In vitro culture of primary airway cells at the air-liquid interface (ALI) preserves ciliary function and mucus production, creating an epithelial monolayer similar to in vivo airways. The preservation of xenobiotic metabolic enzyme activity is not documented in existing in vitro airway cell culture literature beyond gene expression. Naphthalene, which requires bioactivation by cytochrome P450 enzymes (P450s) to cause toxicity, was used to determine the impact of in vitro cellular metabolic capacity on toxicity testing. Human small airway cells were purchased, primary trachea cells from C57Bl6 mice and rhinos ma-caques were isolated, and HBE1 cells were used for baseline analysis. Primary cells were also maintained at ALI for 1 month in vitro. Phase I metabolic potential of cells was defined using gene-expression measured by digital-PCR, enzyme activity using Promega P450-1A2-Glo, and metabolism of naphthalene measured by mass-spectrometry. Phase II metabolic potential was defined by analysis of gene-expression of glutathione synthesis and metabolic enzymes, measurement of baseline reduced and oxidized glutathione using HPLC, and measurement of the glutathione response of cells to naphthoquinones. For P450s and microsomal epoxide hydrolase, in vitro gene-expression was the highest in mouse C57Bl6 and rat HBE1 cells; Mucosal HBE1 cells expressed the highest amount of Gclc (~5X higher than HBE1), Gclm (~50X higher), and GSTM1 (~100,000X higher). GSTP1 expression was 10X lower in mouse ALI cells versus HBE1 cells. Assays of mouse ALI cells for metabolism of 1A2-substrate and naphthalene confirmed maintenance of P450 activity in vitro, while the HBE1 cells were found to lack P450 activity. Relative to the freshly isolated mouse trachea cells, the mouse ALI cells preserved ~30% of the P450-1A2 activity. About half of the naphthalene in the mouse ALI exposure was metabolized to form glutathione-conjugates, whereas HBE1 cells did not generate any metabolites. The source species of airway cells impacts the resulting xenobiotic metabolic capacity in vitro. Direct measurement of enzyme activity and glutathione content in addition to gene-expression is recommended to detect metabolically-derived toxicity in airway cell culture systems as activity is not well preserved in a cell line, even when differentiated. Comparative Study of Multiwalled Carbon Nanotubes and Pro-inflammatory IL-1 Beta Production: The Role of Purification and Surface Functionalization

H. Lee1, A. Taylor-Just1, D. You1, D. Lison2, S. Brüle2, C. Ziemann2, O. Creutzzenberg3, S. Simon2, A. Vulpo2, F. Turcu2, and J.C. Bonner1. 1North Carolina State University, Raleigh, NC; 2Université Catholique de Louvain, Louvain, Belgium; 3Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; and 4Babes-Bolyai University, Cluj-Napoca, Romania.

With advancements in nanotechnology, the application of multi-walled carbon nanotubes (MWCNTs) in commercial products has been increasingly expanding. Consequently, increase in exposure of humans to MWCNTs has raised questions about their potential risks of such materials. The efforts to characterize specific features of MWCNTs that may potentially be associated with adverse health effects have been challenging as variations in the purification process and surface functionalization alter physicochemical properties. As part of the ERA-NET SIINN project ICONS (’International Collaboration On Nanotube Safety’), we examined the consequence of purification, followed by surface functionalization, on MWCNT-induced production of interleukin 1 beta (IL-1 beta) by human macrophages in vitro and in the lungs of mice in vivo. A library of eight differently purified (chemically or thermally) and functionalized (-COOH or -NH2) MWCNT samples were prepared from a single batch of industrially relevant Nanocyl NC7000. THP-1 monocytes were PMA-differentiated to macrophages (40 ng/mL, 48 hrs) and exposed to 1, 10, 100 µg/cm2 MWCNTs. Cells supernatants were analyzed for IL-1 beta via ELISA. Mice (C57BL6 strain, N=4 per group) were exposed via oropharyngeal aspiration to the same library of MWCNTs at doses of 1.6 and 4 mg/kg. After 3 days, BALF was collected and analyzed via ELISA. THP-1 cells exposed to thermally-purified MWCNTs functionalized with -COOH or -NH2 produced more IL-1 beta than when exposed to NC7000. Thermally-purified MWCNTs functionalized with either -COOH or -NH2 produced greater IL-1 beta in the BALF from mice compared to NC7000, whereas chemically purified MWCNTs functionalized with either -COOH or -NH2 produced less IL-1 beta in BALF compared to NC7000. These data suggest that the purification method used prior to surface functionalization is an important determinant in mediating inflammasome activation and IL-1 beta release as part of the innate immune response to MWCNTs. Toxicity Screening of Volatile Chemicals Using a Novel Air-Liquid Interface In Vitro Exposure System

J. Zavala1, J. Gause1, L. A. Dailey1, N. M. Hanley1, Q. Krantz2, D. Davies3, P. Evansky1, J. Harrill1, and M. Higuchi1. 1US EPA/ORISE, Research Triangle Park, NC; 2US EPA, Research Triangle Park, NC; and 3US EPA, Chapel Hill, NC.

Traditional in vitro dosing methods require, for example, the addition of particulate matter (PM), PM extracts, or chemicals in dimethyl sulfoxide (DMSO) or water into cell culture medium. However, about 10% of chemicals nominated for study in the US Environmental Protection Agency’s (US EPA) Toxic Substances Control Act (TSCA) chemical substance inventory are insoluble in DMSO, water, or are volatile, thus their toxicity cannot be adequately tested using traditional in vitro dosing methods. To circumvent the difficulties in screening for volatile/insoluble chemicals, we developed a new cell culture exposure system (CCES) that permits cells to be exposed at an air-liquid interface (ALI). The ALI method permits a direct pollutant-to-cell interaction in which the test substance is in its natural state, thus providing a more realistic exposure scenario. This novel system is capable of testing 6 different chemical concentrations simultaneously to generate concentration-response curves. In our on-going study, we use the BEAS-2B cell line and primary normal human bronchial epithelial (NHBE) cells to assess the toxicity of volatile chemicals in the TSCA work plan. We exposed cells for 2 h to six concentrations in half-log dilutions, plus an air (vehicle) control to generate concentration-response curves; 1,3-butadiene, 1-bromopropane, acetaldehyde, acrolein, carbon tetrachloride, dichloromethane, formaldehyde, and trichloroethylene have been tested to date. We assessed cell viability 4 h post-exposure via the CellTiter-Glo Assay while we assessed cytotoxicity by measuring lactate dehydrogenase (LDH) in the basolateral medium. Cell lysates were collected 4 h post-exposure for whole transcriptome targeted RNA-Sequencing (i.e., BioSpyder TempO-Seq™). The objective of this study is to evaluate the capability of the transcriptomic data to identify concentration-dependent changes in mechanism/mode-of-action for volatile/insoluble chemicals. This study leverages the ability of the transcriptomic data to group chemicals by similar bioactivity profiles for potential grouping and read across applications. Our highest doses per chemical induced <20% cytotoxicity, while our lowest doses were targeted to not observe adverse effects. Abstract does not reflect views or policies of the US EPA.
2048 Amiodarone-Induced Lung Injury is Associated with Alterations in Alveolar Macrophages and Mesenchymal Stem Cell Populations in Mice

Amiodarone (AD) is an antiarrhythmic drug that causes pulmonary toxicity in 10-17% of patients which can progress to fibrosis. In these studies, we developed an intratracheal administration model of AD toxicity in mice to analyze the response of pulmonary macrophage and mesenchymal stem cell populations and to assess the efficacy of nitrated oleic acid (OaNO2), a potential anti-fibrotic agent, in mitigating toxicity. Male C57BL/6 mice (8-9 weeks old) were administered vehicle control or AD (0.8 mg/kg intratracheally every 5 d) with and without OaNO2 (50 µg per animal) and euthanized 7 d and 14 d after the initial treatment. Cell numbers and total protein content were enumerated in bronchoalveolar lavage fluid (BAL), and alveolar macrophage (AM) and mesenchymal stem cell (MSC) phenotypes were analyzed in BAL and tissue digest, respectively, by flow-cytometry. Administration of AD resulted in reduced weight gain compared to controls 5 d after AD administration; this was associated with a 2-fold increase in BAL cell number and 1.6-fold increase in BAL total protein at 7 d. By 14 d post AD, changes in body weight, BAL cell number, and total protein were similar to controls. AM (CD45+F4/80+SiglecF+) and CD90+ MSC numbers were similar to controls at 7 d, this was partly mitigated by co-administration of OaNO2. CD90+ MSC numbers were similar to control levels at 14 d. Development of a mouse model of AD induced lung injury will be useful for studies examining a role of AM subpopulations and CD90+ MSCs in lung tissue homeostasis and pulmonary toxicity during the pathogenesis of pulmonary injury and fibrosis. Supported by NIH grants ES047738, HL086821, ES005022, and ES007148.

2049 The Multi-kinase Inhibitor, C374, Perturbs Excitation-Contraction Coupling in Human iPSC-Derived Cardiomyocytes

1VAST Pharma Solutions, Harrogate, United Kingdom; 2Gilead Sciences, Foster City, CA; 3Clyde Biosciences, Glasgow, United Kingdom.

In a previous 5-day repeat dose study in telemetry-caged cynomolgus monkeys, the multi-kinase inhibitor, C374, caused a dose related, sustained tachycardia and a negative inotropic and lusitropic effect which developed over the duration of the study leading to cardiac lesions. The current study used human iPSC derived cardiomyocytes (hiPSC-CM) to investigate the direct actions of C374 on in vitro cardiac preparation. Action potential (AP), Ca2+ transient (CaT) and contractility (Cnt) were monitored in hiPSC-CMs (CytoSeek) using CellOPTIQ® (Clyde Biosciences Ltd). C374 (0.3, 1.0, 3.0 or 10 µM) was investigated using two protocols: 1) a time course study of the spontaneous AP and Cnt with recordings at 2, 24 and 48 hours following the addition of compound and 2) the effect of C374 on cells paced at 1.5Hz to separate the compound effects on AP, CaT and Cnt from those that are a consequence of chronotropic effects. For protocol 1, at 2 hours, C374 induced a modest concentration related reduction in beat rate (max 1.3x at 10 µM) and a marked prolongation of relaxation time (max 16x at 10 µM) but no effect on Cnt amplitude indicating negative chronotropic and lusitropic effects. This was also evident at 24h but had returned to control levels by 48h. AP duration was prolonged in parallel with the reduction in spontaneous rate. For protocol 2, in cells paced at 1.5Hz, C374 had no effect on time taken to contract or relax or amplitude of Cnt i.e. no inotropic or lusitropic effects at fixed stimulation rates. However, there was a concentration related increase in the duration of the CaT (max 1.8x at 10 µM) which was not reflected in contractility. In conclusion, C374 elicited chronotropic and lusitropic effects in hiPSC-CMs. Lusitropic effects were directionally similar to the in vivo monkey study, whereas, the chronotropic effects were the opposite. This difference in profile is likely due to the differences in the test systems i.e. cardiac function assessed over 5 days in a monkey vs. function of cultured iPSC-CMs assessed over 2 days indicating different underlying cellular mechanisms in hiPSC-CMs compared to the in vivo system. The observed uncoupling between CaT and Cnt indicates a potential mechanism of action for the functional adverse cardiovascular effects of C374.

2050 Calcium Imaging Assay Using Human iPSC-Derived Cardiomyocyte for Cardiotoxicity Risk Assessment of Inotropic Compounds

In drug development, cardiotoxicity is one of the most common cause of clinical safety failure, and it is important to predict cardiotoxicity in preclinical study. Human iPSC-derived cardiomyocyte (hiPSC-CM) is recently used as a tool for in vitro cardiotoxicity screening. Although a lot of studies reported that hiPSC-CM is useful for the risk assessment of QT prolongation and Torsades de pointes, it is unclear whether or not the other cardiotoxicity risk such as positive and negative inotropy effects can be captured in hiPSC-CM assay based on their pharmacological properties. In this study, we evaluated positive (bay K 8644: Ica+ channel activator, digoxin: Na+/Ca2+ exchanger inhibitor, dobutamine: beta 1 receptor agonist, isoproterenol: beta receptor agonist, levosimendan: calcium sensitizer, omecamtiv mecarbil: myosin activator, and forskolin: cAMP activator) and negative (KB-R7943: Na+/Ca2+ exchanger inhibitor, PI-103: TORC1/2 inhibitor, thapsigargin: sarco/endoplasmic reticulum Ca2+-ATPase inhibitor, and verapamil: Ica+ inhibitor) inotropic compounds using hiPSC-CM by calcium imaging analysis. The hiPSC-CMs were cultured on 96 well plates for 7 days. The Ca2+ transient in hiPSC-CMs was acquired by a high-speed acquisition imaging platform (FDSS/µCell, Hamamatsu Photonics K.K.) with Ca2+ sensitive fluorescent dye (Cal520®). AAT Bioquest, Inc.). The multi-parametric data of calcium fluorescence waveform were analyzed by Spotfire 7.6.1 (PerkinElmer Inc.). In the positive inotropic compounds, bay K 8644, digoxin and forskolin increased calcium amplitude. While KB-R7943 decreased calcium amplitude. Verapamil decreased calcium amplitude. While KB-R7943 decreased calcium amplitude and increased peak width duration, verapamil caused the opposite reaction. These waveform changes were consistent with the intracellular calcium kinetics expected form the pharmacological properties of the compounds. In conclusion, the positive and negative inotropic compounds are detected in the calcium imaging analysis using hiPSC-CM based on their pharmacological properties. Our approach will contribute to the improvement of predictability of drug-induced cardiotoxicity.

2051 Mitoxantrone Prompts Early Energetic and Proteomic Changes in HL-1 Cardiomyocytes and Late Oxidative Stress in Clinically Relevant Doses

1UCIBIO-REQUIMTE, Porto, Portugal; 2CEBIMED (Centro de Estudos em Biomedicina), Universidade Fernando Pessoa, Porto, Portugal; 3UCIBIO-REQUIMTE, Lisboa, Portugal; 4UCIBIO-REQUIMTE, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, Lisboa, Portugal; 5UCIBIO-REQUIMTE, Lab Toxicologia, Faculdade de Farmácia, Universidade do Porto, Porto, Portugal; 6Universidade de Coimbra, Coimbra, Portugal; 7Universidade do Porto, Porto, Portugal; 8Universidade do Porto, Porto, Portugal.

Mitoxantrone (MTX) is used in the treatment of cancer and in multiple sclerosis, with cardiotoxicity being a severe side effect. We aimed to study the cardiotoxicity mechanisms of MTX in murine HL-1 cardiomyocytes. Cells were exposed to MTX (1 and 10µM) for 12, 24 or 48h. Phase contrast microscopy, neutral red uptake and MTT reduction assays showed that MTX induced cytotoxicity as early as 12h. At 12h, intracellular ATP levels were increased and media lactate levels decreased following 10µM MTX, while proteomic analysis of total protein extracts found 40 protein spots with significant relative abundance differences (pH gradients 4-7 and 6-11). Of note, the expression of the regulatory 14-3-3 protein epsilon was significantly increased after MTX. Total glutathione significantly increased following 24h exposure to 1µM MTX, which was dependent on gamma-glutamylcysteine synthetase activity, whereas oxidized glutathione only increased at 48h. At 24h, MTX activity was significantly to decrease proteasome chymotrypsin-like activity in a concentration-independent manner, while increasing caspase 3 activity. These data clearly demonstrate that MTX is able to significantly alter proteome, energetic and oxidative stress homeostasis in cardiomyocytes at clinically relevant concentrations.
Cardiovascular (CV) toxicity is one of the leading causes for drug withdrawal in clinical development over the past decades. Some common assays to assess CV toxicities during drug development include hERG binding assays, QT-interval prolongation, and Torsade de Pointes (TdP) using non-clinical models. For in vitro assessment, human induced pluripotent stem cells (iPSC) derived cardiomyocytes are widely used on multi-electrode array (MEA) for studies of cardiac pacemaking. This approach is supported by US FDA Guideline and Comprehensive In Vitro Proarrhythmia Assessment (CIPA) consortium. The use of iPSC cardiomyocytes on MEA platform is useful for an initial CV toxicities screen but has limitations if one desires to study further physiological effects on cardiac function. The limitations come from the immature state of the cardiomyocytes and the 2D platform, which makes it difficult to study in vivo like cardiac function such as pressure to voltage (P-V) relationship. The 3D technology Biowire™II has improved these limitations by 9 weeks of electromechanical conditionings of the iPSC cardiomyocytes. After 9 weeks of conditionings, iPSC cardiomyocytes cultured on Biowire™II display mature cardiac functions such as increased positive force frequency relationship and post rest potentiation and decreased spontaneous beating. We also employed next generation sequencing to evaluate gene expression levels of previously reported 203 adult cardiac genes among the following five groups: One is adult ventricles, and other four groups are from iPSC cardiomyocytes that are either cultured for 1 week on a plate or Biowire™II. The result suggests that the 9 weeks conditionings, rather than the Biowire™II platform, elevates the expression levels of the 203 genes. To understand the global distribution of whole transcriptome in Biowire™II in comparison with adult ventricles and the traditional 2D culture, further gene expression analysis was conducted using long read sequencing. This allows to identify unique gene sets that were improved only by Biowire™II but not the traditional 2D culture. These changes were confirmed by immunostaining assays. In conclusion, the advanced in vitro cardiac models, Biowire™II, will bridge between traditional in vitro 2D cultures and in vivo non-human animal models and enhance transatability to clinical development.

Waterpipe smoking has become increasingly popular despite its centuries-long history, yet little is known about the long-term impact of waterpipe smoke (WPS) on the cardiovascular system. Methods: To investigate the effects of waterpipe smoke (WPS) on cardiovascular disease, hyperlipidemic, apolipoprotein E deficient (ApoE−/−) male and female C57BL/6 mice (n=5) were exposed to either WPS or filtered air as a control for 5 months. The nose-only exposure was 2 hours per day, 4 days per week followed by 3 days of rest each week. Cardiac physiology was assessed by collecting electrocardiograph (ECG) data using implanted radiotelemetry devices, and the ECG data was further analyzed for heart rate variability (HRV). All animals were allowed over 6 hours of recovery time in their housing to limit the effect of exposure stress on HRV measures. HRV was measured by standard deviation of normal R-R intervals (SDNN), root mean squared of successive differences (RMSSD), and High-Frequency (HF) HRV. SDNN represents overall HRV whereas RMSSD and HF HRV are known to represent the fluctuations in vagal inputs to the heart and beat-to-beat variability. Results: HRV showed an initial period of no difference between control and WPS-exposed groups for 3 to 5 weeks. Following this, marked differences in HRV response to WPS was seen between sexes. Males show a response of increased SDNN, RMSSD and HF HRV on the days of exposure in WPS-exposed animals compared to controls. WPS shows a diminished effect on HRV in males on non-exposure days. In contrast, females showed minimal effect of exposure on HRV for the first 4 months on exposure days, but instead have a latent effect apparent on rest days with no exposure throughout the length of the study. On rest days, a decrease in SDNN, RMSSD and HF HRV is seen in females as compared to controls with the difference between exposure groups growing larger throughout the 5-month study. The disparity between exposure and rest day HRV responses points to a latency in the effect of WPS on the cardiovascular system, particularly in long-term cumulative exposure. This study of WPS exposure and HF in hyperlipidemic mice indicates that WPS influences the cardiovascular system as well as the parasympathetic nervous system in a sex-dependent manner.
Arsenic increases atherosclerotic plaque formation in PCSK9-1 AAV transgenic mice.

McGill University, Montreal, QC, Canada; and 2 Jewish General Hospital, Montreal, QC, Canada.

Arsenic toxicity is a global concern to human health and is related to increased incidence of cancer, bronchopulmonary and cardiovascular diseases in exposed populations. Cardiovascular diseases are ranked as the primary cause of death worldwide and the majority of them stem from atherosclerosis, the gradual occlusion of arteries by fibro-fatty plaques. Mice are relatively resistant to the development of atherosclerosis; therefore, several genetically manipulated mouse models have been produced to study this condition. Apolipoprotein E (ApoE)-/- is a widely used mouse model, wherein, the glycoprotein ApoE is knocked out, resulting in an impaired LDL and VLDL clearance and a subsequent atherosclerotic phenotype. Our previous findings have shown that low to moderate arsenic concentrations increase atherosclerotic plaques in ApoE-/- mice and alter plaque components. In order to expand potential models of arsenic-induced atherosclerosis, we tested a newer model of atherosclerosis where adeno-associated virus mediated delivery of PCSK9-1 (AAV-PCSK9) induces hypercholesterolemia by increasing the degradation of LDL receptors, thereby decreasing the hepatic uptake of LDL. Here, we evaluated the effects of arsenic exposure in the AAV-PCSK9 mouse model. C57BL/6 male mice were injected intraperitoneally once with AAV-PCSK9 and the following week, randomized to either tap water or 200 ppb arsenic in the drinking water. All mice were fed standard low arsenic diet (not a high-fat diet). Compared to the controls, the arsenic-exposed AAV-PCSK9 mice displayed higher serum cholesterol and LDL levels accompanied by increased atherosclerotic plaque formation after 13 weeks of arsenic exposure, as determined by gross plaque imaging and Oil Red O lipid staining of aortic arch and sinus. In contrast to the ApoE-/- model, we did not observe significant changes in plaque components (i.e. vascular smooth muscle cells and collagen) in arsenic-exposed versus control groups. To fully assess the utility of this model for arsenic exposure studies, further studies will be carried out in the future. Use of the AAV-PCSK9 model will facilitate the generation of further knock-out models to scrutinize the pathways of arsenic-induced atherosclerosis, where crossing of multiple transgenic models is time-consuming and has resulted in embryonic lethality.

The effect of inhaled multiwalled carbon nanotubes on blood pressure in spontaneously hypertensive rats.

1 NIOSH, Morgantown, WV; and 2 West Virginia University, Morgantown, WV.

It is well documented that hypertension is one of the main underlying risk factors for cardiovascular disease and is highly prevalent in the general US population. Considering the large percentage of the population with hypertension and the similarity between the pathogenicity of engineered nanoparticles (ENs) and environmental ultrafine particles, the risk assessment of pulmonary exposure to ENs in subjects with pre-existing hypertension is of great relevance. We reported previously that inhalation of multi-walled carbon nanotubes (MWCNTs) transiently elevated systolic, diastolic and mean blood pressure in rats with normal blood pressure. The present study further investigated the effect of inhaled MWCNTs on spontaneously hypertensive rats. Male normotensive Sprague-Dawley or spontaneously hypertensive Wistar rats were pre-implanted with a telemetry device, and exposed by inhalation to MWCNTs at a concentration of either 5 mg/m^3 or 2 mg/m^3 for 5h/day for three consecutive days. The electrocardiogram (EKG) and blood pressure were recorded in real time by the telemetry system at pre-exposure, during exposure, and 1 day and 7 days post-exposure. Inhalation of MWCNTs at a concentration of 5 mg/m^3 significantly increased both systolic and diastolic blood pressure, and decreased heart rate in normotensive Sprague-Dawley rats during the first day of exposure but these parameters rapidly adapted to continuous exposure. However, inhalation of MWCNTs at a lower concentration of 2 mg/m^3 consistently elevated systemic blood pressure for at least 7 days in spontaneously hypertensive Wistar rats. Our study indicates that the blood pressure of spontaneously hypertensive rats is more vulnerable and less tolerant to pulmonary MWCNT exposure.

Inhibition of TGFβ signaling in rat valvular interstitial cells redirects the activated phenotype.

Bristol-Myers Squibb, Pennington, NJ.

Valvular interstitial cell (VICs) are responsible for maintaining the structural integrity of the valve. TGFβ signaling is integral for proper functionality of the VICs and various TGFβ receptor inhibitors have been reported to cause valvulopathy in the rat. It has been speculated that VICs are the cellular target of toxicity of TGFβ receptor inhibitors. We used primary cultures of rat VICs to characterize by cellular, biochemical and molecular methods, early changes in response to inhibition of TGFβ signaling. We found that rat VIC cultures treated with TGFβ present robust stimulation of p-5MAOD3 with effective concentration-responsive inhibition of p-5MAOD3 following treatment with TGFβ receptor inhibitors, indicating that VIC cells are a target of TGFβ signaling. A concentration range of TGFβ inhibitor treatment (0.001-10 μM) was determined to not cause toxicity by apoptosis, necrosis and cellular morphology evaluations. At these sub-toxic concentrations, the VICs presented decreases in ATP production and cellular respiration that may indicate alteration of mitochondrial function. However, there was also a decrease in reactive oxygen species (ROS) suggesting enhanced oxidative stress was not part of the response. Transcriptional evaluation of a series of targets involved in EMT and ECM revealed a concentration-related alteration of EMT markers, TAG2A and Tagln, and ECM targets, MMP2 and COL1A1. Furthermore, a majority of the VIC were of the activated phenotype, positive for alpha-smooth muscle actin (α-SMA) and spindle shaped, whereas other cells were positive for vimentin and had cuboidal or rounded appearance. Following 48-hour treatment with TGFßR inhibitors, a majority of the cells were positive for vimentin with rounded appearance and cells positive for α-SMA presented less organized actin filaments, with concentrated staining near the cell membrane. Taken together, these results suggest the pathogenesis of TGFßR inhibitor-induced valvular toxicities may involve redirection of the activated VIC phenotype to a more mesenchymal-like or quiescent phenotypes that have decreased ability to engage in repair or response to injury.

Statistical power analysis for cardiovascular safety pharmacology studies in dogs.

1 Columbia University, New York, NY; and 2 US FDA, Silver Spring, MD.

One of the major causes of drug attrition is drug-induced effects on cardiovascular system. The ICH S7B guideline describes a non-clinical testing strategy for assessing the potential of a test article to slow ventricular repolarization prior to testing in humans. The quality of the data and the assessment of cardiovascular safety of the new drug would be affected by the study design and data analysis procedure. The purpose of the present project is to investigate the prospective statistical power on number of dogs for detecting a minimum effect size of the maximum effect between the high dose group and the control group of a test article over time for specific cardiovascular endpoints by different pharmacokinetic (PK) patterns using the simulated data. Eighteen previous cardiovascular safety pharmacology studies submitted to US FDA with a 4-by-4 double Latin square (LS) design with 8 beagle dogs using implanted device were selected as the historical data to assess the centrality and dispersion for the simulation. Between- and within-animal variability and other parameters related to different covariance structures across time (CS and AR(1)) were derived, using the repeated measures analysis of covariance. Four representative PK patterns with various maximum effect size over time were used to construct different simulation data. A linear mixed effect model was used to analyze the test article effect over time. In addition, LS designs with 4 and 12 dogs are also examined with the same approach. The power analysis is conducted to the dose response by a testing procedure which involves both trend test and pair-wise comparison at each time point after dosing. The power analysis shows that a minimum of 8% increment in QTcF can be detected with more than 80% power when 8 dogs were used in a LS design with compound symmetric covariance structure; whereas 6% and 13% increment in QTcF can be detected with more than 80% power for 12 dogs and 4 dogs, respectively. The overall false positive rate of the testing procedure to detect the significance of the dose effect is 7.4%. Furthermore, a minimum of 8% increment in QTcF with first-order autoregressive covariance structure; a minimum of 22% increment in heart rate (HR) with compound symmetric covariance can be detected with more than 80% power when 8 dogs were used in a LS design.
Nitrate and nitrite are present in canine feeds due to incorporation of plant materials high in these compounds, as well as use as a preservative for protein ingredients. These nitrogenous compounds have the potential to induce adverse effects such as methemoglobinema, lipid peroxidation and disruptions in cardiovascular function. Conversely, nitrate and nitrite may improve vascular function and reduce hypertension due to conversion into nitric oxide. To examine this relationship, four commercial pet foods and one lab-made diet were evaluated based on varying protein content and price. Seven dogs were randomly assigned and fed each diet for seven days (n=4-7 for each diet).

At the end of each trial, urine, feces, and plasma were collected for nitrate, nitrite and methemoglobin analysis, as well as echocardiography, flow mediated dilation and blood pressure assessed. Nitrate and nitrite concentrations varied significantly among diets, with feed nitrate concentration increasing with higher incorporation of leafy plant products, but also with higher crude protein content. Dietary nitrate was converted into nitrite since only plasma nitrate varied with diet, leading to concomitant significant differences in methemoglobin levels among diets. In contrast, urinary elimination was the primary route for nitrogenous excretion, with plasma nitrite appearing primarily as nitrate in the urine. Urinary nitrate had a statistically significant, negative correlation with methemoglobin (p=0.013, r=-0.54). This could be explained if low urinary nitrate was due to increased methemoglobin as a potential source for nitric oxide production. In support of this hypothesis, there was a weak, positive correlation between methemoglobin and flow mediated dilation. However, potentially negative effects observed were a weak positive correlation between methemoglobin and diastolic pressure as well as an accompanying negative correlation between methemoglobin and stroke volume. Ultimately, results suggest that incorporating higher dietary nitrate and nitrite from non-protein nitrogen sources have the potential to exert beneficial effects on vascular distensibility, working through increases in plasma nitrite and subclinical increases in methemoglobin.

Nitric oxide production. In support of this hypothesis, there was a weak, low urinary nitrate was due to increased methemoglobin as a potential source for nitric oxide production. In support of this hypothesis, there was a weak, positive correlation between methemoglobin and flow mediated dilation. However, potentially negative effects observed were a weak positive correlation between methemoglobin and diastolic pressure as well as an accompanying negative correlation between methemoglobin and stroke volume. Ultimately, results suggest that incorporating higher dietary nitrate and nitrite from non-protein nitrogen sources have the potential to exert beneficial effects on vascular distensibility, working through increases in plasma nitrite and subclinical increases in methemoglobin.

Metallic stents have been proven clinically for their efficacy in reducing the severity of restenosis. However, chronic complications including stent fracture, recurrence of restenosis in stented vessels, very late stent thrombosis and the permanent loss of vasoreactivity encouraging the development of new neoatheroma drive the innovation of fully bioresorbable scaffolds. In this animal study, coronary PILLA scaffolds were evaluated in swine coronary arteries for 2 years. The protocol was approved by AccelLAB animal care and use committee under compliance with the Canadian Council on Animal Care. Yucatan miniswine pigs weighing 8–10 kg were sacrificed at 4–6 months of age to have scaffolds placed intracoronary and assessed for neointima formation using aortic root harvested in ewes implanted in the aorta. Scaffolds were evaluated based on varying protein content and price. Seven dogs were randomly assigned and fed each diet for seven days (n=4-7 for each diet). At the end of each trial, urine, feces, and plasma were collected for nitrate, nitrite and methemoglobin analysis, as well as echocardiography, flow mediated dilation and blood pressure assessed. Nitrate and nitrite concentrations varied significantly among diets, with feed nitrate concentration increasing with higher incorporation of leafy plant products, but also with higher crude protein content. Dietary nitrate was converted into nitrite since only plasma nitrate varied with diet, leading to concomitant significant differences in methemoglobin levels among diets. In contrast, urinary elimination was the primary route for nitrogenous excretion, with plasma nitrite appearing primarily as nitrate in the urine. Urinary nitrate had a statistically significant, negative correlation with methemoglobin (p=0.013, r=-0.54). This could be explained if low urinary nitrate was due to increased methemoglobin as a potential source for nitric oxide production. In support of this hypothesis, there was a weak, positive correlation between methemoglobin and flow mediated dilation. However, potentially negative effects observed were a weak positive correlation between methemoglobin and diastolic pressure as well as an accompanying negative correlation between methemoglobin and stroke volume. Ultimately, results suggest that incorporating higher dietary nitrate and nitrite from non-protein nitrogen sources have the potential to exert beneficial effects on vascular distensibility, working through increases in plasma nitrite and subclinical increases in methemoglobin.

