to nicotine induces malignant transformation in human kidney epithelial cells through generating oxidative stress that can be potentially inhibited by antioxidant.

1956 DNA Transcription Highly Sensitizes the Del Assay to Ames Assay Negative Carcinogens
R. Schiestl. University of California Los Angeles, Los Angeles, CA.

Genetic instability is a hallmark of carcinogenesis. Furthermore, cells from patients carrying mutations conferring cancer prone phenotypes show a higher level of genetic instability, including DNA deletions. In fact, the original yeast-based DEL (deletion) Assay with 100 chemicals shows an accuracy of 92% to detect carcinogens as compared to 62% detected with the Ames Assay. DEL events in all three formats are inducible by a wide variety of carcinogens including carcinogens that are negative in many other short-term tests. Here we introduce the next generation DEL assay: a novel Saccaromyces cerevisiae strain, Del- Lac. During an exposure to a genotoxic event the sequence is excised and the two lacZ gene fragment showing an internal duplication of DEL-Lac. During an exposure to a genotoxic event the sequence is excised and the two lacZ gene fragment showing an internal duplication of DEL-Lac. During an exposure to a genotoxic event the sequence is excised and the two lacZ gene fragment showing an internal duplication of DEL-Lac. During an exposure to a genotoxic event the sequence is excised and the two lacZ gene fragment showing an internal duplication of DEL-Lac. 1957 Radiation Induces Microhomology Mediated Recombination In Trans

Ionizing radiation causes DNA double-strand breaks and genome rearrangements that can lead to cancer. Illegitimate recombination repairs a DNA double-strand break in the absence of extended sequence homology. Some illegitimate recombination events, also called microhomology-mediated recombination, occur between several basepairs of homology in the genome that generate about 50% of large deletions causing human genetic diseases. Ionizing radiation-induced genome rearrangements often show such microhomologies at their junctions, implying that radiation-induced double-strand breaks are preferentially repaired by such recombination events. However, events at undamaged sites have so far not been documented. Here, we report that both ionizing radiation and restriction enzymes induce microhomology-mediated integration of the DNA substrate in trans at sites that are not damaged. Irradiated yeast cells displayed 82% microhomology-mediated homologous integration, compared to only 27% in unirradiated cells. Restriction enzymes enhanced both integration events at genomic restriction sites and random non-restriction sites via microhomology-mediated recombination. Furthermore, exposure of yeast and mammalian cells to ionizing radiation before transformation of an end-joining substrate showed increased utilization of microhomology of end-joining events in a transfected plasmid that has not been exposed to radiation. These results suggest that genomic double-strand breaks caused by ionizing radiation or restriction enzymes induce a genome-wide microhomology-mediated illegitimate recombination pathway that facilitates integration in trans at non-targeted sites and might be involved in the generation of large deletions and rearrangements.

1958 The Extent to Which Sunscreen SPF Correlates with Ability to Protect against UV-Induced Mutations In Vitro

A commercial sunscreen’s sun protection factor (SPF) measures how much longer it protects skin against erythema induced by UVB light versus unprotected skin. Studies have shown DNA is a major chromophore for erythema, with erythema color intensity correlating with amount of DNA damage as measured by pyrimidine dimer formation (Young et al., 1998). However, the direct correlation between SPF level and protection against DNA damage has not previously been established. In this study, the relationship between SPF levels in commercial chemical sunscreen and protection against UVB-induced mutations was measured in vitro. Salmonella typhimurium TA 102 bacteria cells were exposed to UVB light with an SPF 15, 30, 50, or 100+ layer of sunscreen between the light source and petri dish. The number of revertant colonies (colonies) was counted after incubation, indicating the number of bacteria that mutated (Ames et al., 1973). Three trials at each SPF level were performed. For a UVB exposure of 45 seconds at 0.08 mw/cm², no significant differences were found between the mean number of colonies formed at each SPF level (SPF 15:295, SPF 30:358, SPF 50:395, SPF 100+376). The positive control, which was exposed to UVB light without sunscreen, had a statistically significant higher mean of 1671 colonies. A mean of 157 colonies formed in the negative control, which was not exposed to UVB light. The experiment was repeated with a longer exposure of 60 seconds at the same UVB intensity. Again, the mean number of colonies was not statistically different among SPF levels (SPF 15:530, SPF 30:581, SPF 50:539, SPF 100+469; pos. control: 2257, neg. control: 173). However, the means of the lower SPF levels (15:530 and 30:581) were higher than the means of the higher SPF levels (50:539 and 100+469), suggesting that high-SPF products may be more protective for longer exposures. This is expected based on the definition of SPF. How 45 to 60 seconds of UV exposure in a bacterium translate into hours of UV exposure hours in human is unknown. However, the results warrant further research into the exposure duration at which higher-SPF products become more protective against mutagenesis than lower-SPF products. Further research could guide the selection of the SPF sunscreen level necessary for protection against mutagenesis for the duration of time spent outside. The results suggest that while high SPF sunscreen may be unnecessary for short exposure, they may offer superior protection for longer exposure to the sun.

1959 Pimavanserin Tartrate, a Novel Anti-Parkinson Drug Suppresses Pancreatic Tumor Growth by Inhibiting Akt/Gli-1 Signaling Axis

S. Ramachandran, and S. K. Srivastava. Texas Tech University Health Sciences Center, Amarillo, TX.

Despite major advances in cancer treatment, pancreatic cancer is still incurable and the treatment outcomes are limited. In the current study, we evaluated the anti-cancer effects of pimavanserin tartrate (PVT), an anti-parkinson drug used for the treatment of Parkinson’s disease psychosis. Our observations indicated that, PVT significantly suppressed the proliferation of pancreatic cancer cells by inducing apoptosis. Anti-proliferative and apoptosis inducing effects of PVT were mediated by the inhibition of pAkt (Ser473), Akt, Gli-1, Oct-4, Sox-2, Nanog, and c-Myc. Akt and Oct-4 inhibition by PVT treatment was further validated by immunofluorescence analysis. Apoptotic effects of PVT was confirmed by increase in cleavage of caspase-3 and PARP. In addition, PVT inhibited the formation of tumourspheres in PANC1 pancreatic cancer cells. Inhibition or silencing of Akt and Gli-1 using specific inhibitors or siRNA enhanced the growth suppressive effects of PVT in pancreatic cancer cells. Oral administration of PVT suppressed BxPC3 tumor xenografts by 50% in athymic nude mice. In another in vivo experiment, PVT treatment inhibited the growth of orthotopically implanted PANC1 tumors by 75%. Chronic administration of PVT did not exhibit any general signs of toxicity or behavioral side effects in mice. Since, PVT is already available in clinic with an established safety profile, our results will accelerate its clinical development for treatment of patients with pancreatic cancer. Taken together, our results indicate that pancreatic tumor growth suppression by PVT is orchestrated by inhibition of Akt/Gli-1 signaling.

1960 Design, Synthesis, and Evaluation of Novel Penfluridol Analogs with Optimized Toxicity Profile

M. Ashraf-Uz-Zaman, M. Sajib, C. Mikelis, and N. German. Texas Tech University Health Sciences Center, Amarillo, TX.

Penfluridol (PFL) is an antipsychotic agent that was used in the treatment of chronic schizophrenia since 1968. In the late 1980s, P. B. Mortensen has explored the potential use of PFL as an antineoplastic agent. Later, several groups have confirmed cytotoxicity of this drug in a variety of in vitro and in vivo cancer models, supporting an idea of the potential use of PFL in the treatment of cancer patients. However, monitoring of likely central nervous system (CNS) related extrapyramidal side effects was not performed. Majority of reported anticancer studies identified 10 mg/kg dosing as the most relevant for observing the desired effect. We have established that a 10 mg/kg dose of PFL (i.p. or oral) corresponds to a level of 1 µM of this compound in the brain. Such concentration is enough to block a majority of CNS receptors, including serotonin (Kd = 4.8, 5.6 µM) and PF331 (Kd = 4.8, 5.6 µM) and PF331 (Kd = 4.8, 5.6 µM) receptors and elicit unwanted side effects in patients undergoing chemotherapy. Thus, the use of PFL as an anticancer agent can be complicated by its ability to interact with CNS receptors. We proposed to eliminate the CNS toxicity of PFL by previously reported differences in structural requirements for its antipsychotic and anticancer properties. Design and synthesis of analogs were followed by in vitro evaluation of compounds using MTT assay in MDA MB 231 and LLC luc cell lines and by assessing the corresponding CNS receptors (major sub classes of dopamine, serotonin, sigma, opioids, and histamine) and transporters (DAT, NET, and SERT) binding profile (percentage of inhibition at 10 µM and Kd, values). As a result, we were able to identify compounds PF131 (IC50 = 4.8, 5.6 µM) and PF331 (IC50 = 5.4, 2.7 µM) with a substantial reduction in affinity towards CNS receptors and transporters when compared to PFL. Further, we have evaluated the toxicity profile (change in body weight, vital organ weight and clinical chemistry analysis of blood samples) of these compounds at the end of 7 days of treatment and assessed their distribution profile (C57BL6 female mice, i.p. dosing of 10 mg/kg, 0-96 hours). Finally, the anticancer activity of compound PF331 was analyzed in vivo using lung cancer model (C57BL6, i.p. daily dose of 10mg/kg) where 80% tumor size reduction was observed. In conclusion, we have identified a novel analog of PFL with improved toxicity profile and ability to reduce tumor size by 80% in vivo.
1961 Inhibition of Endothelial RhoA-ROCK Pathway Blocks Cancer Metastasis

Texas Tech University Health Sciences Center, Amarillo, TX.

The principal health complication of cancer patients is metastasis: the disemination of cancer cells from the primary tumor to distant parts of the body. It is the cause of more than 90% of cancer-related deaths and the main goal in cancer research. An important step in metastatic process is the migration of the disseminating cancer cells through the endothelial monolayer during entrance or exit from the vasculature. The molecular mechanisms underlyng metastasis, especially the interaction of cancer cells with the endothelial lining of the vasculature is poorly understood. It has been shown that endothelial RhoA-Rho kinase (ROCK) pathway is responsible for vascular permeability through cytoskeletal remodeling. In the present study we investigated the role of endothelial RhoA-ROCK pathway in cancer cell trans-endothelial migration and eventually cancer metastasis. We have used a quantifiable, highly reproducible, transwell-based, two-cell co-culture model of trans-endothelial migration, where Green Fluorescent Protein (GFP) or Red Fluorescent Protein (RFP) expressing cancer cells transmigrate through an endothelial monolayer. Endothelial RhoA and the downstream signaling pathway were blocked by siRNA or pharmacological inhibitors. Biochemical assays were performed to identify the molecular mechanisms of cancer cell-induced RhoA activation in the endothelial cells. In vivo, endothelial specific RhoA-deficient mice were used in experimental metastasis models and Fasudil, a clinically relevant inhibitor of the RhoA pathway was utilized in wild-type mice to evaluate the clinical potential of our findings. A variety of different cancer cell lines of both murine and human origin were able to potentiate ROCK activation in the endothelial cells. Zt/g4-MMAE at 10 mg/kg in a Q12 x 2 regimen completely eradicated TNBC subpopulation and reduced sphere formation of TNBC stem-like cells.

1962 RON Receptor-Targeted Antibody-Drug Conjugate Therapy Eliminates Cancer Stem-Like Cells and Induces Long-Term Tumor Regressions in Preclinical Models of Triple-Negative Breast Cancer (TNBC)

S. Suthre1, H. Yao2, and M. Wang1, 1Texas Tech University Health Sciences Center, Amarillo, TX; and 2Zhejiang University School of Medicine, Hangzhou, China.

Triple-negative breast cancer (TNBC) is a highly diverse group of malignant neoplasia with poor outcome. Currently, the lack of effective targeted therapy has fostered a major effort to discover new targets to treat this malignant cancer. Here we identified the RON receptor tyrosine kinase as a therapeutic target for potential TNBC treatment by using a novel anti-RON monoclonal antibody (Zt/g4- anti-RON (MMAE)) Anti-RON antibody Zt/g4 was conjugated through a dipeptide linker to MMAE, a potent tubulin inhibitor. The generated Zt/g4-MMAE has a drug-antibody ratio of 3.2:1. The conjugation profile and drug stability were analyzed using HPLC. A panel of TNBC cell lines representing different subtypes and expressing different levels of RON was used as a biological model. Zt/g4-MMAE-induced cell surface RON internalization, cell-cycle arrest, and cellular cytotoxicity. We first analyzed RON expression in 168 primary TNBC samples via tissue microarray using anti-RON IHC and demonstrated that RON was widely expressed in 76.8% TNBC samples with overexpression in 76.2% of cases (45.2%). These findings provide the basis to target RON for TNBC therapy using anti-RON ADC (Zt/g4-MMAE). In vitro, Zt/g4-MMAE rapidly induced RON internalization, resulted in cell cycle arrest followed by massive cell death. Zt/g4-MMAE also effectively killed TNBC stem-like cells with RON+/CD44+/CD24- phenotypes and RON-negative TNBC cells through the bystander effect, which effectively eliminated CSC subpopulations and reduced sphere formation of TNBC stem-like cells. In vivo, Zt/g4-MMAE at 10 mg/kg in a Q12 x 2 regimen completely eradicated TNBC xenografts caused by two TNBC cell lines without the regrowth of xenograft tumors. Increased RON expression is a pathogenic feature in primary TNBC samples. Zt/g4-MMAE is highly effective in eradicating TNBC xenografts in preclinical studies with lasting effects up to 6 weeks without signs of tumor regrowth. The current study has met our objectives. The first was to determine levels of RON expression from primary TNBC samples by anti-RON immunohistochemical (IHC) staining. The second was to validate the efficacy of anti-RON antibody Zt/g4-drug monomethyl auristatin E (MMAE) conjugate for TNBC therapy. These studies provide the basis for targeting RON as a novel strategy for TNBC treatment using anti-RON ADC Zt/g4-MMAE.

1963 Evaluation of the Potential Carcinogenicity of the Pyrethroid Imiprofin in Mice

T. Yamada1, L. Rhomberg1, J. Haseman3, P. Greaves4, H. Greim5, C. Berry6, and S. Cohen7, 1Summito Chemical Co., Ltd., Osaka, Japan; 2Gradient, Cambridge, MA; 3J.K. Haseman Consulting, Raleigh, NC; 4University of Leicester, Leicester, United Kingdom; 5Technical University Munich, Weihenstephan, Germany; 6Queen Mary University of London, London, United Kingdom; and 7University of Nebraska Medical Center, Omaha, NE.

The carcinogenic potential of the non-genotoxic pyrethroid imiprofin was examined in two long-term bioassays, one in SD rats and the other in CD-1 mice. There was no carcinogenic activity in rats up to 5000 ppm of the diet. In mice, imiprofin was administered to males and females at dietary concentrations of 0, 100, 3500, or 7000 ppm, with a reduction of body weight at 7000 ppm indicating systemic toxicity. The Maximum Tolerated Dose (MTD) was exceeded at 7000 ppm for both males and females (body weight reductions of 15% and 22% versus controls, respectively). In addition, significant increases in mortality were seen in females in the 7000 ppm group (45.1%, treated vs. 13.7%, controls). Under these conditions, there was a higher incidence of lung adenocarcinomas in the 7000 ppm male group that was statistically significant (p=0.03) by a Fisher’s exact test. However, the most widely used procedure to adjust for multiple comparisons for commonly occurring tumors (including lung tumors in the male mice) requires p<0.01 statistical significance for a pairwise comparison, so by this criterion the increase is not statistically significant. Moreover, there were no significant increases (even at the p<0.05 level) in the incidences of combined adenomas and adenocarcinomas, the most appropriate evaluation, in any dose group, male or female. There were significant (p<0.05) trends for increased adenomas and combined adenomas and carcinomas with increased dose in females and for adenocarcinomas in males, using the Cochran-Armitage linear trend test and Poly-3 test. However, if the highest dose is removed from consideration owing to its exceeding the MTD, there are no significant increases (trends or pairwise comparisons) in tumor formation. Additional evaluation of lung lesion development indicated that there were no statistically significant increases in any tumor formation in any dose group, even at p<0.05. Based on high susceptibility of this mouse strain for appearance of lung tumors and the lack of a statistically significant increase in tumors, the mouse study does not indicate a carcinogenic effect of imiprofin, and thus no classification for carcinogenicity is appropriate.

1964 Overcoming the Acquired Drug Resistance of Gefitinib in A549 via Downregulations of Twist1

Z. Liu and W. Gao, West Virginia University, Morgantown, WV.

Overexpressed Twist1 in primary and metastatic non-small cell lung cancer (NSCLC) has been identified as a critical therapeutic target. Our previous study has demonstrated that Twist1 was significantly increased in gefitinib-resistant A549 (A549GR) compared to A549, which could play a critical role in the epithelial mesenchymal transition (EMT) observed in A549GR. Our present study showed that compared with A549, A549GR was also resistant to AZD9291, a third generation of epidermal growth factor receptor-tyrosine kinase inhibitor (EGFR-TKI). Knockdown of Twist1 in A549GR was carried out using Twist1 shRNA plasmid (A549GR-KO-T). Significantly increased sensitivity to gefitinib or AZD9291 was observed in A549GR-KO-T compared to A549GR and/or A549GR transfected with scrambled control plasmid (A549GR-KO-C). The IC50s (µM) of A549GR and A549GR-KO-C to gefitinib was 51±1.0 and 50±1.6, respectively, while the IC50 of A549GR-KO-T to gefitinib was 35±2.0. The IC50s (µM) of A549GR, A549GR-KO-C, and A549GR-KO-T to AZD9291 were 12.0±1.0, 11.8±0.7, and 8.3±0.6, respectively. Moreover, it was found that knockdown of Twist1 could significantly enhance the EGFR-TKI therapeutic effects in lung cancer cells with acquired EGFR-TKI resistance.
Among the mechanisms of gene expression regulation involving posttranslational modification of messenger RNA, adenosine N6 methylation (m6A), is the most prevalent. This modification participates in a variety of RNA processing, including splicing, mRNA stabilization as well as in translation regulation. Interestingly, the gene expression associated with stem cell pluripotency and specific differentiation are controlled by m6A levels on mRNAs. The decrease in the m6A mark due to the increased action of the demethylases FTO / ALKBH5 or to a defect on methyltransferases (MTs), leads to the acquisition of cancer stem cell (CSC) markers (CD44, SOX2 and NANOG) and is often linked with cancer development. Exposure to inorganic arsenic is associated with prostate cancer in humans and in vitro cellular models exposed to this toxicant show an increased expression of CSC markers. This observation suggests that in these cells the mechanism associated with m6A RNAs regulation should be altered and could play a role in the malignant transformation of prostate CSCs. In this work we evaluated the demethylases FTO and ALKBH5 and the MTs MTTL3 / MTTL14 transcript levels, as well as stem cell markers CD44, NANOG and SOX2 gene expression in prostate CSCs malignantly transformed with sodium arsenite (As-CSCs). These cells showed a significant over-expression of FTO (p=0.0174) and an increased expression of ALKBH5 (p=0.0772) that correlated with a significant increase in the expression of SOX2 (p=0.0002) and the 5 cmarker CD44 (p=0.0011). These results suggest that inorganic arsenic may favor the selective growth of CSCs that over-express SOX2 as a consequence of an increased removal of the m6A mark in mRNAs that code for this gene; such events may favor the development of cancer in prostate cells.