Antiretroviral therapy has prolonged lifespan for HIV-1 patients. However, cardiovascular complications have become one of the most prevalent causes of death among the HIV-1 infected population. Nucleoside reverse transcriptase inhibitors (NRTI) are the backbone of antiretroviral therapy, and the co-factors of emtricitabine (FTC) and tenofovir disoproxil fumarate (TDF/TDF) is commonly used. In prior studies, acute NRTI treatment induced endothelial dysfunction and increased reactive oxygen species production. These effects were partially rescued by overexpression of the mitochondrial antioxidant enzyme manganese superoxide dismutase. These findings suggest that mitochondrial oxidative stress is involved in the pathogenesis of NRTI-induced endothelial dysfunction. We hypothesized that mitochondrial dysfunction, including a compromised/disturbed mitochondrial homeostasis, has a causal role in an endothelial senescence that can exacerbate cardiovascular disease development. First, we evaluated mitochondrial function in human aortic endothelial cells (HAEC) after chronic FTC (10 μM) and/or TDF (10 μM) treatment for 2-14 passages. Senescence associated β-galactosidase staining in NRTI-treated cells demonstrated a higher level of senescence. In late passage HAEC, there was a lower expression of Parkin, a mitophagy modulator, in NRTI-treated cells compared to controls. Using quantitative PCR, mitochondrial DNA copy number exhibited a higher decrement in late passage HAEC treated with NRTI. Second, we treated HIV-1 transgenic mice, Tg26, with FTC (40 mg/kg) and/or TDF (50 mg/kg) for 3 months. Plasma nitrile levels were decreased in the plasma of FTC-treated Tg26 mice. Endothelium-dependent vasodilation of the thoracic aortas of NRTI-treated Tg26 mice was also reduced. High-resolution respirometry analysis in extensor digitorum longus muscle tissues from Tg26 mice showed that FTC/TDF co-treatment decreased mitochondrial respiration in these mitochondria-dominant tissues. Our work suggests that long-term use of NRTI disrupts mitochondrial homeostasis, induces premature endothelial senescence, and impairs vascular function.
**2064 Mitochondrial Alterations May Play a Role in Cardiotoxicity of the Tyrosine Kinase Inhibitor Regorafenib**

T. Boran, A. Gunaydin, A. Jannuzzi, and B. Alpertunga. Istanbul University, Istanbul, Turkey.

Protein kinases are important enzymes for cell physiology including, cell cycle progression, cell survival and proliferation. Disregulation of these enzymes is associated with cancer. By understanding of these mechanisms in cancer, molecularly targeted and mechanism based therapies have been developed which are mostly targeted to tyrosine kinases and thus are called tyrosine kinase inhibitors (TKIs). Although it has been thought that TKIs are generally well-tolerated for the cancer patients TKIs can lead to serious, fatal adverse effects such as cardiotoxicity. The underlying mechanisms of TK inhibitors induced toxicity is not well understood there is an ongoing effort to clarify them at the molecular level. The aim of this study is to investigate the effects of lenvatinib on H9c2 cardiomyocyte cell model to better understand the molecular mechanisms of TK inhibitors induced cardiotoxicity. It has been hypothesized that the cardiotoxicity of TK inhibitors may be due to mitochondrial toxicity. Cells were treated with 10 µM, 5 µM, 1.25 µM of lenvatinib for 48h and 72h. The cells were examined in aspects of cytotoxicity with methylthiazolyldiphenyl-tetrazoliumbromide (MTT) assay, ATP content assay with luminometry, protein levels with western blot, mitochondrial mass with Mitotracker Green FM and mitochondrial membrane potential (MMP) with JC-1 staining. According to our MTT results; lenvatinib did not cause significant cytotoxicity while with long term exposure cytostatic inhibition occurred at the two drug concentrations 10 µM and 5 µM and the luminometric ATP content assay results showed that the inhibition of the ATP content was 39% and 43%, respectively. Western blotting showed that the expression of Akt-1 was inhibited in the two high doses. P21 protein level increased at 10 µM concentration. Cytochrome c and protein levels of mitochondrial complexes did not show significant difference except for complex I which showed inhibition in 10 µM dose. The results of flow cytometry showed that lenvatinib caused a 44% increase in mitochondrial mass in the 10 µM dose. Lastly, a three fold decrease in the MMP was seen due to depolarization at the highest dose. Considering all these together it can be said that mitochondrial toxicity may be playing a role in cardiotoxicity induced by TK inhibitors.

**2065 Effect of a Cardiotoxic Pollutant-Phenanthrene on the Cardiac Function of Brown Trout (Salmo trutta)**

M. Ainerova1, J. Tinwell1, E. Sørhus2, K. White1, B. VanDongen1, and H. Shiel1. 1University of Manchester, Manchester, United Kingdom; and 2Institute of Marine Research, Bergen, Norway.

Phenanthrene (Phe) is a three-ringed polyaromatic hydrocarbon which is formed from incomplete combustion of hydrocarbons and is also a component of crude oil. Previous studies have shown Phe to be cardiotoxic to marine species. Similar to marine species, this evidence presented here suggest that Phe is cardiotoxic to freshwater salmonids. 2019 SOT Annual Meeting

**2066 In Vitro Investigation of the Antineoplastic Agent Lenvatinib Induced Cardiotoxicity in Terms of Mitochondrial Toxicity**

A. Gunaydin, T. Boran, A. Jannuzzi, and B. Alpertunga. Istanbul University, Istanbul, Turkey.

Lenvatinib is an oral multitargeted tyrosine kinase (TK) inhibitor which has been approved by US FDA for the treatment of radioiodine refractory differentiated thyroid cancer, unresectable hepatocellular carcinoma, and renal cell carcinoma in combination with everolimus. Cardiac failure is one of the written warnings in the drug label of lenvatinib. Although TK inhibitors are generally considered to be safe antinecancer drugs they can cause adverse side effects such as cardiotoxicity. While the underlying mechanisms of TK inhibitors induced toxicity is not well understood there is an ongoing effort to clarify them at the molecular level. The purpose of the present study is to examine the molecular mechanism of RGF induced cardiotoxicity by using cardiomyocyte cell model. H9c2 cells were exposed to 5 µM, 10 µM, 20 µM RGF for 48h and 72h. Trypan blue evaluation showed that RGF does not affect cell viability and according to MTT assay results RGF decreased mitochondrial activity in a dose and time dependent manner. ATP content which was assayed by luminometer, decreased in all RGF concentrations for both end points. ATP content decreased at 20 µM RGF to 30.66% and 9.41% in 48h and 72h exposures, respectively. Mitochondrial mass evaluated with flow cytometry by labeling with Mitotracker Green FM showed that RGF caused 31.46% decrease in mitochondrial mass compared to the control group. Mitochondrial membrane potential (MMP) by using JC-1 dye showed that RGF treated cells showed higher rates of depolarized MMP (0.91% vs 12.16%). According to the western blot results, Akt-1 levels decreased as a result of kinase inhibition in the two highest doses. Mitochondrial complex III showed a small difference and cytochrome c levels increased as a result of kinase inhibition in the two highest doses. Mitochondrial complex II showed a 44% increase in mitochondrial mass in the 10 µM dose. Lastly, a three fold increase of MMP was seen due to depolarization at the highest dose. Considering all these together it can be said that mitochondrial toxicity may be playing a role in cardiotoxicity induced by TK inhibitors.

**2067 The Cardiovascular Effects of Crotonaldehyde In Vivo and In Vitro**

L. Jin, G. Jagatheesan, and D. J. Conklin. University of Louisville, Louisville, KY.

Crotonaldehyde (CR) is a highly electrophilic α,β-unsaturated aldehyde product of incomplete combustion in tobacco smoke and fossil fuels and of 1,3-butadiene metabolism. Little is known about cardiovascular effects of CR exposure. For an in vivo study, mice were exposed to CR gas (1 ppm, 6h/day) for 4 days (acute) or 12 weeks (chronic; 5 days/week). Telemetry was used to measure blood pressure and heart rate in acute CR exposure, while non-invasive blood pressure was measured by tail cuff once a week in a chronic study. Following CR exposures, aortas were isolated and vascular function was measured. Acute exposure to CR, heart rate decreased (63 bpm to 512 bpm; n=1) with no change in blood pressure. In contrast, blood pressure was significantly lower in CR group than in air controls in the chronic study. In isolated aorta of 4-day CR-exposed mice, the relaxation of aorta to sodium nitroprusside (SNP; an NO donor) was increased significantly and a similar response to acetylcholine (ACh) was observed relative to air control. Aortas of chronic CR-exposed mice had a similar response to SNP and ACh. In addition, sensitivity to phenylephrine (PE) was significantly reduced in aorta of CR-exposed mice. Because CR enhanced vascular sensitivity to NO (more vasodilation and lower blood pressure), we tested for a direct effect of CR on blood vessels, aorta and superior mesenteric artery (SMA) in vitro. CR induced relaxation in isolated aorta and SMA. SMA (EC50 = 6.1 µM) was more sensitive than aorta (EC50 = 72±7 µM) to CR. The concentration-dependent (1-300 µM) relaxation was inhibited significantly in SMA by the presence of: 1) mechanically-impaired endothelium; 2) Nω-Nitro-L-arginine methyl ester hydrochloride (L-NAME); 3) the calcium entry antagonist (A967079); and 4) a guanylyl cyclase (GC) inhibitor (ODO). Positive immunofluorescent staining for TRPA1 was co-localized in the endothelium of isolated aorta and SMA. In acute exposure, the inhibition of repolarizing K+ currents which has been observed in myocytes from marine species. Similar to marine species, this evidence presented here suggest that Phe is cardiotoxic to freshwater salmonids.
2068 Effects of Tobacco Product-Derived Unsaturated Aldehydes on Circulating Angiogenic Cells

J. Finch, and D. J. Conklin, University of Louisville, Louisville, KY.

Tobacco smoking is the most significant modifiable risk factor in the development of cardiovascular disease. Mainstream cigarette smoke (MCS) has been linked to the development of systemic inflammation and endothelial dysfunction; endothelial function is a balance of injury and repair, the latter, in part, attributed to number/function of circulating angiogenic cells (CACs), wherein CAC blood levels are associated with endothelial health. Aldehydes are abundant toxins in tobacco-product aerosols, and previously, we linked acrolein exposure with cardiovascular toxicity in humans and mice; however, the effects of coirondehyde (CR), a similar short, unsaturated aldehyde, on endothelial repair are unknown. Thus, we performed a series of exposure studies (1 hpm; 4 days or 12 weeks, 5 days/week; 6 h/day) to determine the systemic and endothelium-related effects of CR exposure. Complete blood counts and plasma biomarkers were measured as indicators of systemic toxicity. The levels of CACs, specifically Flk-1+ Sca-1+ and Sca-1+ cells, were measured by flow cytometry. No significant changes were seen in WBC, RBC, or platelet counts after acute and chronic CR exposures. However, acute exposure decreased triglycerides levels, while chronic exposure increased levels of cholesterol (11±5%). High-density lipoprotein (16±7%), triglycerides (25±12%), and albumin (6±2%), although no changes were seen in Flk-1+ Sca-1+ cells after either exposure, were reduced by 4 days of exposure. But not after chronic exposure. Oxidative stress, as measured using monochlorobimane bound to glutathione, was unchanged in CACs or lymphocytes after exposure. Although CR and acrolein are similar, their effects after acute and chronic inhalation studies (1 ppm) were different. For example, acrolein significantly decreased CACs after 4 days and 12 weeks of exposure, whereas CR exposure did not. Contrary to these data, 4 days of MCS suppressed leukocytes and decreased Sca-1+ cells, but had no effect on Flk-1+Sca-1+ cells. Moreover, 12 weeks of MCS exposure decreased Flk-1+Sca-1+ cells, but had no effect on plasma lipids. Collectively, data from CR and acrolein exposure indicates that unsaturated aldehydes can affect different targets, yet their effects likely contribute to overall MCS-induced cardiovascular toxicity in complex ways. Future studies will define the mechanisms by which aldehydes as harmful and potentially harmful constituents of tobacco-based products induce cardiovascular toxicity.

2069 Gestational Inhalation Exposure to Titanium Dioxide Nanoparticles Increases Maternal-Fetal Vascular Resistance

The reproductive and cardiovascular effects of ENM exposure have been observed in adult populations, but the fetal consequences of gestational ENM exposure have yet to be fully understood. The placenta is a critical barrier protecting the fetus and allowing the transfer of nutrients from the maternal circulation. The purpose of this study was to determine the effects of pulmonary titanium dioxide nanoparticle (nano-TiO2) exposure on placental function and on the reactivity of the umbilical vasculature. We hypothesized that pulmonary nano-TiO2 exposure disrupts placental function and impairs umbilical vascular responsiveness. Pregnant Sprague-Dawley rats were exposed via whole-body inhalation to nano-TiO2, with a primary particle size of 21 nm on GD 11 for 7 days for a daily calculated lung deposition of 31±1 μg. Placentas, umbilical artery and vein were isolated, cannulated on GD 21 nm on GD 11 for 7 days for a daily calculated lung deposition of 31 ± 1.1 μg. Exposed rats of 62.58±4.7 mm Hg and 29.42±9.5 mm Hg respectively. Umbilical arteries from exposed dams had a decreased endothelium-dependent dilation (30.21±8.8%) compared to controls (57.92±6.1%) and an increased sensitivity to ANGII (−36.42±9.7%). These results suggest that gestational nano-TiO2 exposure impairs placental function and umbilical vascular reactivity in maternal-fetal vascular resistance. NIH R01-ES015022 (TRN), NSF-1003907(TRN, ABA), U54GM104942-02 (SH).

2070 Influence of Maternal Engineered Nanomaterial Inhalation on Uterine Adrenergic and Myogenic Microvascular Responses

K. L. Garner1,2, A. B. Abukabda1,2, E. C. Bowdridge1,2, T. P. Batchelor1,2, S. Hussain1,2, W. T. Goldsmith1,2, and T. R. Nukiewicz1,2, Department of Physiology and Pharmacology, West Virginia University, Morgantown, WV; and 2Toxicology Working Group, Morgantown, WV.

Engineered nanomaterials (ENM) are ubiquitously present in diverse human applications but have adverse cardiovascular effects. The reproductive and vascular consequences associated with ENM inhalation are not well understood. Myogenic reactivity is an adaptive gestational component that if impaired may have adverse effects on the maternal-fetal circulation. The adrenergic agonist norepinephrine (NE) exerts arteriolar vasococontractor effects and augments myogenic responsiveness. This study assessed uterine microvascular reactivity to adrenergic stimulation and transmural pressure changes after maternal nano-titanium dioxide (nano-TiO2) inhalation. Sprague-Dawley rats were exposed to nano-TiO2 aerosols during gestation. Evonik-P25 was utilized with a primary particle size of 21 nm and a zeta potential of -56.6 mV. Whole-body exposure (concentration = 10±0.5 mg/m3) was performed for 6 hours/d for 6 days (total lung burden = 217 μg). Rats were euthanized on day (GD) 20. Uterine microvascular reactivity was assessed via pressure myography. Experimental group characteristics: age 106±7 d, mean arterial pressure (MAP) 74±3 mm Hg, mass 372±28 g, litter size 14±1 pups, dry pup mass 0.49±0.02 g, dry placental mass 0.12±0.03 g. Sham characteristics: age 88±3 d, MAP 67±9 mm Hg, mass 387±10 g, litter size 13±1 pups, dry pup mass 0.66±0.09 g, dry placental mass 0.16±0.05 g. To stimulate only α-adrenergic receptors, β-receptors were inhibited with the α-antagonist propranolol (3X10-5 M). NE (1X10-5 M) was then applied. Myogenic responsiveness was assessed by pressurizing the vessels from 0-105 in 15 mm Hg increments. Subsequently, adrenergic facilitation of the myogenic response was evaluated by repeating the myogenic stimulus in the presence of NE. Myogenic reactivity was not significantly altered by ENM exposure (diameter change of 3.4±2.1%). Similarly, the adrenergic stimulation did not alter the myogenic response (4.7±1.7%) nor was the percent maximal response to NE at 60 mm Hg (3.1±1.0%). These results are preliminary ongoing experiments. Additional experimental groups and vasoactive agonists are being assessed (angiotensin II). Support: E0515022 (TRN), U54GM104942 (SH).

2071 Association of Exposure to Volatile Organic Compounds and Cateholamines

Stress is a major risk factor for the development of cardiovascular disease. Human response to stress occurs through activation of the sympathetic nervous system (SNS) to induce a fight or flight response. SNS activation in turn elicits a release of stress hormones like catecholamines. Exposure to toxic environmental chemicals has been shown to induce and stress, thus triggering a response of the SNS. We hypothesized that exposure to volatile organic compounds triggers an SNS response and subsequent release of catecholamines. Our cross-sectional study consisted of 260 nonsmokers who had low to high cardiovascular disease risk. On the day of enrollment, blood pressure of the participants was measured and urine samples were obtained. Urinary levels of ten catecholamines and metabolites and twenty parent VOCs (26 metabolites) were quantified by ultra fast performance liquid chromatography-mass spectrometry. Generalized linear models were used to examine the association between VOC metabolites and catecholamine metabolites in urine. We found significant associations with the two major catecholamines norepinephrine and epinephrine. Norepinephrine was significantly associated with the styrene metabolite, mandelic acid (p=0.0015). Epinephrine was significantly associated with metabolites of coirondehyde, N-acetyl-S-(3-hydroxypropyl-1-methyl)-L-cysteine, and 1,3-butadiene, N-acetyl-S-(4-hydroxy-2-buten-1-yl)-L-cysteine (p=0.0361 and p=0.0258, respectively). Vanillylmandelic acid is the parent compound of epinephrine and norepinephrine. Vanillylmandelic acid was significantly associated with the styrene metabolite, mandelic acid, and toluene metabolite, N-acetyl-S-(benzyl)-L-cysteine (p=0.0007 and p=0.0008). Exposure to environmental chemicals such as volatile organic compounds stress the human response and may contribute to the development of cardiovascular disease.
Safety-related attrition remains a major issue in drug discovery and development. To address this problem, the CIPA paradigm is being integrated into phenotypic characterization of targeted agents. The role of MyD88 signaling in the intestinal cell cycle progression and explains the lack of GI toxicity observed with palbociclib.

In the current study, the IEC6 cell line, a non-transformed rat small intestinal epithelial cell line with well-defined mouse model of nonischemic HF induced by Transverse Aortic Constriction (TAC), we previously demonstrated that Type 1 helper CD4+ (Th1) cells migrate to the heart and induce adverse cardiac remodeling. Moreover, T cell deficient (tcrα−/−) mice are protected from HF, while adoptive transfer of wt Th1 cells to these mice reconstitutes the pathology of HF. The adapter protein myeloid differentiation primary-response protein 88 (MyD88) is an important proinflammatory signaling molecule in innate leukocytes; and recently has been shown to be important in adaptive CD4+ T cells as well. Currently, we demonstrated that adoptive transfer of myD88+ Th1 cells to myD88−/−tcrα−/−host mice results in accelerated progression of HF with significantly higher numbers of Th1 cells in the heart. Therefore, we hypothesize that MyD88 regulates survival and proliferation of Th1 cells, and modulates the pathology of nonischemic HF. To address this, we generated in vitro differentiated myD88−/− and wt Th1 cells to evaluate differential survival and proliferation. Using a combination of flow cytometry and Cytation cell imaging, we demonstrate that myD88− Th1 cells have significantly enhanced survival and proliferation in comparison to wt Th1 cells. These data reveal a new pathway in Th1 cells that control cell survival, and hence the magnitude and duration of inflammation in vivo.

Electronic cigarettes (e-cigarettes) are popular nicotine delivery devices first introduced to the United States in 2007. Despite being advertised as a healthier alternative to conventional tobacco, the health consequences of e-cigarette use remain under investigated. The wide variety of flavors and e-cigarette models makes e-cigarettes appealing to adult and youth smokers and never-smokers. Their growing popularity combined with possible health consequences suggest a need to further research potential health hazards of electronic liquids (e-liquids) used in e-cigarettes. Since conventional tobacco use is a risk factor for osteoporosis, this study examines whether exposure to e-liquids affects bone-forming osteoblasts. Our previous research indicates e-liquid osteotoxicity is flavor-dependent, with flavorless e-liquids being the least osteotoxic and cinnamon-flavored e-liquids being the most osteotoxic. Hence, this study focuses on flavorless and cinnamon-flavored e-liquids. Human osteoblast-like MG-63 cells were exposed for 48 hours to 0.04%, 0.4%, 2% or 4% of unvaped nicotine-free e-liquids or 0.0025%, 0.025%, 0.25% or 2.5% of vaped nicotine-free e-liquids or to a culture medium only control. Changes in cell viability were assessed by MTT assays, and the expression of a key bone protein, collagen type I, was analyzed by immunofluorescence. Cell viability decreased in a dose-dependent manner, which was most pronounced with cinnamon-flavored e-liquids whether the e-liquid was unvaped or vaped. There were no detectable changes in collagen type I protein following exposure to any of the vaped e-liquids. This study demonstrates that osteoblast-like cells are sensitive to both unvaped and vaped e-liquids, particularly to the cinnamon-flavored ones. Additionally, collagen type I does not appear to be a target for the osteotoxicity of vaped e-liquids. In order to understand the mechanism behind e-liquids osteotoxicity, ongoing studies are investigating the effects of e-liquids on oxidative stress. This study provides insight into the potential impacts of e-cigarette use on bone health. This research is supported by an Institutional Development Award (IDeA) from the National Institute of General Medical Sciences of the National Institutes of Health under Grant Number P20GM103408.
2077 Cytotoxic Mechanism of a Mitomycin C-Lexitropsin Hybrid Anticancer Drug

M. Zheng, C. Clement, E. Champeil, and S. Cheng. John Jay College of Criminal Justice, New York, NY; and Albert Einstein College of Medicine, Bronx, NY.

Hybrid anticancer drugs have drawn lots of attention for cancer research to improve clinical efficacy and to target various types of cancer. Mitomycin C and lexitropsin are potent anti-cancer agents, but with different DNA interaction mechanisms. The hybrid compound obtained from linking the pyrrole fragment backbone of lexitropsin to a mitomycin moiety was investigated for both cytotoxic activities against breast cancer cells and molecular pharmacological mechanism. The activation reactions were studied via theoretical (quantum chemistry) calculations. These calculations showed that the mitomycin moiety linked to one pyrrole fragment causes a more favorable energy of reduction than mitomycin moiety linked to two pyrrole fragments or mitomycin alone. Cytotoxicity results indicate that the former is much more effective on killing both breast cancer cells used in this study, MCF-7, and MDA-MB 468 cells. Both compounds have a stronger cytotoxic effect on MDA-MB-468 cells, which are triple negative breast cancer cells with p53 mutation. Mitomycin with one pyrrole ring also can effectively inhibit microtubule polymerization and trigger DNA crosslink at different temperatures. The results from theoretical activation energy calculations and cytotoxic analysis suggested that the compound with one pyrrole ring attached to mitomycin was much more effective on triggering breast cancer cell death. Moreover, this hybrid compound was able to destroy microskeletal network and also able to trigger DNA damage.

2078 Methyglyoxal-Induced Advanced Glycation End Products Promote Proliferation via MAPK/P38/Akt Signaling Pathways in Renal Cell Carcinoma Cell

H. Nam, H. Kim, and K. Lee. Korea University, Seoul, Korea, Republic of.

Sponsor: J. Lee

Advanced glycation end products (AGEs) are the final products formed when carbohydrate-rich food is heated at high temperatures. Although the underlying mechanism of neurotoxicity still remains elusive. Our previous studies showed that the level of noradrenaline declined, and the density of noradrenergic nerve fibers decreased in the brains of rats exposed to ACR by gavage, and that LC3B positive cells were observed in the murine cerebellum. The present study aims to investigate the cytotoxicity of acrylamide in neuron and microglial cell. Firstly, mouse noradrenergic neuron CATH.a and mouse microglial cell BV2 were exposed to acrylamide for 24 hours at different concentrations. Cell viability, LDH, and caspase 3/7 activity were examined as described above. In CATH.a neuron, while the cell viability decreased on the ACR concentrations, the quantity of LDH and caspase 3/7 activity remained unchanged. However, with chloroquine, not LC3B positive cells were observed in the murine cerebellum. The present study aims to investigate the cytotoxicity of acrylamide in neuron and microglial cell. Firstly, mouse noradrenergic neuron CATH.a and mouse microglial cell BV2 were exposed to acrylamide for 24 hours at different concentrations. The present study aims to investigate the cytotoxicity of acrylamide in neuron and microglial cell. 2081 Integrated Networking Analysis of Toxicological Mechanisms of Natural Compounds Using Bio-Sensing Cell Lines

Natural products have been developed as therapeutic agents for various diseases including cancer in the drug discovery area. However, the potential toxicity of natural products could be a big hurdle to develop the drug candidates. To overcome this limitation, the development of high-contents screening method to give the information about toxic mechanism is needed. Here, we suggest the biosensing method to evaluate the cellular stress for the natural compounds using bio-sensing analysis. Several transcriptional factors including AP-1, P53, Nrf2, and NFkB are regulated during an early toxic response by triggering cell proliferation, apoptosis, oxidative stress, and inflammation. To screen the cellular stress response, we constructed the established HepG2 cell lines to express the luminescence and GFP when only these transcriptional factors are activated using the transcription response element. Using biosensing hepatocytes, we screened the toxic effects for the wide ranges of twenty natural compounds including flavonoid, poly cyclic, di-terp-period, and quinoid and quantitative changes were examined by imaging analysis. Several natural compounds including apigenin, the potential hepatotoxic compounds cause the cytotoxic effect mediated by AP-1, and P53 pathways and we can classify the mode of action for the natural compounds using this system. Our results suggest that the biosensing hepatocytes are suitable for an early sensing method for screening the hepatotoxicity and could give critical information about molecular mechanisms to initiate the cellular stress. This approach can be used to build up the adverse outcome pathways (AOP) to unravel the key events associated with liver injury for natural compounds. This work was supported by a grant (NRF-2016M3A9C4953144) from the Ministry of Science, ICT, and Future Planning and a general research grant from the Korea Institute of Toxicology.

2082 Trovafloxacin-Induced Protective Autophagy Is Inhibited by TNFalpha-Mediated Upregulation of mTOR Pathway in HepG2

Hepatotoxic drugs synergistically increase liver toxicity by specific cytokines. In this study, we describe that alteration of autophagy plays an important role in the synergistic effect of drug-induced immune-mediated hepatic injury in human hepatoma cells. We found that TNFα increases the Trovafloxacin-induced cytotoxicity in HepG2 cells but does not affect Levofoxacin- and Nefazodone-induced cytotoxicity. In addition, the Trovafloxacin-induced autophagy is dependent on the mTOR signaling pathway and is the result of the proteasomal degradation of mTOR protein and downstream-proteins. The autophagy-inhibited ATG5 knockdown HepG2 cells increase apoptosis signal, and cytotoxicity by Trovafloxacin compared to the untreated controls and these results suggest that Trovafloxacin-induced autophagy plays a protective role. We found that the treatment of Trovafloxacin up-regulates the phosphorylation of p70S6K(T389) among the mTOR signals, thereby inhibiting Trovafloxacin-induced protective autophagy, which suggests that TNFα that can increase hepatotoxicity through the collapse of the autophagy mechanism by Trovafloxacin. Taken together, our study suggests that autophagy may be the causative factor of idiopathic hepatotoxicity including inflammatory mediators of hepatotoxicity, and may be used as a new parameter to predict toxicity through identification of autophagy mechanisms. This work was supported by a grant (NRF-2016M3A9C4953144) from the Ministry of Science, ICT, and Future Planning and a general research grant from the Korea Institute of Toxicology.

2083 Characterization and Application of a 3D Human Oral Buccal Model for Whole Cigarette Smoke and Smokeless Tobacco Exposure

B. Keyser1, W. Morgan1, A. Maione2, and W. Fields1. 1RAI Services Company, Winston-Salem, NC, and 2MatTek Inc., Ashland, MA.

Oral disease is frequently associated with viral and environmental exposures as well as oral hygiene. The use of tobacco is an additional risk factor in the development of oral disease. However, epidemiology shows that the risk of oral cancer is far higher for smoking than for smokeless tobacco use. The goals of this study were to 1) assess the consistency of whole cigarette smoke-induced cytotoxicity in a 3D human oral buccal model, EpiOral™, using tissues obtained from two donors and 2) to further characterize cytotoxic and oxidative stress responses following exposure to extracts of CORESTA smokeless tobacco reference products (CRPs) in this model. Whole smoke exposures were conducted by exposing the apical side of EpiOral™ tissues to either 3RF4 whole smoke (Health Canada Intense smoking regimen, 0.5 L/min dilution airflow, 20 mL/min vacuum) generated by a VITROCELL® VC1 smoking robot or concurrent clean air control up to 2 hours. Cytotoxicity by either 3-(4,5-dimethyl-2-y1)-2,5-diphenyloxazolium bromide (MTT) or lactate dehydrogenase (LDH) assays was measured 24 hours post exposure. CRPs for snus (CRP1), moist snuff (CRP2), and dry snuff (CRP3) were each exposed in complete artificial saliva (CAS) with a ratio of 300 mg of CRP to 1 mL of CAS. CRP extracts were sterile-filtered and stored at -80°C until the time of exposure. CRP extracts (15 - 300 mg/ml) were applied to the apical side of EpiOral™ tissues for 48 hours continuously and cytotoxicity (MTT/LDH) and oxidative stress (8-iso-prostanet) were measured. A consistent dose-dependent response with significant cytotoxicity was observed in both donor tissues following exposure to whole smoke. IC50 values (mean ± SD) for MTT were 12.64 ± 0.51 cigarettes and 13.69 ± 0.83 cigarettes for donors A and B, respectively. In contrast, minimal (< 20%) cytotoxicity was observed in tissues exposed to CRPs. While the CRP extracts elicited minimal cytotoxicity, dose-dependent effects on oxidative stress were observed: the release of 8-iso-prostanet showed significant increases for each reference product for the two donors; however, the response between products was significantly differentially induced. Collectively, the data suggest that the 3D human oral buccal model, EpiOral™, may be useful in differentiating between tobacco product categories.

2084 Differential Toxicity, Uptake, and Release of Inorganic Mercury and Methyl Mercury in Human Endothelial Cells

J. Fowler, S. Liu, M. T. Tsui, E. Lee, and Z. Jia. University of North Carolina at Greensboro, Greensboro, NC.

Cardiovascular disease (CVD) is the leading cause of morbidity, mortality, and health care costs in the United States, and around the world. Among the various risk factors of CVD, environmental and dietary mercury (Hg), a highly toxic metal traditionally labeled as a neurotoxin, is a potential contributor towards human atherosclerotic development. In this study, we investigated the toxicity, type of cell death, dose-dependent uptake, and release of two forms of Hg commonly exposed in the environment, i.e., inorganic HgII (as HgCl2) and methylmercury or MeHg (as CH3HgCl) in EA.hy 926 endothelial cells. Our results showed that HgII is highly toxic to the endothelial cells, owing to the higher uptake into the cytoplasm and perhaps more importantly less HgII is released than MeHg by the cells, thus the “net” accumulation by the endothelial cells is higher for HgII than MeHg when exposed to the same Hg levels. Exposure to MeHg also increased IL-8 gene expression dramatically. Furthermore both HgII and MeHg were found to induce apoptotic and necrotic cell death. This study has important implications to further understanding of the toxicity of these two common Hg species (obtained upon exposures to different environmental and dietary media), and their contributions to the development of atherosclerosis, a process leading to CVD.

2085 Diphenyl Diselenide Induces Cytochrome C-Dependent Apoptotic Pathway in Triple Negative Breast Cancer Cells

Triple-negative breast cancer (TNBC) is one of the most common and aggressive types of breast cancer. TNBC cells lack the expression of three key receptors: progesterone, estrogen and HER2, hence cannot be treated using existing targeted therapies. Therefore TNBC patients have an extremely poor prognosis compared to other sub-types of breast cancer. Previous studies have shown that selenium containing drugs can treat a range of disorders. In particular diphenyl diselenide (PDPS) has been reported to be cytotoxic against cancer cell lines at concentrations greater than 30 µM. However the effect of PDPS on breast cancer has not been studied. Here we investigated the effect of two synthetic organoselenium derivatives, DPDS and diphenyl selenide (DPS) on three TNBC cell lines (MDA-MB-231, MDA-MB-468 and Hs 578T), and compared drug action with estrogen positive breast cancer cells (MCF-7), human epidemial growth factor receptor 2 positive breast cancer cells (SKBR3), and two non-cancerous cell lines (MCF-10A and human normal dermal fibroblasts). Initially, cell death induced by DPS and DPDS was determined by MTT and Hoechst/PI double labeling assays. DPS showed no anti-cancer effect against breast cancer or non-cancerous cell line; but DPDS showed potent cytotoxicity, with IC50’s in the range 7-18 µM against TNBC cells, and 27 µM against MCF-7s. Interestingly however DPDS did not display cytotoxicity towards SKBR3 cells, or against any of the non-cancerous cell lines. This approach can be used to build up the adverse outcome pathways (AOP) to unravel the key events associated with liver injury for natural compounds. This work was supported by a grant (NRF-2016M3A9C4953144) from the Ministry of Science, ICT, and Future Planning and a general research grant from the Korea Institute of Toxicology.
cells, suggesting selectivity towards TNBC. The data also indicated that DPDS displayed higher cytotoxicity towards MDA-MB-231 cells compared to the other breast cancer cell lines. Therefore we performed further studies with MDA-MB-231 cells to determine the mechanism of DPDS induced cell death. The TO-PRO-1 probe was next used to identify if DPDS caused apoptosis. Quantitative analysis indicated that after 18 hours DPDS had initiated cell death via apoptosis in 20-25 % of the cell population. Next, the expression of cytochrome c from the mitochondria in DPDS treated apoptotic cells was determined by immunocytochemistry. Fluorescence micrographs identified that 20-30 % of mitochondrial cytochrome c was released after only two hours treatment with DPDS, leading to the rapid onset of apoptosis. This was accompanied by a two-fold increase in the activity of caspase-3, detected using the Ac-DEVD-AMC caspase-3 fluorogenic substrate. These data suggest that DPDS is a potential anti-cancer drug capable of selectively activating the intrinsic pathway of cell death in TNBC cells.

**2086 Perhexiline Induces Mitochondrial Dysfunction and Apoptosis in HepG2 Cells**

Perhexiline is a prophylactic antianginal agent developed in the 1970s. Despite its success, its use diminished due to the occurrence of poorly understood side effects including severe hepatotoxicity in certain patients. Here we present the results of studies examining whether or not hepatocyte injury is associated with mitochondrial dysfunction and programmed cell death in both HepG2 cells and HepARG cells. Particularly, the decline of cellular ATP levels caused by perhexiline was dramatically exacerbated when galactose was substituted for glucose as the sugar source, suggesting a potential mitochondrial liability. JC-1 staining confirmed the occurrence of mitochondrial membrane depolarization upon treatment of perhexiline. Bongkrekic acid, a mitochondrial permeability transition pore blocker that targets adenine nucleotide translocase, attenuated both the ATP depletion and LDH leakage induced by perhexiline. Perhexiline significantly increased the activity of caspase 3/7 and caspase 9, and also elevated the gene expression of TNFα on the mRNA level, suggesting that perhexiline activated apoptosis in HepG2 cells. Pretreating cells with pan caspase inhibitor Z-VAD-FMK, or with inhibitors specific for caspase-3, -8, and -9 respectively, attenuated the cytotoxicity of perhexiline. Interestingly, treating HepG2 cells with NecroX S, a necrosis inhibitor, also partially protected cells from the toxicity of perhexiline, suggesting that necrosis may play a role in the cytotoxicity of perhexiline. In addition, the expression levels of Bcl-2 family proteins and TNFα showed significant changes upon perhexiline treatment. Overall, our results suggest that perhexiline induced mitochondrial dysfunction and apoptosis in HepG2 cells.

**2087 The Molecular Mechanism of Cigarette Smoke Induced Necroptosis on Human Vascular Endothelial Cell**

L. Qiao, C. Hua, J. Zhao, P. Shang, X. Li, F. Xie, and H. Liu, Zhengzhou Tobacco Research Institute, Zhengzhou, China. Sponsor: R. Meng

Cigarette smoking is a well-established risk-factor for cardiovascular disease and a major cause for atherosclerosis. Some chemicals in cigarette smoke can activate reactive oxygen species (ROS) generation and disrupt the microenvironment in which the vascular endothelial cells (VEC) reside, inducing the death of endothelial cells as well as a series of pathological responses. It is well known that ROS can trigger endothelial cells apoptosis in the animal models and human samples. However, it remains unclear whether VEC necroptosis occurs when ROS accumulate and what its underlying mechanism is. In our preliminary experiment, we investigated the effect of the cigarette smoke extracts (CSE) on the vascular endothelial cells. Utilizing time-lapse microscopy, we found there were cell apoptosis and necroptosis simultaneously, which initiated after cigarette smoke extracts exposure 3h and gradually increased after exposure 6h. The FACS also revealed that there were obvious cell apoptosis and necroptosis after exposure 6h, and the most of cells were necrosis at 24h. Meanwhile, we observed ROS generation significantly increased in the HUVECs at exposure 3h and 24h respectively. As RIP-RIP3-MLKL pathway played key roles in the cell necroptosis, we further tested their expression level by western blotting. The CSE obviously induced phosphorylation of RIP3 and MLKL at exposure at 24h. Next, we treated HUVECs with N-Acetyl-L-cysteine (NAC), which is commonly used to inhibit ROS generation. The CSE-induced ROS generation was dramatically inhibited by NAC pretreatment, and necroptosis was partially inhibited by NAC-1 as well. Moreover, NAC significantly inhibited RIP3 and its phosphorylation level. These results demonstrated that ROS-induced necroptosis through regulation of RIP3 and its phosphorylation. These studies of the regulatory mechanism and related pathways could help us better understand the pathogenesis of smoking induced arteriosclerotic vascular disease and provide a potential avenue for prevention and treatment.

**2088 Cadmium Exposure Induces Pancreatic β-cell Dysfunction and Death via a Ca²⁺-Triggered JNK/CHOP-Related Apoptotic Signaling Pathway**

J. Lin¹, Y. Chiu¹, C. Yang², K. Lee³, C. Su¹, C. Lin¹, C. Wu¹, S. Liu⁴, Y. Chen¹, and C. Huang¹, ¹China Medical University, Taichung, Taiwan; ²National Taiwan University Hospital, Taipei, Taiwan; ³Tri-Service General Hospital, Taichung, Taiwan; ⁴Changhua Christian Hospital, Changhua, Taiwan; ⁵Department of Public Health, Taipei, Taiwan; and ⁶National Taiwan University, Taipei, Taiwan.

Cadmium (Cd) is known to be ranked the 7th hazardous substance in the Substance Priority List by Agency for Toxic Substances and Disease Registry. The experimental and epidemiological data have indicated that Cd is linked to the development of diabetes mellitus. The molecular mechanism of Cd on pancreatic β-cell cytotoxicity still remains unclear. Evidence has pointed toward that Ca²⁺ is an important regulator of toxic insult-induced β-cell cytotoxicity. The role of Ca²⁺ in the Cd-induced β-cell cytotoxicity is still unknown. In this study, we found that Cd exposure significantly inhibited insulin secretion and cell viability in the pancreatic β-cell-derived RIN-m5F cells. Cd exposure increased the populations of apoptotic cells and sub-G1 hypodiploid cells. Cd exposure induced apoptotic signaling caspase-3/-7/-9 activation, which largely depended on the activation of c-Jun N-terminal kinase (JNK) and C/EBP homologous protein (CHOP). Transfection with siRNAs for JNK and CHOP or pretreatment with specific pharmacological inhibitor of JNK (SP600125) in β-cells effectively prevented the Cd-induced insulin secretion dysfunction and apoptosis. JNK-specific siRNA dramatically suppressed Cd-induced JNK phosphorylation and CHOP protein expression, but JNK phosphorylation could not be inhibited by CHOP-specific siRNA. Furthermore, Cd exposure significantly increased the intracellular (Ca²⁺)⁰ levels. Buffering the Ca²⁺ response with BAPTA/AM effectively abrogated the Cd-induced [Ca²⁺]⁰ elevation, insulin secretion dysfunction, apoptosis, and protein expression of phosphorylated JNK and CHOP. Taken together, these findings demonstrated that Cd-induced β-cell dysfunction activates the extracellular Ca²⁺ entry via a [Ca²⁺]⁰-dependent JNK activation-activated downstream CHOP-related apoptotic signaling pathway.

**2089 Benchmark Dose (BMD) Modeling of Image-Based Phenotypic Profiling Data Yields More Potent Estimates of Chemical Bioactivity Compared to Cell Viability and Apoptosis Assays**

High-throughput imaging-based phenotypic profiling (HTPP) is a chemical screening method that combines automated microscopy and image analysis to identify a large variety of morphological features at the single cell level. Here we describe workflows for concentration-response screening and image analysis using an HTPP assay that quantitatively evaluates changes in organelle morphology (i.e. Cell Painting), as well as calculation of biological pathway altering concentrations (BPACs) using high-throughput concentration-response modeling (BMDExpress 2.2). A set of 16 reference chemicals were tested in six human cell lines (U-2 OS, MCF7, HTP-9, A549, ARPE-19, HepG2). Cells were plated in 384-Well plates and after 24 h treated with 7 concentrations (semi-log spacing, n = 3/plate, 3 cultures) in a randomized pattern. After 48 h, cells were live labeled with MitoTracker (mitochondria), fixed, permeabilized and labeled with Hoechst-33342 (nuclei), SYTO14 (nucleoli) and fluorescent conjugates of concanavalin A (ER), phallolidin (cytoskeleton), and wheat germ agglutinin (Golg/plasma membrane). A multiplexed cell viability (CV) and apoptosis (AP) assay was run in parallel. Confocal images were acquired using an Opera Phenix HCS system and analyzed using Harmony software, yielding ~1200 features per cell. Cell-level data were median absolute deviation (MAD) normalized to DMGO controls. BMD modeling was performed on well-level median values. Most chemicals (n=14) affected cell morphology in a concentration-dependent manner. Distinct patterns of affected cellular features were observed across the chemical set and, in most cases, were consistent with observations from the literature. In general, the chemically most potent cell patterns, with high-confidence toxicity estimates, were across the different six cell lines. For all compounds, HTPP BMDs were at least as sensitive as CV or AP BMDs. In some cell lines, profiling BMDs were >10x lower than CV or AP BMDs. Screening of a larger set of chemicals (n=480) also
A Unique Comparison of Three Intrathecal Administration Techniques for Non-Systemic Delivery of CNS-Targeting Antisense Oligonucleotides in Cynomolgus Monkeys for the Benefit of the 3Rs

S. Korte1, S. Bassett2, L. Gand2, K. Erich1, A. Braendli-Baiocco2, J. Luft1, M. Niehoff1, a von Keutz1, F. Ludwig1, F. Runge1, T. VoI3, P. Dzygielewski4, G. Fischer5, and L. Müller6. 1Covance Preclinical Services GmbH, Münster, Germany; and 2F. Hoffmann-La Roche Ltd., Basel, Switzerland.

Single oligonucleotides have been reported to deliver 5-10x higher brain exposure levels with implanted port catheter (PC) administration than with lumbar puncture (LP). Hence, we designed a study in NHP to compare exposure in the CNS with different IT administration methods with the same LNA (locked nucleic acid) dose and volume. Six Mauritius male monkeys (3.0-3.5 kg and 2 to 5 years) underwent one of the following intrathecal dosing regimens, followed by 1.5 mL artificial cerebrospinal fluid (CSF) (two animals/group): 1) Standard intrathecal bolus administration with a pediatric non-coring needle (LP, lumbar puncture); 2) Intrathecal implanted port catheter (PC, catheter tip reached T10 through T12) and 3) Temporary intrathecal catheter (TC, catheter tip reached T10 through T12). Bioanalysis was conducted on plasma, CSF and on neuronal tissue collected at necropsy 15 days after dosing. Brain exposure using LP administration was up to 2x higher than using PC administration. An increased volume of administration and flushing appears to be the most significant factor to achieve higher brain concentrations with a single administration schedule since previous studies with lower volumes resulted in 10-20x lower exposure using LP administration. Exposure in liver was also about 2x higher with LP. In terms of histopathology, only the well documented procedure-related findings at the injection/implantation sites were observed. In summary, the conducted lumbar bolus method may reduce the number of similar studies in the future, potentially reducing animal usage (as no biocytological comparison study is required) and surge 2, as it was confirmed that a specialized lumbar administration technique, using non-coring pediatric needles, does show similar pharmacokinetic exposure levels.

Two Cases of Lumbar Spinal Cord Infarction in Cynomolgus Monkeys Associated with Intrathecal Bolus Administration

F. Ludwig1, F. Runge1, T. VoI3, A. von Keutz1, S. Friderichs-Gromoll1, C. Leonardi1, M. Wozniak1, S. Korte1, A. Romeike1, and L. Mecklenburg1. 1Covance Preclinical Services GmbH, Münster, Germany; 2Covance Laboratories Ltd., Harrogate, United Kingdom; and 3Medical University of Lublin, Lublin, Poland.

Many potential drugs against neurodegenerative diseases, particularly antisense oligonucleotides (ASO), are administered via intrathecal injection, as they do not cross the blood-brain barrier. This route of administration is well established in cynomolgus monkeys that are used for preclinical safety assessment when other species cannot be used. We have conducted intrathecal injections in >1800 individual monkeys and among those we have observed two cases of spinal cord infarction. This poster describes clinical symptoms, diagnostic approaches, morphological features, and prognosis of this rare injury. Both animals (males) were intrathecally (lumbar) administered an ASO under standard conditions (anesthesia, withdrawal of equivalent CSF volume ahead of dosing, manual bolus infusion over 1 minute using a pediatric pen cil-point needle). They showed lameness of both hind limbs and absence of patellar and foot grip reflexes approximately 0.5 and 4 hours after dosing (case 1 and 2, respectively). Approximately 240 and 96 hours after the administration, respectively, Magnetic Resonance Imaging (MRI) of the lumbar spine was performed under anesthesia employing a 1.5 Tesla MRI scanner (GE Healthcare). In both cases, MRI scanning revealed a linear hyper-intense signal of the lumbar spinal cord, compatible with a spinal cord infarct. In both cases, the locomotor impairment was reversible within 3 weeks. In a follow-up MRI scan of case 1 9 weeks later, the area of hyper-intensity was still present and larger in size (2.8 mm antero-posterior, 3.5 mm latero-lateral and 40.0 mm crano-caudal compared to 2.4 mm, 3.4 mm and 17.0 mm, respectively, during the first scan). Necropsies were performed 29 and 27 days after the administration. Microscopic evaluation of the lumbar intrathecal injection site revealed necrosis within the spinal cord resulting in malacia of the dorsal portion of the cord in case 1 and focal axonal degeneration, foamy macrophages and multifocal vacuolation with axonal degeneration of spinal nerve roots in case 2. MRI represents a useful non-invasive diagnostic method to confirm spinal cord infarction, a very rare mechanical, intrathecal dosing-related complication in cynomolgus macaques.

Default Occupational Exposure Limit for Single-Strand Oligonucleotides in Early Development

D. Bertow1, S. Weber2, M. Glogovac1, M. Schwind3, K. Blumbach1, T. Pfister4, and D. Hoffmann1. 1Evonik Nutrition & Care GmbH, Hanau, Germany; 2Hoffmann-LaRoche Ltd, Basel, Switzerland; 3Navaris GmbH, Basel, Switzerland; and 4Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany.

Development of single strand oligonucleotides (SSOs) as potent pharmacueticals has experienced a boost over the last years. At the moment, there are more than 100 clinical studies ongoing (ClinicalTrials.gov). Therefore, occupationa l toxicologists are challenged by an increasing number of requests to set occupational exposure limits (OELs) for SSOs, especially early in development. Current generation SSOs therapeutics are oligomers of synthetic nucleotides typically of 12 to 20 units in length (MW typically in the range 5000-7000 Da) designed to hybridize to endogenous or pathogens’ nucleic acids according to Watson-Crick base pairing. To improve drug-like properties, their inter-nucleotide links are generally chemically modified, resulting in a diverse class of molecules. Despite their different backbones, common features have been described with regards to toxicological effects. This poster summarizes these similarities. In addition, a default OEL limit in the range of 10-100 µg/m³ has been derived for molecules in early development with limited substance specific data. The default value has been based on intensive review of toxicological and pharmacokinetic data as well as an assessment of currently set OELs for SSOs from 4 companies.

Safety Assessment of Ionis-MAPT mRNA Microtubule-Associated Protein-Tau (MAPT) Lowering Antisense Oligonucleotide (ASO), by Intrathecal (IT) Lumbar Puncture (LP) for 13 and 39 Weeks in Cynomolgus Monkeys

P. Narayanan1, S. Korte2, A. J. Engelhardt3, H. Kordasiewicz4, D. A. Norris5, J. F. Schroeder1, B. Fitzsimmons1, E. Swayne1, L. Mignon6, R. Lane1, C. Bennett1, and S. P. Henry1. 1Ionis Pharmaceuticals, Carlsbad, CA; and 2Covance Preclinical Services GmbH, Münster, Germany.

IONIS-MAPTₚₜₜᵣᵣ is a 2’-O-methoxymethyl ASO targeting MAPT mRNA for the treatment of dementia associated with increased levels of tau protein in the spinal cord and brain. Centrally-acting ASOs need to be given IT as they do not cross the blood-brain barrier. Preclinical safety of IONIS-MAPTₚₜₜᵣ, which has pharmacologic activity in cynomolgus monkeys, was assessed in this species at three dose levels (4, 12, and 35 mg), as a once monthly repeat-dose IT LP bolus injection of 1.0 mL at lumbar (L) 3 - L4 for 13 or 39 weeks. No adverse test article-related effects on neurobehavioral, clinical pathology, CSF cell counts, ophthalmic examinations, electrocardiogram and blood pressure were recorded. There were also no organ weight changes or macroscopic findings related to treatment. Non-adverse, minimal focal neuronal vacuolation in hippocampus, a typical feature of central ASO administration, was an inconsistent finding across 13-week and 39-week studies. Fluorodacade staining of these hippocampal neurons in the 13-week study showed no fluorescence to indicate the presence of degeneration. Other IONIS-MAPTₚₜₜᵣ-related, non-adverse, microscopic observations were mononuclear cell inclusions (nervous system) and granular macrophages (lymph nodes) at all doses. Dose-dependent increase in exposure following IT administration was characterized by increasing concentrations of IONIS-MAPTₚₜₜᵣ in brain, spinal cord, kidney cortex and liver. In the CNS, exposure was generally greatest in the spinal cord with slightly lower levels in the brain. As expected, there was a significant decrease in MAPT mRNA and total tau protein in spinal cord and multiple CNS regions, as compared to controls. In conclusion, IT administration of 4, 12, or 35 mg of IONIS-MAPTₚₜₜᵣ in cynomolgus monkeys for 3 or 9 months (5 to 10 total doses) showed good local and systemic tolerability, no adverse neurobehavioral effects, and no adverse microscopic findings.
Gene therapy is a promising area of drug development for a number of diseases including some not treatable by approved medical treatments. Gene therapy works by delivering nucleotide sequence homology with humans, and need to be used when they are the only species where test article cross-reactivity occurs. An IACUC-approved regulatory toxicity study required bilateral administration of a gadolinium labeled viral vector into four locations into the Striatum with temporarily implanted catheters. Magnetic resonance imaging (MRI) was used for calculation of trajectory and for surveillance of test article delivery during convection-enhanced delivery. 24 monkeys were prepared for a 6-8 h anesthesia including pre-surgical analgesia, induction of anesthesia with ketamine / medetomidine, intubation and placement in a stereotactic frame. Induction anesthesia was conducted with isoflurane. Animals were transferred to the MRI to obtain data for calculation of position, angle and depth for catheter placement, assuring that the trajectory will not cross blood vessels or ventricles. Following transfer to the surgical suite, the stereotactic frame was used to ensure correct placement of the catheters based on the coordinates determined by MRI. The skin was reclined from the skull and holes were carefully drilled. Catheters were cut to specific length and inserted along the calculated trajectories to administer the viral vector to 4 different locations into the Striatum. Catheters were connected to infusion lines containing the gadolinium labeled test article. Infusion (rate 0.3 mL/h) was monitored in the MRI for 80 min to verify correct administration. Thereafter, animals were transferred back to the surgical suite and catheters were explanted. Animals recovered from the 6-8 h anesthesia within 15-30 min and were treated with analgesics and antibiotics. Animals presented laryngeal swelling and were treated with corticosteroids successfully. No animal showed neurological abnormalities. In conclusion, 96 catheters were successfully implanted in 24 animals, allowing intracranial administration into the Striatum (Caudate nucleus and Putamen). Six-week-old female Crl:CD1(ICR) mice were used. Blood sampling was performed 2 (at 0.5 and 4 h) or 3 times (at pre and 24 h) within 24 h from the tail vein by sparse sampling on Day 0. The following sampling volumes were selected: 2.2% (2 x 20 mL), 3.3% (2 x 30 mL), 3.3% (3 x 20 mL), and 5.0% of CBV (3 x 30 mL). After blood sampling, hematology was conducted on Days 1 and 3, and the animals were then necropsied and examined histopathologically. Clinical signs, body weight, and organ weights were also evaluated. Results: No abnormalities were noted in clinical signs, body weight or organ weights in any mouse. No abnormalities were noted in hematology at 2.2% or 3.3% of CBV. Sampling 5.0% caused low erythrocyte count (RBC), hemoglobin concentration (HGB), and hematocrit value (HCT) on Day 1, both reticulocyte ratio (RET) on Day 3. No histopathological abnormalities were observed at up to 5.0% of CBV. Discussion and Conclusion: Based on the above-mentioned results in mice, sampling 5% of CBV caused anemia and hemopoiesis. Low RBC, HGB and HCT on Day 1 and high RET on Day 3 were noted, although no histopathological abnormalities were observed. However, sampling approximately 3% of CBV did not cause any anemia or hemopoiesis. These results suggested that the relationship between total blood sampling to CBV ratio and anemia or hemopoiesis was almost the same in both mice and rats. Accordingly, we concluded that, in rodents, microsampling up to 3% of CBV can be used for both toxicological evaluation and confirmation of systemic exposure in the same animal.

In recent decades, despite dramatic increases in investment, pharmaceutical research and development productivity declines. A recent survey showed that most important reason for drug failure is off-target and on-target related safety, explaining more than 50% of all project closures. In order to help assess target safety we generated a comprehensive database and software. We made computable data from publicly available databases and internally curated data on proteins, biologically active chemicals, their interactions, pathways and pathologies. We cataloged >4 million references, supporting each database entry. All interactions are hyperlinked to appropriate PubMed article as support, while proteins and chemicals are hyperlinked to EntrezProtein, PubChem or the other appropriate public database. We developed toxicology ontology with >2500 toxicity endpoints to support data integration. The system can be queried with protein name or sequence, chemical structure or text searches for toxicities and pathologies. We tested the system by exploring androgen receptor (AR), a high data density target with known safety liabilities. Mapping AR onto GO function module within the system promptly identified AR biological function in sex differentiation and male gonad development including prostate gland development. Mapping AR together with its interacting proteins onto Diseases and Organ and tissue pathologies module, associated AR with several pathologies and toxicities related to development including Swyer syndrome and Y chromosome deletion. In addition, the system associated AR with other pathologies on cellular, organ and organ system level related to cardiac system (heart fibrosis, cardiac hypertrophy), nervous system (neuron degeneration), male and female reproductive system (testis atrophy, oligosperma, prostate toxicity, mammary gland hyperplasia and uterus atrophy), hepatic system and endocrine system (adrenal gland hypertrophy). Mapping AR together with its chemical interaction partners onto Diseases and Organ and tissue pathologies module identified AR role in prostate neoplasia and prostate carcinoma toxicity that corresponds to AR antagonist therapeutic application. On AR example we showed that our tool can contribute to a better understanding of therapeutic potential of a target inhibition and quick target toxicological assessment.
2098 De-risking Preclinical Drug Development by Transcription Factor Activity Profiling

S. S. Makarov, L. Medvedeva, E. Martsen, and A. Medvedev. Attagene, Research Triangle Park, NC.

Drug toxicity is a leading cause of attrition at late stages of development and a major risk factor for post-marketing withdrawal. Most challenging is the detection of idiosyncratic drug toxicity (IDT). In contrast to dose-dependent intrinsic toxicity, which is usually detected in animal studies, IDT occurs rarely and unpredictably and is often detected only at the post-marketing stage. Assessing IDT risks during preclinical development is extremely difficult due to the lack of a clear mechanistic understanding of IDT pathogenesis. Here, we describe a cell-based approach that predicts IDT liability by assessing perturbations of signaling pathways. Using a multiplex reporter assay (the FACTORIAL™), we assessed the activity of transcription factors (TFs) that connect the cellular signaling pathways with regulated genes. The FACTORIAL™ assay produced TF activity profile (TFAP), a quantitative signature of cell response to a drug. We have evaluated 32 IDT drugs from 12 therapeutic classes with known drug-induced liver injury (DILI) liabilities. We found a common trend: at low concentrations, the TFAPs reflected the primary drug activity, but, beyond certain concentration thresholds (C_{OFF}), these TFAPs transformed into different signatures that indicated “off-target” effects. We estimated that therapeutic concentrations (C_{MAX}) of most drugs in vivo did not reach the off-target thresholds, consistent with the lack of intrinsic toxicity. However, most-DILI-concern drugs were substantially closer to the off-target activity thresholds as compared to their safer counterparts (median C_{MAX}/C_{OFF} of 0.135 and 0.0067, respectively, P<0.00005). That explains an increased IDT risk for most-concern DILI drugs in rare susceptible individuals. Furthermore, we found that drugs from different therapeutic classes shared common off-target TFAP signatures. Querying our database of reference TFAP signatures showed that the most frequent off-target TFAPs matched the signatures for mitochondria inhibitors and inducers of oxidative stress. Therefore, TF activity profiling provided clear quantitative metrics enabling an early-stage assessment of risks and mechanisms of IDT. Supported by the NIH grant R44GM125469.

2099 Characterization of a Modified CNS Tetrad Safety Test in Sprague Dawley Rats

A. Mason1, A. Tomkinson1, M. Coffee2, and L. Burns-Naas3. Gilead Sciences, Inc, Foster City, CA; and Charles River, Ashland, OH.

The cannabinoid (CB) receptor has been considered a potential therapeutic target for multiple indications, however clinical candidates targeting the CB1 receptor showed signs of unwanted CNS activity that resulted in their termination, indicating a need for an early screen that might predict these effects during the lead development phase of drug discovery. The CB tetrad test consists of a number of behavioral assessments (spontaneous activity, catalepsy, body temperature, and thermal sensitivity) designed to assess drugs that induce CB-1 receptor mediated CNS effects. The CB receptor agonist, WIN55,212-2 (WIN), tetrad response was characterized in male Sprague Dawley rats, and the inhibitory effects of the centrally active CB-1 inverse agonist, Rimonabant (RIM), established. Both maximal dose response and the time of peak effect of WIN were established. Adult male Sprague Dawley rats (n=12/group) were administered a single dose of WIN by intraperitoneal (IP) injection at dose levels of 1, 5, 7.5, 10 or 20 mg/kg. Tetrad assessments were evaluated prior to and at 0.5, 1, 2, 4, and 24 hours following dose administration. WIN demonstrated expected increased catalepsy and decreases in spontaneous activity, body temperature and thermal sensitivity at all dose levels. Responses were generally both time and dose dependent with WIN response peaking at 0.5 hours post-dose, with no increase in response or duration of response at dose levels above 10 mg/kg. The inhibitory effect of RIM on the WIN-induced tetrad response was subsequently evaluated. RIM was administered by oral gavage at 0.5, 10, or 30 mg/kg, 2.5 hours prior to the administration of 10 mg/kg WIN IP (n=12/group). Timing of dosing for RIM and WIN targeted the peak exposure of RIM to occur at the time of peak response of WIN (0.5 hours post-dose). Tetrad assessments were performed prior to and at 0.5 hours following WIN dose administration. RIM effectively inhibited the WIN-induced CNS effects in a dose responsive manner with no significant increase in inhibition at dose levels above 10 mg/kg. These data demonstrate the potential utility of the tetrad model in revealing the central-mediated effects of CB1 agonists and antagonists that may be under consideration as drug candidates in multiple therapeutic areas.

2100 A Higher-Throughput Acute Slice Micro-Electrode Array Can Be Used for Neurotoxicity Safety Assessment

G. Cheng1, S. Noji2, Y. Satoko3, M. Trujillo1, and I. Suzuki2. 1Alpha MED Scientific Inc, Berkeley, CA; 2Tokohu Institute of Technology, Sendai, Japan; and 3Screen Holdings Co., Ltd, Kyoto, Japan. Sponsor: W. Xu

Micro-electrode arrays (MEAs) offer many distinct advantages for measuring neuronal and cardiac electrophysiological activity in vitro. The flexibility and efficacy of MEAs offer powerful solutions for drug discovery, safety pharmacology, and toxicology screening. Here, we demonstrate the power of a high-sensitivity MEA engineered for acute brain slices for improving the efficacy and reproducibility of neurotoxicity screening in acute hippocampal slice preparations from mice. We measured network spike activity and decomposed frequency analysis of field potential oscillations (analogous to EEG) in response to compounds known to elicit seizure-like activity. Acute hippocampal slices from 6-8 week old mice were assessed for epileptiform activity in response to compounds that are likely to elicit synchronized network activity typical of seizure-like activity (convulsants). We demonstrate the capabilities of the highly sensitive MED64-Quad system, a novel medium-throughput MEA engineered for acute or cultured slice applications in assessing neurotoxic risk from acute mouse brain slices. Spontaneous firing and the decomposed frequency components of the local field potentials were measured in response to 4-Aminopiridine, Pentyleneetetrazole, Picrotoxin, Picloram, Acetaminophen and Strychnine. We demonstrate the power of the MED64-Quad system in detecting the small amplitude of the spike though high signal to noise ratio. Several measures of number of spikes, interspike interval (ISI), spike amplitude, co-efficient of ISI and CV of spike amplitude were calculated among the test compounds. Three principal components of the spikes were identified. Slow wave frequency components were observed in response to 4-AP and pilocarpine. These results of this study indicated that the MED64-Quad system, in conjunction with acute hippocampal slices from mouse, is a useful assay for screening epileptiform activity, which is a useful neurotoxic assay for screening safety risk of investigational compounds.

2101 Preclinical Safety Assessment of JM4, a Novel 19-Amino Acid Peptide, for Traumatic Brain Injury and Multiple Sclerosis

P. Joshi1, Y. Kale2, K. Elsass2, P. Dowling3, S. Cook1, and P. Terse1. 1NIH/NCATS, Bethesda, MD; 2 Battelle Memorial Institute, Columbus, OH; and 3 Rutgers, The State University of New Jersey Medical School, Newark, NJ.