**A Case Study Using a Systematic Review Approach for Cancer Hazard Identification That Incorporates the 10 Key Characteristics of Carcinogens**

Evaluating the carcinogenic mechanisms for a substance is challenging, in part due to the broad range of information and lack of a widely accepted approach. The 10 key characteristics of carcinogens (KCs) offer a way to identify and organize mechanistic information. Systematic review (SR), a review approach particularly useful in handling inconsistent results, aims to answer a specific question while minimizing bias by using a pre-defined protocol to search, evaluate, and synthesize all relevant studies for the question. We used KCs and an SR approach to synthesize cancer mechanistic information of antimyoxid (Sb(O)3), a synergist for flame retardants and catalyst in polyethylene terephthalate (PET) plastics production, along with selected other compounds containing trivalent antimony. First, references were identified in three databases using a systematic literature search strategy and selected with predefined inclusion and exclusion criteria. Second, mechanistic studies were evaluated individually by at least two scientists for quality and for utility to inform mechanisms of Sb(O)3 carcinogenicity. Factors relating to test article (e.g., purity), model system (e.g., animals, cell lines, bacterial strains), method (e.g., consistency with current guidelines for in vitro human cells and spem whale skin cells). We compared these results to data from human cell studies. Whales are our closest marine relatives, have long lifespans, breathe air, and are exposed to environmental Cr(VI). Importantly, they have low cancer rates and cell culture studies indicated that Cr(VI) induced aneuploidy and centrosome amplification in whale cells and compare to data from human cell studies. Whales are our closest marine relatives, have long lifespans, breathe air, and are exposed to environmental Cr(VI). Importantly, they have low cancer rates and cell culture studies show they are resistant to Cr(VI) genotoxicity. Thus, we investigated Cr(VI)-induced aneuploidy and centrosome amplification in sperm whale lung cells and compare to data from human lung cells. Fibroblasts from human lung, bowhead whale lung, and sperm whale skin were treated with zinc chromate, a particulate Cr(VI) compound. Aneuploidy was measured by analyzing solid stained chromosomes. Zinc chromate exposure for 24 h did not cause aneuploidy changes in any cell line. In human cells, 120 h exposure to 0.1, 0.2, 0.3 and 0.4 µg/cm² zinc chromate induced aneuploidy in 13.5%, 17.6%, 23.4%, 25.4% and 36.5% of cells. However, while both cell lines retained low rates of aneuploidy, spindle assembly checkpoint (SAC) bypass can cause aneuploidy by allowing chromosomes to dissociate prior to proper kinetochore attachments. Evidence of SAC bypass was measured via solid stained chromosomes and 120 h treatment of 0.2, 0.3 and 0.4 µg/cm² zinc chromate induced centromere spreading, premature centromere division and premature anaphase in human cells. No increase in SAC bypass was observed in whale cells at any treatment concentration or time point. Supernumerary centromeres can cause CIN through multiple mitoses and asymmetrical chromosomal segregation. Fluorescently immunostained centromeres were counted after Cr(VI) treatment. Centrosome amplification was unchanged after 24 h exposure in all cell lines, but at 120 h increased in human cells by 9-16.4% in interphase and 18-43% in mitotic cells, while whale cells exhibited no increases. These data

**Improving Formalin-Mixed Paraffin-Embedded (FFPE) Samples for DNA-Sequencing Analysis**

L. Wehms, C. Wood, P. Guan, H. Moore, C. Yauk, L. Peel, M. Gosink, and S. Hester. *US EPA, Research Triangle Park, NC; *US EPA (Formerly), Research Triangle Park, NC; *National Cancer Institute, Bethesda, MD; *Health Canada, Ottawa, ON, Canada; †HESI, Washington, DC; and *Pfizer, Inc., Groton, CT.

Archival FFPE samples provide an untapped resource for mining genomic data. However, damage of nucleic acids during formalin fixation leads to latent sequencing artifacts. Previously, we showed that organocatalyst use during RNA isolation protocols improved FFPE RNA-sequencing data. The goal of the current study is to evaluate whether (a) a novel organocatalyst treatment improves FFPE DNA-seq data, (b) RNA-seq variants can be filtered out formalin-induced sequence artifacts in DNA, and (c) time in formalin alters these FFPE DNA-seq analyses. Here, we isolated RNA and DNA +/- organocatalyst from paired FFPE and frozen human kidney and ovarian cancer specimens collected through the Biospecimen Pre-analytical Variables Program-National Cancer Institute. Sample collection/processing was prospectively designed to evaluate common pre-analytical variables. Both renal and ovarian carcina samples were either frozen and embedded in OCT or formalin-fixed for 12 hours prior to paraffin embedding. Ovarian carcinoma samples also included a 72-hour formalin fixation timepoint. Tumor types were microscopically verified and nuclei counts were obtained (Aperio Slide Scan). For nucleic acid normalization and positively associated with RNA and DNA yields (r= 0.142 and 0.383, respectively). RNA and DNA were isolated +/- extended organocatalyst incubation (Qiagen FFPE AllPrep). Total RNA-seq library preparation required 4 to 6 FFPE curls 10 µM thick with more for FFPE DNA where yields were 1.6-16.4-fold higher. Formalin-fixed samples had ~1.8/4.5-fold less RNA/DNA, respectively compared to the 12 hr. formalin-fixed samples (4.7 ± 2.6/1.1 ± 0.9 µg). Total RNA and DNA-exome sequencing were performed by Q2 solutions (Durham, NC). Across FFPE samples, we identified ~2-fold higher reads mapped to intronic regions (50-60% total) and half the reads mapped to exons (25-30%) vs. paired frozen. While use of the organocatalyst improved FFPE RNA yields, it did not with the matching FFPE DNA. This suggests that incubation conditions ideal for reversing formaldehyde damage in FFPE RNA may not be the same as in FFPE DNA. With the growing importance of large-scale genomic analyses, this work will have important applications in mechanistic toxicology and precision medicine. This study does not reflect US EPA policy.

support the hypothesis in comparison to human lung fibroblasts, whale cells have cellular strategies to protect against Cr(VI)-induced centrosome amplification, SAC bypass, and numerical chromosome instability. This work was supported by NIHES grant R01ES016892 (J.P.W.).

1969 Nuclear Receptor 4A1 (NR4A1) as a Drug Target for Endometriosis

S. Safe1, S. Han2, and K. Mohankumar1. 1Texas A&M University, College Station, TX; and 2Baylor College of Medicine, Houston, TX.

Endometriosis is a common but complex inflammatory disease that primarily affects women during their reproductive years, and it is estimated that 5,500,000 women in the United States and 176,000,000 worldwide exhibit symptoms of endometriosis. Current therapies for endometriosis include progestins, oral contraceptives and GnRH antagonists however since these therapies are hormonal these treatments are not viable for women of reproductive age and there is an urgent need for development of new and more effective therapies. The orphan receptor NR4A1 is expressed in cancer and in endometriotic tissue and ongoing studies in this laboratory demonstrate that 1,1-bis(3′-indolyl)-1-(p-hydroxyphenyl) methane (DIM-C-pPhOH) and related compounds act as NR4A1 antagonists and inhibit NR4A1 regulated pro-oncogenic pathways. In this study we have used patient-derived endometriotic cells and normal endometrial cells and DIM-C-pPhOH inhibited growth and induced apoptosis in endometriotic but not in normal cells. Moreover we also observed similar results in cells transfected with oligonucleotides targeting NR4A1 (siNR4A1) demonstrating an important role for NR4A1 in endometriotic cell growth and survival and this was also confirmed in an in vivo model of endometriosis in mice. Moreover, we also observed that specific pathways (eg. mTOR) and genes (survivin and epidermal growth factor receptor (EGFR)) that are well characterized pro-oncogenic factors are also regulated by NR4A1 and treatment by with the NR4A1 antagonist DIM-C-pPhOH or knockdown of NR4A1 by RNA interference inhibited mTOR signaling and decreased expression of survivin and EGFR. These new data suggest that NR4A1 antagonist are novel mechanism-based agents for treating endometriosis.

1970 Definition of Biological Thresholds for the Identification and Mode of Action Classification of Tumorigenic Chemicals

Chemicals induce liver cancer in rodents largely through well-characterized adverse outcome pathways (AOPs). In this study we defined biological thresholds for molecular initiating events (MIEs) and downstream key events (KEs) in liver cancer AOPs in short-term assays. We used the rat in vivo TG-GATES study data to measure MIEs (genotoxicity, cytotoxicity, and activation of AhR, CAR, ER, and PPARα) and associated KEs (cell hypertrophy/proliferation assessed indirectly by liver to body weights) across 77 chemicals that could be linked to doses with previously established effects on rat liver tumor induction. The genotoxicity biomarker was comprised of 7 p53-responsive genes known to be induced upon DNA damage. Gene expression biomarkers for receptor-based MIEs (AhR, CAR, ER, and PPARα) were built using microarray comparisons from the livers of rats treated with prototypical activators. Thresholds for genomic biomarkers were determined by first calculating the significance of the correlation between a biomarker and each filtered gene list derived from a microarray analysis of each chemical-dose-time exposure. For the entire dataset of >1000 comparisons, this analysis was followed by a Haber transformation, linear regression, and calculation of the 99% confidence interval for the -log(p-value) = 4-12). The genomic biomarker thresholds from an independent dataset of microarray data (DrugMatrix) derived using the same methods were very similar to those developed from TG-GATES, demonstrating consistency across chemical sets and microarray platforms. Additionally, chemical-independent thresholds for liver to body weights (~20% increase), ALT (~80% increase), and AST (~100% increase) were defined using similar approaches. The thresholds for the genomic biomarkers derived from the TG-GATES data could predict not only liver tumor induction in the TG-GATES study (balanced accuracy = 96%) but also the DrugMatrix study (balanced accuracy = 92%). The biological thresholds defined in this study could be used to predict tumorigenic potential in short-term studies and determine the mode of action underlying the tumors. This abstract does not represent US EPA policy.

1971 Platinum Leaving Ligand Effects on Mammalian Cells

E. M. Nole, J. Schlabach, B. Duke, and B. B. Williams. Western Kentucky University, Bowling Green, KY.

Cisplatin, Carboplatin, and Oxaliplatin are the three US FDA approved platinum-based chemotherapy agents. Each compound is defined by two ligands attached to a central platinum atom. Intracellularly, the nonleaving ligands remain attached to the central atom. However, the leaving ligands are released from the platinum and allow the platinum to bind to cellular components such as DNA. It is the coordination of the platinum atom with the attached nonleaving ligand to DNA that induces apoptosis, the primary mechanism of death for these compounds. Compound structure correlates with compound efficacy as a cancer treatment. For example, Cisplatin and Carboplatin have similar nonleaving ligands and are approved by the US FDA for treatment in many of the same cancer types. Oxaliplatin is a structurally distinct compound from Cisplatin and Carboplatin and is approved to treat cancers arising from different tissues. This project compares cell-specific toxicity of novel platinum compounds in both cancerous and noncancerous cell lines to better understand the role of structure in cytotoxicity. We tested two novel compounds, Dichloro[ethylenediamine]platinum(II), abbreviated as Pt(en)Cl2, which differs from Cisplatin only in the nonleaving ligand, and Oxalato(S,R,RS)-N,N'-dimethyl-1,2-diaminocyclohexaneplatinum(II), abbreviated as Pt(Me2dach)ox, which differs in both ligands. Pt(en)Cl2, was tested in both cancerous (NTera-2) and noncancerous cell lines (HEK293) and preliminary data shows higher toxicity in cancerous cells lines versus noncancerous lines. Current data indicates an IC50 ~ 90µM for Pt(en)Cl2, in control HEK293 cells.

1972 Nuclear Receptor 4A2 (NR4A2) as a Drug Target for Treating Glioblastoma

K. B. Karki1, U. Jin1, S. Safe1, S. Michelau2, and S. Mittal1. 1Texas A&M University, College Station, TX; and 2Karmanos Cancer Institute, Detroit, MI.

The orphan nuclear receptor 4A2 (Nurr1) is a member of a family of receptors with no known endogenous ligands and was initially identified as a rapidly induced gene in cells under stress. NR4A2 has been extensively characterized in subcellular regions in the brain, and NR4A2+ mice do not generate midbrain dopaminergic neurons and die soon after birth. Studies in several laboratories have been investigating the role of NR4A2 in Parkinson’s disease, and our collaborative research has focused on the effects of 1,1-Bis(3′-indolyl)-1-(p-chlorophenyl)methane (DIM-C-pPhCl (CDIM 12)) on animal models of Parkinson’s disease. We have hypothesized that NR4A2 may also play a role in another neuronal-derived disease, namely glioblastoma multiforme (GBM) and our preliminary studies show that NR4A2 is overexpressed in a unique set of patient derived glioblastoma (GBM) cells (14015s, 14104s, 15037, 15049 and 17008). We used anti sense oligonucleotides (FANA molecules) to knockdown NR4A2 to investigate the roles of this receptor in patient derived glioblastoma cells. Knockdown of NR4A2 in 14015s and 15037 cells decreased cell proliferation, decreased migration/invasion and induced Annexin V staining (apoptosis) and these functional responses were accompanied by downregulation of several genes (survivin, Bcl2, cMet, EGFR, Q5 integrin and β3 integrin) and induction of cleaved caspase-3 and PARP indicative of apoptosis. Our results showed that knockdown of NR4A2 and 1,1-Bis(3′-indolyl)-1-(p-chlorophenyl)methane DIM-C-pPhCl (CDIM 12) is an NR4A2 ligand previously investigated in our laboratory that decreased NR4A2-dependent transactivation in 14015s and 15037 cells and inhibited cell growth, migration/invasion and induced apoptosis thus acting as an NR4A2 antagonist/reverse agonist in GBM cells. Moreover, the effects of NR4A2 knockdown and the C-DIM-NR4A2 antagonist were comparable as inhibitors of NR4A2-dependent genes/pathways. These preliminary results from NR4A2 knockdown studies and treatment with an NR4A2 antagonist demonstrate for the first time that NR4A2 is pro-oncogenic in GBM and can be targeted by NR4A2 antagonists, such as DIM-C-pPhCl and related compounds. Ongoing studies are focused on investigating the mechanism of action of NR4A2 antagonists as a new class inhibitors of GBM and developing a series of more potent analogs for clinical applications in treating this deadly disease.

1973 Using the Key Characteristics of Carcinogens in Carcinogen Hazard Identification

K. Z. Guyton1, and M. T. Smith2. 1IARC-WHO, Lyon, France; and 2University of California Berkeley, Berkeley, CA.

Smith et al. (Env. Health Perspect. 124: 713, 2016) identified 10 key characteristics, one or more of which are commonly exhibited by established human carcinogens. The key characteristics of carcinogens (KCs) reflect the chemical
and biological properties of cancer-causing agents and are distinct from the hallmarks of cancer, which are the properties of tumors. The KCs have been applied in evaluating mechanistic data for more than 30 diverse agents in recent IARC Monograph meetings. The Group 1 and 2A carcinogens identified in these meetings exhibited a range of KCs, including 'is genotoxic', 'is immunosuppressive' or 'modulates receptor-mediated effects', in some cases in combination with other KCs. For most Group 2A and 2B agents, fewer studies relevant to the KCs were identified. Because the KCs are based on empirical observations of characteristics associated with known carcinogens, they provide an agnostic and unbiased survey of the mechanistic literature. This improved uniformity across evaluations, revealing strengths as well as gaps in evidence. A focus on STAT3 signaling was chosen because it is a hallmark of many cancers. Further, this approach also has the advantage of being non-specific to particular disease subtype.

For each agent, the following data were curated:

- The exposure details: These included the chemical exposure concentrations as well as relevance to human exposure.
- The in vivo and in vitro models used.
- The primary endpoints assessed and the results.
- The mechanistic data related to the KCs.

The data were then used to develop a comprehensive understanding of the molecular mechanisms underlying the carcinogenic effects of the agents considered. A molecular signature was developed for each agent that reflects the relevant biological properties and is distinct from the KCs.

1976 Uterine Adenocarcinomas in Isopryrazam-Treated Rats Occur via a Human Non-relevant Mode of Action

P. P. Parsons1, R. C. Peffer2, R. Richards-Doran3, D. E. Cowle1, R. A. Currie1, K. Lichti-Kaiser1, E. McInnes1, D. C. Wolf1, P. Sawhney-Coder1, R. J. Handa1, D. R. Grattan6, and K. Yi4
1 Exponent International, Harrogate, United Kingdom; 2Syngenta Crop Protection, Greensboro, NC; 3Syngenta Crop Protection, Bracknell, United Kingdom; 4Syngenta Crop Protection, Charleston Triangle Park, NC; 5Charles River Laboratories, Ashland, OH; 6Colorado State University, Fort Collins, CO; and 7University of Otago, Dunedin, New Zealand

Female rats treated with 3000 ppm (232.8 mg/kg BW/day) isopryrazam (IZM) for 2 years had a greater incidence of uterine adenocarcinomas, lesser incidence of pituitary and mammary tumors, and ~40% reduction in body weight (BW) gain. For this investigational study, female Han Wistar rats were treated with 0, 500 and 3000 ppm IZM (28 and 194 mg/kg BW/day, respectively) for up to 18 months. Rats were euthanized and necropsied at 13, 26, 52, 66 and 80 weeks. Blood was collected at 4, 13, 26, 52, 66 and 80 weeks for measurement of prolactin and leptin. Selected tissues were weighed, and histology of the influenced by dietary intake and may regulate pro-inflammatory adipokine secretion. Daily vaginal lavages were performed for 2-3 week intervals throughout the study. Decreased fat pad weights, increased liver weights and reduced BW gain followed a dose-responsive pattern. The high dose group cyclically regulated for a longer period of time and had a greater percentage of rats in persistent estrus from weeks 52 to 80 compared to control. Prolactin and leptin levels were significantly less in the high dose group, and dopamine signaling to the pituitary was greater than controls at ≥26 weeks. Based on the data, a mode of action (MoA) is established that begins with decreased food utilization, fat pad weight and body weight, reflected by the decreased leptin levels. As a consequence, there is altered hypothalamic signaling that results in altered pattern of transition into reproductive senescence. The longer time spent in persistent estrus and greater exposure to circulating estrogens leads to the observed increase in uterine adenocarcinomas. Fundamental differences exist between rats and humans in the control of reproductive senescence. The onset of senescence in rats is due to altered signaling within the hypothalamus, while menopause and reproductive senescence in humans is driven by depletion of a set number of primordial follicles in the ovaries with aging. The physiological difference in control of the reproductive cycle and the transition into reproductive senescence between rats and humans indicate that the established MoA leading to uterine tumor formation in rats is not relevant to humans.
Efficient Carcinogenesis via Mutated Inflammation-Activated Stem Cells: A New Theory Explains Why Nrf2-Activation Blocks Aflatoxin-Induced Liver Cancer in Rats

K. T. Bogen, Exponent, Inc., Silver Spring, MD.

Jones et al. (Cancer Prev Res 2014; 7(7):658-65) recently showed that ~100% incidence hepatocellular carcinoma (HCC), by week 104 in male rats dosed by daily gavage with aflatoxin B, (AFB, ) and F for weeks starting at week 6, could be blocked completely—but without similar elimination of AFB-DNA adducts—by co-administering a highly potent anti-inflammatory Nrf2 activator (CDDO-im) for 5 weeks starting at week 5. Time-to-tumor data for rats in that study treated only with AFB, are clearly consistent with a 2-stage doubly stochastic multistage somatic mutation (MSM) cancer model. However, after reducing multiple experimental errors proportional to AFB-DNA adduct reductions measured during/after CDDO-im co-treatment, that MSM model predicts an HCC incidence rate (46%) far greater than was observed (0/20, 2-tail p = 10^{-5} assuming binomially distributed error). A novel alternative theory explains the combined study data: Cancer arises most efficiently in epithelial tissues from just any stem cell with critical mutations, but only from a stem cell that has or will become activated to an epigenetically mediated and maintained state of adaptive/regenerative hyperplasia—a state normally triggered by immune cells that generate and coordinate local inflammation at the site of tissue injury. Normally such inflammation-activated stem cells (IASCs) are relatively rare, because they arise transiently as part of a highly orchestrated process of inflammation and tissue repair tightly restricted to the site of injury. However, the new theory posits that IASCs are each uniquely susceptible to efficient carcinogenesis involving as few as two critical somatic mutations, provided the new theory posits that IASCs are each uniquely susceptible to efficient carcinogenesis involving as few as two critical somatic mutations, provided the new theory posits that IASCs are each uniquely susceptible to efficient carcinogenesis involving as few as two critical somatic mutations, provided the new theory posits that IASCs are each uniquely susceptible to efficient carcinogenesis involving as few as two critical somatic mutations, provided the new theory posits that IASCs are each uniquely susceptible to efficient carcinogenesis involving as few as two critical somatic mutations. A key feature of this inflamed stem cell is its likelihood status as an inflammation-activated stem cell (IASC) that, upon activation, becomes a constitutive and permanent powerful effector of cancer progression.

Mechanistic Role of Cytochrome P450 1 Enzymes in Polycyclic Aromatic Hydrocarbon Mediated Carcinogenesis

G. Gastelum1, A. Veith1, W. Jiang1, L. Wang1, G. Zhou2, and B. Moorthy1.
1Baylor College of Medicine, Houston, TX; and 2University of Texas Health Science Center, Houston, TX.

Lung cancer is the leading cause of cancer-related deaths in the United States. Polycyclic aromatic hydrocarbons (PAHs) are a group of chemicals that increase the risk of lung cancer in humans. Cytochrome P450 (CYPs) enzymes are known to promote detoxification of PAHs. However, the Cyp1 family is also involved in the bioactivation of PAHs, leading to the formation of reactive intermediates that can form mutagenic DNA adducts. In this study, we hypothesized that mice lacking Cyp1 expression will be resistant to polycyclic aromatic hydrocarbon-mediated pulmonary carcinogenesis. Two-month-old A/J (WT) and Cyp1a1/1a2/1b1-triple knockout (Cyp-1-3ko) mice were exposed to 3-methylcholanthrene (MC; 100μmol/kg), benzo(a)pyrene (BP; 200 μmol/kg), or corn oil (vehicle) via a single intraperitoneal injection. Liver and lung tissues were harvested at 1, 8, and 15 days post PAH exposure for our short-term studies. Mice in our tumor study were harvested 36 weeks post PAH exposure for tumor incidence and multiplicity analysis. We found that MC caused significant induction of hepatic CYP1A1/A2 gene expression in WT but not Cyp1-3ko mice at each time point. MC treatment caused formation of DNA adducts in liver and lung for up to 15 days post MC treatment in both genotypes. However, compared to WT animals, Cyp-1-3ko mice had significantly reduced hepatic DNA adducts on day 15 and up to 95% less pulmonary DNA adducts at 1, 8 and 15 days post MC treatment. In addition to the DNA adduct inhibition, Cyp-1-3ko mice formed 93% less pulmonary tumors compared to the MC-treated WT counterparts. The significant reduction in DNA adducts and pulmonary tumors in Cyp-1-3ko mice provide strong evidence of the mechanistic role these enzymes play in PAH-mediated carcinogenesis. The mechanistic insight our study provides will be tremendously important for finding preventative and therapeutic avenues to combat PAH-mediated carcinogenesis.

Synthetic Progestins Elicits Similar Proliferative and Gene Expression Responses as Endogenous Progesterone at Much Lower Concentrations

E. M. Martin, and P. A. Wade. NIEHS, Research Triangle Park, NC.

The use of the synthetic progestin, medroxyprogesterone acetate (MPA), during hormone replacement therapy (HRT) has been linked to increased risk of invasive breast cancer. Currently, the biological mechanism underlying this relationship is unknown. Synthetic progestins are a class of pharmaceutical compounds that bind the progesterone receptor and are predominantly used as birth control and during HRT. It is unclear which commonly used synthetic progestins, besides MPA are associated with invasive breast cancer. The goal of this study is to understand whether breast epithelial cells have the same physiological and transcriptional response to endogenous progesterone and synthetic progestins. T47D cells, a breast epithelial cell line, were grown in culture and exposed to endogenous progesterone (P4) and four common progestins: (1) MPA, (2) etonogestrel (ET), (3) norethindrone (NE), and (4) levonorgestrel. First, a dose course was conducted to determine the effects on cell proliferation, as growth arrest is a hallmark of progesterone exposure. Cells were exposed at physiologically relevant concentrations of P4 (0.2-700nM) and the four progestins (0.2-20nM). Next, gene expression changes were assayed at physiologically relevant doses for both P4 (200nM) and the progestins (2nM). To determine transcriptional responses to progestins, we profiled mRNA levels. Assessment of the biological fate of HT-29 cells overexpressing GLTP demonstrated that GLTP overexpression modulated cell shape change but the magnitude of change differed greatly, with induction of cell death (e.g., in >150nM), as well as the progesterone response sentinel genes, Dual Specificity Phosphatase 1 (DUSP1) and Zinc Finger And BTB Domain Containing 16 (ZBTB16) were assayed across the time points 2, 4, 6, 8, 10, 12 and 24 hours. Gene expression responses peaked between 10-24 hours for all compounds. However, the magnitude of change differed greatly, with induction of ZBTB16 and DUSP1 around 20-fold, while PGR was induced over 200-fold. These results demonstrate that progestin compounds are able to elicit similar proliferative and gene expression responses as P4 at much lower concentrations. Future work will focus on transcriptome level differences between P4 and progestins.

Glycolipid Transfer Protein (GLTP) Regulates Non-apoptotic Cell Death in Colon Cancer Cells: Implications in Cancer Therapy and Cytotoxicity

S. K. Mishra, and R. E. Brown. Hormel Institute, University of Minnesota, Austin, MN.

Sphingolipids are known to affect cancer progression by regulating cell death (apoptosis) and survival (autophagy). Whereas apoptosis is promoted by elevations in sphingosine and ceramide, increases in sphingosine-1-phosphate and ceramide-1-phosphate can tip the balance toward survival. Human glycolipid transfer protein (GLTP) is a small (24 kDa) amphipathic protein encoded on chromosome 12 (locus 12q24.11) that can mediate non-vesicular transport of metabolic enzymes in the Golgi apparatus. Changes in the expression of GLTP has been shown to modulate cell shape change but the effect on regulating cell proliferation and cancer progression remains unexplored. We herein show that GLTP overexpression inhibits the growth of human colon carcinoma cells (HT-29; HCT-116), but spares normal colonic cells (CCD-18Co) largely due to growth arrest at the G0/G1 cell cycle checkpoint. Mechanistically, we found that GLTP overexpression modulated the cell cycle progression of upregulating Kip1/p27 and Cip1/p21 protein and mRNA levels, while decreasing CDK2, CDK4, cyclin E and cyclin D1 protein levels. Assessment of the biological fate of HT-29 cells overexpressing GLTP revealed increased levels of phosphoeylated human mixed lineage kinase domain-like (MLKL) protein, intracellular calcium and necrotic cell death. Overexpression of W96A-GLTP, a mutant incapable of transferring GSLs, failed...
1983 Comprehensive Molecular Characterization of Mitochondrial Genomes in Spontaneous and Chemical-Induced Hepatocellular Carcinomas in B6C3F1/N Mice

M. Xu1, A. Burkholder2, D. Fargo2, J. Marzec2, S. Kleeberger2, G. Solomon2, R. Sills1, and A. Pandiri1. 1NIEMS/NTP, Research Triangle Park, NC; and 2NIEMS, Research Triangle Park, NC. Sponsor: A. Pandiri, Society of Toxicologic Pathology

Mitochondria play an important role in cellular energy metabolism. Under xenobiotic stress, free radical generation and subsequent chronic oxidative stress have been implicated in many carcinogenic processes. The origin and impact of mitochondrial DNA (mtDNA) alterations in chemical induced carcinogenesis are unclear. We performed ultra-deep whole mtDNA sequencing, whole exome sequencing and mtDNA copy number analysis on the fresh-frozen B6C3F1/N male hepatocellular carcinomas (HCCs) that arose either spontaneously (n=10) or due to 2-year exposure to a genotoxic carcinogen, gingko biloba extract (GBE; n=10) and a non-genotoxic carcinogen, antraquinone (n=10); age-matched non-tumor controls (n=10) were also included. In total, 25 somatic substitutions were detected in the mitochondrial genome. Mutation signature analysis of the mitochondrial genome demonstrated a similar pattern (A/C to G/T transitions) across all tumor samples. The mtDNA copy number analysis revealed a significant reduction in spontaneous (p=0.0017) and antraquinone-induced (p=0.0006) HCCs but not in GBE-induced HCCs (p=0.0356). The number of nuclear-encoded mitochondrial genes mutations in the GBE-exposed tumors was slightly higher (122 mutations per sample) compared to the number of mutations in the spontaneous (97.4 mutations per sample) or antraquinone-exposed (91.7 mutations per sample) tumors. Our findings indicate that the endogenous mutational mechanism has greater impact than any other external mutagens in mtDNA and is fundamentally linked to mtDNA replication. Exposure to GBE or antraquinone may have different mechanisms of action on mitochondrial dysfunction. Mutation signatures within mtDNA and nuDNA are distinct within the same tumor arising spontaneously or due to chemical exposure. However, mitochondrial copy number alterations and mutations in nuclear genome are altered by chemical exposures.

1984 Mechanistic Data Can Play a Pivotal Role in IARC Monographs Evaluations When Human Data Are Less Than Sufficient

L. Benbrahim-Tallaa, International Agency for Research on Cancer, Lyon Cedex 08, France.

Based on an integrated evaluation of evidence for carcinogenicity in humans and experimental animals, and of carcinogenic mechanisms, the IARC Monographs identify environmental factors that can increase the risk of human cancer. Mechanistic evidence can aid in identifying carcinogens when human data is less than sufficient. Here we review important recent evaluations that were influenced by strong mechanistic evidence, and highlight types of evidence most influential in classifications of cancer hazard. In 1997, 2,3,7,8-tetrachlorodibenzo-p-dioxin was first classified in Group 1 (carcinogenic to humans) based on sufficient evidence in animals and mechanistic considerations, an evaluation later confirmed by sufficient evidence in exposed humans in 2012. More recently, tetrachloroazobenzene was classified as "probably carcinogenic to humans" (Group 2A) because it belongs, on the basis of mechanistic considerations, to this same class of agents. Furthermore, in 2016, an upgrade from Group 2B to Group 2A was warranted for tetrabromoethylene because it satisfies the mechanistic criterion for Group 2A. Our findings indicate that the endogenous mutational mechanism has greater impact than any other external mutagens in mtDNA and is fundamentally linked to mtDNA replication. Exposure to GBE or antraquinone may have different mechanisms of action on mitochondrial dysfunction. Mutation signatures within mtDNA and nuDNA are distinct within the same tumor arising spontaneously or due to chemical exposure. However, mitochondrial copy number alterations and mutations in nuclear genome are altered by chemical exposures.

1985 Zonal-Specific Transcriptional Programs Associated with PPARα Activation in the Rat Liver and Their Role in Liver Cancer in Rodents

M. E. Andersen1, M. B. Black1, S. N. Pendse1, R. A. Clewell2, E. L. LeCluyse3, and P. D. McMullen1. 1SciotoVation, LLC, Research Triangle Park, NC; 2ToxStrategies, Cary, NC; and 3LifeNet Health, Research Triangle Park, NC.

Previously, we compared whole genome gene expression following exposure to multiple doses of GW7647 - a ligand with high activity for PPARα - in rat and human hepatocytes and in the intact rat liver. Using ChIP methods, we found that the PPARα peroxisomal proliferator response element (PPRE) binding sites in human and rat hepatocytes differed qualitatively for down regulated genes in the rat. In addition, responses in the intact rat were more diverse than in rat hepatocytes with many more gene families significantly down regulated. We thus performed ultra deep sequencing, whole exome sequencing and mtDNA copy number analysis to assess the seven IARC criteria for an α2u-globulin-associated tumorigenic response. One (ethyl acrylate) caused fore-stomach tumors, but human relevance could not be ruled out because it did not lack genotoxic activity.
ences in the capacity of PPARα to cause proliferation, while the differential periporal responses affected by PPARα agonists may be a key step in cell proliferation and carcinogenesis associated with PPARα agonists in rodents.

1986 Application of ToxCast, ToxPi and Read-Across for Analyzing the Potential Carcinogenicity and Mutagenicity of Some Di- and Tri-phenylmethanes

Di-phenylmethanes are commonly used as intermediates in the production of dyes and pigments, and tri-phenylmethanes are often used as food additives or to dye textiles. There are more than a hundred chemicals in this group and most have not been tested for carcinogenicity or mutagenicity. To supplement the limited carcinogenicity and mutagenicity data for these chemicals, we took two approaches. First, we explored the use of high-throughput toxicity screening data available for chemicals in this group within the ToxCast Database (https://www.epa.gov/chemical-research/toxicity-forecasting), IARC’s key characteristics for carcinogens, and Toxicological Prioritization Index (ToxPi, http://toxpi.org/), a visual analytics tool, to predict carcinogenicity. Second, we applied a read-across tool, ToxRead (http://www.toxread.eu/index.php), to predict the mutagenicity of the chemicals in this group that had ToxCast data. We identified ToxCast data for 19 chemicals in this group. Six are di-phenylmethanes, and all but one are intermediates in the production of dyes. Thirteen are tri-phenylmethanes, all are dyes, and four are approved as food additives in either the US or the EU. In order to predict carcinogenicity, we aligned the active ToxCast Assays for each chemical to the key characteristics of carcinogens. ToxPi was then used to rank each chemical, based on level of activity in cancer pathway-related assays. Two of the nineteen chemicals (C.I. Basic Red 9 and Michler’s ketone) are known mutagens and carcinogens, and served as positive comparison chemicals. The results showed that several of the other chemicals share certain similarities in both ToxPi scores and slice patterns with the two comparison mutagenic carcinogens. In the analyses using ToxRead, which selects chemicals similar to the target compound based on molecular descriptors and structural alerts, and which uses modeled as well as experimental data, 16 of the 19 chemicals were predicted to be mutagenic. Several of the chemicals predicted to be mutagens were also predicted to be carcinogens. Our results suggest that alternative toxicity testing methods, such as high-throughput screening assays similar to ToxCast hold great promise for filling data gaps, and facilitating useful predictions for mutagenicity and carcinogenicity of structurally-related chemicals using read-across.

1987 Estrogen Provides Protection against B(a)P-Induced Colon Carcinogenesis

K. J. Harris1, A. E. Archibong2, J. M. Amos-landgraf3, S. E. Adunyah1, and A. Ramesh1. 1.Meharry Medical College, Nashville, TN; and 2.University of Missouri, Columbia, Columbia, MO.

Colorectal cancer (CRC) is the third most common diagnosed cancer and the third leading cause of cancer-related deaths in the United States. The age-adjusted incidence of colon adenomas and colorectal cancer is higher in men than in women. Epidemiological evidence show estrogen might influence the incidence of (CRC) in women by acting in a protective role via estrogen receptor beta (ERβ) but the mechanism of action is not known. Using the Polyposis in Rat Colon (PIRC) animal model, we have showed that male animals develop twice as many polyps in the colon than female animals when treated with the environment toxicant, Benzo(a)pyrene [B(a)P]. In this study, to assess the potential protective role of estrogen against polyp formation in the colon, we treated female PIRC rats, depleted of endogenous hormones by ovariectomy (OVX), with B(a)P and measured polyp development. Here, we show that B(a)P treatment of OVX-female PIRC rats increased when compared to control OVX-female animals. When replacing estrogen through silastic capsules, OVX-female PIRC rats treated with B(a)P showed a significant decrease in total colon polyp formation. These results suggest that estrogen does provide protection against B(a)P-induced colon carcinogenesis. Funded by NIH grants SR25GM059994-3, S5USCA163069-04, and G12MD007586-29.

1989 Nrf2 Induction of Antioxidant Response Increases Bioactivation of the Mutagenic Air Pollutant 3-Nitrobenzanthrone

3-Nitrobenzanthrone (3-NBA) is a potent mutagen and suspected human carcinogen detected in diesel exhaust particulate and ambient air pollution. It requires metabolic activation via nitroreduction to promote DNA adduct formation and tumorigenesis. NAD(P)H:quinone oxidoreductase 1 (NQO1) has been implicated as the major nitroreductase responsible for 3-NBA activation. We investigate the roles of human aldo-keto reductases (AKR1C1-1C3) in 3-NBA reduction and found that AKR1C1-1C3 contribute equally to the nitroreduction of 3-NBA in lung epithelial cell lines (A549 and HBEC3-KT) and combined they represent approximately 50% of the intracellular nitroreductase activity towards 3-NBA. These enzymes are induced by Nrf2 signaling which raises the question whether Nrf2 activation can elicit xenobiotic nuclear receptor NR4A1 (Pax8, Mafk) expression in rhabdomyosarcoma is driven by the targetable nuclear receptor NR4A1, Cancer Research, 77(17):732-741, 2017 [3] Hedrick E, and Safe S. Transforming growth factor β/NR4A1 inducible breast cancer cell migration and epithelial to mesenchymal transition (EMT) is p38α (MAPK14) dependent, Mol. Cell. Biol. 37(18):e00306-17, 2017.

1988 Bis-Indole Derived NR4A1 Antagonist Inhibits TGF-β Induced Rhabdomyosarcoma Cell Invasion

R. Shrestha, and S. Safe. Texas A&M University, College Station, TX.

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma observed primarily in children and adolescents, and current treatment regimens include surgery, radiation, and chemotherapy with cytotoxic drugs. Although so-called cures for one form of RMS is relatively high, a high percentage (>95%) of RMS patients exhibit serious health effects as adults.1 Studies in this laboratory have demonstrated the nuclear orphan receptor NR4A1 is expressed in RMS and exhibits multiple pro-oncogenic activities associated with cell growth, survival, and invasion and these responses are inhibited after treatment with bis-indole-derived NR4A1 antagonists. In this study, we show for the first time that transforming growth factor (TGF-β) (5ng/ml) enhance migration/invasion of RMS cells (RD and SMS-CT) as determined in a Boyden chamber assay. Treatment of these RMS cells with prototypical NR4A1 antagonist 1,1-bis(3-indolyl)-1-(p-hydroxyphenyl) methane (D(C)-p-PhOH/C-DIM8) alone inhibited invasion of these cells and DIM-C-p-PhOH also significantly inhibited TGF-β induced invasion. We also investigated the effects of various kinase inhibitors (SP600125, LY294002, SB203580, and U0126) on TGF-β-induced RD cell invasion where only SB203580 and U0126 inhibited TGF-β induced invasion. These results are similar, in part with previous study showing the kinase induced phosphorylation of NR4A1 resulting nuclear exit of the receptor which forms a complex to degrade SMAD7. However, in these RMS cells, the subcellular location of NR4A1 in the presence or absence of kinase inhibitors was initially problematic due to antibody variability and the location of the receptor is currently being investigated by extraction methods and immunostaining. Transforming growth factor β/NR4A1 inducible breast cancer cell migration and epithelial to mesenchymal transition is p38α (MAPK14) dependent, Mol. Cell. Biol. 37(18):e00306-17, 2017.