JM4, a low molecular weight 19-amino acid nonhemopoitetic erythropoietin (EPO) peptide, is being studied for possible traumatic brain injury and multiple sclerosis indications in humans. GLP toxicology studies in rat and dog were conducted to support its clinical evaluation. JM4 was administered by intravenous slow bolus (1 to 5 minutes) once daily for 28 consecutive days followed by 14 day recovery period. Vehicle control article or JM4 was administered at doses of 15, 75, or 300 (rat) and 15, 45, or 105 (dog) mg/kg. In rat, JM4 did not cause any significant effect on mortality/morbidity, clinical observations, body weights, food consumption, functional observational battery (FOB), ophthalmic examinations, micronuclei assessment, anti-drug antibody analysis, and clinical and anatomic pathology. Non-test article related nine mortalities in male rats (2 control, 2 low dose, and 5 high dose) were observed during the treatment phase. In dog, nonadverse dose dependent increases were observed in emesis, excess salivation, and fecal status changes (including diarrhea, soft feces, and mucoid feces) that were attributed to JM4 administration. JM4 did not produce any significant changes in body temperature, body weight (or body weight gain), food consumption, ECG waveforms or intervals, respiratory rate, ophthalmic examinations, anti-drug antibody analysis, or in clinical and anatomic pathology. Systemic clearance of JM4 was rapid with mean half-lives between 0.085 to 1.477 hours (rat) and 0.128 to 0.406 hours (dog). Based on the endpoint evaluated, 300 mg/kg/day dose of JM4 (mean C_{max} 634,500 ng/mL and mean AUC 179,500 hr*ng/mL) in rat and 105 mg/kg/day (mean C_{max} 468,500 and mean AUC 65,600) in dog were considered NOAELs. Taken together, these non-clinical studies of JM4 support its further clinical evaluation. Supported by NCI-Leidos Contract No. HHSN26120080001E, and NINDS under BrIDGS Program.
**2102 Drug Permeation Assessment through Reconstructed Vaginal Epithelium: The Case of Econazole**

L. Ceriotti\(^1\), A. Granata\(^2\), C. Pellevoisin\(^3\), and M. Meloni\(^1\). \(^1\)VitroScreen, Milan, Italy; \(^2\)LabAnalysis, Pavia, Italy; and \(^3\)EpiSkin Academy, Paris, France. Sponsor: E. Dufour

The Medical Device Developmental Tool (MDDT) program adopted includes the use of commercially available human reconstructed vaginal models and considers as endpoints tissue viability and histology. US FDA is taking into consideration in vitro permeation studies (IVPT) to assess the bioequivalence of dermatological products adopting the technical and quality criteria of the OECD in vitro permeation absorption method (TG 428). In the study, the permeation of econazole, antifungal compound, has been assessed on the reconstructed Human Vaginal Epithelium (HVE) (Episkin, Lyon, France) to investigate the relevance of the in vitro approach in gaining information on active bioavailability, absorption kinetic and its biological impact on the viable tissue. The transmucosal permeation has been assessed on a formulation including 1% econazole for a 24h exposure. Econazole analytical method by HPLC-ULPC has been validated on the formulation and biological samples before performing the study. The receptor fluids have been collected at 8h and 24h and at 24h the apical residuals, tissue homogenates were performed, collected and analysed. The permeation study was complemented by information on the integrity of the mucosal model after product treatment by performing Lucifer Yellow (LY) assay, trans-epithelial-electrical-resistance (TEER) measurements and histomorphological analysis. Results indicated that compared to the amount of product applied, 4% and 27.4% of the antifungal compound is permeated through the tissue after 8h and 24h exposure, respectively. At 8h the morphology of the tissues treated with econazole and their barrier function resulted not significantly different from tissues treated with saline solution. On the contrary, at 24h data suggested a modified permeability and potential toxicity of the compound on the tissue with a significant decrease of electrical resistance and an increase LY flux. The histomorphological analysis confirmed the tissue damage after 24h exposure. Results were compared to available data and for the 8h timepoint they were consistent with in vivo and in vitro literature data. The in vitro approach proposed appears of interest within MD biological evaluation and bioequivalence studies with the aim to replace the in vivo Rabbit Vaginal Irritation test currently performed for pre-market approval, reinforcing sustainability of the approach with respect to EU Directive 2010/63 on the protection of animals used for scientific purposes and the US FDA MDDT Program.

**2103 Human Reconstructed Mucosal Models to Assess Drug Permeation**

M. Meloni\(^1\), A. Granata\(^2\), C. Pellevoisin\(^3\), and L. Ceriotti\(^1\). \(^1\)VitroScreen, Milan, Italy; \(^2\)LabAnalysis, Pavia, Italy; and \(^3\)EpiSkin Academy, Paris, France. Sponsor: E. Dufour

US FDA has been extending its consideration for in vitro methodologies to permeation studies (IVPT), drug safety and toxicology. Compared to skin permeation study for which skin explants are available from surgical waste, the availability of mucosae (non-keratinized tissues) from humans is a not a sustainable option. To gain relevance and predictivity vs humans, 3D reconstructed human mucosal models are the most promising alternative to be introduced to assess as first instance the penetration kinetics and passage of new drugs and ingredients. In the present study, the permeation of caffeine used as model drug has been assessed on the Reconstructed Human Oral Mucosa (RHO) (Episkin, Lyon, France) to gain information on caffeine penetration, kinetic and impact on the living tissue. The quality and acceptance criteria of the OECD TG 428 (in vitro percutaneous absorption method) have been followed. The transmucosal passage of a 2% caffeine in water solution on RHO model has been performed during a realistic exposure of 2h. After 15, 30, 60 and 120 min the receptor fluid has been collected and caffeine content quantified by HPLC-ULPC. The permeation study was complemented by information on the integrity of the tissue after treatment with the drug by performing Lucifer Yellow (LY) assay, trans-epithelial-electrical-resistance (TEER) measurements and histomorphological analysis to confirm that the integrity of the biological model during the permeation study is maintained. The results indicated that after 2h the 93.3% of caffeine is permeated through the tissue compared to the caffeine initially applied and a permeability coefficient which nicely correlates with literature data was calculated. After 2h of treatment, TEER measurements, LY permeation data and the H&E stained sections showed at 24h no significant differences from the control tissues exposed to saline solution. These results highlight the relevance and robustness of the in vitro approach for the evaluation of the permeability of drugs and substance based medical devices delivered through mucosal caviities. The use of reconstructed mucosal models in combination with a multiple endpoint analysis approach introduce a reproducible and versatile tool for screening purposes and limits as first step the scientific and ethical concerns regarding the use of animals in toxicology.

**2104 Antifertility Effect of Antituberculosis Drugs Combinations Containing Ethambutol or Streptomycin in Male Rats**

T. Karatsuba, and G. Shayakhmetova. Institute of Pharmacology and Toxicology NAMS of Ukraine, Kyiv, Ukraine. Sponsor: T. Karatsuba, EUROTOX

The antifertility effect of antituberculosis drugs (ATD) in combination, which contains ethambutol (EMB) and EMB alone, in male rats has been reported by us earlier. Analysis of potential effects of different ATD combinations (with or without EMB) on the male gonads is urgently required for the development of more effective and safer regimens for treatment of infertility.

The aim of the study was comparative investigation of the two ATD combinations, which contained isoniazid (INH), rifampicin (RIF), pyrazinamide (PZA) and EMB or streptomycin (STM), effects on male rats’ fertility and spermatogenesis parameters, as well as antenatal development of their offspring. Male rats were divided into 3 groups: 1 - control; 2 - 1st combination (EMB, RIF, INH, PZA); 3 - 2nd combination (STM, RIF, INH, PZA). ATD were given at maximal doses used in clinic. The degree of destructive changes in the spermatogenic epithelium following administration of both ATD combinations was almost the same, but time of spermatozoa motility after administration of combinations 1 and 2 decreased as compared to control 77 and 34%, respectively. Osmotic resistance of spermatozoa following combination 1 administration decreased 65%, whereas combination 2 did not have a significant effect. Combination 1 caused increase of lipid peroxidation (LPO) in testes (13%) and epididymis (38%), whereas after use of combination 2 intensification of LPO was recorded only in testes. In male groups with combinations 1 and 2 administration fertility indexes were 9.09 and 78.12, respectively. Thus, the replacement of EMB with STM reduced the toxic effect of ATD on gonads to a certain extent. The results of our study broaden the theoretical basis for understanding of male infertility possible causes.

**2105 Preclinical Development of a Novel Intramuscular Male Contraceptive: Dimethandrolole-17β-Undecanoate (DMAU, CDB-4521)**

K. Kim\(^1\), J. Gaahagen\(^2\), T. A. Birkebak\(^3\), D. Fairchild\(^4\), L. Iyer\(^5\), C. Wang\(^5\), T. Burch\(^5\), M. Zelinski\(^5\), D. Blithe\(^5\), M. Lee\(^5\), and T. Parman\(^6\). \(^1\)ISI International, Biosciences Division, Menlo Park, CA; \(^2\)Experimental Pathology Laboratories, Sterling, VA; \(^3\)Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; \(^4\)Oregon National Primate Research Center, Beaverton, OR; and \(^5\)National Institute of Child Health and Human Development, Contraceptive Development Program, Bethesda, MD.

The need for an effective and reversible male contraceptive is still largely unmet. DMAU, a testosterone analogue, exerts both androgenic and progestational effects by releasing its active metabolite DMA, which suppresses testosterone production and spermatogenesis. The goal of this work was to develop DMAU as a long-acting injectable male contraceptive. Four preclinical studies in male nonhuman primates (NHPs) were conducted. First, after a single intramuscular (im) injection of 10 mg/kg DMAU to NHPs (n=4), serum levels of DMAU and DMA were maintained for 231 and 266 days, respectively. Second, weekly im injection of 1 mg/kg DMAU for 3 months to NHPs (n=3) caused no adverse effects. DMAU or DMA did not show significant plasma accumulation with this regimen and no toxicity was observed. Third, im administration of 10-30 mg/kg DMAU chronically suppressed spermatogenesis on fertility is reversible. Fourth, a single im dose of 30 mg/kg DMAU was well-tolerated in NHPs and suppressed fertility as indicated by decreases in testosterone and seminiferous tubular hypospermatogenesis indicating suppression of fertility without any adverse effects. Testosterone reduction in testosterone and seminiferous tubular hypospermatogenesis were divided into 3 groups: 1-control; 2-3\(^{rd}\) combination (STM, RIF, INH, PZA); 4-embo- and HHSN275201500002I; ONPRC P51OD011092. The need for an effective and reversible male contraceptive is still largely unmet. DMAU, a testosterone analogue, exerts both androgenic and progestational effects by releasing its active metabolite DMA, which suppresses testosterone production and spermatogenesis. The goal of this work was to develop DMAU as a long-acting injectable male contraceptive. Four preclinical studies in male nonhuman primates (NHPs) were conducted. DMAU or DMA did not show significant plasma accumulation with this regimen and no toxicity was observed. Third, im administration of 10-30 mg/kg DMAU chronically suppressed spermatogenesis in a reversible manner without adverse effects, supporting its potential as a long-acting male contraceptive. The first-in-man Phase 1 im study of DMAU is currently ongoing. Supported by NIH-NICHD Contracts HHSN27520090001C and HHSN275201500002I; ONPRC P51OD011092.
2106 The Impact of High Heart Rates on Quantitative Electrocardiography Evaluation: Can Overlapping P and T Waves Be Accurately Assessed?

I. Mogensen, J. Walisser, H. Jones, and J. Kremer. Covance, Madison, WI.

Accurate marking of electrocardiogram (ECG) waveforms (P, Q, R, S, and T waves) is integral to meaningful cardiovascular evaluation on nonclinical safety studies. Ketamine, a dissociative anesthetic, is often used to restrain non-human primates (NHP) for multi-lead (ML) ECG collections. Physical or chemical restraint results in higher heart rates, causing ECG waveforms of some NHP to overlap where P waves blend with preceding T waves (P on T); P on T may reduce data quality, cause laboratory rework, and add additional animal stress. This study optimized procedures for ECG evaluation and assessed the impact of including P on T waveforms in ECG evaluation. ECG data (1 min means) were collected from ketamine-restrained NHP using Jacketed External Telemetry (JET) with laboratory procedures that mimicked ML ECG collection. NHP JET data (n=24) were collected to determine if ECGs were optimally evaluated prior to ketamine administration and up to 20 min postdose. PR, QT, and QTc intervals across a range of heart rates were compared between two datasets: one dataset with waveforms from all NHP marked (including NHP with P on T) and another with marks removed from waveforms for the subset of NHP with P on T. The standard time for ML ECG collection (10 min postdose), heart rates were higher by 30 beats per minute (bpm, 20%) compared with predose values and decreased to 21 bpm (14%) at 14 min postdose. By comparison, heart rates in conscious, physically-restrained NHP were 86 bpm (58%) higher compared with heart rates when NHP were unrestrained. Time-course evaluation of heart rate on T indicated that ECGs were optimally evaluated in sedated NHP between 14 to 16 minutes postdose, a time range when no P on T was observed. The impact of marking P on T waveforms, evaluated at 10 minutes postdose, indicated the difference between marking and not marking P on T was up to 2 (3%), 14 (6%), and 13 msec (3%) longer for PR, QT, and QTc intervals, respectively. Taken together, these data demonstrate that ML ECGs collected at 14 to 16 min postdose and when no P on T waveforms collected from ketamine-sedated NHP can be accurately marked, thereby reducing data loss and rework, and increasing the overall ECG data quality on toxicology studies.

2107 High Content In Vitro Cell Monitoring of Adjuvant Chemotherapy Effects in Breast Cancer and Treatment-Related Cardiomyopathy

K. Juhász1,2, O. Reinhardt1, R. Knox4, G. Okeyo3, E. Dragicjevic1, S. Stoelzl-Feix1, F. Alves1,3, and N. Fertigi1. 1Nanion Technologies, Munich, Germany; 2Institute for Nanoelectronics, TUM, Munich, Germany; 3Translational Molecular Imaging Group, MPI of Experimental Medicine, Göttingen, Germany; 4Nanion Technologies Inc., Livingston, NJ; and 3Uni Medical Center, Göttingen, Germany. Sponsor: S. Stoelzl-Feix, Safety Pharmacology Society

Impedance changes of cell-covered electrodes give profound insight into cell proliferation and contractility, even over prolonged time periods, providing significant advantage over standard mostly endpoint cytotoxicity assays. Here, this technology was used for monitoring cell regrowth in breast cancer, after chemotherapy treatment in vitro. As the emerging field of cardio-oncology aims to find a balance between oncologic efficacy and reducing adverse cardiovascular effects, we tested the same treatment on induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs). One of the standard clinical regimens for breast cancer is a combination of cyclophosphamide, Adriamycin (doxorubicin) and 5-fluorouracil (CAF) administered for 4 months. Clinical regimens for breast cancer is a combination of cyclophosphamide, Adriamycin (doxorubicin) and 5-fluorouracil (CAF) administered for 4 months. The high-resolution impedance monitoring provides amenable insights into dynamics of cell proliferation and contraction, for in vitro investigations of adjuvant chemotherapy not only in cancer but in cardiac-oncology field.

2108 Concomitant Effects of Clonidine on QT Interval Duration, hERG Current, Heart Rate and Body Temperature in Cynomolgus Monkeys: QT Correction Formula for Changes in Core Body Temperature

A. El Amrani1, H. Huang2, S. Lorio1, F. El Amrani-Callens1, P. Singh1, S. Authier1, and B. Forster1. 1Citoxlab, Evreux, France; and 2Citoxlab North America, Laval, QC, Canada.

A method of QT-interval correction for changes in core body temperature (BT) accounting for circadian variations in conscious non-restrained cynomolgus monkeys and based on QT Fredericia formula (QTfC) was recently proposed by our team. To evaluate the performance of this formula and a QT Bazett (QTb) based formula, we investigated the effect of clonidine, an α2-adrenergic receptor agonist, on BT, heart rate (HR) QT, QTb, QTcT, and QTbCt (=(QTb−13.8Bt)/Bt) and QTfCt (=(QTf−13.8BT)/BT) in four telemetry-collared Cynomolgus monkeys. The intrinsic repolarisation effect of clonidine was evaluated on hERG current (I_{in}) in three HEK 293 cells using the whole-cell patch-clamp technique. The greatest changes in BT and QT interval were simultaneously observed at 2 hours after intramuscular injection of clonidine (100 mg/kg). Decreases in BT (36.6 ± 0.6 vs 38.2 ± 0.6°C, p<0.001) and HR (79 ± 10 vs 158 ± 9 bpm, p<0.01) were observed with significant increases in QT (385 ± 217 ± 12 ms, p<0.001), QTb (433 ± 18 vs 350 ± 11 ms, p<0.001), QTfCt (416 ± 24 vs 298 ± 11 ms, p<0.001), QTbCt (406 ± 19 vs 352 ± 12 ms, p<0.001) and QTfCt (382 ± 16 vs 301 ± 10 ms, p<0.001). Clonidine inhibited I_{in} current by 7.8%, 23.8%, 38.8%, 62.5% and 72.9% at 3, 10, 30, 100 and 300 μM, respectively. I_{in} current was established at 30.6 µM. These results highlight a concomitant collection of effects on QT and HR shortening by acting simultaneously on BT, HR, and hERG current. Under our experimental conditions QTbCt performs better than QTfCt in correcting QT for changes in BT. As clonidine produced a slight inhibition in hERG current, significant increases in QTb and QTfCt were still observed after correction for changes in BT. Additional investigations involving other coadministered drugs and measurements of free plasma concentrations are required to fully validate the use of these QT correction formulae for changes in BT.

2109 An Improved Model for Thorough QT (TQT) Clinical Trials That Explicitly Includes RR and Does Not “Correct” QT

W. D. McGuinn Jr. Drug Development Services, Indianapolis, IN.

The US FDA requires TQT clinical trials of many new drugs to define their effect on the QT interval with the aim of reducing drug induced arrhythmias. The standard statistical method for TQTs applies a mathematical “correction” to the QT interval based (erroneously) on model equations derived by Bazett (1920) and Fridericia (1925). The standard method subtracts placebo QTc values from the QTc values of the treatment group to obtain ΔQTcT at T_{max}. Nevertheless, the removal of RR from the relationship artificially decreases the variance of QTcT. This potentially leads to incorrect sample sizes and type I or 2 errors. QT correction also artificially increases the values of QT. The standard method assumes that the drug has no important effects on RR; this is frequently not the case. Using publicly available data from an US FDA sponsored trial, I reanalyzed QT and RR values from volunteers given dofetilide, verapamil, ranolazine, and quinidine in a linear mixed effect model. I included RR and uncorrected QT explicitly in the new model allowing for interaction between RR and concentration. The model is: QT ~ Intercept + RR + Concentration + RR:Concentration + 1|Volunteer. To obtain model estimates of the drug effect at 60 bpm, I set RR = 1000 ms in the model solution. I set the value of concentration to the maximum concentration for each volunteer to obtain the maximum difference from placebo. I compared the results with those from the placebo group using Student’s t-test and determined means to obtain the maximum difference from placebo. I compared the results with those from the placebo group using Student’s t-test and determined means to obtain the maximum difference from placebo. 

For in vivo tumor regrowth investigation, H8N8 T3.2 cells were treated with CAF for a second time. Changes in impedance and confluency of these cells, were used as a measure of toxicity with cell viability monitored for 500h, under physiological conditions. Intrinsically dose-dependent effects of CAF clinical treatment: decreased tumor growth and treatment cycle-dependent regrowth of tumor cells was observed. We further investigated putative cardiovascular side effects of CAF mix and paclitaxel and their long-and short-term implications on IPS-ECMs viability. Our results show a dose-dependent negative effect of paclitaxel on the viability of IPS-ECMs, as seen by the base impedance reduction. This was also observed for doxorubicin alone, but not the rest of the CAF compound mix. Paclitaxel and CAF also induced negative changes in cell contraction properties. In summary, long-term high-resolution impedance monitoring provides amenable insights into dynamics of cell proliferation and contraction, for in vitro investigations of adjuvant chemotherapy not only in cancer but in cardiac-oncology field.

2019 SOT Annual Meeting 262
relationship between QT and RR. QT "correction" renders these changes invisi-
ble. Incorrect estimates of the pharmacodynamic effect of a drug on the QT
interval may lead to misinformed regulatory or commercial decisions.

2110 A 4-Week Repeated Dose Toxicity Study of
TPN672 in Beagle Dogs
L. Gong, G. Huang, J. Wu, H. Lu, L. Li, Z. Wang, J. Shen, H. Jiang, and
J. Ren, Shanghai Institute of Materia Medica, Chinese Academy of Sciences,
Shanghai, China.

TPN672, a novel chemical structure targeting multiple receptors for treating
schizophrenia, is currently in phase 1 clinical trial. TPN672 was effective in
treating phenycyclidine-induced psychosis at doses as low as 0.03mg/kg in
mice. The objective of this study was to evaluate the potential toxicity of
TPN672 in Beagle dogs. TPN672 was orally administered to dogs (5/six/dose)
at doses of 0 (0.5% CMC-Na, vehicle control), 0.1, 0.6 and 3.0 mg/kg once daily
for 4 weeks followed by a 4-week recovery period. Toxicity was assessed by
examining clinical signs, body weight, food consumption, body temperature,
ophthalmoscopy, ECG, blood chemistry, hematology, coagulation, urinaly-
sis, gross pathology, organ weights and histopathology. Key findings were
as follows. All the animals were well tolerated. No obvious changes were
found in hematology, plasma chemistry, coagulation, urinanalysis and prolactin.
Decreased bodyweight was found in both dose males on the first week and
then when that was recovered gradually. Pupillary dilatation, vocalization, tremor
occurred in some animals. Decreased serum glucose was observed at 3 mg/kg.
Slight increase of serum alanine aminotransferase were observed in 3 mg/kg group.
These effects were likely exaggerated pharma-
cological effects of TPN672. Besides, an increase of heart rate was observed for
all dose animals. A slight alopecia of the prostate occurred in males dosed
at 3 mg/kg. These changes were recovered after the 4-week recovery period.
Taken together, we concluded that a dose of 0.1 mg/kg/day was the lowest
observed-adverse-effect level (LOAEL) in both sexes. At the LOAEL, the Cmax
and AUC0-24h of TPN672 at week 4 were 60.5± 35.2 ng/mL and 778.0±642.4
ng·h/mL, respectively, for males and 53.9±9.6 ng/mL and 572.0±149.3 ng·h/
ML, respectively, for females. Compared to the two anti-schizophrenia drugs, no
changes in prolactin levels were found in this study suggesting that TPN672
may have less adverse effects related to hyperprolactinemia in clinical use.

2111 Safety Studies and Preclinical Development of
Novel EPAC Inhibitors as Promising
Therapeutics for Drug-Resistant Rickettsiosis
L. L. Rausch, K. Kim1, E. Riccio, R. Doppalapudi, K. O’Loughlin1, T.
Birkebak, N. Ye, Y. Zhu, F. C. Mei1, P. Wang, J. Zhou, X. Cheng2, and
T. Parmann 1, SRI International, Meno Park, CA; 2, University of Texas
Medical Branch, Galveston, TX.

Rickettsiae are major human pathogens and potential bioterrorism threats. It
has been forecasted that temperature increases due to global climate change
will lead to more widespread incidence of rickettsiosis, a tick-borne disease.
Although broad-spectrum antibiotics, strains-resistant Rickettsia prowazekii have been developed in some laboratories. Rickettsia australis can be fatal if not treated in a timely manner. It has been demonstrated that cyclic AMP (cAMP)/Epac1 signaling axis plays a key role in con-
trolling various cellular functions in endothelial cells including initial bacterial
adhesion and invasion. The inhibition of cAMP/Epac1 axis in the endothelial
cells is important in the prevention of rickettsiosis. The reported data from
Epac1 knockout mice demonstrated that deletion of the Epac1 gene in mice
protected against a lethal dose of Rickettsiae, making Epac 1 a novel therapeu-
tic target for treatment of rickettsiosis. To this end, our team is developing the first-in-class Epac 1-specific inhibitors as group 1 treatment. About 35 ESIs
were screened for genotoxicity using the in vitro Ames mutagenicity assay
with 3 compounds tested in the in vitro Mouse Lymphoma (MOLY) assay. ESIs
with high in vitro potency and no genotoxicity were tested in in vitro metabo-
ism, as well as in safety and pharmacokinetic studies in mice. Three drug
candidates (ES109, NY0173, and NY0541) with minimal toxicity and desirable
pharmacokinetic profiles were selected to move forward to preclinical safety
assessment in rats and dogs. NY0173 and NY0541 have been identified suit-
able for Investigational New Drug Application (IND)-enabling studies as novel
rickettsioses therapeutics. Here we discuss the safety and preclinical develop-
ment of ESIs leading to the selection of the final two promising therapeutic
candidates. Supported by NIH-NIAID grant 1R01AI111464.

2112 A 9-Month Oral Toxicology, Efficacy,
and Pharmacokinetic Study of
Dimethandrolone-17β-Undecanoate (DMAU, DDB-4521)
J. Gaehagen1, D. Fairchild1, C. Green1, C. McFarlane1, R. Sweezy1, C.
Wang2, D. Blithe2, M. Lee, and T. Parmann 1, SRI International, Bio-
divesions Division, Menlo Park, CA; 2, Los Angeles Biomedical Research Institute at
Harbor, Torrance, CA; and University of California: Health and Human
Development, Bethesda, MD.

DMAU is being developed as a potential oral male contraceptive. In this study,
toxicity of DMAU and its active metabolite DMA was evaluated. Adult male
Cynomolgus macaques received daily oral doses of 0, 0.3, 1.5, 3 and 0.75/10
mg/kg/day for 9 months followed by a 3-month recovery period. One group of
males received 0.725 mg/kg/day for 6 months followed by 0.75/10 mg/kg/day
during the first 6 months of the study with animals in the recovery groups
gaining moderate to significant weight from baseline. The toxicokinetic (TK)
analysis did not show significant plasma accumulation of DMAU and DMA
during treatment. Peak DMAU plasma levels on Day 1 ranged from 2.68-23.02
ng/mL for doses of 0.3-3.3 mg/kg/day with Tmax ranging from 2-3.4 hr. DMA TK
profiles on Days 190 and 269 suggested steady DMA levels up to 24 hr post
each dose. DMA peak plasma values on those days ranged from 3.25-10.75
ng/mL with Tmax ranging from 2-16.7 hr due to apparent steady DMA plasma
levels. Dose increase to 10 mg/kg/day on Day 190 did not result in elevated
total plasma exposure since there was no appreciable accumulation of DMAU
and DMA over time and inter-dosing periods. The adverse event profile with
DMAU at the oral doses given daily was well-tolerated and the no observed
adverse effect level (NOAEL) exceeded 3 mg/kg/day for approximately 6
months and 10 mg/kg/day for 3 months. The maximum tolerated dose (MTD)
could not be determined since all dose levels were well tolerated. Work sup-
ported by NIH-NICH Contracts HSNS275200900014C and HSNS275201500020.

2113 Investigation of Potential Target-
Independent Uptake Mechanisms of ADC
Induced Thrombocytopenia
P. S. Mahalingaiah, R. Clurionis, S. Nottoli, G. J. Jenkins, S. Jeffries, and T.
R. Van Vleet, Abbvie, North Chicago, IL.

Antibody-drug conjugates (ADCs) are emerging novel anticancer chemother-
apeutics designed to increase the therapeutic index of chemotherapeutics
with more selective delivery of highly cytotoxic agents to cancer cells. How-
ever, non-target mediated hematotoxicity (toxicity to blood cells) mainly
affecting megakaryocytes (platelets) lineage cells, is commonly reported as a
target-independent dose limiting toxicity for multiple ADCs with microtubule
inhibitors in pre-clinical and clinical studies. In this study, we investigated the
lineage-specific hematotoxicity (thrombocytopenia) potential of a non-bind-
ing MMAF based tool ADC using in vitro human bone marrow derived CD34+ hematopoietic stem/progenitor cells. Expansion and differentiation of CD34+
lineage cells into specific hematopoietic lineages (myeloid, erythroid and megakaryo-
cytic lineages) and expression of non-target mediated uptake mechanism
related candidate receptors were evaluated by RT-PCR and flow cytometry
analyses. In general, expression of activating type FcγIRa expression was high in
all three lineages differentiated from CD34+ cells, whereas inhibitory type
FcγIRb expression was observed only in myeloid and erythroid lineages, not in
megakaryocytic lineage cells. Also the rate of non-specific endocytosis (dextran uptake) was relatively low in megakaryocytes when compared to
typical myeloid lineage and other phagocytic cells. Treatment of non-binding ADC
targeting the non-mammalian protein (tetanus toxoid) conjugated to MMAF
with non-clearable mAb linker during different stages of differentiation (7 and
14 days) revealed relatively higher toxicity in megakaryocytic lineage cells. In
addition, pre- and co-treatment with FcγRII blocking antibody significantly
reduced internalization, intracellular free payload release and ADC-induced
megakaryocyte loss. Further testing of different tool ADCs engineered to alter
FcγR binding revealed that mutant IgG (with loss of FcγR binding) contain-
ing ADCs had significantly reduced toxicity in megakaryocytic lineage cells.
Results of this study conclusively confirmed that FcγRII-mediated non-target
mediated uptake in differentiating megakaryocytes is an important mecha-
nism for MMAF based ADC induced thrombocytopenia.
2114 Characterization of a Novel Oxygenating Therapeutic

A. Dabi, G. V. Aquino, F. Zhang, and E. D. Bruce. Baylor University, Waco, TX.

Ox66TM is a novel therapeutic with possible uses in oxygenation of blood and tissues. However, the exact structure and mechanism by which the compound may be able to induce oxygenation is not yet understood. This study aims to understand the chemical structure and formula of Ox66TM, thereby opening the way to understanding the mechanisms by which oxygen can be released and absorbed following exposure to the drug particles. In order to elucidate chemical structure and activity, various analytical chemical techniques were used, including energy-dispersive X-ray spectroscopy, infrared spectroscopy, mass spectrometry, and x-ray crystallography. All analytical techniques used a nanosized form of the particle with a particle size of around 600 - 700 nm. Solubility for purposes of mass spectrometry was achieved using a basic solution of ammonia, water and methanol. The results reveal that the compound is amorphous, composed mainly of oxygen and aluminum, and contains a larger and more complex structure than simple aluminum compounds such as alumina, aluminum sulfate, or aluminum nitrate. Furthermore, when dissolved in a basic solution containing ammonia, the aluminum ions exhibit a dynamic chemical behavior where various ligands are exchanged off within a liquid. This study contributes to the understanding of the mechanism of oxygenation of Ox66TM and opens the way to understanding the mechanisms by which oxygen can be released and absorbed following exposure to the drug particles.

2115 Preclinical Evaluation of Pharmacokinetics and Toxicity of AT1965, a Novel Immunotherapeutic Agent

A. Sengupta1,2, M. Samarla2, M. Pandey1,2, A. Sarkar1,2, M. Roy1,2, and S. Sengupta1,2.1 Invictus Oncology Pvt. Ltd., Delhi, India; 2Akamara Therapeutics Inc., Philadelphia, PA; and 3Bingham and Women’s Hospital, Cambridge, MA. Sponsor: A. Sengupta, American Association for Cancer Research

Triple-negative breast cancer (TNBC) is an aggressive form of cancer occurring in 15-20% of breast cancer patients, with a median survival of 13 months. There is an urgent need for new approaches that are efficacious and safe for TNBC patients. We have designed AT1965, a novel therapeutic with remarkable anti-tumor activity in murine TNBC models as well as potential therapeutic utility in the clinic. AT1965 was predominantly excreted through hepatobiliary and renal routes. The PK of AT1965 determined in 4T1 tumor bearing female Balb/c mice; female Sprague Dawley rats and female Beagle dogs at various doses and schedules reveal that AT1965 exhibited a high exposure, slow systemic clearance and a proportional increase in drug exposure. For safety assessment of biologicals, the non-human primate (NHP) is often selected for longer-term studies if toxicity profiles are ‘similar’ in two species in short term studies. An NC3Rs/Association of the British Pharmaceutical Industry (ABPI)-led international consortium is reviewing the need for two species in regulatory toxicity studies. We collected data on 172 molecules from 18 organisations, including 46 monoclonal antibodies (mAbs), 15 recombinant proteins (RPs), 10 synthetic peptides (SP) and 6 antibody-drug conjugates (ADCs) that followed ICHS6 guidelines. We investigated which molecules used one or two species, and for those using two, whether any reduced to one species during the package. We also collated the incidence of similar target organ toxicities between species in short term (2-13 weeks) First-in-Human (FIH) and long-term studies if toxicity profiles are ‘similar’ in two species in short term studies. An NC3Rs/Association of the British Pharmaceutical Industry (ABPI)-led international consortium is reviewing the need for two species in regulatory toxicity studies. 2119 Micro-CT and Histopathology Characterization of Atherosclerotic Plaque in Aorta from High Fat Diet-Fed Ovariectomized Apolipoprotein E Knockout Mice

M. Guillot\textsuperscript{1}, J. Boyd\textsuperscript{1}, J. Bienvenue\textsuperscript{1}, M. Feli\textsuperscript{1}, C. Glaus\textsuperscript{2}, J. Turk\textsuperscript{2}, V. Stadelmann\textsuperscript{3}, and A. Varela\textsuperscript{4}. \textsuperscript{1}Charles River Laboratories, Senneville, QC, Canada; \textsuperscript{2}Amgen, Thousand Oaks, CA; and \textsuperscript{3}Scanco Medical AG, Bruttisellen, Switzerland.

Atherosclerosis is a systemic, multifactorial disease affecting arteries throughout the body causing severe health consequences and representing a serious concern that can be assessed in nonclinical studies. The objective is to quantify the morphologic changes in atherosclerotic plaques in aortas from high fat diet-fed ovariectomized (OVX) Apolipoprotein E (Apoe) knockout (KO) mice by micro-Computed Tomography (μCT) and characterize associated plaque histopathology. Forty-two Apoe KO and Wild Type (WT) C57BL/6 female mice (Jackson Laboratories) were fed a high fat diet starting at 5-6 weeks of age and were OVX at 8 weeks of age. The procedures involving the care and use of animals were approved by CRL’s Institutional Animal Care and Use Committee. Prior to undergoing a whole-body cardiac perfusion, animals were euthanized at 13, 18 and 26 weeks of age (14/group) by cardiac puncture while under isoflurane anesthesia. The aortas in situ were transferred in formalin, cleaned of adipose tissue and scanned at 10 μm voxel size using a Scanco Medical AG μCT-100. Images were analyzed using 3D morphology to quantify atherosclerotic mineralized and total plaque volume after immersion in a 5% phosphatungstic acid solution. The tissues were then transferred for histopathology examination. OVX Apoe KO mice presented progressive increases in plaque volume and showed statistically significant increases in total plaque volume (+205%, +1346% and +7838%, at 13, 18 and 26 weeks of age, respectively) compared to OVX WT mice. Mineralized plaques were only detected at 26 week of age in OVX Apoe KO mice. Atherosclerotic plaques noted in the aorta were categorized according to Stary-derived types 1 through 5, with a variable number of plaques showing areas of necrosis and cartilaginous metaplasia. Results were consistent with the expected progressive development of atherosclerotic plaques in this model. Micro-CT and histopathological evaluations provided a complementary assessment of atherosclerotic plaque formation and can be used as either as a model for efficacy or as potential safety endpoint for drugs with potential atherosclerotic plaque liability.

2120 Detection of Organometallic Compounds and Their Toxicity in Zebrafish Using ICPMS Metal Equivalents

B. Karas\textsuperscript{1}, L. Córte-Real\textsuperscript{2}, L. White\textsuperscript{1}, A. Valente\textsuperscript{1}, K. Cooper\textsuperscript{1}, and B. Buckley\textsuperscript{1}. \textsuperscript{1}Rutgers, The State University of New Jersey, Piscataway, NJ; and \textsuperscript{2}Universidade de Lisboa, Lisboa, Portugal.

Organometallic anticancer drugs are being developed at an increasing rate which drives a need for a high through-put toxicological assessment. The zebrafish model has become a powerful platform for screening large numbers of these novel compounds. In this toxicological screening assay there is a necessity for analytical methods which can detect tissue doses for comparison across eukaryotic systems. Although zebrafish are an attractive assessment tool, because of lower cost, and higher through-put compared with rodents, their low mass (<1g adults and 100 µg eggs) make determining tissue dosages difficult. We hypothesize that measuring metal equivalents using ICPMS after organometallic exposure has the sensitivity to determine zebrafish tissue dose and to establish NOAELS and LOAELS. Two anti-cancer drugs, cisplatin and a novel Ru-based compound, PMC79, were evaluated. Nominal cisplatin concentrations of 0, 3.75, 7.5, 15, 30 and 60µg/mL were evaluated. The corresponding cisplatin tissue doses were 0.05, 8.7, 23.5, 59.9, 192, and 461.9 Pt(ng)/embryo. The cisplatin toxicological endpoint was LC50: 31 mg/L (158 µM) and EC50 for delayed-hatching was 5 mg/L (25.6 µM). The LOAEL was 3.75mg/L (19.2 µM) and the tissue dose was 8.7 Pt(ng)/embryo (44pmoles). The PMC79 water-borne analytically determined were 0.17, 0.44, 0.67, and 0.76 mg/L of Ru, respectively. Viable larvae at the three lowest concentrations had tissue doses of 0.19, 0.41, and 0.68 mg/larvae, respectively. The LC50 was 0.79 mg/L (7.8 µM). The NOAEL was determined to be 0.17 mg/L (1.7 µM) and the LOAEL was determined to be 0.44 mg/L (4.3 µM). Cisplatin and PMC79 resulted in distinctly different lesions, and PMC79 was more potent than cisplatin. The ICPMS method has been successfully applied to 5 additional novel Ru-based anticancer compounds for which the zebrafish LC50 values were established. Coupling a sensitive analytical method with the zebrafish model allows for evaluation of potency and organ system toxicity on a delivered tissue dose basis. This research was funded by NIAES-Rutgers NJ01201, NIH-MIEHS P30 ES050022, and Training Grant T32 ES 007148, FCT (project UID/QUI/00103/2013), FCT/2013 Initiative Project IF/013023/2013 FCT, POPH and FSE - European Social Fund. Ph.D. Grant (SFRH/BD/100515/2014).

2121 Multiplexed Screening of Drug Induced Mitochondrial Dysfunction and Cytotoxicity

Recent years have seen a growing appreciation of the importance of the mitochondria and associated metabolic machinery as sites for off-target drug effects, contributing to safety-related attrition and post-market withdrawals. High-throughput in vitro metabolism assays are of particular importance in both the identification and delineation of such liabilities. However, combining both cytotoxicity and mitochondrial toxicity measurements into a single assay offers an opportunity to both simplify testing and provide more context to the characterisation of drug-induced mitochondrial dysfunction observed after longer term exposures. Here we describe a multiplexed assay measuring both mitochondrial function and cell viability in a single 96 well plate. Mitochondrial function is determined directly using an oxygen consumption assay (MitoXpress Xtra), while cell viability is determined in the same well by interrogating cell membrane integrity using Calcein AM. A simple mix-and-measure workflow prevents cross-talk minimises wash steps, and provides robust metabolism and cytotoxicity read-outs (Z’ >0.67). Method utility is evaluated using a compound panel including Antimycin, Oligomycin, Flutamide, Nefazodone, Tamoxifen and Chloramphenicol. Compound responses are unaffected by multiplexing. Additionally; compounds such as Flutamide, with a known direct mitochondrial liability display a more rapid and pronounced effect on cell metabolism than on viability (IC\textsubscript{50}= 8 μM for oxygen consumption assay, ≥100 μM for viability assay after 48h on HepG2 cells), while generally cytotoxicants such as Tamoxifen reveal similar metabolic and cytotoxic responses. The value of measuring maximal respiratory capacity (FCCP treatment) is also assessed, and in the case of Chloramphenicol, is shown to better enable detection of eroded metabolic capacity. Together these data illustrate that a multiplexed assessment of cytotoxicity and mitochondrial dysfunction is feasible, thereby simplifying safety screening, while differential sensitivity can inform on the specifity of any observe mitochondrial dysfunction.

2122 Use of Cytotoxic TNF Interaction to Classify Drugs According to Their Ability to Cause Idiosyncratic, Drug-Induced Liver Injury: Influence of Classification Modeling and of Categorization Criteria

H. Mollon, R. Roth, and P. Ganey, Michigan State University, East Lansing, MI.

Published results indicate that numerous drugs which cause human idiosyncratic, drug-induced liver injury (IDILI) synergize with tumor necrosis factor-alpha (TNF) in killing hepatocytes in vitro. Using a 24-drug set and logistic modeling of drug concentration-response (cytotoxicity) curves in the presence and absence of TNF in HepG2 cells followed by receiver operating characteristic analysis, we were able to classify drugs according to their IDILI liability with high sensitivity (0.93) and specificity (1.00) (Mairui et al. 2017). In the present study, we compared this approach to a simpler one in which the basis for classification was whether the drug was cytotoxic alone or in the presence of TNF. At concentrations of 10 μM, the resulting specificity and sensitivity were lower than that achieved with the modeling approach. In this exercise and in the Mairui et al. (2017) study, the “true” IDILI+...
2123 Establishing a Toxicologically-Based Level for β-Glucans

C. Schubert, and C. Moudabal,

β-glucans (βGs) are polysaccharide characterized by a variety of different beta-galactosidic bonds, typically 1,3,1,6 glycans. Bonds with branches of either 1,4 or 1,6 linkages that are present in cell walls of a wide variety of prokaryotic and eukaryotic organisms such as yeast, fungi, and seaweed. They appear as potential contaminants in large molecule (LM) pharmaceuticals, primarily from the use of cellulosic filters. In addition, naturally derived raw materials such as sucrose and trehalose during LM pharmaceutical manufacturing. βGs are large molecules and similar to endotoxins (even if weaker) in that they may elicit inflammatory responses leading to potential safety concerns following exposure to pharmaceutical products contaminated with this sugar. While USP has provided limit values for endotoxins in common injectables, this may elicit inflammatory responses leading to potential safety concerns following exposure to pharmaceutical products contaminated with this sugar. While USP has provided limit values for endotoxins in common injectables, there are no such limit values available for βGs. Hence, internal safety limits can be adhered to by developing a toxicologically based level (TBL) for βGs. Published non-clinical data are based on oral and parental testing of various types of βGs including soluble, particulate, and yeast glucan in various animal models. A TBL for βGs was calculated by analyzing toxicologically based levels in cell lines.

2123a A Risk Assessment Pathway (RAP) Map for Setting Impurity Limits for Pharmaceuticals

R. Sandhu, M. A. Maier, R. A. Jolly, D. D. Dolan, E. Lovsin Barle, and J. Berce,

A health-based dose limit set for any substance is a culmination of a myriad of decisions made by risk assessors during the risk assessment process. These decisions address data utilisation, risk assessment technique selection and confidence estimation, among other considerations. Since risk assessments are complex, and decisions made in the face of variable uncertainty, different risk assessors can arrive at different limits even for the same chemical and exposure scenario. In the absence of transparency in evaluation, such differences appear inexplicable and erode confidence in the process and outcomes of risk assessment. To help address this problem, we created a decision support framework for pharmaceutical impurity risk assessment that is reconfigurable in light of existing frameworks that focus on limited mutagenic (e.g., setting a limit in the absence of mutagenicity data). To establish the prototype framework, we first evaluated pharmaceutical impurity guidances from several organizations such as ICH M7, ICH Q3C, Risk MaPP and EMA HBEL guidances as well as peer-reviewed publications focused on developing harmonized methods. We extracted information from these guidances and existing frameworks to generate a map based on key characteristics identified in our analysis: exposure scenario applicability (e.g., route, duration, dose rate), data quality and quantity requirements, substance mode of action properties and regulatory domains. We integrated these elements in a structured format to help decision makers systematically weigh evidence related to objectives, options, and considerations for each key step in the limit derivation process. The framework was evaluated using three case studies of different types of impurities; a potentially mutagenic pharmaceutical intermediate with no data, a buffer present in an intravenous formulation and a leachate. The results showed that the framework was workable, as judged by its ability to assist the user in arriving at reasonable conclusions but required iterative modification with each additional case study. Further refinement of the decision support tool will be achieved by additional testing against case studies with different types of impurities and scenarios. The framework is intended to grow in expressivity and adapt for different compound classes as needed to assist risk assessors to use it to conduct their risk assessments, so that it continually improves with time.

2124 MASOT Education and Outreach Committee Partners with Women in Science and GOALS for Girls to Present Forensic Toxicology Concepts to High School Students

A. Dhaneshwar, D. Hardej, and B. Gonzalez,

On August 10th, 2018 the MASOT Education and Outreach Committee partnered with the Women in Science (WIS) Association from St. John’s University and the GOALS for Girls Program from the Intrepid Sea, Air and Space Museum to conduct a pharmacology and toxicology program for 50 rising 9th and 10th grade girls in the GOALS (Greater Opportunity for Advancement and Leadership in Science) program. The experiment provided for the two 1-hour sessions, called “Forensic Toxicology”, utilized a commercially available kit produced by Innovating Science by Aldon Corporation. The experiment involved the use of simulated urine samples from the substances (alcohol, opiates, cannabis and cocaine) and the use of prescriptive tests such as Simon’s and Marquis Tests for initial detection. Participants worked in groups of 4-5 and were supervised by MASOT Education Committee members and WIS scholars to perform the experiments. The girls were introduced to the concept of forensic toxicology, given information on each of the substances that might be found in the simulated urines and were presented with scenarios before carrying out the experiment. Emphasis was placed on the special care required for forensic specimens to maintain chain of evidence and follow up experiments for definitive analysis after presumptive tests. Participants engaged in all phases of the experiment as they distributed urine to test tubes, added detection chemicals and observed color changes indicative of the substances being detected. The students recorded their results after each experiment. Skills that were learned during these sessions included: proper handling of scientific specimens, accurate application of test agents, observation and estimation of color changes associated with the detection methods and recording and interpreting results. The participants observed positive results with each of the experiments and discussed results obtained from each group. Following the workshop, participants were surveyed to indicate what skills and knowledge were achieved due to the session.

2125 Hands-On Genetics Instruction during a Toxicology High School Summer Program

Introducing students early in their education to the fields of toxicology and environmental health sciences is critical to developing the next generation of talented and dedicated scientists. Towards this effort, the Toxicology, Health and Environmental Disease (THEED) program was established to engage high school students interested in pursuing scientific careers. A critical goal of THEED is to provide the basic concepts and skills of designing and conducting toxicology studies including dose-response relationships, histopathology, immunohistochemistry, and genetics. Each year, the program is assessed by the students through pre- and post-surveys. For the past 6 years, the genetics laboratory has received the highest scores in student satisfaction. The genetics exercise exposes students to different methods of modern biological research. They are responsible for (1) extracting and isolating their own DNA (supplied from cheek cells), (2) using polymerase chain reaction (PCR) to amplify their DNA, (3) digesting PCR products, and (4) analyzing PCR products by gel electrophoresis. Phenylthiocarbamide (PTC) is an organic compound that either tastes very strong, mild or is virtually tasteless, depending on the genetic makeup of the taster. The ability to taste PTC is a genetic trait. If a single nucleotide polymorphism (SNP) is present, the receptor still cleaves the DNA and a restriction fragment length polymorphism will separate on an agarose gel. In this case, the student is likely a strong or weak taster of PTC.
the SNP is not present, no cleavage will occur, and the student will likely not be able to taste the PTC. Before unveiling the results, the students taste the PTC paper and compare their taste of PTC to their genetic results. Students observed a strong correlation between genotype and phenotype. Using a Likert scoring system of 1 (low) to 7 (high), students (N=44) rated the genetics laboratory a 5.95 (mean). The principles learned in this activity can be applied to forensic toxicology for use in DNA analysis, medicine to determine genetic predispositions, and animal experimentation such as inbreeding. In summary, a genetics-based laboratory activity exposes high school students to the importance of genotype-phenotype relationships in biology and toxicology. Supported by NEHS T32ES007148, P30ES005022, and U54AR055073.

2126 Engagement of Undergraduate Students in Community-Based Environmental Health Science

C. Doherty1, R. Guerrier2, L. C. Smith3, D. L. Laskin4, E. Pivnick1, L. M. Aleksunes1, and B. T. Buckley5. 1Rutgers, The State University of New Jersey, Piscataway, NJ; 2Benjamin Franklin High School, Philadelphia, PA; and 3Isles, Inc., Trenton, NJ.

Fieldwork is an integral component of learning for students pursuing science majors, but is often overlooked while performing laboratory research. Fieldwork allows students to actively participate in sample collection, and make direct connections between sample site selection and the outcomes of their laboratory analyses. We provided 12 undergraduate students in the Rutgers Undergraduate Research Program (RURP) with an opportunity to conduct fieldwork as part of their 10-week fellowship, which included interactive sessions on heavy metal toxicity and environmental contaminants. The purpose of this activity was to engage students with a community that has a long industrial history, and concerns regarding the consequences of heavy metal contamination. Of particular concern is exposure to high levels of lead (Pb) in children, which affects the central nervous system and may lead to developmental delays. For this effort, 12 students, 2 teachers, and 1 postdoc fellow worked with 6 members of Isles Inc., a community development and environmental organization based in New Jersey, to sample soil and street dust for Pb contamination in an urban environment. Four sampling sites in Trenton were preselected, although students determined the individual soil and dust sample locations. The sites included a former smelter, a former ink/battery manufacturing facility, and a redeveloped land for housing/commercial use. Students kept field notes on sample characteristics and drew maps of each sample location with proximity to roads, schools, and public parks. ICP-MS analysis revealed widespread elevated Pb levels (>125 ppm) above naturally occurring levels (<10-50 ppm) throughout the study region. Mean Pb levels in soil were 155 ppm (range: 19-566 ppm, n=24) and dust were 125 ppm (range: 14-533 ppm, n=22). The highest Pb levels (>500 ppm) were observed in land around the former Magic Marker/Philco Battery site. Mean Pb levels in soil were 155 ppm (range: 19-566 ppm, n=22) and dust were 125 ppm (range: 14-533 ppm, n=22). The highest Pb levels (>500 ppm) were observed in land around the former Magic Marker/Philco Battery site.

2127 Using Low-Cost Air Pollution Sensors as an Educational Tool in an Undergraduate Science Course

J. Mirowsky, SUNY College of Environmental Science and Forestry, Syracuse, NY.

Studying air pollution – particularly air particles - can be complicated due to the high cost of sampling equipment, the long times required to collect samples, and sensitive balances and environmental conditions needed for weighing. This can be remedied by using air particle monitors, which traditionally are very expensive, costing thousands of dollars per monitor. However, in the past few years there has been a recent influx in the creation of low-cost air particle monitors, which range from $100-$2,500 each, are commercially available, and come in a wide variety of designs and capabilities. It should be noted that currently no low-cost air pollution sensor meet US EPA requirements for regulatory applications, but their use is becoming more widespread to supplement US EPA monitors and for citizen science projects. However, to our knowledge, very little work has been done trying to incorporate these new low-cost air sensors into an educational curriculum, where their cost and ease of use can overcome the previous barriers of studying air particle concentrations in various settings. Therefore, a series of laboratory exercises have been developed for an upper-level undergraduate science course using one type of low-cost particle sensor - the AirBeam. There were 4 main parts to this experiment. In the first part, students compared particulate matter (PM) concentration when they burned scented vs. unscented candles to determine whether adding a scent to a candle influences PM concentration. In the second part, students compared PM concentrations when they burned one vs. three candles to determine whether adding an additional source of PM influenced the overall concentration. In the third part, students used a chemical flame hood to assess how air flow influences PM concentration by burning incense in the middle of the hood and changing the location of the AirBeam to be either “upwind” or “downwind” of the incense. In the last part, the students took the AirBeam to a location of their choosing to assess “real world” concentrations of PM. Previous locations assessed were bathrooms, elevators, near smoking areas, and from e-cigarette vaping smoke. Using this sensor allowed the students an opportunity to measure PM concentrations in real-time using a cost-friendly and user-friendly new tool.

2128 Improvisation as a Teaching Tool to Be Incorporated into Summer Undergraduate Research Programs

M. Phelps, L. Xiang, and H. Swanson. University of Kentucky, Lexington, KY.

Summer undergraduate research programs are uniquely poised for not only offering authentic “hands-on” laboratory experiences, but also programming to enhance students’ career readiness. Areas of professional development of particular interest are small group activities focused on improving the students’ leadership and communication skills. Improvisation, when used as a small-group collaborative learning exercise, is thought to help students learn how to respond to others, embrace their fears and develop better listening skills. Many of these skills require empathy. With this in mind, we developed a three-hour improvisation workshop involving undergraduate students and their near-peer mentors, all of whom were participants in our summer undergraduate research program. The workshop used a variety of verbal and nonverbal exercises including “Yes and...”, “storytelling”, and “mirror mirror”. To evaluate empathy, the 15 participants completed a self-report questionnaire (known as the Empathy Quotient, EQ) prior to and following the workshop. Total EQ scores and the scores of subscales of empathy; emotional reactivity, cognitive empathy, and social skills were evaluated. Pre-workshop, total EQ scores of the participants ranged from 19-59. However, there was no significant difference between the pre-workshop EQ scores as compared to those obtained post-workshop. At the end of the 10-week program a survey was administered to evaluate all of the program activities. In this survey, 28.6% of the respondents indicated that with respect to enhanced communication and self-confidence, the improvisation workshop helped “a lot” while 57.2% reported that it helped “a little/moderate” while 14.2% reported that it helped “a lot”. Thus, while student participation in a single improvisation workshop did not appear alter the students’ empathy, it may be of value for promoting their self-confidence and communication skills.

2129 ToxMSDT: An Innovative Toxicology Research Education Pipeline Program Targeting Underrepresented Undergraduate Students to the Field of Toxicology

W. K. Rumbeila1, E. Gilbreath2, D. Alexander3, A. Correia4, S. Bradbury5, J. Danielson2, P. Leigh1, and J. Wolt1. 1Iowa State University, Ames, IA; 2Tuskegee University, Tuskegee, AL; and 3Ohio State University, Columbus, OH.

Exposure of undergraduate students, who have interests in STEM careers, to toxicology as a career choice is uncommon across US colleges and universities. Thus, the depth and breadth of a pool of undergraduates applying to graduate programs in toxicology is limited because students who are otherwise interested may not be aware of toxicology as a career option. This is particularly true for underrepresented undergraduates with toxicology careers and training in toxicology fundamentals and skills that will level their entry into graduate programs. Key objectives of the ToxMSDT program are 1) paired student mentee-mentor teams; 2) Responsible Conduct of Research training; 3) online learning modules (http://www.toxmsdt.com) accessible 24/7 and open to the general public that teach students fundamentals and core competencies of toxicology; 4) face-to-face mentorship and networking by participating in 4 meetings: an Inaugural Workshop at ISU, the annual Society of Toxicology Conference, shadowing at mentor’s work place, and a Capstone Conference at TU where the students present on their experiences in the program. Currently, 5/9 (55.6%) of our senior graduates have joined the pipeline in areas of interest to the NIH; 21/30 (70%) of ToxMSDT graduates are still enrolled as undergraduates.
2130 Undergraduate Education Programs at the Northeast and Ohio Valley Regional Society of Toxicology Chapters: Large Impact for a Low Cost
J. P. Gray1, C. P. Curran2, and L. Williams3. 1US Coast Guard Academy, New London, CT; 2Northern Kentucky University, Highland Heights, KY; and 3Bates College, Lewiston, ME.

The Undergraduate Diversity Program at the national meeting celebrates its 30th anniversary this year. It has impacted a diverse range of undergraduate students from colleges and universities nationwide. However, participation in this program is limited due to significant travel costs, restrictions on conference space, and lack of awareness at institutions without toxicology programs. To increase the pool of undergraduates exposed to toxicology, the SOT Undergraduate Education Subcommittee initiated a pilot project involving two Regional Chapters in 2017 with a total budget of $1,000. The Northeast Regional Chapter of the Society of Toxicology (NESCOT) sponsored the $20 registration cost for 25 undergraduates to attend their annual meeting in 2017. After attending the morning scientific session, the students participated in a breakout session modeled on national SOT programs. Following "Lunch with an Expert", presentations utilizing the "Introduction to Toxicology" slide set by Larissa Williams, liver toxicology by José Manatou, and an active learning opioid exercise by Josh Gray and Larissa Williams were presented. The breakout culminated with a guided tour of the animal facilities at Charles River Laboratories. The OVSOT has a long history of offering undergraduate poster awards and involving undergraduates in mentoring events; however, the geographic region of OVSOT is large. Overall, 44 students attended at a cost of ~$25/student. The following data demonstrate impact for the NESCOT students, most of whom had heard of but not enrolled in toxicology. After teaching the course using different formats, the students were asked to respond to the survey. The survey included questions about their interest in pursuing a career in toxicology and how the course had impacted their understanding of the field. The survey also asked about their impressions of the course format and if they would recommend it to others. The results indicated that the program was effective in helping students learn how to work effectively in teams, which is a key program goal in the Environmental Science program.

2132 Strategies for Effectively Incorporating Team-Based Learning in an Undergraduate Toxicology Course
C. P. Curran. Northern Kentucky University, Highland Heights, KY.

Team-based learning has demonstrated value in increasing communication skills and professional development in numerous fields including medicine, pharmacy and business. As a multi-disciplinary field, toxicology education can also be enhanced by team-based learning (TBL). The challenges to implementing TBL in an undergraduate lecture course can be substantial. High-achieving students often resist sharing responsibilities with fellow students they perceive to be less capable. Time management is another constraint, particularly at institutions with a high percentage of students who need outside jobs to meet their tuition payments. TBL was successfully instituted in an Environmental Toxicology class at Northern Kentucky University through a series of assignments that culminated in a service learning project benefiting a local community partner. Online coursework was used to maximize and track participation by each team member. Anonymous surveys allowed students to provide feedback on individual team members. In-class time was allocated to ensure all team members could meet regularly and receive guidance. Most of the students indicated they would like to have a TlxScholar visit at their institution. These successes indicate that Regional Meetings are appropriate places to hold undergraduate-focused introductions to toxicology and expand the outreach to undergraduates throughout North America. As a result of the pilot project success, the Undergraduate Education Subcommittee expanded the program to fund four regional chapters in 2018.

2133 Establishing Foundational Toxicology Education in Sierra Leone Using Active Learning Modules
R. H. Wilson1, M. T. Walcheck2, F. Arowolo3, L. Gonzalez Vazquez4, M. M. Morgan5, B. Sanchez-Sedillo1, S. Thomas1, J. S. Yee1, M. Avilla1, C. A. Bradford3, and A. U. Njai1,2,3. 1University of Wisconsin-Madison, Madison, WI; 2University of Sierra Leone, Freetown, Sierra Leone; and 3Project 1808, Inc., Madison, WI.

In Sierra Leone, there are concerns regarding the human and environmental implications of prolonged toxicant exposure. Sierra Leoneans are routinely exposed to polluted air and water from everyday practices like cooking, vehicle emissions, and mining. Another major source of exposure stems from unregulated hazardous waste dumps that are burned to create space for agriculture, resulting in uptake of a myriad of toxic compounds into food sources. A primary reason that these conditions persist is due to a lack in educational infrastructure regarding the biological effects of toxicants as well as the exposure hallmark toxicological principles. To address the void in toxicology education, graduate students at the University of Wisconsin-Madison have partnered with Project 1808, Inc., a Madison, WI nonprofit and Sierra Leone community-based organization, to develop a series of modules that aim to introduce college students in Sierra Leone to general toxicology principles. This course also aims to establish awareness to relevant human health and environmental concerns and basic environmental monitoring skills, while encouraging dissemination of this information into the community. The model for developing the toxicology education in Sierra Leone is built around the idea that the modules use case studies and examples that are locally relevant. This pedagogical approach can be effectively implemented in a classroom setting and for students to disperse the information to their communities. This has the potential to impact the health and well-being of the community at large. The modules include lectures accompanied by active learning activities, such as local case studies, field trips, and workshops. This approach allows for the incorporation of local knowledge and expertise, ensuring the relevance and practicality of the content for the students and their communities.

2131 Use of Case Studies to Introduce Undergraduate STEM Students to Environmental Regulations
J. M. Shimel. Indiana University School of Public Health, Bloomington, IN.

Engaging undergraduate students in the learning process. The BSPH in Environmental Health requires students to complete a course titled Environmental Regulations. After teaching the course using different formats, the use of case studies to explain the background and origins of the regulations was found to be successful. The students were given case studies that were relevant to their interest and were asked to respond to the survey. The survey included questions about their interest in pursuing a career in toxicology and how the course had impacted their understanding of the field. The survey also asked about their impressions of the course format and if they would recommend it to others. The results indicated that the program was effective in helping students learn how to work effectively in teams, which is a key program goal in the Environmental Science program.
2134 Publishing Trends of Graduate Students in an Interdepartmental Toxicology Program over a 6-Year Period

L. M. Aleksunes. Rutgers, The State University of New Jersey, Piscataway, NJ.

Publishing data in peer-reviewed journals is a fundamental part of graduate training in toxicology. Completion of first author papers enables students to transform their dissertation into publications. Likewise, participation as a co-author on a publication reflects the increasing need for team-based science. The purpose of the present evaluation was to assess publishing trends across MS, PhD, and dual degree PhD students at Rutgers, The State University of New Jersey, who graduated from an interdepartmental toxicology graduate program between 2012 and 2018. Data were collected from pubmed.gov using student and mentor last names and matched with programmatic data regarding degree type, eligibility and appointment to a T32 training grant, and gender. Publication records from a total of 37 students (7 MS, 25 PhD and 5 dual degree) were analyzed. Dual degree students included those individuals who received their clinical degree (MD, PharmD, VMD) at Rutgers or another US institution. The percentage of students with at least one publication from their graduate training included 71% of MS students, 88% of PhD students and 100% of dual degree students. Within these groups, the average number of publications were 0.83 for MS students, 3.6 for PhD students, and 5.6 for dual degree students. Of all 127 publications evaluated, 47% were first author publications. Analysis revealed that those PhD and dual degree students appointed to the T32 training grant (N=18) had an average of 4.8 papers/student compared to an average of 2.6 papers/student for those students who were eligible, but not appointed to the T32 grant (N=8). No differences in average publication number between genders were observed. A review of the subject for the journals selected for publication revealed that 60% of the 127 papers appeared in Pharmacology/Toxicology Journals compared to other journal types (such as Physiology or Molecular Biology).

In conclusion, periodic assessment of publication trends within a graduate program is important for continual improvement and refinement of training goals. Supported by NIH T32ES007148 and P30ES005022.

2135 International ToxScholar: Promoting Toxicology Careers Globally

R. J. Dearman1, B. L. Baisch2, and B. J. Eidemiller3. 1University of Manchester, Manchester, United Kingdom; 2Henkel Corporation, Trumbull, CT; and 3Society of Toxicology, Reston, VA.