2019 SOT Annual Meeting 233
1990 Combined Use of Sulforaphane and Zinc Provides a Better Protection against Diabetic Cardiomyopathy Than Either One Alone in Type 1-Diabetic OVE26 Mice

J. Wang1,2, S. Wang3, W. Wang1,2, J. Chen1, Z. Zhang1, Q. Liu2, and L. Cai1.
1University of Louisville, Louisville, KY; 2First Hospital of Jinlin University, Changchun, China; and 3Stanford University, Palo Alto, CA.

Diabetic cardiomyopathy (DCM) is the main cause of heart failure in diabetic patients. Oxidative stress is considered to be one of the most important pathophysiological factors. Therefore, treatments targeting oxidative stress may represent suitable strategies for the effective prevention of DCM. Nuclear factor-E2-related factor 2 (Nrf2), a transcription factor responsible to oxidative stress, governs the nuclear and cytoplasmic expression of several antioxidant genes. Metallothionein (MT) is a protein that can bind heavy metal ions such as copper and zinc (Zn). It is also a potent scavenger of free radicals because of its high thiol contents. Overexpression of both Nrf2 and MT was reported to protect from DCM, however, whether up-regulation of both simultaneously would provide a better protection against DCM than either alone remains unclear. Considering that sulforaphane (SFN) and Zn are well-defined activator for Nrf2 and MT, respectively, here we tested our hypothesis that combined use of SFN and Zn to up-regulate Nrf2 function and MT expression might provide better protection against DCM than either SFN or Zn alone. Five-week old OVE26 mice that genetically develop type 1 diabetes (T1D) at 1 week after birth were confirmed with hyperglycemia and then treated with SFN (0.5 mg/kg) and/or Zn (5 mg/kg) for 18 weeks. Twenty-three week old OVE26 mice showed typical DC, reflected by cardiac dysfunction, assessed by echocardiography, and significantly oxidative damage, inflammatory and cardiac dysfunction and pathological features were observed. Furthermore, treatment of OVE26 mice either with SFN or Zn significantly prevented the development of DCM, along with up-regulating Nrf2 function and overexpressing MT protein, respectively. The protection from DCM was better in SFN/Zn-treated OVE26 mice than either SFN- or Zn-treated OVE26 mice. Therefore, combined use of SFN with Zn provides a better protection against DCM than use of either SFN or Zn alone in OVE26 mice.

1991 Application of Imaging-Based Nrf2 Pathway Activation to Support a Read across of Phenolic Compounds

J. P. Schimming1, L. Bischoff1, M. J. Mone1, B. ter Braak1, D. Noort2, J. P. Langenberg2, and B. van de Water2. Leiden University, Leiden, Netherlands; and 1NIO Defence, Safety and Security, Rijswijk, Netherlands.

Biological support for read across approaches is gaining major attention. Damage caused by oxidative stress and soft electrophilic compounds are common during chemical induced liver injury. The correct identification of the liability of a compound to cause such damage is essential for mechanism-based testing and adversity prediction. Various studies proposed similar pharmacological compounds are liable for causing oxidative stress-mediated cytotoxicity. The Nrf2-mediated antioxidant stress response is activated after oxidative and electrophile-derived cell stress. Here we evaluated whether fluorescent protein reporter cell lines for the Nrf2 pathway complemented by TempOSeq targeted RNAseq could support a read across for structural similar phenolic compounds. BAC HepG2 GFP-Nrf2 and GFP-SRXN1 reporter cell lines were exposed to 6-hydroquinone like compounds with redox-cycling potential, 12 redox-cycling and showed an increased PAR association. TFII-I regulates the calcium- dependent gene expression and all compounds that induced SRXN1-GFP also induced stabilization and nuclear translocation of Nrf2-GFP. Cell death was induced at high concentrations for all redox-cycling phenols. Dual-exposure of hydroquinones showed an additive dose effect. The redox-cycling negative phenols were inactive in both Nrf2-GFP activation as well as SRXN1-GFP induction. Alkylated phenols induced onset of cell death, likely independent from oxidative stress induction. To deepen our mechanistic understanding of the phenol-induced toxicity, we also used TempOSeq targeted RNAseq of ~3000 toxicity related genes, including Nrf2 target genes, in HepG2 and cryopreserved primary human hepatocytes. The transcriptomics analysis confirmed the selective activation of Nrf2 target genes by redox-cycling phenols and did provide further insight in the differential pathway activation by the three different phenol groups. In conclusion, our data indicate that our Nrf2 GFP-BAC reporter cell models are a valid test system to provide biological support for read across in cases of anticipated oxidative stress activation. 1992 Caffeic Acid Derivatives Are Effective Bacteriostatic Compounds against Paenibacillus larvae by Increasing Oxidative Stress

N. Lowen, W. Collins, and D. Blake. Fort Lewis College, Durango, CO.

American Foulbrood (AF) is a deadly bacterial disease affecting large numbers of pupal and larval honey bees. AF is caused by the endosporforming bacterium Paenibacillus larvae (PL). Propolis is a product of bee foraging and is a resinous substance derived from botanical substances found primarily in trees, and used in the hive to fill small structural gaps. It has been previously reported that propolis contains a variety of organic compounds that have putative biological activities. A number of compounds found in propolis come from the class of caffeic acid esters and have been shown to have anti-bacterial activity against PL. In this study, six different caffeic acid esters were synthesized and tested for their activity against PL to determine the minimum inhibitory concentrations (MICs). Caffeic acid isopropenyl ester (CAIE), Caffeic acid benzyl ester (CABE), and Caffeic acid phenethyl ester (CAPE) were the most effective in inhibiting PL growth with MICs of 125 μg/ml when used individually, and a MIC of 31.25 μg/ml when used in combination against PL. To determine a possible mechanism of action, flow cytometric analysis and oxidative stress quantifications were utilized to assess the effect of CAIE, CABE, and CAPE on PL cells. Our results indicated all three compounds (CAIE, CABE, and CAPE) inhibited bacterial growth through a bacteriostatic effect, which revealed no lysis of PL cells. Moreover, incubation with CAIE, CABE, and CAPE at or above their given MICs significantly increased oxidative stress within PL after 18 hours. These data indicate that caffeic acid esters are potent bacteriostatic compounds against PL and may inhibit bacterial growth by increasing oxidative stress in PL cells leading to cell cycle arrest. Future research will identify the possible biological targets (DNA, protein or lipid) of these oxidants in order to further elucidate a possible mechanism.

1993 The General Transcription Factor II-I Increase PAR-Association during ROS-Mediated Cell Death

A. Islas-Robles1,2, S. Lau1, and T. Monks3. University of Arizona, Tucson, AZ; and Wayne State University, Detroit, MI.

2,3,5-(Glutathion-S)-hydroquinone (TGHQ) is a nephrotoxic and nephrocarcinogenic metabolite of hydroquinone. TGHQ generates ROS causing hyperactivation of poly(ADP-ribose) polymerase-1 (PARP-1) and reciprocal increases in intracellular calcium concentrations ([iCa2+]2). These data indicate that caffeic acid esters are potent bacteriostatic compounds against PL and may inhibit bacterial growth by increasing oxidative stress in PL cells leading to cell cycle arrest. Future research will identify the possible biological targets (DNA, protein or lipid) of these oxidants in order to further elucidate a possible mechanism.

This work was supported through the EU EU-ToxRisk project (grant agreement 681002).

2019 SOT Annual Meeting
1994 Identification and Characterization of Metallothionein-3 as a Pesulfide-Binding Protein

Y. Ding, Y. Shinkai, and Y. Kunagai. University of Tsukuba, Tsukuba, Japan.

Persulfides/poly sulfides which contain sulfane sulfur atoms with six valence electrons and no charge (S\(^n\)) exhibit high nucleophilicity and play a role in redox homeostasis. For example, persulfides/poly sulfides can scavenge hydrogen peroxide (H\(_2\)O\(_2\)) and also capture electrophiles such as methylmercury (MeHg), leading to formation of sulfur adducts. We recently reported that cysteinyl-tRNA synthetase 2 produces persulfide-binding protein (PSPB) during protein translation (Akaike T et al. Nature Comm 2017). We also found that there are a variety of PSPBs in hepatic cytosol of mouse and that GSTP1 is identified as a PSPB to capture MeHg, thereby yielding (MeHg)S with less toxicity (Abiko Y et al. Chem Res Toxicol 2015). The purpose of present study is to identify and characterize PSPB from mouse brain, which is susceptible to oxidative stress. Separation of the cytosolic proteins by column chromatography with derivatization of sulfane sulfur atom by addition of [B-(4-hydroxyphenyl)ethyl]iodoacetamide, followed by LC-MS analysis revealed that 16 kDa protein highly purified on SDS-PAGE was identified as metallothionein-3 (MT3). Recombinant human MT3 contained multiple sulfane sulfur atoms in the molecule and exhibited antioxidant capability. Knockdown of MT3 significantly enhanced H\(_2\)O\(_2\) - and MeHg-induced cytotoxicity in human glioblastoma U87 cells. These results suggest that MT3 is a PSPB and the sulfane sulfur atoms in the protein appear to contribute to protection against oxidative and/or electrophilic stresses.

1995 Cholesterol Biosynthesis Dysruptors Alter the Redox Biology of Developing In Vitro Cultures of Primary Rat Cortical Neurons

J. Kim\(^1\), A. M. Palubinsky\(^1\), P. A. Wages\(^1\), N. A. Porter\(^1\), and B. McLaughlin\(^2\).

\(^1\)Vanderbilt University, Nashville, TN; and \(^2\)Vanderbilt University Medical Center, Nashville, TN.

The brain is responsible for the synthesis of its own cholesterol because the Blood-Brain Barrier isolates neural pools from systemic and dietary cholesterol. One of the most critical enzymes in the regulation of sterol metabolism is 24-Dehydrocholesterol Reductase (DHCR24). DHCR24 was first shown to be a neuroprotective protein linked to Alzheimer’s Disease but its primary purpose was ultimately determined to be the conversion of desmosterol to cholesterol. In fact, the accumulation of desmosterol caused by mutations in the DHCR24 gene leads to devastating clinical symptoms ranging from craniofacial deformities to psychomotor developmental delay and even premature demise. Based on both clinical and experimental evidence DHCR24 is considered essential for proper neurodevelopment. Our group recently identified a number of US FDA-approved drugs that selectively inhibit DHCR24. Using small molecule inhibitors, our goal is to determine whether these pharmacologically pose an unknown health risk to humans. To determine the impact of pharmacologically inhibiting DHCR24, four well-characterized inhibitors - Imatinib (Gleevec), Pregnenolone (PS), Triparanol (TRP), and U-18666A (U) - were screened in primary rat neuronal cultures for changes in neuronal morphology. Primary cortical neurons grown in vitro for three days were exposed to 100 nM of each compound for 72 hours, a pharmacologically relevant concentration for Gleevec and PS. Cells were probed for various markers of mitochondrial and protein stress using immunocytochemistry including TOM20 (mitochondrial morphology) and FK2 (ubiquitin marker) and quantified for NST (neuron specific tubulin) and DAPI (nuclear morphology). Exposure to TRP and U results in a dramatic reduction in the volume of neuronal processes, increased mitochondrial retraction, and increased ubiquitin levels. Cultures exposed to Gleevec showed modest elevations of ubiquitin levels. PS, an endogenous downstream metabolite of cholesterol biosynthesis, demonstrated none of the aforementioned phenotypes. These data demonstrate that known DHCR24 inhibitors can impede process outgrowth and also concurrently induce mitochondrial and protein stress. These findings hint to an important need to test DHCR24 activity of future drug candidates, especially as it relates to developmental neurotoxicity.

1996 Synergistic Cytotoxic Responses of Co-exposure to Mixtures of Acrolein and Formaldehyde through Oxidative Stress on Human Bronchial Epithelial BEAS-2B Cells

FA (formaldehyde) and ACR (acrolein) are common pollutants in air, and the adverse health effects may not only result from their individual toxicity but also from the combined toxicity. However, combined toxicity of these pollutants has been unknown so far. This study was aimed at investigating the combined cytotoxicity of single FA and ACR in human bronchial epithelial BEAS-2B cells. IC\(_{50}\), of FA (85.49 µM) and ACR (7.63 µM) estimated by CCK-8 assay showed that ACR is more toxic than FA. Significant dose-dependency and time-course could be observed on the cytotoxic effects based on CCK-8 assay, when BEAS-2B cells were exposed to subcytotoxic concentrations (5, 10, 20, 40 and 80 µM) of FA and subcytotoxic concentrations (0.5, 1, 2, 4, 6 and 7.5 µM) of ACR alone or in combinations. Significant synergistic effects (<0.05) were noted upon exposure to 10 (20,40 and 80) µM of FA + 7.5 µM ACR. Moreover, ROS levels, GSH levels and the activities of antioxidants (CAT, SOD and GPX) significantly increased (<0.05) in the synergistic style, when Beas-2B cells were exposed to 40 (80) µM of FA + 7.5 µM of ACR. In addition, the cell viabilities of Beas-2B cells at 40 (80) µM of FA + 7.5 µM of ACR were significantly elevated from 88% (57%) of control to 111% (100%) of control by antioxidants NAC, and the synergistic effects turned to additive effects. So oxidative stress is an important mechanism responsible for the synergistic cytotoxic responses of co-exposure to mixtures of FA and ACR. Taken together, prolonged exposure to mixtures of FA and ACR at subcytotoxic concentrations could induce significantly synergistic effects on cytotoxicity of BEAS-2B cells. And the oxidative stress not only can be responsible for the single toxic effects of FA and ACR but also for the combined toxicity.

1997 Inhibiting 7-Dehydrocholesterol Reductase Elevates Protein Adduction and Depletes Intracellular Glutathione

P. A. Wages, H. H. Kim, and N. A. Porter. Vanderbilt University, Nashville, TN.

The brain is vulnerable to oxidative injury in part due to its high lipid content. In fact, more than a quarter of the body’s cholesterol (Chol) resides in the brain. Although Chol is unreactive, its immediate precursor 7-dehydrocholesterol (7DHC) is one of the most oxidizable lipids in biology. Under most conditions neurons have low levels of 7DHC. However, inhibiting DHCR7, the enzyme responsible for converting 7DHC to Chol, causes an increase in 7DHC levels. We have identified over 100 US FDA-approved drugs that inhibit DHCR7. Despite evidence that chronic elevations of 7DHC is neurotoxic, no mechanism of toxicity is established for acute exposure to a DHCR7 inhibitor. Protein adduction by reactive oxysterols derived from 7-DHC is a likely key event in DHCR7 inhibitor toxicity. To study sterol-protein adduction events our lab developed traceable sterol compounds that contain alkyne groups such as alkynyl-7DHC (aDHC) and a reactive oxysterol, alkyne-7DHC epoxide (aDHcep). The alkyne moiety offers the means to analyze adduction with immunoblots or proteomics using “click” chemistry. Using these tools in cells deficient in DHCR7 we identified a number of adducted adaptive response proteins such as glutathione reductase. Utilizing the neuroblastoma cell line, Neuro2a, and the well-characterized DHCR7 inhibitor, AY-9944 (AY), we tested whether elevated levels of 7DHC impair the cellular adaptive response. Exposing Neuro2a cells to AY for 48h decreased total glutathione levels in a concentration-dependent manner down to 20% of control. We next incubated cells with a traceable sterol precursor that is biosynthetically converted to aDHC for 48h concurrently with 100 nM AY. Immuno blot analysis revealed AY treatment increased protein adduction 2.5±0.5-fold. To test for an interaction between glutathione and reactive oxysterols we depleted intracellular glutathione levels with a 500 uM BSO treatment for 24h followed by a 4h exposure to a7DHcep. a7DHcep alone increased protein adduction with a 10 μM, 4h treatment elevating adduction 3±0.4-fold. However, pretreatment with BSO profoundly reduced a7DHcep-induced adduction at all concentrations tested. Our data suggest that chemical inhibition of DHCR7 increases protein adduction and that targeting glutathione levels provides a means to offset 7DHC-induced proteotoxicity. Supported by NIEHS T32 ES00267 (PW) ES024133 (NP).
Current consensus is that reactive oxygen species (ROS) produced by environmental chemical exposure potentially mediate redox signaling through S-oxidation of thiols with lower pKa value on sensor proteins (e.g., phosphatases), associated with substantial activation of their effector molecules (e.g., kinases, and transcription factors). We found that 9,10-phenanthraquinone (9,10-PQ) contaminated as an abundant polycyclic aromatic hydrocarbon quinone in diesel exhaust particles and particulate matter 2.5, produces excess ROS through redox cycling by interacting with electron donors in cells (Kumagai Y et al. Chem Res Toxicol 2002; Taguchi K et al. Free Radic Biol Med 2007 and 2008), indicating that 9,10-PQ might modulate redox signaling through ROS generation. In this study, we examined that 9,10-PQ could activate epidermal growth factor receptor (EGFR) signaling in A431 cells through S-oxidation of its negative regulator protein tyrosine phosphatases (PTPs) such as PTP1B, and thus affect cell survival. Exposure of A431 cells to 9,10-PQ activated EGFR-ERK1/2 signaling, coupled with the decrease of cellular PTPs activity. ROS produced during 9,10-PQ exposure were abolished by pre-treatments with 3-phosphoglycerate (3PG) scavenger. Under this condition, PEG-CAT significantly blocked the 9,10-PQ-mediated activation of EGFR-ERK1/2 signaling, indicating involvement of 9,10-PQ-mediated ROS generation in this activation. Consistent with this, a CAT protected diminished recombinant HPTP1B activity caused by 9,10-PQ. UPLC-MS analysis revealed that a 9,10-PQ oxidized PTP1B was present. Interestingly, an EGFR inhibitor enhanced cytotoxicity of 9,10-PQ, indicating that EGFR-ERK1/2 activation is a cytoprotective response to the toxicity. Collectively, these results suggest that 9,10-PQ-activated ROS activate EGFR-ERK1/2 signaling presumably through oxidative modification of PTP1B and, at least in part, the activation of the signal cascade plays a role in cellular defense against 9,10-PQ in A431 cells.