The goals of the SOT Education Committee’s International ToxScholar (ITS) Award are to expand awareness of toxicology and promote toxicology careers in developing countries through interaction of toxicologists with undergraduate and graduate students. Since 2010, 27 ITS visits and 45 host institution visits involving scientists from 20 countries have been completed. In 2018, the focus was on promoting careers in toxicology, and 3 scholars visited 11 institutions. Dr. Gurjot Kaur (University of Konstanz, Germany) spent several days visiting 4 institutions in India that are without current toxicology syllabi, presenting to a mixture of undergraduates, masters and doctoral students. She also had an event with high school students focusing on air and water pollution and careers in science and toxicology. Dr. Logeswari Ponnamy (Zoets Inc., USA) travelled to 4 rural institutions in India with the aim of informing veterinary students about toxicology as a specialty. She discussed careers (domestic and abroad) in toxicology, the graduate school application process and the resources and membership opportunities available through SOT. Since completing the visits, 12 students have contacted Dr. Ponnamy for mentoring and more details on applying to USA-based toxicology programs. The final visit was by Dr. Haiyan Tong (US Environmental Protection Agency), who visited institutions in China. She presented on career paths in toxicology at institutions and the Chinese Environment & Health Conference, and connected with over 50 graduate/undergraduate students with an interest in toxicology. Following their visits scholars submitted a final report and shared their experiences in SOT’s Communiqué. These blogs have been very popular, with the first two scholars’ blogs (posted March 2018) garnering 1313 and 999 hits, respectively. These numbers are considerably higher than in previous years, which had under 1000 total hits. The final blog was posted recently (September 2018) and has already received 45 hits. The combination of multiple visits and the success of the blog postings highlights that this program continues to expand awareness of toxicology in developing countries. The Education Committee is committed to increasing the number and diversity of countries visited by scholars applying for this award, which are key to promoting toxicology globally.

N. Li1, Y. Liu1, N. Alepeee2, and Z. Cai1. 1L’Oréal Research & Innovation, Shanghai, China; and 2L’Oréal Research & Innovation, Aulnay-Sous-Bois, France. Sponsor: E. DuFour

An OECD Guidance Document No. 286 on Good In Vitro Method Practices (GIVIMP) for the development and implementation of in vitro methods for regulatory use in human safety assessment was recently endorsed. This guidance document applies to in vitro methods already accepted by the OECD. In China, this is therefore primordial for the implementation and acceptance of in vitro alternatives methods. Since 2011, L’Oréal initiated the EpiSkin™ Skin Irritation Test (SIT) implementation program in China, 61 scientists received formal trainings and the method has been established in 34 organizations including authority, industry and testing service laboratories. Taking the multi-center study (MCS) of in vitro SIT as example, we demonstrated a standard method establishment process in good alignment with GIVIMP. The quality of EpiSkin™ was assured by Shanghai EPISKIN Biotech providing relevant safety information for transport, use and disposal (GIVIMP 1.2, 5.3). All tested chemicals, commercially available from certified suppliers, were selected from scientific publications that supported the adoption of the test method into TG 439 (GIVIMP 4.2, 6.1, 8.4). The formal step-by-step training according to EpiSkin™ SIT SOP was provided to 4 authority labs including 2 scientists in each lab (GIVIMP 1.1, 2.6, 7.1, 7.2, 8.2), those 4 labs together with L’Oréal conducted the MCS. Six chemicals as training set were performed independently by each scientist strictly following the SOP. By showing qualified results, scientists were allowed to conduct the MCS of 2 blindly coded chemicals described in TG 439. A powerful and simple statistic tool, control trend charts for all tested negative and positive controls were used to monitor batch reproducibility and operators’ performance (GIVIMP 2.3, 2.4), obtained >90% within-lab reproducibility in all 5 labs and 95% inter-lab reproducibility (GIVIMP 8.3). The overall predictive capacity was 70% specificity, 94% sensitivity and 82% accuracy met the criteria defined in TG 439 (GIVIMP 8.3, 9.5). In conclusion, the EpiSkin™ SIT implementation program in China, exemplifies the practical way in which the GIVIMP guidance can assist interested parties in the transfer and establishment of in vitro approaches, and also pave the way towards future scientific recognition and acceptance of in vitro alternative toxicology OECD accepted testing methods in this fast-developing country.

2137 Reducing Exposure to Lead-Based Ammunition to Improve Child Health

S. Gilbert1, and R. Shaffer1. 1INND, Seattle, WA; and 2University of Washington, Seattle, WA.

The US Centers for Disease Control and Prevention (CDC) has declared that there is no safe level of lead exposure, particularly for children. Well-recognized exposure routes include water and paint from homes (built prior to 1978), but exposure may also occur through the use of lead-based ammunition for hunting, target practice, or recreational shooting. Exposure to lead occurs when the gun is fired and particulate or lead-based propellant is vaporized, which can be inhaled or contaminate skin and clothing. Lead toxicity is due, in part, to its propensity to substitute for calcium in the body. Because of their rapid bone growth, children will absorb about 50% of the lead ingested, in contrast to only 10% among adults. Lead causes a wide range of adverse effects, but one of the most serious is a reduction in intellectual development, leading to a lifetime of damage. In the US, there are approximately 20 million shooters using an estimated 20,000 shooting ranges and about 1,700 junior military training groups. Most of these groups use lead-based ammunition, which is particularly concerning for individuals under the age of 21; studies have documented cases of high blood lead levels among adolescents that result from shooting range exposures. One way to protect the health of these most vulnerable individuals is to require the use of only unleaded ammunition for users under the age of 21. We will discuss the strategies and feasibility of protecting the health and wellbeing of young gun users by restricting the sale and use of lead-based ammunition for those under 21 years of age. We have an ethical responsibility to protect our children from the health hazards of lead exposure.
Phosphine (PH₃) is a potent, odorless, and colorless toxic gas generated from commercially available metal phosphide pesticide tablets. Due to these factors, PH₃ is recognized as a toxic industrial chemical (TIC). While phosphine's precise mechanism of toxicity is unknown, it may act as a mitochondrial toxicant through blockade of the electron transport chain. Humans exposed to PH₃ present an array of symptoms, with some of the most clinically significant being the delayed development of respiratory distress, cyanosis, and edema. To elucidate the mechanism(s) behind phosphine’s toxic effects, a genomic analysis was performed on adult female Sprague-Dawley rats exposed to either PH₃ (16,500 ppm x min) or filtered air. The heart, lungs, liver, kidney, and whole blood samples were collected from exposed animals at 1, 3, 6, or 24 hours post-exposure. Total RNA was isolated from the tissue/blood samples, processed using 3’ in vitro transcription, and analyzed via microarray. Differentially expressed genes were identified using Partek Genomics Suite and mapped to biological and toxicologically relevant pathways using Ingenuity Pathway Analysis (IPA) software. Microarray analysis revealed organ- and time point-specific alterations in gene expression following PH₃ exposure. PH₃ exposure induced gene expression changes in cardiac tissue associated with cardiac cell death pathways and sinus node dysfunction at 1 hour post-exposure, differentiation of muscle cells at 3 hours post-exposure, and hypertrophy of heart at 6 hours post-exposure. Lung tissue gene expression was associated with primary pulmonary hypertension. To confirm these findings, PH₃ exposure was induced at 1 hour post-PH₃ exposure. Genomic analysis of PH₃-exposed rodents has identified potential molecular mechanisms leading to cardiac injury and death following PH₃ inhalation. Additionally, these data will be used to identify candidate therapeutic targets and mathematical countermeasures for PH₃-induced toxicity.

**Swine Model of High Dose Sulfur Mustard Inhalation, and Improved Outcome after Rescue with Fibrinolytic Treatment**

R. Brace ¹, M. Doyle-Eiselle ², T. Hendry-Hofer, J. Rioux ¹, C. Phillips ¹, A. Truitt ³, L. Bloomquist ³, R. Garlick ³, D. Krakco ³, W. Weber ³, C. White ³, J. McDonald ³, and L. Veress ³

¹University of Colorado Denver, Denver, CO; ³Lovelace Research Institute, Albuquerque, NM.

Inhalation of high levels of sulfur mustard (SM) has been shown to result in death from severe airway obstruction by luminal casts of fibrin. No antidote or specific treatment exists to prevent mortality after SM exposure. A rodent model of severe SM inhalation has been developed, and a promising fibrinolytic therapeutic successfully tested, showing great efficacy at improving survival and recovery outcomes associated with this form of pulmonary damage. The Animal Rule will require that treatment efficacy be shown in a disease-relevant (large) animal model that mimics the human condition. For this reason, we developed a Yorkshire swine model of severe SM inhalation exposure, and tested the same fibrinolytic therapy for efficacy. Sedated/intubated swine were exposed to 15 mg/kg dose (at 12h) of SM vapor via inhalation using a newly developed exposure system, then awakened/extubated. Clinical signs were monitored continuously. Morbidity was assessed every 15 min by oxygen saturation (Spo₂), heart rate, auscultation, respiratory distress score, and arterial blood gas (ABG; hourly) and complete blood count (CBC) assessment. Fibrinolytic therapy was dosed via sedation/free breathing protocol within 1 hour of exposure (<50 mmHg). After necropsy (12h), lungs were fixed and evaluated for cast obstruction and histopathology. All control animals (n=4) exposed to high dose SM died by 10 hours, and had concurrent severe hypoxemia (Spo₂ <75%; PaO₂ < 40 mmHg), severe work of breathing (retractions, open mouth breathing, and coughing), and abnormal auscultation findings (ronchi, expiratory wheezing, diminished breath sounds) prior to humane euthanasia. At necropsy, all control animal lung lobes had severe airway obstruction by fibrin casts (70-100%), confirmed via histology. CBC showed increased white blood cells (>28x10⁹/ul) and neutrophils (>20x10⁹/ul) by 6h, and mild lymphopenia. All animals receiving fibrinolytic therapy (n=3) survived to study endpoint (12h), and showed clearance of airway casts, and improvement in many other morbidity measures. High dose SM inhalation in swine causes respiratory failure and death due to airway casts. Treatment with fibrinolytic therapy in this model shows great efficacy, with improved survival and other endpoints. Fibrinolytic treatment shows promise in improving outcome after high dose SM inhalation injury.

**Regulation of Macrophage Phenotype by Farnesoid X Receptor during Nitrogen Mustard-Induced Lung Injury**

A. Murray ¹, T. Banota ¹, L. C. Smith ¹, E. Abramova ¹, D. T. Rizzolino ¹, A. Venosa ¹, B. Kong ¹, J. Andres ¹, G. L. Guo ¹, A. J. Gow ¹, J. D. Laskin ¹, and D. L. Laskin ¹

Nitrogen mustard (NM) is a cytotoxic vesicant known to cause acute lung injury which progresses to fibrosis. This is accompanied by increases in proinflammatory cytokines, M1 anti-inflammatory/wound repair macrophages in the lung. Therapeutics aimed at mitigating lung injury and inflammation. In these studies, we analyzed mechanisms regulating macrophage phenotypic activation, focusing on the role of pulmonary lipids, which are dysregulated following NM exposure. Farnesoid X receptor (FXR) is a bile acid-activated nuclear receptor involved in lipid homeostasis. It has also been shown to regulate inflammatory responses. In these studies, we showed that expression of FXR, along with two of its targets, ApoA and ApoE, was upregulated in lung macrophages following NM exposure. To analyze the role of FXR in macrophage activation, we used FXR⁻/⁻ mice. WT and FXR⁻/⁻ mice were treated with control (PBS) or NM (0.08 mg/kg, i.t.). Bronchoalveolar lavage (BAL) and lung tissue were collected 14 d later. NM caused histopathologic alterations in the lung including inflammatory cell infiltration, septal damage and epithelial thickening. These were more prominent in FXR⁻/⁻ mice. Additionally, in FXR⁻/⁻ mice, but not WT mice, we observed evidence of fibrosis as assessed by Gomori trichrome staining. This correlated with exacerbated increases in BAL protein and cell content. Immunohistochemistry showed that expression of heme oxygenase-1 (HO-1), a marker of oxidative stress, and ADP-ribosylation factor-like GTPase 11 (ARL11), a marker of M1 macrophage activation, were upregulated in FXR⁻/⁻ mice when compared to WT mice. Conversely, arginase 1, a marker of M2 macrophages and tissue repair, was downregulated. Flow cytometric analysis of lung macrophages revealed the presence of pro- and anti-inflammatory subpopulations following NM exposure; these were reduced in FXR⁻/⁻ mice. These findings demonstrate that FXR modulates the response of macrophages to NM and is involved in controlling inflammation. These findings may be useful in the development of therapeutics aimed at mitigating lung injury and inflammation.
2142 Detection of Galectin-3 and Its Interaction with Microparticles in Airway Surface Liquid Following Exposure of Rats to Nitrogen Mustard

R. C. Rancourt1,2, N. Wahba1, M. Zhang3, R. Malaviya1, J. Cervelli1, H. Chang4, J. D. Laskin1, and D. L. Laskin1. 1Rutgers, The State University of New Jersey, Piscataway, NJ; and 2Environmental and Occupational Health Sciences Institute, Piscataway, NJ.

Exposure to the toxic alkylating agent nitrogen mustard (NM) injures the respiratory tract, which can lead to central airway scarring and fibrosis. The underlying pathogenesis of these fibrotic outcomes is not well defined. Galectin-3 (Gal-3) is a 35-kDa carbohydrate-binding protein expressed on the surface of many cells; recent evidence indicates that Gal-3 may play a pro-fibrotic role in the lung by polarizing macrophages toward a pro-fibrotic M2 phenotype and stimulating myofibroblast activation. In these studies we analyzed Gal-3 in rat lung following NM intoxication. Sprague-Dawley rats were exposed by intratracheal instillation to vehicle (PBS) or NM (0.15 mg/ kg). Rats were euthanized 24 hr later and bronchoalveolar lavage fluid (BAL) collected. SDS-PAGE gel electrophoresis and western blotting demonstrated a significant increase in Gal-3 levels in BAL from NM-exposed rats, when compared to controls. NM was also found to increase levels of cell-derived microparticulates (MPs) in BAL relative to control, as determined by flow cytometry and lactadherin binding. A series of ultracentrifugation and washing steps was performed to isolate MPs from BAL. Western blotting revealed that Gal-3 is associated with MPs. This co-localization was confirmed by incubation of vehicle control BAL (exhibiting negligible Gal-3) with 20 ng of recombinant Gal-3 protein. These findings show that airway MPs are capable of binding soluble Gal-3. Future studies will investigate whether MP interactions with Gal-3 functions as a signaling element for cell-cell communication in response to NM inhalation injury. Supported by NIH AR050732 and ES050202.

2143 Circulating Cell-Free Nucleic Acids in the Pathogenesis of Sulfur Mustard Analog-Induced Acute Respiratory Distress Syndrome

N. Mariappan, M. Husain, I. Zafar, K. G. Smithson, S. Ahmad, and A. Ahmad. University of Alabama at Birmingham, Birmingham, AL.

Circulating cell-free nucleic acids are increasingly being recognized as mediators of injury in a number of diseases. They are known to activate several pathways, including coagulation and inflammation. Exposures of rats to aerosolized 2-chloroethyl ethyl sulfide (CEES), an analog of the war agent sulfur mustard, caused lung injury and increased levels of extracellular nucleic acids in the bronchoalveolar lavage fluid (BALF) and plasma. In this study we have investigated the effect of nucleic acid neutralizing (NAN) agents in mitigating CEES-induced injury. CEES exposure increased respiratory distress and hypoxemia that were significantly improved by NAN agent treatment. Blood gas analysis showed that the NAN agent mitigated CEE-induced decrease in arterial blood pH and PaO2/FiO2 ratio. There were also increases in fibrin and HMGB1 in the BALF indicating lung inflammation and activation of coagulation pathway. These were consistent with a phenotype resembling acute respiratory distress syndrome. Administration of NAN agents also decreased cell-free nucleic acid levels, mitigated lung injury and prevented mortality.

2144 Understanding Tissue-Specific Pathologies following Ocular Exposure to Sulfur Mustard Vapor: Towards Improved Therapeutic Design

Following ocular exposure to moderate or high doses of the chemical warfare agent sulfur mustard (SM), many victims develop a persistent disease known as mustard gas keratopathy (MGK). The pathophysiological origin of MGK is unknown, and diverse therapeutic approaches have completely failed to prevent MGK. It is the primary pathological target of ocular SM injury in the cornea. While the effects of SM on the highly regenerative corneal epithelium are extensively described, the effects on the non-regenerative corneal endothelium are completely unknown. The corneal endothelium is a monolayer of cells that maintain the cornea in a dehydrated state through acting as a semi-permeable barrier and osmotic pump. Disrupted endothelial function results in clinically treatable chronic diseases. Hypothesizing that endothelial toxicity may present a novel injury modality that could explain the idiopathic etiogenesis of MGK, we characterized endothelial integrity and function using a well-described rabbit model of corneal vapor exposure that exhibits acute and long-term sequelae commensurate with human outcomes. Convergent methods demonstrate that ocular SM vapor exposure results in acute endothelial toxicity, gross disruption of endothelial barrier function and long-term endothelial pathologies in MGK eyes. Furthermore, we demonstrate that the extent of the endothelial lesion is correlated with MGK. These data indicate that endothelial toxicity occurs at the right time and with the appropriate pathophysiology to contribute to MGK and furthermore explicate many of the previously confusing aspects of clinical progression in SM-injured eyes. Based on these findings, we have proposed a new model of corneal SM injury. We hypothesize that (a) the endothelial lesion is predictive of corneas that will develop MGK (b) corneal epithelial pathologies in MGK eyes are likely secondary to persistent edema in response to corneal endothelial barrier failure (c) the efficiency of endothelial repair influences whether corneas resolve or develop MGK. This model suggests the potential for new strategies based on inhibition from impaired regenerative capacity, and identifies tissues-specific therapeutic targets. Our current studies are designed to further evaluate this hypothesis.

2145 High-Throughput miRNA Library Screen Reveals HSA-let-7c-5p and HSA-let-7d-5p as Regulators of Sulfur Mustard-Induced Injury in an In Vitro Ocular Model

Sulfur mustard (HD) is a potent vesicant historically utilized as a chemical warfare agent. Acute exposure to HD can produce severe ocular, cutaneous, or respiratory injury. Although this agent has been investigated for over a century, the exact mechanisms of injury are still not completely understood. In this project, a microRNA (miRNA) mimic library was utilized to screen for potential targets that modulate the ocular injury response. A miRNA is a small (approximately 22 nucleotides), non-coding RNA that post-transcriptionally regulates gene expression through binding to partially complementary sequences in the 3' UTR region of mRNAs. High-throughput screening was conducted in an immortalized human corneal epithelial cell line. Cells were transfected with miRNA 48 hrs prior to exposure to a 1.0 x LD50 of HD. Cell viability and pro-inflammatory cytokine production were measured as experimental endpoints 24 hrs after exposure. Of the 1237 targets in the mimic library, 150 reached the significance threshold and were advanced into the mimic/inhibitor pair screen. Targets at this stage were considered hits if both the mimic and inhibitor sequences had significant and opposite effects; twenty-one targets reached this threshold. A dose-response variation of the mimic/inhibitor pair screen was used to validate the remaining targets. Of these, HSA-let-7c-5p and HSA-let-7d-5p had the most robust dose-response effect. Members of the HSA-let-7 family of miRNAs have been reported as regulators of cell proliferation, apoptosis, and the inflammatory response. However, as miRNAs function through partially complementary binding, it is difficult to identify their specific gene targets. Direct administration of the miRNA inhibitor could potentially serve as an efficacious therapy. Further work will be necessary to clarify the pathways regulated by these miRNAs and to evaluate their possible therapeutic benefit in response to HD-induced ocular injury.

2146 Effects of Nitrogen Mustard Gas on Mast Cell Activation

There were a notable number of chemical warfare agents (CWA) used during the Gulf War (1990-1991) and as a result left 25-32% of veterans suffering from Gulf War Illness (GWI). The vesicating agent, sulfur mustard (SM) gas is by far one of the most noteworthy CWA used during this time. SM toxicity symptoms closely relate to those seen in veterans experiencing GWI. Prior research has demonstrated that SM targets the bone marrow and has the potential to influence immune cells including mast cells. Our previous data in mice exposed to SM demonstrated a significant increase in pro-inflammatory cytokines IL-6, IL-1β, TNF-α, and IL-2 followed by infiltration of neutrophils and macrophages in the lung. In the skin, exposure to SM was reported to induce mast cell degranulation. Therefore, the aim of this study was to determine if nitrogen mustard (NM) (a surrogate for SM) exposure promotes activation of mast cells. Studies from our laboratory and others have established nitrogen mustard (NM) as a valuable surrogate to decipher the toxicity effects of SM. For these studies we utilized rat basophilic leukemia (RBL) cells that are commonly used as a representative model of mast cells.

2019 SOT Annual Meeting
2149 BIPS, a Type-IV Collagenase Inhibitor, Modulates Epidermal Keratin Expression in Mouse Skin Treated with Sulfur Mustard

Y. Chang, T. Peng, R. A. Hahn, M. K. Gordon, J. D. Laskin, and D. R. Gerecke, Rutgers, The State University of New Jersey, Piscataway, NJ.

Sulfur mustard (SM) is a potent alkylating vesicant that induces edema, epidermal erosions, inflammation, and prolonged wound repair in skin. Earlier studies have shown that overexpression of matrix metalloproteinase 9 (MMP9) degrades proteins of the extracellular matrix and leads to the separation of epidermis from dermis in skin exposed to SM. We have found that MMP9, a type IV collagenase, disrupts collagen IV (Col IV) a major component of the basement membrane (BM) zone in skin wounds post SM exposure. Col IV in the BM network has been recently reported to be a regulator of epithelial differentiation and keratin expression during wound repair. In the present study, we evaluated BIPS [N-hydroxy-3-phenyl-2-(4-phenylbenzenesulfonyl) propanamide], an MMP inhibitor, on epidermal repair and wound healing following SM exposure in a murine ear vesicant model. Markers examined include histopathologic changes, degree of epidermal hyperplasia, skin thickness, and expression of Col IV, MMP9, keratin 10 (K10, a differentiation marker), and keratin 6 (K6, a wound-inducible marker). We found MMP9 mRNA expression increased 24-168 h post SM exposure. Dual immunofluorescence studies using Col IV α1 and MMP9 antibodies showed BM zone breakdown of Col IV and increases in MMP9 expression in the epidermis and the adjacent dermal matrix of the SM injured skin. Strong keratin 6 expression was evident in the tissue, in contrast, keratin 10 expression decreased. BIPS significantly reduced edema and epithelial thickness by 72 h post-SM exposure. BIPS also significantly downregulated mRNA expression of MMP9. Immunofluorescence studies showed that BIPS significantly reduced MMP9 expression. Col IV expression was similar to the unexposed control skin. Dual immunofluorescent studies also show reduced K6 and increased K10 expression. These results indicate that BIPS, by inhibiting MMP9, effectively restores BM integrity by promoting epithelial differentiation and wound re-epithelialization. Targeting MMP9 may be an effective strategy for countering SM-induced cutaneous injury. Supported by NIH grants ES005022, ES007148 and AR055073.

2150 Nitrogen Mustard Modifies and Cross-Links Wild Type and Mutant p53 in Human Epithelial Cells

Y. Jang, D. Heck, D. Laskin, and J. Laskin, Rutgers, The State University of New Jersey School of Public Health, Piscataway, NJ; New York Medical College, Valhalla, NY; Ernest Mario School of Pharmacy, Piscataway, NJ; and Rutgers, The State University of New Jersey School of Public Health, Piscataway, NJ.

Nitrogen mustard (HN2, mechlorethamine) is a bifunctional alkylating agent commonly used in cancer chemotherapy and as a model vesicant to investigate mechanisms of sulfur mustard-induced tissue injury. Exposure to HN2 causes DNA damage and activation of DNA damage response signaling as a consequence of its ability to modify cellular macromolecules, in particular, DNA. The tumor suppressor protein p53 is a transcription factor known to play a critical role in regulating stress including DNA damage. In the present study, we examined the action of HN2 on p53 expression in several human cell lines varying in p53 status. HN2 caused a concentration- and time-dependent induction of p53 in HaCaT keratinocytes which express mutant p53 (H179Y, R282W), A431 epidermoid cells which also express mutant p53 (R273H), p53 wild type HEK293 kidney epithelial cells and A549 lung epithelial cells. These data indicate that the actions of HN2 in induction of p53 are status independent. HN2 was found to cross-link p53 in HaCaT cells, as well as A431 and HEK cells, forming several high molecular weight complexes. Thus, HN2 can...
modify p53 despite mutations that alter the functional status of p53. In HaCaT cells, the p53 cross-linked proteins rapidly degraded (>50% within 6 h post HN2 treatment) indicating that HN2-induced p53 cross-linking enhanced protein degradation. Mechanisms mediating protein cross-linking were studied using recombinant wild type human p53 cross-linked with HN2. LC-MS/MS analysis revealed that HN2 selectively alkylated Cys135, Cys141, Cys229, Cys238, Cys242 on the protein, forming both monoaducts and peptide loop links. Additionally, HN2 cross-linked Cys124 on one molecule of p53 and Cys229 on a second molecule of p53, forming protein dimers. Taken together, our data demonstrate that p53 is a molecular target for mustard vesicants. Modulation of p53 by vesicants is likely to play a critical role in determining downstream responses to HN2 including DNA repair and this contributes to vesicant-induced cytotoxicity and tissue injury. Support: NIH grants AR055073, NS079294, NS108956, ES004738, and ES005022.

2151 A Comparison of the Dermatotoxicity of Mchelorethamine In Vivo, Using the Mouse Ear Vesicant Model, and In Vitro, Using a Reconstructed Human Skin Model

B. J. Cuffari, H. C. R. Tumul1, M. A. Pino2, T. J. R. Rao1, S. M. Menon1, and R. Billack1
1St. John's University, Jamaica, NY; and 2New York Institute of Technology, Old Westbury, NY.

Mchelorethamine (HN2) is an alkylating agent which is used in anticaner therapy. Dermal exposure of HN2 is associated with extravasation and tissue blistering reactions (vesicant) which can cause death. A major purpose of the present study was to investigate the time dependent dermatotoxicity of HN2 using the mouse ear vesicant model (MEVM). To this end, our operational definition of dermatotoxicity included tissue responses to HN2 consistent with an increase in the wet weights of mouse ear punch biopsies, an increase in the morphometric thickness of H&E stained ear sections and an elevation in histopathological scoring values for tissue edema, hyperplasia, inflammatory cell infiltration and vesication. The ears of male Swiss Webster mice were exposed to a single dose of HN2 (0.5 μmol/ear) or DMSO and the mice were then euthanized at 15 min or 1, 2, 4, 8, 12 or 24 hr following exposure. Mouse ears exposed to HN2 showed an increase in wet weight, morphometric thickness, edema, inflammatory cell infiltration and vesication at all time points. Tissue vesication sharply increased between 4 and 8 hr after HN2 exposure and remained elevated at 12 and 24 hr after exposure. It is worthy to note that ears treated with DMSO vehicle also exhibited an increase in wet weight and morphometric thickness at 15 min, 1, 2, and 4 hr following treatment; however, these vehicle effects eventually subsided by 8 hr. To determine the extent to which HN2 could cause vesication in a reconstructed human skin full thickness model, a preliminary study was performed using samples of T-skin® treated topically with HN2 (0.5 μmol/ear) or DMSO and biopsied 24 hr after exposure. H&E staining of samples of HN2-treated skin showed signs of tissue injury and decreased viability compared to untreated samples or those treated with DMSO; however, none of the samples showed signs of vesication. The extent to which these types of in vitro models can be used to investigate vesication by nitrogen mustards is therefore worthy of further study. On the other hand, the results obtained here using the MEVM provide a better holistic understanding of the kinetics of vesication, and indicate that time points earlier than 24 hr may be useful in assessing the effects of medical countermeasures to mustards.

2152 Effect of Chemical Warfare Agent Simulants on the Regulation of Endothelial Barrier Function

Endothelial cells (ECs) line the internal portion of the vasculature and are responsible for maintaining homeostasis within the body. This function is accomplished through tightly regulating the passage of both fluid and nutrients from the bloodstream to various tissues. When this regulation is disrupted by inflammation or exposure to specific toxic compounds, fluids and macromolecules will accumulate in the surrounding tissues, resulting in edema. This accumulation of fluids is typically regulated through the paracellular pathway, which is defined as the movement of fluids and macromolecules through gaps formed at intercellular junctions. Several chemical warfare agents (CWAs), including the organophosphates V/G-series nerve agents, have been shown to disrupt the endothelium and induce edema following sub-lethal exposures in experimental animals. Outside of reporting edema during in vivo studies, the direct effects of CWAs on the endothelium is widely unexplored. To do this, we examined the effects of four different CWA simulants on the immortalized dermal microvascular EC line (HMEC-1) through the measurement of cell viability and cellular impedance. The CWA simulants chosen for this study included organophosphates (malathion/maloxon), a vesicant simulant [bis(2-chloroethyl)amine hydrochloride], and a microbial toxin (endotoxin). We then compared these results to those obtained from primary cultured microvascular ECs from skin, lung, and heart to determine if HMEC-1s are suitable for evaluating the vascular toxicity of CWAs. Exposure to increasing concentrations of the selected CWA simulants induced similar patterns of responses in the ECs examined. Our results demonstrate that HMEC-1s are suitable for assessing the vascular toxicity associated with CWAs and allow for the generation of toxicity estimates without the use of primary cultured ECs.

2153 Toxicity and Mechanisms to Identify Therapeutic Targets of Phosgene Oxime Skin Exposure

D. G. Goswami1, J. Roseman2, P. Anantharam2, C. R. Crompt2, D. J. Orlicky1, R. Agarwal3, and T. J. Rao1
1University of Colorado Denver, Aurora, CO; and 2NIRGlobal, Kansas City, MO.

Phosgene Oxime (CX), an urticas and nettle agent categorized as a vesicant, is a potential chemical warfare and terrorist weapon. CX exposure can result in devastating toxic effects resulting in high mortality due to its fast penetration and ability to cause immediate severe cutaneous injury. Its easy synthesis makes it a dangerous chemical with both military and terrorist potentials. It could be weaponized with other chemical warfare agents to enhance their deleterious effects and cause prompt incapacitation and death. CX is one of the least studied chemical warfare agents with no effective treatments available. Skin damage associated with CX, necrosis and inflammation following CX-induced exposure to CX and mustard vesicants, e.g. sulfur mustard (SM) and nitrogen mustard (NM), is similar; however, CX also causes severe skin injury with immediate urticaria and blanching as well as mortality. The skin urticaria from CX resembles urticaria caused by allergic and non-allergic reactions to various environmental substances and can occur alone or can be associated with lethal allergic reaction, anaphylaxis. Data from our studies in SKH-1 hairless mice showed that CX exposure, using a more accurate and consistent exposure system, causes mast cell degranulation, and release of histamine, tryptase and TNFα that could activate inflammatory pathways, causes an increase in pro-inflammatory cytokines such as COX-2 and that HMEC-1s are responsive to HN2 including DNA repair and this contributes to vesicant-induced cytotoxicity and tissue injury. 2154 Amelioration of Nerve Agent Injury

C. Dalton, S. Graham, and J. Jenner. Dstl, Salisbury, United Kingdom.

Recent events in the UK and Syria have shown the importance of medical countermeasures against nerve agents. When considering percutaneous poisoning, it is of interest that nerve agents can cause more severe damage from skin contamination in the skin surface in a timely manner. Nerve agent therapies should be administered upon exhibition of signs and symptoms. Rapid transport to definitive medical care is then the priority. Timely intervention using a suite of medical countermeasures offers the best chance of casualty survival. Dstl is addressing the issue of increasing decontamination efficacy. Methodology has been developed to allow evaluation of decontamination regimens in vitro. The current work compared the UK in service decontamination DKP-1 Mk3 fullers’ earth pad (blot, bang, rub) regimen against a microfiber cloth based regimen after VX nerve agent contamination. Franz type static diffusion cells (diffusional surface area 14.87 cm²) were used. Pig abdominal flank skin was used as a surrogate for human skin. The receptor fluid was 50% aqueous ethanol. 14C-VX (10 μl) was placed onto the centre of the skin surface within the donor chamber. Four minutes post VX application the decontamination regimens were carried out. Receptor fluid samples were taken at regular intervals and 14C was measured by scintillation counting. Measured penetration rates (Jmax, μg cm⁻² h⁻¹) were 25 ± 20 (no decontamination), 0.8 ± 1.0 (DKP-1 Mk3) and 17 ± 21 (microfiber cloth). All values are mean ± standard deviation of n=8 individual animal replicates. Statistical significance (P <0.05, two way ANOVA with Sidak’s multiple comparison test) was shown between
cumulative 14C VX penetration for the no decontamination control and DKP-1 MK3 (from 7 hours) and microfiber cloth decontamination (from 12 hours). The likely discrepancy in decontamination efficacy lies with the skins microstructure. The furrows and wrinkles present in skin make it difficult to decontaminate with the weave of the microfiber cloth. Future work will evaluate a range of decontamination candidates against a range of nerve agents prior to testing in an in vivo model with therapeutic intervention administration. J. 2155 Genetic-Based, Differential Susceptibility to Exposure to Combined Organophosphate and Increased Glucocorticoid in a Mouse Model of Gulf War Illness

B. C. Jones1, J. P. O’Callaghan2, D. B. Miller1, L. Lu3, W. Zhao1, and D. Ashbrook1. 1University of Tennessee Health Sciences Center, Memphis, TN; and 2NIOSH, Morgantown, WV.