1999 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD)-Elicited Metabolic Reprogramming in Primary Mouse Hepatocytes Supports Antioxidant Defense Mechanisms

C. M. Doskey, R. Nautilus, K. A. Fader, and T. R. Zacharewski, Michigan State University, East Lansing, MI.

Induction of the M2 isofrom of pyruvate kinase (PKM2) is a central feature of the Warburg Effect in cancer cells. The reduced glycolytic flux causes accumulating upstream intermediates to be redirected to antioxidant and/or proliferation pathways. We have previously shown that 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) dose-dependently induces PKM2 in normal differentiated C57BL/6 mouse hepatocytes. We hypothesize that PKM2 induction supports defensive responses to ary hydrogen carbons (AHR)-mediated oxidative stress. To investigate the role of TCDD-elicited PKM2 induction in central carbon metabolic reprogramming, tracer studies were performed using primary hepatocytes from PKM2 isoform-specific conditional knockout (PKM2-fl) and wild-type (WT) mice. The hepatic arterial versus portal vein (HA:PV) ratio of [13C]-labeled Ru5P, -3-phosphoglycerate (3PG), -glycerine, -serine, -5-methyltetrahydrofolate, -pyruvate, and -lactate, suggesting redirection of glycolytic intermediates toward NADPH-producing pathways. In PKM2-fl mice, earlier increases in 3PG is suggestive of increased glycolytic flux, while reduced levels of 13C-labeled Ru5P, serine, glutathione, and TCA cycle intermediates indicate central carbon metabolites were not redirected as in TCDD-treated PKM2-fl hepatocytes. Moreover, dose-dependent treatment with H2O2 showed increased sensitivity to oxidative stress in PKM2-fl hepatocytes compared to PKM2-fl controls following TCDD treatment, demonstrating its crucial role in antioxidant defenses. Collectively, these data support the hypothesis that TCDD-elicited PKM2 induction is a novel antioxidant defense response that combats oxidative stress and increases cell survival.
2002 Manganese Superoxide Dismutase (MnSOD) Attenuates Hyperoxia-Induced Cell Death and Alters ERK Activation

J. Woo, L. L. Mantell, and A. Gauthier. St. John’s University, Jamaica, NY.

Supraphysiological concentrations of oxygen (hyperoxia) are often utilized to treat patients with respiratory failure. However, prolonged exposure to hyperoxia results in severe lung injury and pulmonary cell death. Hyperoxia generates reactive oxygen species (ROS) in the mitochondria, damaging their structure and function. Here, we demonstrate that lung epithelial cells overexpressing MnSOD (+200%) are more resistant to oxidative injury, and that the activation of ERK plays a role in such protection. To test whether the overexpression of MnSOD in mitochondria protects cells from hyperoxia-induced cell injury and alters ERK signaling, fibroblasts overexpressing MnSOD or catalase in mitochondria were exposed to 95% oxygen for up to 6 days, mimicking hyperoxic conditions. Mitochondrial injury and cell death were assessed by MTT, nuclear condensation, and Trypan Blue exclusion assays. Most (>94±0.8%) cells overexpressing MnSOD (2.5-8 fold) in mitochondria survived after exposure to hyperoxia for 4 days compared to vector controls. This protective effect by mitochondrial MnSOD was associated with increased DCF labeling. Overexpression of catalase offers protection against hyperoxia. Higher basal levels of ERK activation, determined by in vitro kinase assays, were observed in MnSOD overexpressers in hyperoxia. There was a correlation found between ERK activation and survival in hyperoxia. Pretreatment with the MEK inhibitor, PD98059, reduced ERK activity and cell death in hyperoxia. The data suggest that moderate overexpression of MnSOD in the mitochondrial significantly protects against hyperoxic non-apoptotic cell death. Intracellular H2O2 may play an important role in mediating ERK activation and modulating survival in response to hyperoxia.

2003 Redox Proteomics Analysis Reveals Slc7a11 Restores Age-Dependent Change of Redox State of Proteins in Pathways of Protein Turnover and Cell Death

Y. Zheng¹, J. Caí, M. Merchant¹, T. Burke¹, J. Ritzenthaler², J. Roman², and W. Watson¹. ¹University of Louisville, Louisville, KY; and ²Thomas Jefferson University, Philadelphia, PA.

System Xc− is an antiporter that imports cystine (CySS) and exports glutamate. It plays a critical role in cell defense against oxidative stress because cysteine (Cys) reduced from CySS is used for and limits synthesis of GSH. Specificity of system Xc− is conferred by the Slc7a11 subunit. Down-regulation of Slc7a11 is responsible for oxidation of extracellular Cys/CySS redox potential (EC50/CySS) in lung fibroblasts from old mice. However, whether expression of Slc7a11 affects intracellular redox environment of these mouse lung fibroblasts remains unexplored. The purpose of this study is to evaluate the effect of Slc7a11 on the redox state of intracellular proteins. Redox proteomics was used to determine intracellular protein oxidation. IodoTMTs were used to label and reduced oxidized Cys residues in primary lung fibroblasts from young and old mice, as well as old fibroblasts transfected with Slc7a11. After labeling, 3 kinds of fibroblasts were mixed, digested, and affinity purified prior to multiplexed MS/MS. The ratio of oxidized/reduced forms (i.e., redox state) of proteins identified in each kind of fibroblast was determined. Change of ratio between different kinds of fibroblasts was calculated. GO and IPA were conducted for protein function and pathway enrichment analyses. STRING and Cytoscape were used for protein-protein interaction analysis. Slc7a11 over-expression restored global age-dependent trend of oxidation of cysteine residues in multiple peptides. Specifically, redox states of 151 proteins were changed in old fibroblasts compared to young fibroblasts. Slc7a11 over-expression restored redox states of 104 of these proteins. GO analysis based on those 104 proteins showed cell adhesion, protein translation and RNA binding were the top enriched functions. IPA exhibited age-dependent changes of redox states of components in pathways of protein translation initiation, ubiquitin-proteasome-mediated degradation and cystoskeleton-associated signaling were reversed by Slc7a11 over-expression. Cell death and survival were predicted to be the most affected with necrosis being on the top. This study finds that aging results in changes of redox states of multiple proteins, including those involved in protein turnover and cell survival, and that targeting Slc7a11 can restore the redox states of these proteins.

2004 The Activation of NF-κB in Airway Epithelia Protects against Hyperoxia-Induced Proinflamatory Lung Injury

L. Daley¹, M. Wang¹, M. Zur¹, M. Entezari¹, M. Jaydan², and L. L. Mantell. ¹St. John’s University, Queens, NY; and ²Feinstein Institute for Medical Research, Manhasset, NY.

The therapeutic use of mechanical ventilation with hyperoxia, often used for hypoxic conditions, can cause oxygen toxicity and inflammatory acute lung injury (ALI). ALI induced by hyperoxia can lead to excessive proinflammatory responses, endothelial and epithelial cell damage, and alveolar edema. It has been demonstrated that NF-κB activation has a protective effect on cultured lung epithelial cells, making them less susceptible to oxidative cell injury. The objective of this study is to investigate the role of NF-κB activation in airway epithelial cells in a mouse model of hyperoxia-induced lung injury. CC101-i-kbαSR transgenic mice, that do not express the wild-type gene that activates NF-κB, were exposed to 95% oxygen for 3 days. The bronchoalveolar lavage fluids (BALF) and lung tissues of the mice were collected and examined. Transgenic mice showed significantly more severe lung injury than wild-type mice. The more severe lung injury was characterized by higher wet/dry weight ratios of lung tissue and increased total protein content in BALF. Elevated neutrophil infiltration and extracellular HMGB1 accumulation in the BALF were associated with the more severe injury in transgenic mice. In addition, we found that prolonged exposure of cultured lung epithelial cells to hyperoxia induced the release of HMGB1. To determine if deficient NF-κB activation also leads to higher levels of HMGB1 in hyperoxia, human bronchial epithelial (HBE) cells were exposed to BAY 11-7082, an inhibitor of NF-κB activation. Higher levels of extracellular HMGB1 were indeed observed in those cells cultured with BAY 11-7082. These results indicate that the NF-κB signaling pathway in airway epithelial cells plays an important protective role against HMGB1-mediated hyperoxic inflammatory lung injury.

2005 Macrophages Hyperoxia-Compromised Phagocytic Function Improved by Nrf-2 Inducer

J. Wu, K. Dial, W. Wu, and L. Mantell. St. John’s University, Queens, NY.

Prolonged exposure to hyperoxia can compromise the ability of alveolar macrophages to phagocytose invading pathogens due to excessive production of intracellular reactive oxygen species (ROS). This can lead to the increased susceptibility to pulmonary infections observed in ventilated patients. Induction of the nuclear factor 2-erythroid-related factor (Nrf-2) pathway has been shown to regulate intracellular levels of ROS. The present study investigates whether resveratrol (RES), a Nrf-2 inducer, can ameliorate hyperoxia-compromised macrophage function. RAW 264.7 cells, a murine macrophage-like cell line, and bone marrow-derived macrophages (BMMDM) were exposed to hyperoxia for 24 hours in the presence or absence of RES. Macrophages treated with RES had significantly higher phagocytic activities compared to the control macrophages treated with vehicle alone. In addition, hyperoxia-induced accumulation of extracellular HMGB1, which can also impair macrophage functions, was reduced in RES treated macrophage culture media. These observations are accompanied with the increased levels of endogenous antioxidant compound, HO-1, a down-stream event of Nrf-2 activation. These data suggest that pharmacological activation of Nrf-2 pathway is efficacious in attenuating hyperoxic adverse effects on macrophages. Thus RES may provide a therapeutic approach to improve innate immunity of patients on ventilator in the treatment of ventilator associated pneumonia.

2006 Supplementation with Omega-3 Fatty Acids Potentiates Oxidative Stress in Human Airway Epithelial Cells Exposed to Ozone

E. Corteselli¹, and J. Samet². ¹University of North Carolina at Chapel Hill, Chapel Hill, NC; and ²US EPA/NHEERL, Chapel Hill, NC.

The health benefits of dietary fish oil consumption have been widely reported. Eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, two omega-3 fatty acids found in fish oil, have been associated with anti-inflammatory and pro-resolving effects through their displacement of arachidonic acid (AA) and metabolism to specialized pro-resolving mediators (SPMs). However, the 5 and 12 double bonds in EPA and DHA reduce their potential to be resolved by peroxidation by O2., a major photochemical pollutant to which millions of Americans are exposed. Products of unsaturated fatty acid peroxidation by O2. have been proposed to mediate some of the functional and inflammatory effects of O2. exposure. Thus, cellular supplementation with omega-3 fatty acids has the potential to both support the inflammatory response induced by O2.
inhalation as well as promote its resolution. To investigate this paradox, we supplemented 16-HBE human airway epithelial cells (HAE) expressing the fluorogenic glutathione redox potential (E_GSH) sensor roGFP overnight with EPA, DHA, the monounsaturated fatty acid oleic acid (OA), or the saturated fatty acid stearic acid (SA). Alterations in E_GSH were monitored in real time using live-cell microscopy during exposure to OA. We found that supplementation with EPA and DHA, but not OA or SA, caused a marked potentiation of the O_2•^- induced increases in E_GSH evident as both an accelerated response time and increase in the magnitude of response. Notably, the potentiation of GSH oxidation occurred at O_2•^- concentrations approximating the current National Ambient Air Quality Standard level. However, supplementation with DHA or OA did not significantly alter the production of the pro-inflammatory mediator prostaglandin E_2 (PGE_2) induced by O_2•^- exposure. These results suggest that membrane fatty acid saturation is a determinant of the oxidative effects, but does not modulate the production of pro-inflammatory eicosanoids in HAE exposed to O_2•^- These findings may have implications for dietary recommendations for populations exposed to O_2•^- This abstract does not necessarily reflect US EPA policy.

2007 Ambient Air PMx Reactive Oxygen Species Generation Capacity
D. Sarigiannis, M. Kermenidou, and S. Karakitsios. Aristotle University of Thessaloniki, Thessaloniki, Greece.

Differences in PM toxicity based on particle source and composition is still a matter of scientific debate that has significant regulatory repercussions. Although the World Health Organization uses similar concentration-response functions for PM emitted from all combustion sources (equitoxicity), there is an increasing body of evidence highlighting the differences in PM toxicity. In order to identify the differences in PM toxicity, the oxidative potential of particular matter PM has been evaluated in the frame of large European research projects (TRANSFORM, HEALS, CROME, ICARUS). The analysis was based on PM chemical speciation data over a period of 6 years (2012–2016) distinguishing between sampling sites typical of traffic and urban background pollution. The oxidative potential of PM was evaluated using the dichrothion (DHTT) assay. Based on the measurements and chemical analysis data used for source apportionment, it was found that during winter time, all PM fraction levels were higher at the urban background sites than at the traffic sites, as a result of the extensive biomass-fueled domestic space heating in several European cities. Regarding the PM oxidative potential, it was found that their toxicity is higher and is driven by the presence of organic compounds (PAHs and phenols) and inorganic elements (toxic metals) present in the lower PM fractions (PM1 and below), as a result of the process of formation of the smaller particles (accumulation mode) that results in higher concentrations (per mass of PM unit) of these oxidative components. The contribution of different sources to the oxidative properties of various PM fractions, was determined using Positive Matrix Factorization analysis. At the urban background sites, biomass burning contributed to 63% of the DHTT activity of PM, while vehicular emission and oil combustion together accounted for 35%. On the contrary, at the traffic sites, contributions contributed to 31% to the DHTT activity of PM, while secondary oxidation processes contribution was up to 57%. Overall, these results highlight that biomass burning results not only in higher PM levels, but also to PM that are characterized by a higher capacity of oxygen species generation.

2008 Critical Windows of Redox Modulation for Pancreas Development and Embryo Survival

Altered development of the pancreas by toxicant exposure can lead to altered pancreas morphology that has been linked to later-life diabetes. In this study, zebrafish (Danio rerio) was used as a model to compare critical windows of exposure to redox modulators for pancreas organogenesis and embryonic survival. Transgenic embryos were used to evaluate endocrine (ins:GFP and gcga:GFP) and exocrine (ptfaa:GFP) pancreas development. Embryos were exposed to water and dimethyl sulfoxide (DMSO) as controls, antioxidants N-acetyl cysteine (NAC) and sulforaphane (SFN), and pro-oxidants tert-butyl hydroperoxide (tBOOH) and tert-butyl-hydroquinone (tBHQ) at 24, 48, or 72 hours post fertilization (hpf) to assess endocrine islet and exocrine pancreas morphology at 96 hpf. tBOOH significantly decreased exocrine pancreas length at 48 and 72 hpf by 15% and 7% respectively. Both chemical-, stage-, and cell-type specific effects of redox modulation were observed on the endocrine pancreas. Endocrine pancreas was most sensitive at 48 hpf, where tBHQ resulted in β-cell cluster area reduction by 22.83% and 26.45% respectively, and increased variance islet frequencies by 30.3% and 36.67% respectively. On the other hand, antioxidants NAC and SFN significantly increased β-cell cluster area by 20.68% and 25.7% respectively. Cluster area of a-cells was only affected at 48 hpf where tBOOH and tBHQ decreased a-cell cluster area by 8.87% and 7.9% respectively. In addition, dose response curves were generated for both pro-oxidants to identify critical window of exposure and LC_50. In contrast to pancreatic endpoints, embryos were most sensitive to pro-oxidants at 72 hpf. Estimated LC_50 values at 24, 48 and 72 hpf for tBOOH were 6.90, 1.56 and 0.57 μM respectively, and for tBHQ, (HAAs) (H2O2) and acetamides. Cytotoxicity-assays revealed a structure-activity relationship wherein iodoacetic acids and acetamides are the most toxic congeners, followed by bromo- then chloro-DBPs. Unexpectedly, NF2-mediated oxidative stress was strongly induced by iodo- and bromoacetamides but not by HAAs, highlighting the differences in toxic pathways. The objective is to investigate their exact mechanisms via chemical proteomics by employing an alkyne-modified iodoacetamide chemical probe for in-gel fluorescence imaging. Accordant with cytotoxicities, iodo- and bromo-DBPs bind to more proteins than chloro-DBPs, as evidenced by increased probe competition. Interestingly, halogenated acetic acids and acetamides were found to bind to different proteins although both of them have been reported to be cysteine reactive. We further identified the target proteins using biotin-mediated affinity pulldown mass spectrometry analysis, which revealed that more than 500 proteins are modified by these DBPs. The identified proteins were compared to those of essential genes, previously determined by CRISSP, to identify the major cytotoxic pathways. Consistent with in-gel fluorescence imaging, the protein targets of halogenated AAs and acetamides were different. For example, phosphoglycerate kinase (PGK1) was identified as a specific protein target of iodoacetamide. Of the modified proteins, a recurring theme was the covalent binding of anti-oxidant enzymes such as peroxiredoxins. We validated our proteomics results using enzyme kinetic assays of anti-oxidant enzymes. Thus, we have provided the first evidence that cysteine reactive halogenated DBPs may induce diverse toxicities by targeting different proteins. Application of chemical proteomics to investigate the toxic mechanisms of broader classes of DBPs is of great interest.

2009 Chemical Proteomics Reveals Different Toxic Pathways of Halogenated Acetic Acids and Acetamides

Epidemiological and animal exposure studies alike both highlight the potential adverse health effects of disinfection-by-products (DBPs), but the toxic mechanisms of DBPs remains elusive. Our previous studies profiling pre- and post-chlorinated drinking water samples have demonstrated that NF2-mediated oxidative stress is the primary toxic pathway of DBPs. Motivated by this, we chose to investigate the toxic pathways (i.e. protein targets) of two prominent classes of DBPs: monohalogenated acetic acids and acetamides. Cytotoxicity-assays revealed a structure-activity relationship wherein iodoacetic acids and acetamides are the most toxic congeners, followed by bromo- then chloro-DBPs. Unexpectedly, NF2-mediated oxidative stress was strongly induced by iodo- and bromoacetamides but not by HAAs, highlighting the differences in toxic pathways. The objective is to investigate their exact mechanisms via chemical proteomics by employing an alkyne-modified iodoacetamide chemical probe for in-gel fluorescence imaging. Accordant with cytotoxicities, iodo- and bromo-DBPs bind to more proteins than chloro-DBPs, as evidenced by increased probe competition. Interestingly, halogenated acetamides and HAAs were found to bind to different proteins although both of them have been reported to be cysteine reactive. We further identified the target proteins using biotin-mediated affinity pulldown mass spectrometry analysis, which revealed that more than 500 proteins are modified by these DBPs. The identified proteins were compared to those of essential genes, previously determined by CRISSP, to identify the major cytotoxic pathways. Consistent with in-gel fluorescence imaging, the protein targets of halogenated AAs and acetamides were different. For example, phosphoglycerate kinase (PGK1) was identified as a specific protein target of iodoacetamide. Of the modified proteins, a recurring theme was the covalent binding of anti-oxidant enzymes such as peroxiredoxins. We validated our proteomics results using enzyme kinetic assays of anti-oxidant enzymes. Thus, we have provided the first evidence that cysteine reactive halogenated DBPs may induce diverse toxicities by targeting different proteins. Application of chemical proteomics to investigate the toxic mechanisms of broader classes of DBPs is of great interest.

2010 Possible Prooxidant Actions of Tetra bromobisphenol A
K. E. Nixon1, M. O. Claville2, R. M. Uppu2, and S. Babu1. 1Hampton University, Hampton, VA; and 2Southern University and A & M College, Baton Rouge, LA.