In 1990-1991, the USA sent 700,000 troops to the first Gulf War. Approximately 25% of the deployed soldiers developed a chronic multisystem illness with many features of "sickness behavior." This disorder now has been termed Gulf War Illness (GWI) and, remarkably, for those so afflicted, most have symptoms that persist to this day, nearly 30 years later. The cause of GWI has been thought to center on a variety of exposures that occurred in theater, including organophosphate nerve agent (sarin) and insecticides (e.g. chlorpyrifos). We have developed an animal model of GWI that combines exposure to corticosterone as a physiologic stressor mimic with trifluoroleflorphosphate (DFP) (as nerve agent analogue) to mirror some of the exposure/conditions that occurred in theater. The model was developed in the C57BL/6 (B6) mouse strain. The question raised was whether 25-30% of the troops became ill, what about those who did not -- all else being equal? The B6 mouse strain is one of the founders of a large panel of recombinant strains (BxD) derived from crossing the DBA/2 (D2) strain. The mouse model of individual differences in susceptibility to combined OP and high circulating glucocorticoid (corticosterone -- CORT) is to test the D2 strain and several of the BxD strains (and both sexes). The protocol involved adding corticosterone to the drinking water (20mg/kg) of the mice for 7 days followed on the 8th day by injection of diisopropyl-flourophosphate (DFP, 4mg/kg) followed 6h later by euthanasia and harvesting the frontal cortex. The index for neuroinflammation was change in expression of proinflammatory cytokine genes, IL1beta, IL6 and TNFalpha. The results showed that the D2 mice were less sensitive to CORT+DFP than the B6 and that there were large differences among 30 of the BxD strains. We then performed genome-wide mapping of the IL1beta results and found a significant marker (quantitative trait locus) on distal chromosome 7. Searching that area on Chromosome for possible candidate genes, we identified Spondin 1 as a candidate. The gene is cis-regulated and its expression is significantly correlated (r=0.76, p<0.01) with the expression of IL1beta expression under exposure to CORT+DFP. These results show that susceptibility to GWI likely has a genetic component and we will show that further testing of the BXD mice will produce more candidates. We can then identify biochemical pathways that differ and possibly develop treatments and means of prevention.

2156 Neuroinflammation Detected by Longitudinal TSPO Positron Emission Tomography (PET) is Associated with Deficits in Learning and Memory in a Rat Model of Acute Organophosphate (OP) Intoxication [BH1]

B. A. Hobson1, Y. Dou2, S. Bandara2, D. Rowland2, Z. Harmanay1, D. Brun2, D. Harvey1, A. Chaudhari1, and P. J. Lein1. 1University of California Davis, Sacramento, CA; and 2University of California Davis, Davis, CA.

Current medical countermeasures for acute OP poisoning do not protect against chronic cognitive impairment, underscoring the need for preclinical models that enable longitudinal monitoring of novel therapies. Previous studies using a rat model demonstrated neuroinflammation coincident with progressive neuronal necrosis following acute intoxication with the OP diisopropylfluorophosphate (DFP), suggesting neuroinflammatory mechanisms of chronic deficits. The goal of the current study was to determine whether OP-induced neuroinflammation, assessed by PET imaging with the TSPO radioligand [18F]PBR111, was associated with cognitive impairment. Adult male Sprague Dawley rats were treated with pyridostigmine (0.1 mg/kg, im) prior to administration of DFP (4 mg/kg, sc), atropine sulfate (2 mg/kg, ip) and 2PAM (25 mg/kg, im), with a subset receiving a benzodiazepine (BDZ) (5 mg/ kg diazepam, ip or 0.7 mg/kg midazolam, im) 45 min post DFP. TSPO expression in the brain was imaged using a Siemens F120 or Inveon DPET microPET scanner; anatomic registration was obtained using a Bruker 7T MRI. Animals were imaged on a Bruker 7T MRI at 7, 28, 65, 91, 182 d post DFP. DFP elicited moderate-to-severe seizure activity in all rats as determined using a modified Racine scale. DFP significantly increased TSPO labeling within multiple brain regions, including the hippocampus, thalamus, amygdala and piriform cortices. Regional quantification of [18F]PBR111 uptake was significantly correlated with baseline TSPO expression and amygdala assayed by c-Fos staining. The results demonstrate that BDZ therapy attenuates, but does not prevent, significant regional neuroinflammation following acute DFP intoxication. These findings suggest this neuroinflammation may contribute to cognitive impairment observed in survivors of acute OP intoxication. Supported by NIH CounterACT program (NS079202).

2157 Crossing the Blood-Brain Barrier to Combat Nerve Agent

Organophosphorus (OP) nerve agents inhibit the acetylcholinesterase (AChE) enzyme, disrupting the hydrolysis of acetylcholine. An excess of acetylcholine can lead to seizure activity, convulsions, respiratory distress, and even death. Oximes reactivate OP-inhibited AChE by detaching the OP from the enzyme. Pralidoxime (2-PAM) is the standard oxime countermeasure used by the US Army; however, 2-PAM is unable to cross the blood-brain barrier, making it ineffective against the central effects of nerve agent. Here, serum carboxylesterase knockout (Es1 KO) mice were used to investigate the in vivo reactivation of OP-inhibited AChE by the novel oximes SwRI-80 and SwRI-144, as compared to 2-PAM. Since carboxylesterase is required for OP hydrolysis, this is a vicious bioscavenger of nerve agent in mice. Es1 KO mice are comparable to a human model of OP toxicity. AChE activity was measured via Ellman’s assay for brainstem, cerebellum, cerebral cortex, hippocampus, midbrain, diaphragm, heart, and skeletal muscle. One-way ANOVAs were performed to control contrasts, which received the nerve agent sarin (GB), cyclosarin (GF), or VX followed by saline, to groups which received the corresponding nerve agent followed by one of three doses (n=8-9 per group) of 2-PAM, SwRI-80 or SwRI-144. 2-PAM significantly reactivated GB-inhibited AChE in heart, and VX-inhibited AChE in heart and diaphragm, but did not significantly reactivate GF-inhibited AChE in any tissues. SwRI-80 had no significant effect against GB-inhibited AChE, but it significantly reactivated VX-inhibited AChE in skeletal muscle and two brain regions (hippocampus and cerebellum) not affected by 2-PAM. Against GF, SwRI-80 also significantly reactivated AChE in skeletal muscle and two brain regions (midbrain and cerebellum) not affected by 2-PAM. SwRI-144 significantly reactivated GF and GB-inhibited AChE in all tissues, except GB-inhibited cerebellum and GH-inhibited GF AChE. Similarly, SwRI-144 significantly reactivated VX-inhibited AChE in all tissues, except cortex. The SwRI compounds appear to cross the blood-brain barrier and reactivates OP-inhibited AChE in various brain regions as well as skeletal muscle not affected by the standard oxime countermeasure 2-PAM.

2158 An Ex Vivo and in Vivo Comparative Study with MMB4 and 2-PAM to Determine Liabilities Associated with Toxic Levels of the Oximes

S. R. Roof, R. L. Hamlin, and C. L. del Rio. QTest Labs, Columbus, OH.

Oximes represent the standard of care against nerve agent poisoning, but several studies have shown that they can also induce striated muscle paralysis and cardiovascular changes. MMB4 has been proposed a potentially safer and more efficacious alternative to 2-PAM, the current therapeutic standard. Studies have shown that they can also induce striated muscle paralysis and cardiovascular changes. MMB4 has been proposed a potentially safer and more efficacious alternative to 2-PAM, the current therapeutic standard. OXIMES reactivate OP-inhibited AChE by detaching the OP from the enzyme. Pralidoxime (2-PAM) is the standard oxime countermeasure used by the US Army; however, 2-PAM is unable to cross the blood-brain barrier, making it ineffective against the central effects of nerve agent. Here, serum carboxylesterase knockout (Es1 KO) mice were used to investigate the in vivo reactivation of OP-inhibited AChE by the novel oximes SwRI-80 and SwRI-144, as compared to 2-PAM. Since carboxylesterase is required for OP hydrolysis, this is a vicious bioscavenger of nerve agent in mice. Es1 KO mice are comparable to a human model of OP toxicity. AChE activity was measured via Ellman’s assay for brainstem, cerebellum, cerebral cortex, hippocampus, midbrain, diaphragm, heart, and skeletal muscle. One-way ANOVAs were performed to control contrasts, which received the nerve agent sarin (GB), cyclosarin (GF), or VX followed by saline, to groups which received the corresponding nerve agent followed by one of three doses (n=8-9 per group) of 2-PAM, SwRI-80 or SwRI-144. 2-PAM significantly reactivated GB-inhibited AChE in heart, and VX-inhibited AChE in heart and diaphragm, but did not significantly reactivate GF-inhibited AChE in any tissues. SwRI-80 had no significant effect against GB-inhibited AChE, but it significantly reactivated VX-inhibited AChE in skeletal muscle and two brain regions (hippocampus and cerebellum) not affected by 2-PAM. Against GF, SwRI-80 also significantly reactivated AChE in skeletal muscle and two brain regions (midbrain and cerebellum) not affected by 2-PAM. SwRI-144 significantly reactivated GF and GB-inhibited AChE in all tissues, except GB-inhibited cerebellum and GH-inhibited GF AChE. Similarly, SwRI-144 significantly reactivated VX-inhibited AChE in all tissues, except cortex. The SwRI compounds appear to cross the blood-brain barrier and reactivates OP-inhibited AChE in various brain regions as well as skeletal muscle not affected by the standard oxime countermeasure 2-PAM.
rats. Serial blood samples were taken to determine plasma levels. In isolated rat diaphragms, MM84 exhibited a concentration-dependent reduction of nerve-evoked twitch tension starting at ~2 mM with complete paralysis occurring at 5.4 mM (IC_{50} = 3.2 mM). In vivo, both MM84 and 2-PAM elicited a progressive depression in diaphragmatic and skeletal muscle function, culminating in complete diaphragmatic inhibition. A less steep dose-response was observed for Oxime 15 compared to NIMP and PXN. The plasma exposure values at the start of diaphragmatic decline and complete paralysis were 0.6 and 3.9 mM for MM84 and 0.42 and 1.27 mM for 2-PAM. Therefore, the 'estimated safety index' (a fictional index defined as the plasma concentration ratio at collapse / start of decline) was greater with MM84 (6.6) than 2-PAM (3.0). In contrast, the seizures which can cause damage in the rat brain, our lab investigated substituted phenoxyalkyl pyridinium oxime acetylcholinesterase reactivators (US Patent 9,227,937) that penetrate the rat blood-brain barrier (BBB) in vivo tests with a sarin surrogate (nitrophenyl isopropyl methylphosphonate). When new serine hydrolase targets were found, atropine was added to the study. The results indicated that diaphragmatic depression (most likely due to neuromuscular blockade) is the primary liability of MM84 and 2-PAM in vivo, and 2) indicated that MM84 is safer than 2-PAM. In addition, these experiments demonstrated the feasibility of simultaneously assessing neuromuscular and cardiovascular toxicities in vivo, while showing that the ex vivo phrenic nerve-hemidiaphragm preparations may underestimate in vivo effects.

2159 Organophosphate-Induced Neuropathy in the Rat Hippocampus Is Mitigated by Novel Brain-Penetrating Oxime Acetylcholinesterase Reactivators

M. Dail, C. Leach, R. Pringle, E. Meek, C. Green, and J. Chambers.

The nerve agent sarin and the active metabolite of the insecticide parathion, paraoxon (PXN), inhibit acetylcholinesterase, causing excess synaptic acetylcholine and neuronal damage in the rat brain. Our lab investigated substituted phenoxyalkyl pyridinium oxime acetylcholinesterase reactivators (US Patent 9,227,937) that penetrate the rat blood-brain barrier (BBB) in vivo tests with a sarin surrogate (nitrophenyl isopropyl methylphosphonate). When new serine hydrolase targets were found, atropine was added to the study. The results indicated that diaphragmatic depression (most likely due to neuromuscular blockade) is the primary liability of MM84 and 2-PAM in vivo, and 2) indicated that MM84 is safer than 2-PAM. In addition, these experiments demonstrated the feasibility of simultaneously assessing neuromuscular and cardiovascular toxicities in vivo, while showing that the ex vivo phrenic nerve-hemidiaphragm preparations may underestimate in vivo effects.

2160 Novel Pyridinium Oximes in Combination with 2-PAM Potentiate Survival and Neuroprotection following Organophosphate (OP) Exposure

E. Meek and J. Chambers, Mississippi State University, Mississippi State, MS.

Inhibition of the enzyme, acetylcholine esterase (ACHE), in the central nervous system (CNS) by OPs, including nerve agents and some insecticides, results in overstimulation of the nervous system and may lead to death. Therapeutic response for OP exposures includes atropine, a muscarinic receptor antagonist, and an oxime, 2-PAM in the US, to reactivate inhibited ACHE. Although 2-PAM is an effective ACHE reactivator and can increase survival following OP intoxication, a limitation is its limited ability to cross the blood-brain barrier (BBB) and reactivate inhibited ACHE in the CNS. A series of novel pyridinium oximes have been synthesized to increase lipophilicity and the likelihood of BBB penetration. These novel oximes have shown the ability to cross the BBB, reactivate OP inhibited ACHE, attenuate seizure-like behavior and decrease neuropathology. The most efficacious novel oximes, determined from previous studies, were tested in binary mixtures with 2-PAM to maximize survivability and neuroprotection in rats administered lethal doses of nerve agent surrogates or paraoxon. A sarin surrogate, nitrophenyl isopropyl methylphosphonate, NIMP (0.6 mg/kg), and paraoxon (PXN, 0.8 mg/kg) were administered SC in rats following IM administration atropine (0.65 mg/kg) and binary mixtures of 2-PAM and novel oximes (146 µmoles/kg each) at the onset of seizure-like behavior. Novel oximes in combination with 2-PAM yielded 53-87%, 53-93% and 67-93% for NIMP, NIMP/Oxime 15 and PXN, respectively, while 2-PAM alone yielded 40%, 30%, and 50%. Subsequently, 24-hour survival was determined for mixtures of 2-PAM and novel oximes in guinea pigs (MRLGlobal) challenged with a LD_{50} of sarin. Guinea pigs were monitored and scored for signs of toxicity. Survival for binary mixtures of novel oximes and 2-PAM ranged from 63-87%. Toxic signs scores were lower for animals receiving binary mixtures of 2-PAM and novel oximes, indicating neuroprotection. Preliminary safety studies were conducted in rats on the novel oximes in binary mixtures with 2-PAM (146 µmoles/kg each). Rats were administered oxime mixtures and observed for two weeks. Daily body weights were tracked and serum chemistries were analyzed. No signs of toxicity were observed. Results suggest these oximes have therapeutic potential for OP exposures. Support: NIH U01/NS083430.

2161 Identifying New Serine Hydrolase Targets of a Sarin Analogue and Reactivation with Novel Phenoxyalkyl Pyridinium Oximes

C. Price, M. Dail, and J. Chambers, Mississippi State University, Mississippi State, MS.

Organophosphorus compounds (OPs) are known to inhibit several serine hydrolases, such as carboxylesterases, butyrylcholinesterase, and, most well-known, acetylcholinesterase through which it causes its fatal neurotoxic effects. Reactivating additional OP sensitive serine hydrolases could aid in attenuating these effects. The current in vitro study utilizes activity based protein profiling (ABPP) with fluorophosphoenzyme-biotin (FP) to determine the presence of brain serine hydrolases previously unknown to be sensitive to nerve agent inhibition by the sarin surrogate NIMP (nitrophenyl isopropyl methylphosphonate). When new serine hydrolase targets were found, attempts were made to reactivate them with novel phenoxyalkyl pyridinium oximes (US Patent 9,227,937) being developed in our laboratory as brain-penetrating reactivators. Microsomal fractions of brains from adult male Sprague Dawley rats were incubated with NIMP (in ethanol) to inhibit the serine hydrolases. For reactivation, the oxime in DMSO:ethanol (1:1) was added. The reaction was stopped with SDS loading buffer, heated at 90°C, subjected to 10% SDS-PAGE electrophoresis and probed with avidin-horseradish peroxidase following standard Western blot techniques. Protein bands were visible for non-inhibited serine hydrolases and invisible in inhibited samples. Controls included no FP and heat denatured samples. Of the eight serine hydrolases observed, one occurring at about 60 kDa was reactivated using our novel oximes. This new 60 kDa serine hydrolase target was identified as probably being fatty acid amidase hydrolase (FAAH) due to its interaction with PF-04457845, a covalent inhibitor for FAAH. FAAH is a metabolic serine hydrolase that regulates important signaling molecules of the endocannabinoid system such as anandamide and oleamide. OP-induced inhibition of FAAH and resultant anandamide accumulation has been implicated in being responsible for some OP-induced neurotoxicity. Thus, reactivation of brain FAAH during OP-induced toxicity may contribute to some of the neuroprotection observed for these novel oximes. Support in part from NIH U01/NS083430 and in part from the Center for Environmental Health Sciences, College of Veterinary Medicine, Mississippi State University.

2162 Effect of a Novel Brain-Penetrating Oxime Acetylcholinesterase Reactivator on Sarin Surrogate-Induced Changes on Gene Expression in the Rat Brain

D. Stanford, M. Dail, E. Meek, and J. Chambers, Mississippi State University, Mississippi State, MS.

Novel phenoxyalkyl pyridinium oximes (US Patent 9,227,937) penetrate the blood-brain barrier (BBB) and reactivate acetylcholinesterase (ACHE) in vivo tests with the sarin surrogate nitrophenyl isopropyl methylphosphonate (NIMP). Organophosphates are believed to induce expression of stress genes in the rat brain in addition to ACHE inhibition. If correct, NIMP would upregulate mRNA expression of stress genes as compared to the control group or...
the group exposed to NIMP followed by a novel oxime. A PCR array was used to examine changes in mRNA levels of 84 rat genes known to be regulated by stress and toxic cellular responses. Rats were administered 0.325 mg/kg NIMP or the biocompatible vehicle (Multisol) sc, and one-hour post-NIMP exposure administered novel Oxime 20 or 2-PAM (146 μmoles/kg) in Multisol im. Brains were removed and piform cortex was dissected 2 hours post oxime treatment. Treatment groups were vehicle control (Multisol), NIMP, NIMP/ Oxime 20, and NIMP/2-PAM. Tissues were homogenized, total RNA was extracted, and cDNA synthesized. The cDNA was added to Qiagen’s RT- SYBR Green ROX qPCR Mastermix for analysis using the Qiagen Stress and Toxicity Pathway Finder RT® PCR array on the Stratagene Mx3000P. All test groups were compared to Qiagen’s GeneGlobe Data Analysis Center. NIMP exposure seems to alter gene expression associated with cell cycle and cell death processes. In the presence of Oxime 20, different genes are significantly upregulated relating to oxidative and osmotic stress compared to the NIMP group. Compared to controls, the NIMP/Oxime 20 group had over twice as many significantly expressed genes as did the NIMP/2-PAM group supporting the concept of Oxime 20 efficiently penetrating the BBB whereas 2-PAM fails. Additional evidence that 2-PAM is unable to effectively penetrate the BBB comes from the lack of significant expression changes seen when the NIMP/2- PAM group was compared to the NIMP group. Significant differences were observed, however, when the NIMP/Oxime 20 group was compared to the NIMP group. Supported by Center for Environmental Health Sciences, Mississippi State University, Mississippi State, MS and NIH U01 NS107127.

2163 Inhibition and Reactivation Potential of Novel Phenoxyalkyl Pyridinium Oximes on Rat Serum Butyrylcholinesterase and Acetylcholinesterase
R. Nichols, and J. Chambers, Mississippi State University, Mississippi State, MS.

Oxime reactivators are a critical piece in treating poisoning by organophosphates (OPs), which are nerve agents and some insecticides, that potently inhibit acetylcholinesterase (AChE) and butyrylcholinesterase (BChE). Prolonged inhibition of AChE leads to seizures, cardiac arrest, and death if left untreated, while BChE can function as a stoichiometric scavenger of OPs. Oxime reactivators are strong nucleophiles and act by removing the OP from the enzyme, thus restoring normal enzyme function. The current oxime platforms lack broad spectrum protection and they display poor brain penetration to protect against OP neurotoxicity. Our laboratories have developed new oxime reactivators that can reactivate BChE to provide a pseudo-catalytic function, and they penetrate the blood brain barrier more effectively to reactivate brain AChE. This study investigated the in vitro reactivation potential of our novel phenoxyalkyl pyridinium oximes (US patent 9,227,937) and 2-PAM on both AChE and BChE after inhibition by surrogates of sarin (phthalimidyldimethylisopropyl methylphosphonate; PIMP) and VX (niproxyphen ethyl methylphosphonate; NEMP) and the insecticidal metabolite paraaxon in rat serum, as well as the inhibitory potential of these oximes over the concentration range of 1-200μM. In a standardized in vitro protocol, high reactivation efficacy was observed toward rat BChE by novel oxime 15 vs 2-PAM for PIMP (78% vs 46%), NEMP (86% vs 8%) and paraaxon (95% vs 32%) while 2-PAM was more efficient at reactivating AChE for all OPs. Relatively high inhibition potency was observed with novel oxime 20 for both BChE and AChE, and low inhibitory potential with novel oxime 15 for BChE and moderate inhibitory potential for AChE. 2-PAM displayed low inhibitory potential for both enzymes. Since oximes can act as anticholinesterases, identifying concentrations that can allow for adequate AChE or BChE reactivation without appreciable AChE inhibition will be of great value. Even though the novel oximes have inhibitory potential for both cholinesterases, in rats at realistic therapeutic levels in vivo these oximes have shown impressive efficacy for survival of OP dosages that produce seizure-like behavior and attenuation of histopathology. Therefore this platform could be a promising alternative approach in treating OP poisoning. Support: NIH U01 NS083430.

2164 Novel Pyridinium Oximes Enhance 24-Hour Survivability against Lethal Organophosphate Dosages in Adult Female Rats
J. Garcia, and J. Chambers, Mississippi State University, Mississippi State, MS.

Anticholinesterase organophosphate (OP) compounds were developed as insecticidal pesticides and are also used as nerve agents in chemical warfare. Treatment against acute OP toxicity includes oximes which reactivate phosphorylated acetylcholinesterase restoring enzymatic activity. The oxime currently approved for use in the U.S., pralidoxime (2-PAM), has limited efficacy penetrating the blood-brain barrier. Our laboratory has developed novel substituted phenoxyalkyl pyridinium oximes (US Patent 9,227,937) designed to more effectively penetrate the central nervous system to enhance survivability and attenuate seizure-like signs. Previous studies with male Sprague-Dawley rats indicated that survivability was enhanced against the nerve agent (sarin) surrogate, 4-nitrophenyl isopropyl methylphosphonate (NIMP) and paraoxon (PON), the active metabolite of the insecticide parathion. Against NIMP, novel oximes 15 and 20 demonstrated odds ratios of 2.3 and 1.8 compared to 2-PAM while novel oximes 15 and 55 increased PXN survivability 5.7 and 2.3 times greater than 2-PAM, respectively. Sex is an important biological variable that must be taken into account when testing efficacy of novel antidotes. In this study, female adult Sprague-Dawley rats were treated with LD₅₀ concentrations of NIMP (0.6 mg/kg SC) or PXN (0.8 mg/kg SC). After development of seizure-like behavior, atropine (0.65 mg/kg IM) and one of four oximes, 2-PAM, novel oxime 15, 20, or 55 (0.146 mmol/ kg IM) or Multisol vehicle was administered. Animals were closely monitored for signs of cholinergic toxicity and 24-hour survivability. Odds ratios and p-values were calculated using 2-PAM as the referent. Survival percentages of animals surviving the 24-hour NIMP challenge dose were 40% for 2-PAM and 60%, 73%, and 33% for novel oximes 15, 20, and 55, respectively. The most effective oxime against NIMP was novel oxime 20 demonstrating an odds ratio of 4.1 over treatment with 2-PAM (p = 0.072). Survival percentages of animals surviving the 24-hour PXN challenge dose were 67% for 2-PAM and 93% for all of the novel oximes. All of the novel oximes demonstrated an improved odds ratio of 7.0 over 2-PAM (p = 0.007). These data indicate that the novel pyridinium oximes enhance survivability against lethal OP toxicity as compared to 2-PAM in adult female rats. Support: NIH U01 NS083430 and U01 NS107127.

2165 Evaluation of Allopregnanolone as Treatment for Nerve Agent-Induced Status Epilepticus in Pediatric and Adult Rats

Nerve agents (NA) are organophosphorous compounds that inhibit acetylcholinesterase, causing a buildup of acetylcholine that can lead to salivation, lacrimation, convulsions, status epilepticus (SE) and even death. Thousands of men, women, and children have been exposed to NAs in the past decade, but the vast majority of NA research in animals has only focused on adult males. In this project, post-natal day (PND) 21, 28, and 70 male and female rats were challenged with sarin (GB) or VX to determine anticonvulsant effective doses (ED50) of the neuroactive steroid allopregnanolone (Allo), which has been reported to stop SE. Rats, previously implanted with electroencephalographic (EEG) electrodes to monitor seizure activity, were administered either GB or VX; five min after SE onset, animals were treated with Allo. ED50 values were determined using an up-down testing method based on four reversals (Dixon & Massey, 1983). ED50 values for Allo-treated PND70 rats ranged from 20-60 μg/kg, with rats exposed to VX generally requiring higher Allo doses to terminate seizures. ED50 values tended to be lower in pediatric animals, ranging from 13.5-31 mg/kg. While Allo is effective in terminating seizures, these ED50s are higher than those of benzodiazepines, such as midazolam (MDZ), which has ED50 values ranging from 1-3 mg/kg in this model. The latency to seizure termination in Allo-treated animals is comparable to that of animals treated with MDZ. This makes Allo a sound choice in treatment of NA-induced SE.

2166 Comparing the Anticonvulsant Efficacy of the Neurosteroids Ganaxalone and Allopregnanolone in a Rat Model of Delayed Treatment of Nerve Agent Intoxication
S. Mills, B. Barker, C. Jackson-Piercy, J. McDonough, and H. McCarron, USAMRICD, Gunpowder, MD.

Nerve agent attacks on soldiers and civilians by terrorist organizations, militant governments, and assassins have been prominent in recent years. Nerve agents irreversibly block acetylcholinesterase activity, resulting in accumulation of excessive acetylcholine (ACH) at neural synapses. This can lead to a state of prolonged seizure activity, known as status epilepticus (SE). As little as 20 minutes of SE is sufficient to produce frank neuropathology that causes chronic neurological dysfunction. Benzodiazepines, the current anticonvulsant standard of care, become less effective as the time-to-treatment increases, likely due to internalization of synaptic GABA receptors. Neurosteroids (NS), which modulate both synaptic and extrasynaptic GABA receptors, offer a promising mechanism to terminate nerve agent-induced SE at delayed treatment time points. Here we utilize a rat model of soman-
duced SE evaluate the efficacy of the NS ganoxalone and allopregnanolone administered in conjunction with standard medical countermeasures. Adult male rats with cortical EEG electrodes were exposed to soman and administered a NS test treatment or vehicle along with midazolam 20 minutes post-SE onset. SE terminated in 6/9 rats treated with ganoxalone, 4/9 rats treated with allopregnanolone, and 0/10 vehicle-treated rats. The latency to SE termination was 34.0 ± 11.2 min for ganoxalone and 15.8 ± 6.5 min for allopregnanolone. Likelihood of SE termination did not differ between NS treatments (Chi-square, p = 0.34), nor did latency to SE termination (t-test, p = 0.20). However, ganoxalone significantly reduced EEG spike frequency and gamma power relative to controls at multiple time points, while allopregnanolone was only effective at a single time point. Following EEG analysis, fluoroJade B (FJB) staining was used to assess the neuroprotective effects of the two NS. Surprisingly, allopregnanolone reduced the number of FJB+ cells relative to controls in the amygdala, piriform cortex, and parietal cortex, while ganoxalone was only effective in the piriform cortex. In conclusion, both ganoxalone and allopregnanolone offer potential anticonvulsant and neuroprotective benefits, but further optimization of NS structure could enhance both outcomes.

### 2167 Lethality and Acetylcholinesterase Inhibition in the Larval Zebrafish Can Be Used as Screening Endpoints for Assessing Organophosphate Acute Toxicity in Humans

Organophosphate (OP) nerve agents (e.g. Sarin, VX, Tabun) and pesticides elicit toxicity through cholinergic shock via inhibition of the enzyme acetylcholinesterase (AChE). AChE is an enzyme responsible for the breakdown of the neurotransmitter acetyl choline in the synaptic cleft for the regulation of neuronal function. Zebrafish express the highly conserved AChE gene as early as the 5-7 somite stage and progress toward full expression AChE by 7 days post-fertilization (dpf). Five dpf embryos also express Cytochrome P450 detoxification enzymes responsible for biotransformation of many xenobiotic compounds. Zebrafish have gained recent popularity as a potential model for human toxicity in response to environmental chemicals and neuroactive pharmaceuticals. In this study, we sought to develop an acute toxicity larval screening tool for AChE inhibiting compounds. We utilized 6 dpf Danio rerio embryos to examine nerve agent lethality and cholinesterase inhibition relative to well-known OP pesticides parathion (PT) and chlorpyrifos (CPF). In addition, we assessed the OP potent, cyto-dependent desulfonated metabolites of the OPs, paraoxon (PT-O) and chlorpyrifos-oxon (CPF-O). We first compared the 24 hour lethality response to VX with the OP pesticides and the oxon counterparts. VX was ~400x more potent than CPF and over 1000x more potent than PT. We then compared the AChE inhibiting potential of VX relative to the OPs when normalized to the lethal dose. VX induced a 100% inhibition of AChE, which was not observed with the less-active commercial pesticides that caused approximately 75% inhibition (PT) after a 24 hour exposure to the LD50. The oxon derivatives of the OP pesticides were notably more toxic than the parent compound (13x for PT-O and 47x for CPF-O) indicating the importance of metabolism in the 6 dpf embryo model. VX, which does not require bio activation, demonstrated lethality and AChE inhibition potential, more similarly to the active oxons than the parent OPs. Overall, this work shows the potential of the 6 dpf zebrafish to be an acceptable model for nerve agent potency and propensity for AChE inhibition, both of which factor into the human toxicity assessment for emerging threat compounds. Approved for public release; distribution unlimited.