Tetra bromobisphenol A (TBBPA) and its derivatives are used as flame retardant in consumer products such as circuit boards and household electrical equipment. Recently, US EPA rejected a petition to mandate manufacture to conduct direct testing on TBBPA. Emerging evidences suggest that TBBPA exposure in zebrafish embryos and fish Channa punctatus (Sharma 2018 Drug and Chemical Toxicology, 1-6) increased oxidative stress and caused developmental toxicity. We hypothesize that the prooxidant actions of TBBPA is responsible for the increased oxidative stress, which may in turn cause damage to DNA, protein and lipids. To understand the TBBPA-induced alterations in cellular redox status, we have investigated the prooxidant effects of TBBPA in comparison with four other phenolic compounds, viz., phenol (P), 4-bromophenol (BP), 2,2,6,6-Tetramethylpiperidin (TBBPA), and 4-nitrophenol (NP). The phenolate radicals of P, BP, TBBPA, and NP, generated in situ via 1-electron-oxidation of the corresponding phenol (0.1 mM each) in the HRP/H2O2 system, were allowed to react with equal amount of rifampicin (0.1 mM) and monitored at 472 nm. In the rifampicin assay, higher rates of oxidation were observed with the radicals of BP (50.71 ± 4.75 μM/min) and P (36.24 ± 6.65 μM/min) as compared to those of TBBPA (23.38 ± 18.41 μM/min) and NP (13.2 ± 3.81 μM/min) and the corresponding control assay (17.33 ± 6.25 μM/min).
2012 Mucin Muc5ac Deficiency Enhanced Airway Susceptibility to Environmental Toxins

H. Cho, L. Miller-DeGraff, R. Langenbach, and S. Kleeberger, NIEHS, Research Triangle Park, NC.

Gel-forming mucins protect respiratory tracts. MUC5AC is the major secreted airway mucin that is associated with various diseases including asthma, chronic obstructive pulmonary disease, and fibrosis. To determine the role of Muc5ac in airway disorders in which abnormally heightened mucus is featured, Muc5ac−/− mice and wild type mice (Muc5ac+/+) were infected with respiratory syncytial virus (RSV, intranasal infection) or exposed to ozone (0.3 parts per million). Pulmonary and nasal airway injuries were assessed by bronchoalveolar lavage and histopathologic analyses. RSV was detected more intensely in nasal (septal epithelium and sub-epithelium, blood vessels) and pulmonary (bronchial epithelium, pleura) airways of treated, but not wild type mice. Impaired nasal and pulmonary airway defenses against virus and ozone. Subepithelial mucous glands in nasal airways may contribute to compensatory protective mechanism of Muc5ac−/− mice.

2013 Effect of Diet and Occupational Exposure in Different Rat Strains on Serum Biomarkers and Peripheral Blood Mononuclear Cell Telomere Length: Development of an Animal Model to Examine the Exposome

The exposome is a measure of all exposures of an individual and how those exposures relate to health. Important components of the exposome include lifestyle (diet), environmental and occupational exposures, and individual genetic predisposition. Mapping of the exposome will improve the understanding of disease and aid in prevention strategies and possible cures of many diseases. The goal was to develop an experimental model of the exposome by collecting biological samples during critical life stages of an exposed animal that are applicable to worker populations. Genetic contributions were assessed using three strains of male rats with different genetic backgrounds. A. Martinez, S. Kleeberger, and an unidentified, soil sample-based bacteria) would grow significantly faster in the presence of 3-NBA. Nitro-reductases secreted from the bacteria metabolized 3-NBA, and a current investigation of a NCBI gene database for these bacteria will attempt to locate which genes allow the bacteria to produce these nitro-reductases. There are strong matches with genes such as CB03577 and CB00878. 3-NBA was injected into a solution of nutrient broth with bacteria and left to grow for two hours. After the bacteria were allowed to grow in this solution, the solution would turn pink (from yellow), and its wavelength absorbance would show peaks resembling those of 3-Aminobenzanthrone. 3-ABA is significantly less toxic to 3-NBA and its metabolism is extraordinarily harmful and leads to DNA adducts. Allowing the bacteria to metabolize 3-NBA, rather than allowing the human body to do
Occupational and indoor exposure to asbestos can lead to the development of pulmonary fibrosis years after exposure has ceased, leading to significant morbidity and mortality. Asbestos fibers can lodge within the bronchoalveolar duct junctions and small airways of humans and mice respectively, persisting for years. Although multiple cell types have been implicated as important participants in the development and progression of asbestos-induced lung fibrosis, the specific mechanisms and key cellular players involved are not known. Using a comprehensive combination of unbiased single cell transcriptional profiling (scRNA-Seq), genetic lineage-tracing, flow cytometry and in situ RNA hybridization, we tested the hypothesis that monocyte-derived alveolar macrophages are key drivers of asbestos-induced pulmonary fibrosis via epithelial cell injury and fibroblast proliferation. C57Bl6 mice were exposed to TiO$_2$ (control) or asbestos fibers intratracheally. Lungs were harvested 14 days later to capture the early stages of pulmonary fibrosis and scRNA-Seq libraries were prepared from cell suspensions using the 10X Chromium platform. Profiling 24,060 cells identified 24 known cellular populations represented in all experimental conditions. All populations exhibited transcriptional changes during the development of fibrosis. Importantly, the emergence of a new distinct subpopulation of alveolar macrophages was observed in asbestos-exposed animals. This subpopulation was characterized by an immature phenotype and elevated expression of genes known to be causally associated with fibrosis such as Mmp12, Retnla, Chia1 and Pdgfa (involved in fibroblast proliferation). Furthermore, these cells expressed Itgam and Cxcr2, suggesting a monocyte origin. Remarkably, this new subpopulation was represented only by cells from asbestos-exposed mice and was absent in control conditions. Flow cytometry, lineage-tracing analyses and immunohistochemistry confirmed this subpopulation to be monocyte-derived alveolar macrophages. Immunofluorescent microscopy confirmed that Pdgfra-expressing cells were specifically recruited to the areas of fibrosis and were located in the proximity of Pdgfra-expressing fibroblasts. Creflox-mediated genetic deletion of this population by targeting Casp8 prevented the development of pulmonary fibrosis. Collectively, these studies are the first to show a causal association between asbestos-induced epithelial lung injury, localized recruitment of monocyte-derived alveolar macrophages and subsequent development of spatially restricted lung fibrosis.

2016 Lack of Lung Tumor Promotion after Inhalation of a Copper-Nickel Welding Fume in A/J Mice

P. Zeidler-Erdely$^1$, A. Erdely$^1$, R. Salmen$^1$, L. Battelli$^1$, T. Dodd$^1$, M. Keane$^1$, W. McKinney$^1$, S. Stone$^1$, M. Donlin$^1$, H. Leonard$^1$, J. Cumpston$^1$, J. Cumpston$^2$, R. Mercer$^1$, S. Stone$^1$, J. Antonini$^1$, and L. Falcone$^1$

The International Agency for Research on Cancer classified welding fumes as genotoxic (carcinogenic to humans) in 2017. The process of stainless-steel welding creates fumes rich in carcinogenic metals such as chromium (Cr). Our lab has previously demonstrated that stainless steel welding fumes promote lung tumors in susceptible A/J mice. Consumables devoid of Cr are being produced and an attempt to limit worker exposures to potentially carcinogenic metals. The aim of this study was to characterize a new copper-nickel (Cu-Ni) fume and then investigate if inhalation of this fume would promote lung tumors in mice using a two-stage (initiation-promotion) model. To determine particle mass size distribution, a Micro-Orifice Uniform Deposit Impactor (MOUDI, model 110; MSP corp., Shoreview, Minn.) with additional Nano-MOUDI stages (MSP model 115) was used. Characterization of the fume indicated that most of the particles were between 0.1 and 1 µm in diameter, with a mass median aerodynamic diameter of 0.43 µm. Male A/J mice (4 - 5 weeks old) were initiated with 3-methylcholanthrene (MCA; 10 µg/g IP) and corn oil and, beginning 1 week later, were exposed to air or Cu-Ni welding fumes for 4 hours/day, 4 days/week, for 9 weeks. At 30 weeks, mice were sacrificed and lung tumor multiplicity and incidence were evaluated. MCA/Cu-Ni welding fume exposure significantly decreased tumor number and tumor size compared to MCA/air controls (7.11 ± 0.93 tumors vs. 15.57 ± 0.75 tumors and 0.57 ± 0.01 mm in diameter vs. 1.15 ± 0.02 mm in diameter, respectively). Future studies are planned to investigate the pneumotoxicity of Cu-Ni fume in A/J mice.

2017 Functional Significance of the SLC26A4 Gene in Silica-Induced Pulmonary Toxicity

National Institute for Occupational Safety & Health, Morgantown, WV.

Occupational exposure to silica may result in potentially fatal diseases such as silicosis and cancer. Understanding molecular mechanisms responsible for silica-induced pulmonary toxicity is of great importance in preventing silicosis and other effects associated with occupational silica exposure. Previous studies in our laboratory identified a correlation between silica-induced pulmonary toxicity and SLC26A4 gene overexpression in the lungs of rats. However, the functional significance of this gene in silica induced pulmonary toxicity is not understood. To determine the role of the SLC26A4 gene in silica-induced pulmonary toxicity, SLC26A4 wild type (WT) and knockout (KO) mice were employed. All mice were exposed to either air or crystalline silica (15 mg/m$^3$, 6 hours/day, 4 days) and pulmonary toxicity was assessed at 1 day, 3 months, 6 months, and 9 months post-exposure. Pulmonary response parameters including, lactate dehydrogenase (LDH) activity, oxidant production, cell counts (including infiltrating neutrophils and alveolar macrophages), and gene expression were monitored. Silica inhalation caused a significant increase in pulmonary toxicity and inflammation in both the WT and KO mouse strains, compared to corresponding air exposed controls. However, there were significant differences (p<0.05) in the measured pulmonary toxicity parameters between silica exposed WT and KO groups. For example, induction of pulmonary inflammation in the silica exposed WT mice was accompanied by a significant increase in infiltration of neutrophils in the lung. This infiltration was vastly different between the WT and KO groups. Specifically, at 3 months post-exposure neutrophil infiltration in the WT mice was 480 fold higher compared to air exposed controls while being 205 fold higher in the KO mice. At 6 months post-exposure, neutrophil infiltration in the WT mice was 192 times higher than air controls while the KO mice had, a significantly lower, 54 fold increase in PMN number, compared to air controls. At 9 months post-exposure neutrophil number was 45 fold higher in WT mice and only 9 fold higher in KO mice compared to air controls. In conclusion, both the WT and KO mice presented with an enhanced inflammatory response with a distinct pattern. However, the severity of silica induced pulmonary toxicity was more in the WT mice compared to the KO mice. These findings support the hypothesis that the SLC26A4 gene does, in fact, play a role in silica induced pulmonary toxicity.

2018 Understanding the Lung-Gut Axis by Modeling the Influence of Welding Fume Inhalation Exposure and Lifestyle on the Profile of Gut Microbiome and Systemic Immune Cells

National Institute for Occupational Safety & Health, Morgantown, WV.

The gut microbiome has a regulatory influence on various systemic organs, and altered microbiome diversity correlates with various diseases and pathological conditions. The goal of the current work was to profile and correlate the influence of occupational pulmonary exposure (welding fume), lifestyle (high fat diet) and age on the gut microbiome and immune cell phenotype populations in blood, lung lymph nodes and spleen. Male Sprague-Dawley rats were maintained on a regular chow (RO) or high fat (HF) diet for 24 wk. At wk 7, groups of rats maintained on each diet were exposed by inhalation to stainless steel welding fume (WF: 20 mg/m$^3$ x 3 hr/day x 4 wk x 5 wk) or filtered air until wk 12, at which time some animals from each group were euthanized. A separate set of rats from each group were allowed to recover from WF exposure until wk 24. At these time points, immune cells from various systemic locations were profiled using flow cytometry. The DNA from the lower gut feces was extracted and sequenced for 16s. The ratio of firmicutes to bacteroidetes consistently decreased in RG-fed rats and increased for HF-fed rats over the 24 wk period. This was further exacerbated in WF-exposed animals. Random Forest analysis was employed to identify specific alterations at genus and species level for the various treatments. There was no change in total leukocyte number but there was a significant increase in neutrophils recovered from the blood of rats fed the HF vs the RG diet. In the lungs, there was no change in the leucocyte profile between rats fed WF exposure diets after 7 weeks exposure. However, after a recovery period, lung neutrophil and lymphocyte numbers, in addition to percent of pulmonary macrophages, remained significantly elevated in rats maintained on
the HF diet. In the spleen and lymph nodes, like the lung, WF exposure did not change the response with various diets. However, as the animals aged, the HF diet caused a significantly elevated B'T lymphocyte ratio in both the spleen and mesenteric lymph nodes compared to the RG diet. The percent of CD8+-T-lymphocytes remained elevated in the lymph nodes of the HF but not RG-fed rats. Taken together, the data suggests that diet by itself causes a dysbiosis of normal microbiome and immune populations. This effect is irrevocably exacerbated over time when exposed to a secondary pulmonary insult, such as welding fume.

2019 Reducing the Respiration Rate and Improving Animal Welfare in Inhalation Large Animal Studies by Using a 3D Printer and Designing Specific Masks

S. Moore, and E. Moore. Envigo, Huntingdon, United Kingdom.

Inhalation large animal dosing requires the use of a facemask to deliver the aerosol to in vivo species. Exposure dosing exposure period can be up to 240 min depending on the target dose. However, the historical masks that have been used by the industry are modified from existing off the shelf clinical or veterinary masks and generic in size and as such are a compromise for their application. Envigo designed and manufactured new masks to improve animal welfare by making them specific for inhalation dosing masks by using 3D printing. Casts were made of various sizes of large animals and photographed at 30° divisions using a 3D-scanner. The individual photos from each cast were then merged into a single 3D image by the AutoCAD/CAM software. Prototype masks and seals were then produced using 3D printer software that could be adhered to the animals face with the use of Velcro straps. Validation consisted of delivering 5% CO2 introduced from the back of the mask to simulate a large animal attached to the exposure system to ensure that ECO2 (end-tidal CO2) values returned to baseline between breathes over a wide range of operating parameters. Upon introduction of the new masks, decreased the mean in vivo dog respiration rates from a mean of 24.9 and 20.0 breaths/min in the males and females to 16.9 in both sexes. Decreases in respiration rates in mature primates were also observed from 42.4 and 43.3 breathes/min in the male and females to 34.6 and 40.8. The mean respiratory values decreased from 71.4 breathes/min in the males and 77.5 in the females to 64.7 and 64.1 respectively. These decreases in the respiration rate was also accompanied by anecdotal visual dosing observations that the animals appear noticeably calmer especially primates and thus improving animal welfare. This personalized approach to mask fitting and design has been adopted for all future studies.

2020 Comparison of Deposition Efficiency and Uniformity of Monodisperse Solid Particle Deposition in Two Air Liquid Interface (VITROCELL 24/48 and AMES 48) In Vitro Exposure Systems with Computational Fluid Dynamic (CFD) Predictions

M. Oldham1, J. Zhang1, G. Gilman3, P. Kosachevsky1, F. Lucci2, A.K. Kucza1, N.D. Castro1, A.A. Rostami1, Y.B. Pithawalla1, J. Hoeng1, W.J. McKinney Jr.1, and K.M. Lee1. 1Altia Client Services LLC, Richmond, VA; 2Enthaply Analytical, Richmond, VA; 3Philip Morris Products, S.A., Neuchatel, Switzerland; and 4Philip Morris Products S.A., Neuchatel, Switzerland.

For toxicological assessment of inhalable chemicals, in vitro exposure systems that enable aerosols to be delivered directly to the apical surface of respiratory cells (air liquid interface; ALI) provide a more realistic exposure method than traditional submersion in vitro cultures. Quantitative aerosol dosimetry (delivered dose) is critical for interpretation of biological results generated from these ALI in vitro exposure systems and potential extrapolation to humans in the gut microenvironment available ALI in vitro exposure systems (VITROCELL® 24/48 and AMES 48) particle deposition efficiency and uniformity of deposition across the cell culture inserts and petri dishes were experimentally quantified and compared with CFD predictions. Four diameters of monodisperse fluorescent particles (0.51, 1.1, 2.1, and 3.2 μm mass median aerodynamic diameter) were used and experimentally measured. For the VITROCELL® 24/48 exposure system, experimentally measured particle deposition efficiency ranged from a mean (N= 3 runs) of 0.013% to 0.86% as a function of particle diameter. Variability in the uniformity of particle deposition across the cell culture inserts was observed and ranged from 40% to 150% of the mean number of particles. There was good agreement between experimentally measured and CFD predicted particle deposition efficiency and uniformity of particle deposition for the VITROCELL® 24/48 exposure systems. For the VITROCELL® AMES 48 exposure system, three different sampling flows (5, 10, and 20 cc/min) were evaluated. The 10 cc/min sampling flow provided the most consistent number (65 - 135% of mean number of depositing particles), regardless of particle size. Experimentally measured deposition efficiency (10 cc/min flowrate) ranged from a mean (N=3 runs) of 0.07% to 0.43% as a function of particle diameter. Quantitative aerosol dosimetry in these two ALI exposure systems enables improved experimental design and extrapolation to human exposures.

2021 HIF-1α and IL-1β Are Two Key Events of the Lung Inflammation and Fibrosis Induced by Particles Used in Li-Ion Batteries

V. Sironval, M. Palmai-Pallag, Y. Yakoub, D. Lison, and S. van den Brule. Université Catholique de Louvain, Brussels, Belgium.

Rechargeable Li-ion batteries (LIB) offer undeniable advantages compared to other technologies and are increasingly used worldwide. They contain micrometric and low solubility particles, consisting of toxicologically relevant elements, implying a potential for inhalation exposure in occupational settings. New proposed applications such as printable or spray-paintable batteries might also expose consumers. As the health hazard of these materials is not documented, we performed the first study on the respiratory hazard of 3 leading LIB components (LiFePO4, or LFP, Li2TiO3, or LTO, and LiCoO2 or LCO) and investigated their mechanisms of action. Lung responses were assessed in mice after oro-pharyngeal aspiration of LIB particles or crystalline silica used as reference. Acute inflammatory lung responses and oxidative stress were recorded with the 3 LIB particles and silica, LCO being the most potent. Inflammation persisted 2 m after LFP, LCO and silica, in association with fibrosis in LCO and silica lungs. Only LCO stabilized hypoxic-like factor (HIF)-1α, a pro-inflammatory and carcinogenic transcriptional factor stabilized by Co ions, after 3 d [1]. In view of the large variety of existing and in development LIB particles, their increasing production, use and disposal, a predictive in vitro assay of their lung toxicity and potential for occupational health risks. By inhibiting HIF-1α or IL-1β responses, we identify these 2 markers as key events of LCO lung toxicity. The in vitro and in vivo study of a large range of LIB particles with different % of cobalt allows us to confirm the predictive value of the in vitro assay for large number of LIB particles. We conclude here that particles used in LIB represent a respiratory hazard. Exposure to LIB particles should, therefore, be strictly controlled in occupational settings. LCO was more potent than crystalline silica to induce inflammatory and fibrotic responses. IL-1β and HIF-1α stabilization represent key events in the lung toxicity of LIB particles and appear useful biomarkers to compare the large number of LIB particles in development or on the market. 2022 Timing of Rat Gestational High-Fat Diet and Sex Determine Increased Susceptibility to Allergic Responses in Offspring

S. Gavett1, M. Hargrove2, S. Snow1, P. Phillips1, C. Gordon1, and U. Kodavanti1. 1US EPA, Research Triangle Park, NC; and 2ORISE, Research Triangle Park, NC.

We previously showed offspring from Long-Evans rat dams given a high-fat diet (HFD) before, during, and after pregnancy had increased pulmonary and metabolic responses to acute ozone exposure. Increased susceptibility to allergy and asthma may also result from maternal HFD consumption. To determine if there is a window of susceptibility to allergic responses in offspring due to HFD consumption during gestation, dams were fed a control diet (CD) throughout gestation, HFD on gestation days (GD) 1-11 followed by CD on GD 12-22 (HFD/CD), CD from GD 1-11 followed by HFD on GD 12-22 (CD/HFD), or HFD throughout gestation (HFD). Male and female offspring (average 16 weeks old on day 0) were sensitized and challenged intranasally with increasing concentrations of house dust mite (HDM) antigen on days 0 and 7 and challenged i.n. on day 21. Non-allergic rats received saline vehicle only on sensitization days. Respiratory responses to methacholine aerosol (0, 10, 20, and 40 mg/ml saline) were assessed by whole body plethysmography 2 days after challenge. Enhanced pause (PenH), an indicator of labored breathing, was significantly increased in female HDM-allergic HFD and CD/HFD groups compared with the female allergic CD group during 40 mg/ml MCh exposure. There were no differences among male groups, and other indices of respiratory function were not affected by maternal diet in non-allergic or HDM-allergic groups. Alveolar macrophages not treated ~99% of bronchoalveolar lavage fluid (BALF) cells in all non-allergic groups. BALF neutrophils, eosinophils, and lymphocytes together comprised ~6% (females) to ~12% (males) of total cells in HDM-allergic groups, indicating mild allergic inflammation, but there were no effects of maternal diet on inflammatory responses. Maternal diet also had no influence on BALF protein and albumin concentrations and inflammatory cytokine levels in allergic and non-allergic groups. In contrast, BALF γ-glutamyl transferase, a marker of lung injury, was significantly increased (1.8-1.9-fold) in both
non-allergic and HDG-allergic CD/HFD and HFD male groups compared with CD males. Together these data suggest increased susceptibility to allergic airway hyperresponsiveness in female offspring due to maternal HFD through- out or in the latter half of pregnancy. Greater lung injury in male offspring due to the same maternal diets may predispose to increased susceptibility to air pollutants. This abstract does not reflect US EPA policy.

2023 Evaluation of Diacetyl Mediated Pulmonary Toxicity in Physiologically Relevant Air-Liquid Interface Models of Human Primary Bronchial Epithelial Cells

Diacetyl, an α-diketone, is used extensively in artificial flavorings due to its butter like aroma. Exposure to diacetyl vapors is associated with the development of bronchiolitis obliterans in workers of microwave popcorn and flavor manufacturing industries. Therefore, we aimed to investigate diacetyl induced pulmonary toxicity using physiologically relevant air-interface model (ALI) models of human primary bronchial epithelial cells (PBEC). The PBEC-ALI models were exposed to clean air (sham) or to 1, 3, 10 and 30 ppm of diacetyl vapor for 30 minutes using an in-house developed exposure system. Cell viability was analyzed with LDH-assay. Transcript expression of pro-inflammatory (CXCL8, IL6, IL1B, TNF, and NFκB1), oxidative stress (HMOX1, SOD3, G5A1 and GPX3), tissue injury/repair (MMP9/TIMP1) and anti-protease β-defensin (SLPI) and H2O2 markers were assessed 6 and 24h post-exposure using qRT-PCR. Secretion of CXCL-8 and MMP-9 were measured in both basal media (BM) and apical media (AM) using ELISA. More than 90% cells were viable after exposure to both sham and diacetyl vapors. Significantly increased secretion of MMP-9 was detected 24h post-exposure compared to 6h post exposure group in both AM and sham (P<0.05). However, secretion of CXCL-8 remained unaltered. Significantly altered expressions of pro-inflammatory (NFκB1, TNF, IL6), oxidative stress (GPX3, G5A1, PTGES2) and tissue injury/repair (MMP9/TIMP1) markers were more pronounced at 24h post-exposure to diacetyl compared to 6h post exposure. Transcript expression of anti-protease marker (SLPI) was significantly increased at 24h post-exposure to 1ppm diacetyl, whereas at 6h post-exposure to 30 ppm diacetyl results in reduced expression of SLPI. Our study shows that diacetyl exposure results in significantly increased expression of pro-inflammatory, oxidative stress, anti-protease, and tissue injury/repair markers. Altered expression of these markers may play a pivotal role in diacetyl modulated pulmonary toxicity. Further, the physiologically relevant ALI models with exposure system used here are a highly suitable in vitro approach to assess occupational exposure induced health hazards.

2024 Docosahexaenoic Acid Supplementation Effectively Treats Toxicant-Triggered Autoimmunity in Lupus-Prone Mice

Systemic lupus erythematosus (lupus) is a chronic and debilitating autoimmune disease that affects approximately 1.5 million people in the United States. Pulmonary exposure to crystalline silica dust (cSiO2) has been implicated as an environmental trigger of lupus. We have recently reported that consumption of docosahexaenoic acid (DHA) prevents cSiO2-triggered autoimmunity in lupus-prone mice. Specifically, DHA supplementation suppressed cSiO2-induced 1) pulmonary ectopic lymphoneogenesis, 2) cytokine and autoantibody responses in both bronchoalveolar lavage fluid (BALF) and plasma, and 3) glomerulonephritis in the female NZBWFI mouse model. The present study is designed to address the question: Can DHA supplementation alone, or in combination with cSiO2, ameliorate the development of these lupus-like symptoms? To test this hypothesis, we induced disease in only C57BL/6 female mice using a single, low dose nCuOCOOH nanoparticles. Additionally, because response to transition metal nanoparticle was as highly enriched GO term (FDR BE-13) from the subset of 48 highly overlapping DE genes, these genes may represent biomarkers to a potentially large variety of metal/metal oxide nanoparticles.

2025 Natural History of Inhaled Sulfur Mustard Poisoning in Rats

R. Malaviya1, R. Rancourt1, E. Abramova2, A. Bellomo1, Z. Henry3, C. Crouch4, J. Roseman4, E. Peters5, B. P. Casillas6, C. Amuzie7, V. Sunil1, J. D. Laskin1, and D. L. Laskin1. 1Rutgers, The State University of New Jersey, Piscataway, NJ; 2Winston-Salem State University, Winston-Salem, NC; 3MRIGlobal, Kansas City, MO; and 4Janssen Research & Development, Spring House, PA.

In humans, inhalation of sulfur mustard (SM, bis (2-chloroethyl) sulfide), causes acute lung injury which progresses to fibrosis. Herein, we characterized the manifestations of SM-induced pulmonary injury in rats. Spontaneously breathing male Wistar rats were anesthetized, intratracheally intubated, and exposed to 0.4 mg/kg SM by vapor inhalation. Animals were euthanized 3, 7, 16 and 28 d after and bronchoalveolar lavage (BAL) and lung collected. At 3 d post SM, pulmonary edema, inflammatory cell accumulation, thickened alveolar septal walls and ulceration of bronchial epithelium were observed in histologic sections. Expression of HO-1 and iNOS were also markedly upregulated in the lung, along with mucin, fibrinogen and COX-2, consistent with SM-induced oxidative and nitrosative stress, lung injury and inflammation. This was associated with increased in BAL cell protein content and levels of HMGB-1, RAGE, MPO, and SP-D, demonstrating alveolar epithelial and inflammatory cell involvement in lung injury. Gene expression changes were also noted in the lung at 7 d post SM, but at reduced levels. At 16 d post SM, lung HO-1 and mucin expression were increased, relative to 7 d. Additionally, bronchial epithelial- and mesothelial-hyperplasia/hyperplasia, interstitial fibrosis and dysregulated epithelial repair were evident. At 28 d post SM, a secondary increase in inflammatory cell infiltration in BAL, cilia, airway and bronchi, and MPO, RAGE, SP-D and fibrinogen levels, as well as HO-1 and COX-2 expression was observed which was comparable to or greater than 3 d post SM. This correlated with the appearance of proteinaceous bronchiolar and alveolar exudate entrapping inflammatory cells, diffuse squamous metaplasia, aberrant bronchial epithelial repair and multilayered interstitial and peribronchial fibrosis. These data demonstrate a similar pathologic sequela of events in rats and humans following SM exposure. Development of a rodent model of injury that reflects human exposure will be useful for the identification of efficacious therapeutics for mitigating SM-induced acute injury and fibrosis. NIH Grants: US4AR055073, R01ES004738, P30ES050522.

2026 Molecular Signature of Asthma-Enhanced Sensitivity to Aerosols of Pristine and Carboxylated CuO Nanoparticles, Identified in 3D Cell Models

I. M. Kooter1, M. Ilves2, M. Grollers-Mulderij1, P. Tromp1, E. Duistermaat4, D. Greco3, J. Ndika4, and H. Alenius1. 1TNF, Utrecht, Netherlands; 2University of Helsinki, Helsinki, Finland; 3TNF, Zeist, Netherlands; and 4Triskelion, Zeist, Netherlands. Sponsor: R. Woutersen.

More than 5% of any population suffers from asthma, and these individuals may be more sensitive to nanoparticle aerosols than the healthy population. There is as yet a paucity of data on the molecular underpinnings and mechanisms involved. We therefore investigated global transcriptic responses of human bronchial epithelial cell (BE-2) models to pristine and carboxylated CuO nanoparticles (CuOCOOH) in the lung lipids. Pulmonary exposure to 0.4 mg/kg SM by vapor inhalation. Animals were euthanized 3, 7, 16 and 28 d after and bronchoalveolar lavage (BAL) and lung collected. At 3 d post SM, pulmonary edema, inflammatory cell accumulation, thickened alveolar septal walls and ulceration of bronchial epithelium were observed in histologic sections. Expression of HO-1 and iNOS were also markedly upregulated in the lung, along with mucin, fibrinogen and COX-2, consistent with SM-induced oxidative and nitrosative stress, lung injury and inflammation. This was associated with increased in BAL cell protein content and levels of HMGB-1, RAGE, MPO, and SP-D, demonstrating alveolar epithelial and inflammatory cell involvement in lung injury. Gene expression changes were also noted in the lung at 7 d post SM, but at reduced levels. At 16 d post SM, lung HO-1 and mucin expression were increased, relative to 7 d. Additionally, bronchial epithelial- and mesothelial-hyperplasia/hyperplasia, interstitial fibrosis and dysregulated epithelial repair were evident. At 28 d post SM, a secondary increase in inflammatory cell infiltration in BAL, cilia, airway and bronchi, and MPO, RAGE, SP-D and fibrinogen levels, as well as HO-1 and COX-2 expression was observed which was comparable to or greater than 3 d post SM. This correlated with the appearance of proteinaceous bronchiolar and alveolar exudate entrapping inflammatory cells, diffuse squamous metaplasia, aberrant bronchial epithelial repair and multilayered interstitial and peribronchial fibrosis. These data demonstrate a similar pathologic sequela of events in rats and humans following SM exposure. Development of a rodent model of injury that reflects human exposure will be useful for the identification of efficacious therapeutics for mitigating SM-induced acute injury and fibrosis. **2027 Comparative Toxicities of 1,1′-Methylenedioxy(4-[(hydroxylimino)methyl]pyridinum) (MMB4) at Rat and Rabbit Diaphragm Neuromuscular Junctions**

1,1′-methyliden(4-[(hydroxylimino)methyl]pyridinium) (MMB4) is a leading candidate for next-generation nerve agent treatment. Although MMB4 appears clinically nontoxic at up to 400 mg/kg in rodents, MMB4 has been shown to cause respiratory arrest in rabbits at doses exceeding 200 mg/kg. To determine the mechanistic basis for MMB4 toxicity, we evaluated concentration- and use-dependent effects of MMB4 on diaphragm function by measuring ex vivo nerve-elicited isometric twitch, tetanic contraction strength, and synaptic transmission via intracellular electrophysiology in female New Zealand white rabbits and Sprague Dawley rats. Results from muscle function studies indicate that MMB4 more potently inhibits diaphragm muscle contraction in rabbit than in rat. Intracellular recording studies demonstrate that MMB4 causes a dose-dependent reduction in rat end plate potentials (EPP) and miniature end plate potential (mEPP) amplitudes, with compensatory increases in quantal content. While concomitant decreases in rabbit EPP and mEPP amplitudes were also observed, quantal content remained unaffected by MMB4. These data indicate that the increased toxicity of MMB4 at rabbit versus rat phrenic neuromuscular junctions results from (1) a lack of compensatory synaptic homeostatic mechanisms in rabbit; (2) inhibition of compensatory mechanisms in rabbit; or (3) augmentation of compensatory mechanisms in rat. We also observed increased EPP and mEPP half-widths in rat and rabbit recordings, indicating that MMB4 inhibits AChE. Finally, while there was no evidence of use-dependent effects of MMB4 in rabbits, pronounced tetanic fade was seen in rats, suggesting the potential antagonism of presynaptic nicotinic acetylcholine receptors. Collectively these results demonstrate that oximes such as MMB4 can have a multifactorial effect on cholinergic synaptic transmission and provide an explanation of a potential mechanism for the increased sensitivity of rabbits versus rats to MMB4 overdose.

**2028 Development of a Computational Model for the Transient Receptor Potential Vanilloid Subfamily Type 1 Protein (TRPV1)**

Sensory irritation, perceived irritation in the nose, throat and eyes, is a common manifestation of exposure to irritants and is frequently used as a critical effect in setting airborne occupational exposure limits (OELs). The transient receptor potential vanilloid subfamily type 1 protein (TRPV1); capsaicin receptor) is an important biological target for potential sensory irritation but there are no available in silico or in vitro predictive models. The goal of our work was to mine existing public data and develop a computational model that predicts the likelihood an unknown compound will or will not interact with TRPV1. We compiled a master database of >30000 compounds known to interact with TRPV1 and >8500 compounds that do not. We developed a random-forest machine-learning prediction model that derives, predicts and analyzes structural fingerprints, conserved scaffolds and protein-docking binding energies. Our machine-learning prediction model that derives, predicts and analyzes structural fingerprints, conserved scaffolds and protein-docking binding energies. Our model showed very high sensitivity (95%) and balanced accuracy (82%), with a specificity of 68%. Furthermore, analysis of binding energetic from docking revealed TRPV1 active substances to have significantly higher binding energies relative to controls (p<0.0001). In conclusion, we have built the only available computational model for TRPV1, an important biological target. We can now use our model to screen in vivo databases for potential involvement of this target.

**2029 A Read-Across Study on Diketones**

B. Kühne, D. Ritter, J. Knebel, J. Boei, H. Vrieling, P. Hiemstra, S. Escher, and T. Hansen. *Fraunhofer ITEM, Hannover, Germany; and Leiden University Medical Center, Leiden, Netherlands. Sponsor: C. Dassenbrock*

The alpha-diketone diacetyl (2,3-butanedione) is used as butter flavorant in the microwave pop corn industry and suspected to cause a rare obstructive pulmonary disease (popcorn lung). Smoking is also a potential route of exposure to diacetyl and the potentially less toxic alternative 2,3-pentanediol. In this case study we are developing new-approach methodologies (NAMs) to reduce the uncertainty of read-across pre-dictions. Primary bronchial epithelial cells were exposed to the alpha-diketones diacetyl, 2,3-pentanediol and 2,3-hexanediol or the beta-diketone 2,4-pentanediol under air-liquid interface (ALI) conditions using the P.R.I.T. ExpoCube device. This unique exposure device provides a highly efficient exposure situation by preventing contact between the test compound and the culture medium. Primary human bronchial epithelial cells (PBECs) from tumor-free lung tissues from four donors were differentiated in airway epithelium at ALI conditions. Test atmospheres were generated by evaporation of the volatile test compounds and diluted in clean air. FT-IR spectroscopy enabled online analysis of the exposure concentration. PBECs were exposed for 1h once or repeatedly on three consecutive days. Cellular viability was measured by LDH-leakage and monolayer integrity by measuring the transepithelial electrical resistance (TEER) 24h after the final exposure. Exposure concentrations ranged from 100 to 1840 ppm (diacetyl) and from 50 to 5000 ppm (other diketone analogues). Lowest observed adverse effect levels (LOAELS) were lower after repeated exposure compared to the single exposure. Read-across derived with alpha- and beta-diketone specific toxicity since 2,4-pentanediol displayed significantly lower cytotoxic effects in comparison to its analogues. In conclusion, in vitro testing of volatile gases enabled ranking of test compounds with regard to inhalation toxicity. Moreover, further comprehensive evaluations may adequately predict specific lung toxicity of structurally related compounds. Acknowledgement: This project received funding from the European Union’s Horizon 2020 research and innovation programme (grant agreement No 681002).

**2030 Effects of Low Level Hydrogen Sulfide Exposure on the Pathogenicity of Influenza A Virus Pathogenicity in a Swine Model**

C. M. Santana, and W. Rumbeila. Iowa State University, Ames, IA.

Hydrogen sulfide (H2S) is a toxic gas that affects the respiratory, cardiovascular and central nervous systems. In intensive swine confinement operations, H2S is a hazard for both humans and swine. It has been shown that H2S is an upper and lower respiratory tract irritant. Influenza A virus (IAV) is a zoonotic disease of public health significance. However, the effects of repeated low level exposures of H2S on the pathogenicity of IAV or toxicity of H2S have not been investigated. We hypothesized that repeated exposure to low concentrations of H2S increases the pathogenicity of IAV. To test this hypothesis, thirty pigs were exposed to H2S concentrations ranging from 0 to 50 ppm for 6 hours daily for 12 days; five controls were exposed to breathing air (BA). Pigs were exposed for 7 days before challenge with approximately 3×10^5 TCID50/ml H3N2 IAV (C) or given placebo (NC) on day 0. The experimental design was as follows: Group 1 BA (0ppm H2S)/NC; Group 2 0ppm H2S/C; Group 3 0.5ppm H2S/C; Group 4 5ppm H2S/C; Group 5 50ppm H2S/NC; and Group 6 50ppm H2S/C. Pigs were weighed upon arrival, and on days 0 and 5 post-inoculation (dpi). Body temperature and clinical observations were collected daily including coughing, respiratory distress, lethargy and eye irritation. All pigs were euthanized after exposure on dpi 5. The lungs were removed, weighed, and scored for percent lesion severity. Sections of lungs were collected for histopathology and electron microscopy. Preliminary results indicate that H2S at 50ppm/NC reduced growth rate compared to other groups. Group 3 pigs experienced the most significantly elevated body temperature. Clinically, pigs exposed to H2S and influenza exhibited significantly more severe clinical signs compared to inoculated groups without H2S exposure. Grossly, pigs in group 1 and 2 had ‘1’ and ‘2’ lesions that do not. We developed a random-forest machine-learning prediction model that derives, predicts and analyzes structural fingerprints, conserved scaffolds and protein-docking binding energies. Our model showed very high sensitivity (95%) and balanced accuracy (82%) with a specificity of 68%. Furthermore, analysis of binding energetic from docking revealed TRPV1 active substances to have significantly higher binding energies relative to controls (p<0.0001). In conclusion, we have built the only available computational model for TRPV1, an important biological target. We can now use our model to screen in vivo databases for potential involvement of this target.

**2031 In Vitro Phenotypic Profiling of Diacetyl and Other α-diketones in Human Lung Cells**

Diacetyl is an α-diketone (DK) occurring naturally in many foods, beverages, and dairy products. It is also commonly used as a food additive. Occupational exposures to diacetyl may lead to bronchiolitis obliterans. Therefore, other DKs with longer sidechains, such as 2,3-pentanediene (PD), have been proposed as diacetyl substitutes. Previous animal studies found that PD may also induce bronchial fibrosis. However, it is unclear that, in the human lung cells, if these other DKs induce similar or different cellular effects as diacetyl. We have previously developed an in vitro pulmonotoxicity assay based on High-Throughput In Vitro Phenotypic Profiling (HITTox) of a human bronchial epithelial cell line, BEAS-2B. We used machine learning to identify a high-
ly-predictive phenotypic feature measuring the spatial cross-correlation of cellular DNA and yH2AX stains (F1), which can achieve 88.8% balanced accuracy (84.6% sensitivity, 93.0% specificity) in predicting the in vivo pulmonary toxicity of 33 reference chemicals. Here, we present a study to use the assay to compare diacetyl and three other Dks: PD, 2,3-hexadiene, and 2,3-heptadiene. Cells were treated with the chemicals at seven concentrations (0.87 μM - 2 mM) for 16 hours; and fixed, stained, and imaged with Hoechst 33342, phalloidin, anti-yH2AX, and CellMask®stains. For diacetyl, we also performed an alkali Comet assay at 4 and 16 hours to measure DNA strand breaks (DSBs), and a resazurin assay at 72 hours to measure cell viability. We found that 2 mM diacetyl significantly increased the value of the predictive feature (mean log-ratio of F1 = 0.026 ± 0.036, P = 0.003 ± 0.039, t-test). The Comet assay revealed that 2 mM diacetyl induced DSBs at 4 hours (mean % tail DNA = 0.81, P = 0.02, t-test), but not at 16 hours (mean % tail DNA = 0.15, P = 0.58, t-test). Our results showed that diacetyl and other Dks induce DNA damage in human bronchial epithelial cells. Diacetyl causes early DSBs, which may be repaired later. However, the cells would still die eventually. Diacetyl is more active than other Dks with longer sidechains, but all the tested Dks induce similar effects to the lung cells, and predicted to be positive by our HIPPTox lung assay.

2032 A Method for Determination of Tracheobronchial Airway Geometries from Four Different Strains of Mice
C. Foong1, M. J. Oldham2, F. Lucci3, S. Cockram4, S. Luke5, D. Yeo6, J. Chua7, J. Hoeng1, M. C. Peitsch8, and A. K. Kucaj1

Accurate lung morphology is fundamental for predicting aerosol dosimetry. Currently, lung morphology is only available for 2-3 strains of mice (B6C3F1, BALB/c, and A/J). Based upon in situ prepared silicone rubber mouse lung casts, a complete process including their micro-CT scanning, segmentation, and automated algorithmic processing enabling the determination of airways geometries was developed for four strains of mice (BALB/c, A/J, ApoE/- and C57BL/6). Silicone rubber lung casts were prepared in situ from 20 ApoE/- and C57BL/6 mice. The cured mouse lung casts were manually inspected for casting quality and manual morphometry measurements were performed (tracheobronchial generations 1-6) on selected lung casts prior to high resolution micro-CT scanning. Micro-CT scanning of existing in situ lung casts from BALB/c and A/J mice were also performed. Micro-CT Images were then segmented to reconstruct a 3D model of the individual lung casts. A skeleton of each processed lung cast was automatically created by shrinking the 3D model of each airway to its centerline. Algorithms were developed for automatic detection of possible skeleton exceptions like closed loops, trifurcations and isolated nodes to be subsequently manually resolved. Finally, the skeleton was automatically measured extracting major airway morphometry characteristics (e.g. airway generation number, length, diameter, bifurcations angles, and angle to gravity). The automated measurement procedure was performed (tracheobronchial generations 1-6) on selected lung casts prior to the 3D model of each airway to its centerline. Algorithms were developed for automatic detection of possible skeleton exceptions like closed loops, trifurcations and isolated nodes to be subsequently manually resolved. for 7 days and maintained in room air or placed in oxygen (85% O2) for 7 days or 14 days. After hyperoxia exposure, the newborn animals were sacrificed and lung and liver tissues were collected for histopathology, morphometry, mRNA levels, protein content and enzyme activities of CYP1A1/1A2/1B1, and major angiogenesis genes. Newborns exposed to prenatal BP displayed more severe lung injury at PND7 and PND14 as compared to other groups with increased pulmonary edema, abnormal alveolarization and vaso-obliteration. Postnatal VA treatment of these newborn rats ameliorated the lung injury due to both postnatal hyperoxia and prenatal exposure to BP. These results indicate that VA attenuates the BP mediated and hyperoxia induced lung injury. There was a significant increase in liver CYP1A1/1A2 and lung CYP1B1 mRNA levels in VA treated hyperoxia group compared to others. Interestingly, VEGF protein was also significantly increased in lungs after VA treatment in hyperoxia and BP exposed group. These results suggested that VA attenuated hyperoxia and BP mediated neonatal lung injury by CYP1A/B1 dependent mechanisms and by activating VEGF as a key paracrine factor with cytoprotective and anti-inflammatory protective effects. It is possible that VA treatment imparted a protective due to the preservation of the lung alveolar and vascular development. This study could have major implications for the prevention or treatment of neonatal lung diseases due to hyperoxia and/or maternal environmental exposures to BP.

2036 Human Multi-Organ-Chip Co-Culture Approach of Bronchial Airway and Liver Models for Substance Exposure Studies

S. Frentzel1, K. Schimek2, K. Kuettich2, B. D. Boyard3, J. Ruetzsch1, L. Boden2, F. Rambo2, A. Winter1, U. Marx2, and J. Hoeng1. 1Philipp Morris Products S.A., Neuchâtel, Switzerland; and 2TissUse GmbH, Berlin, Germany.

At present, the predictability of cell culture-based methods to assess the effects of substances on the human body is limited, as they fail to emulate organ complexity and cross-talk. Biology-inspired microphysiological systems, such as TissUse’s Multi-Organ-Chip (MOC) platform, provide pre-clinical insights into absorption, distribution, metabolism, and toxicity of substances on a systemic level using human tissues. Here we describe a co-culture of a human liver equivalent based on the HepaRG™ cell line, combined with human stem cell-derived airway epithelial cells and a bronchial equivalent based on the MuclAir™ model. The co-culture has been designed to elucidate the toxicity of inhaled compounds and to predict their effects and metabolism in a trans-organ environment. To address this challenge, a new MOC design and adequate co-culture conditions were established. Compared with an earlier version, the MOC was redesigned to optimize medium supply as well as to allow better oxygenation of the organ models. The tissue constructs were integrated in separate culture compartments of the closed circulatory perfusion system, interconnected by microfluidic channels, for up to 14 days. Tissue viability and homeostasis could be demonstrated by adenosine triphosphate-based cell viability assay, lactate dehydrogenase release, and metabolic profiling. Oxygenation was monitored over the culture period using an oxygen sensor (PreSens). Integrity and function of MuclAir™ tissues were additionally evaluated by histological analysis and measurements of trans-epithelial electrical resistance and cilia beat frequency. Furthermore, immunohistochemistry, gene expression analysis, and albumin secretion quantification verified liver tissue function in the course of the co-culture. In summary, the new MOC setup enables exposure studies of inhaled substances in order to investigate their toxic effects on a trans-organ level, emulating systemic substance effects on the human body.

2037 A Multi-tiered In Vitro Approach for Sensitive and Predictive Respiratory Safety Assessment

M. Stamou1, K. Balogh-Sivars1, J. Horndahl1, E. Hamrud1, H. Johansson1, J. Johansson1, M. Persson1, and J. Hornberg1. 1Drug Safety and Metabolism, IMED Biotech Unit, AstraZeneca, Gothenburg, Sweden; 2Bioscience, Respiratory Inflammation and Autoimmunity, IMED Biotech Unit, AstraZeneca, Gothenburg, Sweden; and 3Zeneca AB, Lund, Sweden.

The chance to successfully bring a novel drug candidate to patients is highly dependent on its safety profile. By integrating predictive toxicology in the drug discovery process, we aim to timely identify and mitigate safety concerns. That strategy relies in part on the employment of in vitro assays that predict clinical safety and provide mechanistic understanding of drug-induced toxicity. The impact of that approach on successful progression of novel drug candidates has become evident, but there are areas for improvement. In the hunt for novel treatments of respiratory diseases, there is a need for universally accepted in vitro strategies to assess drug-induced respiratory toxicity. To address this gap, we developed a multi-tiered strategy to identify and quantify drug-induced effects on airway epithelial integrity, cellular differentiation, inflammatory responses and transcriptomic signatures. To assess effects on airway epithelial differentiation, we developed a confocal imaging assay in which primary human bronchial epithelial cells differentiated on an air-liquid interface (HBEC-ALI) are simultaneously assessed for the expression of acetylated tubulin (ciliated cells), MUC5AC (Goblet cells) and cytokeratin 5 (basal cells) by imaging directly through the insert. We have used this assay to demonstrate loss of cilia and overproduction of MUC5AC in HBEC-ALI exposed to respiratory toxicants. Alongside, inflammatory responses could be induced by increased cytokine secretion. In a separate assay, epithelial barrier integrity was assessed using high-throughput imaging of Calu-3 cells. We could distinguish respiratory toxicants (n=6) from non-toxicants (n=7) by quantifying the tight junction protein ZO-1 at earlier timepoints (48h vs 12 days) and at 20-fold lower concentrations than those required for cell viability studies. Next, we continued our efforts in transplanted Electrical Resistance in HBEC-ALI. Finally, using a novel transcriptomic signature of 68 genes in Calu-3 cells, we achieved 94% predictivity in distinguishing between lung irritants (n=7) and non-irritants (n=11). In summary, we present a novel in vitro assay toolbox for sensitive and predictive assessment of drug-induced respiratory toxicity.
molecule, AE001, was well tolerated and there were no adverse clinical observations or systemic effects detected by assessment of clinical pathology parameters or following histopathological examination of all major organs. The respiratory tract were examined histologically with no indications of local toxicity. The stability of the absorption-enhancer in dose formulation solutions up to 50 mg/ml was determined in vitro by assessing the biological activity on epithelial cell-adhesion. The absorption enhancer, AE001, was capable of disrupting adhesion of confluent epithelial cells.

2040 Carbon Black and Ozone Co-exposure Present Novel Prospects of Disease Susceptibility

Environmental exposures are inherently mixed in nature; however, all the current exposure limits are based on single toxicant exposures. Even with reduced mass based exposures, the severity or incidence of environmental and occupational diseases has not necessarily been reduced. We hypothesize that environmental mixtures/co-exposures can have differential consequences as compared to individual/single toxicant exposures as ultrafine particles can carry gaseous components of environmental pollution to the deeper lung. We developed a whole-body inhalation system for co-exposure to ozone (O3) and ultrafine carbon black (CB). Mice were exposed to 2.0±0.01 ppm O3 and/or 10±1.4mg/cm3 CB for 3 hours. Particle mobility diameter was 140 nm as measured by scanning mobility particle analyzer (SMPS 3938). Aerosol aero-dynamic diameter of 84 nm was measured by an electrical low pressure impactor (ELPI+). Co-exposure aerosols demonstrated a 31% increase in abiotic oxidative potentials as demonstrated by ferric reducing ability of serum (FRAS) assay and a 6% increase in surface oxygen contents. Ultra deep RNA-seq analysis revealed differentially activated pathways related to development, immune and inflammatory processes. A significant modulation of oxidative free radical formation was measured using immune-spin trapping. A 3-4 fold higher and more persistent lung inflammation was induced by co-exposures. We observed alterations in Tev01, airway hyperresponsiveness, tissue elastance and tissue damping indicating more severe lung function decline in co-exposure groups. In conclusion, our results signify the urgent need to evaluate environmental co-exposures and to revisit permissible exposure levels. The field of nanotechnology is growing exponentially, with investments totaling more than $25 billion. Multi-Walled Carbon Nanotubes (MWCNTs), a type of engineered nanoparticle, possess superior conductive and mechanical properties, resulting in an increase in their production and use. MWCNT toxicity is affected by a variety of factors, including exposure concentration, size, and dose. Current research shows variable outcomes to MWCNT exposure. The primary objective of this study was to determine the fate and transport of MWCNTs in the lungs, their ability to induce inflammation, and their relative retention in the lungs. Mice and rats were separately exposed by inhalation to target concentrations of MWCNT (0, 0.06, 0.2, or 0.6 mg/m3; n=5/group) for 6 hours/day, 5 days/week, over a period of 30 days. Lungs were analyzed 1 and 5 weeks post-exposure (PE). Bronchoalveolar lavage (BAL), cell differentials of BAL protein concentration, and lung histopathology were assessed. There was a significant increase in the total number of cells in the BAL of mice at 1 week PE in the 0.6 mg/m3 group compared to control. By 5 weeks PE, total number of cells returned to within control values. In rats, there was a significant dose-dependent increase in BAL neutrophils at 1 week PE in the 0.6 mg/m3 treatment group compared to all other groups. By 5 weeks PE, the neutrophilic inflammatory response was attenuated, but a minimal dose response was still observed. Although inflammation subsided by 5 weeks PE, there remained a high retention rate of MWCNTs in BAL at this time point in both species. There was a significant increase in concentration of CXCL1 protein for the 0.6 mg/m3 treatment group compared to control in both species at 1-week PE. No lung histopathology was noted in either species for any doses or time points compared to control. Mice and rats display a dose-dependent inflammatory response to MWCNTs in total number of cells and neutrophils. These values return to control values within 5 weeks PE. Continued retention of MWCNTs in the lungs at 5 weeks PE raises concerns regarding possible lasting effects, such as pulmonary fibrosis or cancer.

2042 Critical Analysis of Diacetyl and Bronchiolitis Obliterans

Diacetyl, a natural component of fermented foods and a butter-flavoring agent, was linked to cluster of purported bronchiolitis obliterans (BO) in a group of workers from a single microwave popcorn plant in 2002. Not all animal toxicity, occupational health, and exposure studies agree that diacetyl can cause BO. We conducted a weight of evidence analysis to assess whether the animal studies predict BO in humans generally and among popcorn consumers. A comprehensive PubMed literature search was performed to identify animal studies with relevant routes of exposure (inhalation, intratracheal instillation, or oropharyngeal aspiration). Identified studies were critically reviewed and organized in a systemic manner (by type of respiratory tract lesions). Results indicated rodent pulmonary lesions occurred mainly in nasal passages, less frequently in the upper respiratory system, and rarely in lower airways; the depth of respiratory tract lesions correlated directly with exposure concentrations, which was consistent with diacetyl’s hydrophilic nature. There is a fundamental disparity between the predominantly nasal/upper respiratory tract lesions caused by diacetyl inhalation in rodents and the deep-lung injury observed in cases of BO. The hypothesis for the pathology discrepancy lies in differences between rodent and human breathing patterns and nasal morphometrics, causing diacetyl to be more efficiently absorbed by the nasal cavities of rats than humans. In rats breathing 1 ppm, modeling predicts the nasopharynx absorbs ~80%, trachea/bronchi regions ~18%, and <2% enters the bronchial region. In nasal breathing humans, the nasal region absorbs ~30%, trachea/bronchial regions ~62%, and ~8% enters the bronchial region. Bronchiolar penetration may approach 24% in humans upon coupling light exercise with exclusive mouth breathing, but our review indicated that the modeling assumptions may not be valid. The recent NTP inhalation studies exposed rats to relatively high diacetyl concentrations and observed no lung lesions in rats exposed up to 25 ppm over 3 months or 12.5 ppm over 2 years (i.e., lung lesions were observed only when rats were exposed to 50 ppm for 3 months or 25 ppm for 2 years; NTP, 2018). We found the animal toxicity datasets, together with occupational and consumer diacetyl exposure concentrations, do not support a link between diacetyl and BO.

2043 Moderate Aspergillus versicolor Inhalation Exposure Triggers Neuroinflammation

Increasing evidence implicates indoor mold exposure in cognitive deficits in children, a process hypothesized to also occur in adults. However, the mechanisms by which inhaled mold and the associated allergic pulmonary response might impact the brain are unknown. Though neuroinflammation is associated with memory deficits and impaired cognition, the environmental triggers of neuroinflammation are poorly understood and the central nervous system (CNS) pro-inflammatory consequences of inhaling mold spores is largely unknown. To address whether a moderate exposure to a common mold found in damp indoor environments, Aspergillus versicolor (AV), could cause neuroinflammation, 8 week old female B6C3F1/N mice were exposed to filtered air, 1x103 heat inactivated AV spores, or 1x104 live AV spores 2 times per week for 1, 2, or 4 weeks. At 48 H after the final exposure, the neuroinflammation marker profile was assessed by RT-qPCR. Analysis of brain tissue from the 4 week exposure revealed significantly elevated pro-inflammatory markers in response to only the live AV exposure in several brain regions: the olfactory bulb (TNFa), frontal lobe (TNFa, IL-10, and CX3CR1), midbrain, and cerebellum (TNFa and CX3CR1). To discern how early neuroinflammation began in response to AV inhalation, 1 and 2 week exposure samples were tested for TNFa mRNA expression. Interestingly, results demonstrate that heat inactivated AV significantly increased TNFa mRNA levels in the olfactory bulb in the 1 week exposure, but not in the 2 or 4 week exposures. In response to inhalation of live AV, TNFa mRNA levels were significantly elevated in brain tissue from 1 week exposure (olfactory bulb and midbrain) and 2 week exposure (frontal lobe, midbrain, and cerebellum). Taken together, these results demonstrate that inhalation of live AV spores triggers neuroinflammation in several brain regions with 1, 2, and 4 week exposures, suggesting a generalized CNS response. However, heat inactivated spores were shown to exert a CNS pro-inflammatory response in only the initial, early 1 week exposure.
Asthma is an airway disease characterized by airway hyperresponsiveness (AHR), inflammation, and remodeling. Enhanced contractile phenotype of airway smooth muscle (ASM) cells in mediates bronchoconstriction and AHR in asthma. Free fatty acids are emerging as signaling molecules with importance in metabolic and inflammatory diseases. Studies showed that long-chain free fatty acids (FFA) acting through G protein-coupled receptors (GPRC), elicited bronchoconstriction in guinea pig models. Hypothesis: We hypothesized that the free fatty acid receptors FFAR1 and FFAR4 modulate excitation contraction (EC) coupling in human ASM cells to regulate AHR. HASM cells were treated with vehicle (ethanol) or GW9508, a synthetic FFAR1/4 agonist, (1-10µM) for short duration (10 min) or 24 h. Myosin light chain (MLC) phosphorylation was determined in the presence or absence of the contractile agonist carbachol (Cch, 10 uM). In parallel, GW9508-treated HASM cells were loaded with fluo-8 and binding dye and carbachol-induced cellular Ca2+ mobilization was measured using fluorescent microscopy. In short duration (10 min), GW9508 significantly attenuated baseline and Cch-induced MLC phosphorylation (n=3 donors) and significantly induced basal and Cch-induced Akt phosphorylation (n=3 donors). Following 24 h exposure, GW9508 significantly attenuated baseline and agonist-induced MLC phosphorylation (n=3 donors). The short duration (10 min) and 24 h exposure to GW9508 have little effect on Cch-induced Ca2+ mobilization in HASM cells. Our findings show that GW9508 attenuates MLC phosphorylation, a biochemical marker of ASM cell shortening in HASM cells, therefore has the potential to broncho-protect human airways from hyper-reactivity.

Preservation of Xenobiotic Metabolizing Capacity in Airway Cells In Vitro: A Species Comparative Approach Using Cells from Mice, Monkeys and Humans