### 2168 Intramuscularly Administered A1 Adenosine (ADO) Receptor Agonist (±)-5'-Chloro-5'-Deoxy-ENBA (cdENBA) Induces Isoelectric Brain State in Rats

Organophosphorus nerve agents (NA), such as soman (GD), irreversibly bind and inhibit acetylcholinesterase, the enzyme responsible for degradation of acetylcholine (ACh). The subsequent overstimulation of cholinergic receptors by this excess ACh can result in sustained seizure activity, or status epilepticus (SE), and subsequent neuropathology. The efficacy of current standards of treatment for NA in controlling seizure activity is dependent on the rapidity of administration. In a mass casualty chemical event, prompt treatment of victims may not be feasible, so new countermeasures capable of terminating SE soon after delayed administration are needed. Past research has shown that activation of A1 ADO receptors can inhibit widespread neuronal excitability, which could aid in seizure termination. cdENBA can induce an isoelectric brain state (indicating strong anticonvulsant efficacy) when administered via intraperitoneal (IP) injection (62 mg/kg) in rats. However, IP injections in the field are not practical, and a more realistic route of administration is needed. Thus, the current study examined the ability of cdENBA to induce an isoelectric brain state when given via intramuscular (IM) injection. Adult male Sprague-Dawley rats with EEG electrode implants were monitored for 30 minutes prior to IM cdENBA injection (45-90 mg/kg) and for an additional 5 hours following injection. Power analysis of EEG data demonstrated that a 50 mg/kg IM injection of cdENBA could induce an isoelectric brain state in a comparable amount of time (2.66 ± 0.98 minutes, N=4) to a 62 mg/kg IP injection of cdENBA (2.60 ± 0.76 minutes, N=6). Quick induction of an isoelectric state could be beneficial in treating GD-induced SE, so these results are promising for further studies of IM-administered cdENBA as an effective NA countermeasure for not only immediate, but also delayed treatment.

### 2169 Delayed Treatment with Midazolam Increases Survival but Is Not Fully Protective against Soman-Induced Epileptogenesis and Neuropathology in Male and Female Carboxylesterase Knockout Mice

E. Kundrick1, B. Marrero-Rosado1, M. de Araujo Furtado2, M. Stone1, C. Schultz2, K. Walker1, S. O’Brien3, R. Lee1, and L. Lumley1, USAMRICD, Aberdeen Proving Ground, MD; and BioSeAD, Rockville, MD. Sponsor: L. Wright

Chemical warfare nerve agents (CWNA) are inhibitors of acetylcholinesterase (AChE) and in animal models lead to status epilepticus and spontaneous recurrent seizures (SRS) and severe neuropathology when treatment is delayed. In addition to binding to AChE, some organophosphorus (OP) CWNA such as soman (GD) also inhibit carboxylesterase (CaE), which acts as a bioscavenger and can greatly affect the severity of the toxicity of OP agent exposure. Unlike humans, rodents have plasma CaE activity. The CaE knockout (ES1/-) mouse specifically lacks plasma CaE and might better model human GD exposure compared to wildtype rodents. Since delayed treatment with midazolam leads to benzodiazepine-refractory SE, we characterized the dose response effects of delayed midazolam treatment in male and female mice, for future use as a model to evaluate combination therapies. In Exp. 1 a sequential stage-wise approach was used to establish a 24 h lethality dose-response curve of GD, in both sexes, accounting for stage of estrus in females. In Exp. 2, mice implanted with telemetry transmitters for electroencephalography (EEG) seizure identification were exposed to 62 µg/kg GD (~4LD50) and treated with an admix (ip) of atropine sulfate (4 mg/kg) and H1-6 (50 mg/kg) 1 min after exposure, and with midazolam (1, 3, or 9 mg/kg/ip) at 40 min after seizure onset. Mice were continuously recorded to evaluate initial seizure duration and SRS and then euthanized 2 weeks after exposure for neuropathology assessment. In estrus were the least susceptible to the lethal effects of GD. Delayed treatment with midazolam increased survival in a dose-dependent manner in both sexes, but was unable to terminate behavioral and EEG seizure activity and did not prevent the development of SRS or neuronal loss following GD exposure. This study demonstrated that delayed treatment of SE with midazolam is not fully protective against the GD-induced epileptogenesis and neuropathology, exemplifying the need for adjunct treatment to midazolam to prevent or reduce effects of GD-induced SE. Research was supported by the CounterACT Program, NIH OD, and the NINDS (Grant 1R21NS103820-01 to LA Lumley-Lange).

### 2170 Characterization of a Mouse Model of Tetramethylenedisulfotetramine (TETS)-Induced Status Epileptics

TETS is a potent convulsant rodenticide that is considered a credible chemical threat agent. In humans, acute intoxication with TETS at high doses can trigger seizures that can progress to status epilepticus (SE) and death. Survivors are at increased risk for developing neurobehavioral deficits. Persistent neuroinflammation has been associated with decrements in cognitive, psycho-motor and affective behavior; therefore, in this study we assessed the effects of acute TETS intoxication on neuroinflammatory responses and behavior in adult male C57BL/6j mice. Mice were injected with nirole (5 mg/kg, ip) 10 min prior to injection with TETS (0.3 mg/kg, ip). Using this exposure paradigm, animals exhibited >1 h of persistent seizure activity as assessed by electroencephalography and behavioral observation. In the absence of rescue therapy, ~90% of the animals died by 24 h post-TETS exposure. Diazepam (1.8 mg/kg, ip) or midazolam (1.8 mg/kg, im) administered 40 min after the initiation of seizure activity increased survival at 24 h post-TETS to > 50%. Correlative...
histology revealed time-dependent reactive astrogliosis and microglial activation as determined by GFAP and Iba-1 immunoreactivity, respectively. The magnitude of the neuroinflammatory response was positively correlated with the duration of seizure. C57BL/6/J mice who survived acute intoxication demonstrated increased anxiety-like behavior and hyperactivity at one week post-exposure, and these phenotypes persisted at one month post-exposure. Collectively, these studies identify the C57BL/6/J mouse as a model that exhibits more robust neurologic responses to TETs-induced SE than the previously characterized NIH Swiss mouse model of TETS-induced SE. These findings suggest that the C57BL/6/J mouse may be a better model for assessing candidate therapeutics for efficacy in protecting against delayed and persistent neurologic sequelae. Supported by the NINDS CounterACT Program (grant US4 NS079202).

2171 Acute Intoxication of Juvenile Rats with Diisopropylfluorophosphate (DFP) Causes Sex-Specific Seizure Behavior and Neuropathology

E. A. González, S. Supasai, and P. J. Lein. University of California Davis, Davis, CA.

Organophosphates (OPs) are used globally as pesticides and chemical threat agents, and cause hundreds of thousands of deaths per year as a result of intentional and accidental poisonings. Acute OP intoxication inhibits acetylcholinesterase (AChE), which can trigger seizures that progress to status epilepticus (SE). Neurotoxicity and death. Efforts to develop improved medical countermeasures against OPs have largely focused on adult male models. However, OP-induced neurotoxicity is known to differ between juveniles and adults, as well as between males and females. Therefore, the goal of this project was to develop a juvenile model of acute OP intoxication that elicits seizure behavior and neuropathology. Juvenile (postnatal day 28) Sprague-Dawley male and female rats were acutely intoxicated with the OP chemical threat agent DFP (3.4 mg/kg, s.c.) or an equal volume of vehicle (saline, s.c.) followed by a combined injection of atropine sulfate (0.1 mg/kg, i.m.) and 2-PAM (25 mg/kg, i.m.). Exposed animals were monitored for seizure behavior during the first 4 h post-exposure. At 1 d post-exposure, all animals were evaluated for cortical AChE activity as determined by the Ellman assay. Body weight, neuroinflammation as determined by quantitative immunohistochemistry of Iba-1 (microglia), CD68 (phagocytic microglia), and GFAP (astrocytes), and neurodegeneration as measured by FJC staining. Both males and females showed significant AChE inhibition. Following DFP intoxication; however, females showed minimal seizure behavior compared to males, who showed pronounced seizure behavior for up to 4 h. Following DFP intoxication, females showed increased body weight whereas males showed decreased body weight relative to sex-matched vehicle controls. DFP males displayed severe neuroinflammation and neurodegeneration in the cortex and hippocampus, but DFP females did not. These findings suggest that sex differences exist in DFP-induced neurotoxicity in juvenile animals, and that seizure behavior likely contributes to neuropathology following acute intoxication of the juvenile brain. Supported by the NIH CounterACT program (NS079202) and a predoctoral fellowship to EAG (NIH GM5676520, Initiative for Maximizing Student Development).

2172 Delayed Adenosine A1 Receptor Agonist (±)-5’-Chloro-5’-Deoxy-ENBA (cdENBA) Treatment Terminates Soman-Induced Status Epilepticus

K. Meads, A. Wegener, T. Thomas, and T. Shih. USAMRICD, Aberdeen Proving Ground, MD; and US Army Research Laboratory, Aberdeen Proving Ground, MD. Sponsor: J. Dillman

Nerve agent (NA) intoxication initiates a cascade of deleterious physiological responses that ultimately, induce a state of unremitting seizure known as status epilepticus (SE). As intoxication progresses, different neurotransmitter systems emerge as targets for terminating SE. Current medical countermeasures act upon specific neurotransmitter systems and, therefore, may not be effective in terminating certain phases of intoxication. Previous research has demonstrated that administration of the adenosine A1 receptor agonist cdENBA (62 mg/kg, IP) one minute after NA exposure prevented seizure onset and negated accompanying neuropathology. In this study, we assessed cdENBA’s ability to terminate SE using a delayed-intervention model that simulates realistic medical response times. Adult Sprague Dawley rats were exposed to soman (1.2 x LD50) and remained untreated (N = 8) or received cdENBA treatment (62 mg/kg, IP) 30 (N = 8) or 60 (N = 10) minutes after onset of SE. Five hours after exposure, 50% of the animals treated at 30 minutes and 100% of the animals treated at 60 minutes were alive, compared to 37% of untreated animals. Frequency analysis of the 5-hour post-exposure EEG of surviving animals showed that SE terminated in 3 of 4 rats in the 30-minute group, and 9 of 10 rats in the 60-minute treatment group. No seizure termination was observed in the untreated group. cdENBA demonstrated a novel ability to terminate SE across a range of immediate and delayed administration time points, making it a strong candidate as a countermeasure for soman-induced SE. Future experiments will identify a window for treatment where the brain can be protected against neurotoxicity and the eNOS pathway. cdENBA will be pursued. The views expressed in this abstract are those of the author(s) and do not reflect the official policy of the US Department of Army, US Department of Defense, or the US government. The experimental protocol was approved by the Animal Care and Use Committee of the US Army Medical Research Institute of Chemical Defense, and all procedures were conducted in accordance with the principles stated in the Guide for the Care and Use of Laboratory Animals and the Animal Welfare Act of 1966 (P.L. 89-544), as amended. This research was supported by an Interagency Agreement (IAA) between NIH/NIADDK (IAA Number AOD12058-001-00000) and the USAMRICD (Number A120-B.P2012-02).

2173 A Targeted Approach for Terminating Tetramethylenedisulfotetramine (TETS)-Induced Status Epilepticus and Attenuating Neurotoxicity in Zebrafish

Zebrafish have been used as a seizure model for nearly two decades; however, important questions regarding the mechanisms of seizure termination as well as persistent neurologic effects are not well characterized. Our lab is poised to address these concerns using a targeted pharmacological approach encompassing pharmacologic and advanced genetic techniques, including CRISPR/Cas9. In this study, NGR wild-type zebrafish (Danio rerio) were used to screen small molecule enhancers of GABAergic neurotransmission, including CD111, a putative γ-aminobutyric acid receptor type A (GABA_A, R) subunits for efficacy in terminating seizures induced by tetramethylenedisulfotetramine (TETS), a potent GABA_A, R antagonist and credible chemical threat agent. Larval zebrafish were allowed to develop under normal rearing conditions until 4 days post fertilization (dpf) whereupon individual larva were separated into separate wells of a 96-well plate. Following a 24 h acclimation period, each GABA_A, R subunit-specific PAM and the positive control, midazolam (3 μM), were tested in two treatment paradigms: pretreatment for 20 min prior to the addition of 4 μM TETS, and post-treatment 20 min after 4 μM TETS. GABA_A, R α1 subunit-selective compounds were the most effective in reducing seizure behavior following TETS exposure. LS38417 (1 and 10 μM), NS11394 (1 μM), and TCS1105 (1 and 10 μM) also significantly reduced seizure behavior in larval zebrafish when added following TETS exposure. In addition, α2-selective compounds TCS1105 (1 and 10 μM) and LS73847 (10 μM) reduced seizure behavior near midazolam levels when added post-TETS. Our future objective is to characterize the efficacy of GABA_A, R PAMs for efficacy toward attenuating neurotoxic endpoints following TETS exposure. Through this research, we hope to improve current methods for identifying therapeutics for terminating chemical-induced seizures and protecting against imminent seizure toxicity. Supported by the NIH CounterACT program (NS079202).

2174 RNA Seq Transcriptome Analyses Reveals Genes and Pathways Involved in Acute Exposure to Hydrogen Sulfide

D. Kim1, P. Anantharam1, P. Padhi1, D. R. Thedens2, G. Li3, and W. K. Rumbelha1. Iowa State University, Ames, IA; and 1University of Iowa, Iowa City, IA.

Hydrogen sulfide (H2S) is a gaseous molecule produced endogenously and in the environment. Acute exposure to high concentration of H2S causes severe brain damage and induces long-term neurological sequelae. The exact mechanisms underlying the H2S-induced dysfunction of central nervous system have not yet been clearly elucidated. RNA Seq transcriptome analysis was performed to identify key elements and pathways that contribute to H2S-induced neurotoxicity. C57BL/6J black mice were exposed by whole body inhalation to 700 ppm for 4, 1, or 0.5 h. At 6 h post TETs, the mice were sacrificed. The rats were fixed on subsequent days to evaluate immediate, early and late responses, respectively. The H2S-treated groups showed behavioral motor deficits and developed lesions in inferior colliculus (IC), among other regions. The IC was dissected at 2 hr post H2S exposure for each group and used for the RNA Seq analysis. Acute exposure to H2S induced 283, 193 and 278 DEG (q-value < 0.05, fold-change > 1.5) for immediate, early, and late responses, respectively. Dysregulated biological pathways were further analyzed using Ingenuity Pathway Analysis. H2S...
2175 Antidotal Protection Enhancement of the Cyanide Antidote DMTS by Formulations with Combinadine Derivatives

I. Petrovikovs1, L. Kiss1, K. Kovacs1, M. Kiss1, M. Buda1, C. Chio1, A. Ebrahimpour2, A. Chan3, G. R. Boss3, and G. Rockwood4, 1Sam Houston State University, Huntsville, TX; 2University of California San Diego, San Diego, CA; and 3USAMRICD, Aberdeen Proving Ground, MD.

Dimethyltrisulfide (DMTS) is an established sulfur donor type cyanide (CN) antidote candidate. The focus of this study is to demonstrate how appropriate formulations and combinations with other CN antidotes having different mechanisms of action, can enhance the antidotal efficacy of the neat DMTS. The following formulation compositions and DMTS doses were investigated: 1) Micellar DMTS (2 mg/mL in PEG2000-DSPE, 12.5 mg/kg); 2) DMTS in emulsion (peanut oil, polysorbate 80, glycerol, water, 20 mg/mL, 100 mg/kg); 3) Poly80-formulated DMTS (15% aqueous polysorbate 80, 50 mg/mL, 25 and 50 mg/kg). The combination partners for the Poly80-formulated DMTS (doses: 25 and 50 mg/kg) were a) Nitrocoibinamide (4NCbi): (dose: 20 mg/kg); b) Aqo-hydroxycobinamide (AHcbi): (doses: 50, 100, and 250 mg/kg). The antidotal efficacy was determined by using the Dixon up-and-down method on mice, and expressed as antidotal potency ratio (APR). The “Dunnnett’s Multiple Comparison Test” was employed for significance determination. The APR values of 1.2 (dose: 25 mg/kg) and 1.5 (dose: 50 mg/kg) of the neat DMTS were significantly enhanced by the investigated formulations. When Poly80-DMTS (doses: 25 and 50 mg/kg) was combined with 4NCbi (dose: 20 mg/kg), significant increases in the APR values were noted. AHCbi enhanced the APR of Poly80-DMTS significantly only at the dose of 250 mg/kg. These studies prove the importance of formulations and combinations for DMTS as CN antidote. The Institutional Animal Care and Use Committee (IACUC) permission number is 15-09-14-1015-3-01.

2176 Partitioning and Elimination Kinetics of the Cyanide Antidote Candidate Dimethyl Trisulfide in Sheep Blood

C. T. Rios, A. Ebrahimpour, E. Kefer, M. Carpenter, L. Kiss, A. C. Whiteman, D. Thompson, and I. Petrovikovs. Sam Houston State University, Huntsville, TX.

Cyanide inhibits cytochrome C oxidase, the terminal oxidase of the mitochondrial electron transport chain, thereby suppressing cellular oxygen utilization and aerobic ATP production. Dimethyl trisulfide (DMTS) is recently well investigated as a cyanide antidote candidate. It is a small, highly lipophilic, naturally occurring molecule, present in garlic and onion in the highest concentrations. Studies have shown that DMTS has significantly higher in vitro sulfur donor reactivity and in vivo antidotal efficacy than the present cyanide therapy thiocyanate. This study focuses on the DMTS partitioning between red blood cells (RBC) and plasma as well as the DMTS elimination kinetics in these blood components. This in vitro blood study clearly demonstrates that DMTS accumulates 6.2 times more in RBC than in plasma. The DMTS elimination is substantially faster in plasma (t1/2 = 1.5 min) than in RBC (t1/2 = 2.2 min). Based on the blood partitioning and elimination kinetics, RBC can be considered as an efficient carrier for distributing DMTS to other organs.

2177 In Vitro and Ex Vivo Models in Medical Chemical Defense Research

T. Wille, J. Herbert, K. Marquart, N. Amend, F. Worek, and H. Thiermann, Bundeswehr Institute of Pharmacology and Toxicology, Munich, Germany.

The recent use of organophosphorus nerve agents (OPNA) in military conflicts and for assassinations highlights the threat by these compounds and the need for optimized medical countermeasures (MedCM). As animal experiments are expensive, time-consuming and increasingly under public scrutiny, well-conceived in vitro and ex vivo models are important to pre-select candidate MedCMs. The main target of OPNA is inhibition of acetylcholinesterase (AChE). The use of a dynamic flow-through model allows exposure of erythrocytes, muscle and brain AChE to OPNA and MedCM simulating toxicco- and pharmacokinetics combined with real time determination of AChE activity. In the model, inhibition of AChE was with a combination of HI-6 and obidoxime showed no additive effect but the reactivation spectrum was broadened, which could bridge efficiency gaps until a single reactivator with broader spectrum is available. To address the potential of OPNA- and MedCM-induced dysrhythmias, a multi electrode array (MEA) using hiPS-derived cardiomyocytes and a Langendorff apparatus were established. The OPNA cyclosporin resulted in a dose-dependent increase in corrected field potential duration (600 nsec; 9.4±0.5%), which was fully reversible by atropine but not by HI-6. The approved oximes obidoxime and pralidoxime and the candidate reactivators HI-6 and MMB-4 did not induce dysrhythmia in the MEA and the Langendorff heart. Cholinergic crisis results in smooth muscle contraction. Consequently, a small bowel and lung tissue model were established. For the small bowel model, material from patients undergoing routine surgery was used. Specimens were exposed to the OPNA sarin and treated with scopolamine as the most potent compound with an EC50 of 50 nM. The reactivator HI-6 was more potent than obidoxime (EC50 3.8 µM vs. 197.8 µM). As lung tissue model, precision cut lung slices allow to assess the efficacy of asthma and COPD therapies in OPNA-poisoning after acetylcholine-induced airway contraction. β2-agonists had a negligible effect whereas glycopyrrolate (EC50 15.8 nM) and ipratropium (EC50 2.3 nM) efficiently reversed acetylcholine-induced airway contractions in VX poisoning. Significant effects were also achieved by combining formoterol or salbutamol with atropine, vocating a RCT in patients poisoned by OP pesticides. Complex in vitro and ex vivo models are successfully established and can serve as important tools to accelerate development of MedCM and allow optimized planning of focused in vivo experiments.
Exposure to carbon nanotubes and multi-walled carbon nanotubes (MWCNT) is due to their use as drug carriers and medical devices. These MWCNTs that enter the blood circulation end up in the liver and are trapped in the reticuloendothelial cells. We have reported an increase in high mobility group box-1 (HMGB1) expression in hepatocyte cell line (HC-04) due to MWCNT exposure. HMGB1 is considered a mechanistic marker of liver injury since its release is associated with cellular necrosis and immune cell activation. Ethanol and Acetaminophen (APAP) are commonly used agents that produce liver toxicity during overdosing. The toxic effects of MWCNT during co-exposure to known hepatotoxictants (APAP or Ethanol) is not known. Therefore, the goal of the study is to evaluate the cytotoxic nature of MWCNT during co-exposure with hepatotoxictants in HC-04 cells. HC-04 cells were exposed to MWCNT for a period of 72 hours and subsequently treated with either 15 mM APAP or 360 mM Ethanol for 24 hours. At the end of the study, the cytotoxicity was quantified by measuring the lactate dehydrogenase (LDH) leakage into the media. HMGB1 protein expression was measured by western blotting. Percent LDH leakage due to APAP increased from 24% to 46% compared to the control and to 47% due to co-exposure with MWCNT. Similarly, Ethanol also increased the LDH leakage from 27% to 37% and to 42% during co-exposure with MWCNT. No significant change in LDH leakage was evidenced in groups treated with MWCNT alone. Intracellular HMGB1 protein expression decreased by 0.85-fold due to APAP alone and by 0.65-fold during co-exposure with MWCNT. The decrease in intracellular HMGB1 was consistent with the increase in secreted HMGB1. Secreted HMGB1 increased by 40-fold in APAP group alone and by 73-fold during co-exposure with MWCNT. By contrast, Ethanol treatment alone increased HMGB1 expression by 1.4-fold, but during co-exposure with MWCNT, the increase was only 1.1-fold. No secreted HMGB1 was detected due to western blotting. Taken together, these findings demonstrate for the first time the potential for enhanced hepatocellular necrosis during co-exposure of MWCNT with common hepatotoxictants. The mechanism(s) and functional consequences of HMGB1 release is unknown and is currently being investigated.

### 2186 Assessing the Effects of Dietary Additives, Stress, and Bacteria on Intestinal Function in an In Vitro Gut Model

M. Malik, C. N. Marques, and G. Mahler, Binghamton University, Binghamton, NY.

Inflammatory bowel disease (IBD), irritable bowel syndrome (IBS) and Crohn’s disease are increasingly common gastrointestinal disorders marked by intestinal barrier dysfunction. Their incidence has increased at a rate similar to the increased food additive consumption. Intestinal disorders have also been linked to stress and gut microbial dysbiosis. A Caco-2 and HT29-EM6 cell co-culture model was exposed to chemically additive-glucose salt. TWEEN 20 (emulsifier), titanium dioxide nanoparticles (TiO2 NP), gluten, and food-grade TiO2 NP from M&M candies and gluten from whole wheat bread following an in vitro digestion. The effects of these additives on intestinal permeability and intestinal alkaline phosphatase (IAP), a gut mucosal defence factor involved in maintenance of intestinal homeostasis, activity were quantified. Inflammation was modelled using TNFα, a pro-inflammatory mediator. A Lucifer yellow permeability assay showed a permeability increase across the model with high glucose (p<0.001), TNFα + high glucose (p<0.0001) and TNFα + food grade TiO2 (p<0.05) as compared to their respective controls. Exposure to food grade form of TiO2, and gluten resulted in a higher permeability than their chemical form. Increasing the model in 1% salt resulted to a 1.5-fold increase in permeability (p<0.01) and higher IAP activity than 0.1% salt. To study the influence of microbiota and diet together, Lactobacillus rhamnosus GG and Escherichia coli were used in combination with the food additives. Bacteria led to a decrease in permeability with high glucose, 1% salt (p<0.0001), 1% TWEEN 20 (p<0.01), the chemical grade TiO2 and gluten (p<0.01) and increased permeability with food grade TiO2 (p<0.01) as compared to their respective controls. Post exposure, bacterial viability was quantified to assess the effect of food additives on bacterial growth. Due to the role of indole in increasing paracellular resistance in epithelial cells, indole production by E. coli was measured using the luminol enhancement assay. Both bacteria showed similar increase in permeability, their mechanisms of action were different. L. rhamnosus resulted in a significant increase in IAP activity with high glucose, indicating a possible correlation between intestinal permeability and IAP. E. coli + 1% salt produced more indole per colony forming unit (mU/cFU) compared to 0.01% salt, suggesting indole production as a possible mechanism by E. coli. While stress and food additives disrupt the intestinal barrier function, intestinal bacteria work towards reinstating the integrity of the barrier in response to certain food additives.

### 2187 Physiochemical Properties of NiO and Ni(OH)2 Nanoparticles Correlate with Cytotoxicity in A549 Cells

Y. Huang1, M. H. Cambre2, H. Lee3, C. C. Chusuei, R. R. Pandey4, and F. S. Hou5, 1Missouri University of Science and Technology, Rolla, MO; 2National Dong Hwa University, Hualien, Taiwan; 3Middle Tennessee State University, Murfreesboro, TN; and 4University of Wisconsin-Milwaukee, Milwaukee, WI.

We characterized two forms of nickel nanoparticles (NP), NiO and Ni(OH)2, and delineated cytotoxicity in the A549 mammalian cell line. We measured the relative number of available binding sites on the NP surfaces using X-ray photoelectron spectroscopy (XPS). After both NPs were subjected to 48 hr constant pH dependence, composition reactions at both pH 4.5 and 7.4, samples were vacuum filtered and dried to obtain the powders. The NP powders were then subjected to an XPS system analysis. The XPS integrated peak areas of the O 1s binding core level were used to quantify the relative number of available binding sites for biomolecules to interact with the NP’s surface. Quantification was achieved by noting the physisorbed versus chemisorbed oxygen on the NP surfaces. At pH 7.4, there was a 1.6-fold increase in binding sites available on Ni(OH)2, NPs as compared to those on NIO NPs. At pH 4.5, there was a 5.2-fold increase available on Ni(OH)2 NPs as compared to NIO NPs. The effect of pH and suppression of cell proliferation are inter-related. Cellular injuries correspond with the measured properties of the NPs, with Ni(OH)2 being more toxic than NIO.
The blood brain barrier (BBB) represents a significant hurdle in delivering drugs for treating neurological diseases. To date, amongst many other approaches attempted, polyethyleneimine (PEI) has been the most popular non viral vector for oligonucleotide and gene delivery. However, it has the disadvantages of being cytotoxic to cells, tendency to agglomerate and easily taken up by reticuloendothelial system without appropriate shielding. Hydroxethyl Starch (HES), a biodegradable polymer, has been recently introduced as a shielding agent in conjugation with PEI to deliver genes in vitro and shows promise to be used with PEI for targeted delivery to the brain. However, optimization studies are necessary to elucidate the best combination of HES and PEI in terms of molecular weight, particle size, cytotoxicity and DNA condensation properties. A library of different HES-PEI conjugates having different combinations of molecular weights were synthesized as described previously with certain modifications. The HES moiety in the conjugates were then biotinylated with Biotin-PEG4-Hydrazide, purified and lyophilized. The degree of biotinylation of the conjugates were then assessed by the HABA assay. The optimum conjugates for further study were then selected based on cytotoxicity assay, particle size analysis, zeta potential measurements and oligonucleotide condensation studies with Ethidium Bromide with NFkB decoy ODNs. The studies were done in different N/P ratios (3:1, 6:1 and 9:1) in absence or presence of serum and at different HES-PEI mixtures (50:50 and 10:90). The conjugates shielded the PEI at varying degrees when compared to naked PEI, as seen with particle size analysis and zeta potential analysis. HES-PEI conjugates had significantly lower cytotoxicity compared to PEI alone as seen up to 24 hours. HES520-PEI20 and HES510-PEI20 yielded particle sizes ranging from 200-400 nm, whereas HES510-PEI4 and HES520-PEI4 conjugates were found to have much more favorable particle sizes. However, the HES510-PEI4 particle sizes were larger when mixed with different ratios of PEI compared to HES520-PEI4. HES20kDa-PEI4kDa to be the most optimal conjugate with minimal toxicity suitable for further studies in conjugation with targeting antibody.

Engineered nanoparticles (NP) are used in industry and consumer products; however, we are just beginning to mechanistically understand how inhalation exposure to NP impacts human health. Research efforts have focused on pulmonary endpoints such as fibrosis, allergic-type reactions, and cancer, while the area of viral susceptibility remains less well explored. Work by our group has determined that exposure of human small airway epithelial cells (SAECs) to single-walled carbon nanotubes (SWNTs) increases host susceptibility to influenza A virus (IAV) infection by increasing viral titers and repressing anti-viral gene expression (interferon-stimulated genes (ISGs)). To elucidate mechanisms that contribute to these outcomes, we investigated how SWNTs modulate lipid that influence immune signaling pathways, focusing on sphingosine-1-phosphate, its precursors/products, i.e. ceramide (CER), phosphoethanolamine (PE), and metabolic enzymes, sphingosine kinase 1 (SK1) and sphingosine-1-phosphate lyase (SPL). We hypothesized that SWNTs inhibit expression of SPL, resulting in decreased expression of ISGs, and thus increased viral titers. For our approach, we exposed SAECs to 20 µg/mL SWNTs for 24 hrs, followed by exposure to IAV for 24 hrs. We quantified mRNA expression of SPL, SK1, and ISGs via quantitative real-time PCR and protein expression via Western blotting. Changes in lipids were analyzed by liquid chromatography-mass spectrometry. Gene expression analysis revealed that ISGs (Lifts, IFTM6) are suppressed in SWNT + IAV exposures, while expression of SK1 and SPL are unchanged by the presence of SWNTs. IAV induces transcription of SK1, but not SPL post-infection in both IAV only and SWNT + IAV groups, suggesting that changes in protein level or enzyme activity are important. Levels of PE and CER species were significantly different between SWNT-exposed and control samples. These observations demonstrate a role for SWNTs in perturbing lipid metabolism, with downstream impacts on innate immune pathways. Future work will focus on impacts of inhibition or over-expression of SK1 or SPL on the effects of SWNTs and IAV in SAECs. These studies highlight the important role that lipid metabolism plays in the immune response to viruses and targets these pathways in SWNT toxicity.
Multi-walled carbon nanotubes (MWCNTs) are emerging nanomaterials that are widely used in industrial, engineering, biological and medical researches due to their unique physicochemical, optical and electrical properties. The release of these nanomaterials into the environment poses a potential for human exposure following inhalation and ingestion. The purpose of this study was to assess the in vitro toxicity of four MWCNTs with outside diameter of <8 nm, 13-18 nm, 20-30 nm, and >50 nm and two functionalized MWCNTs (-OH, -COOH) with outside diameter 20-30 nm in a rat intestinal cell model (IEC-6 cells). Pluronic (0.1%), a non-ionic surfactant was used to stabilize MWCNT dispersion. Hydrodynamic diameter and zeta potential were calculated to determine the sonication time at which the MWCNTs were optimally dispersed. Based on the results, the MWCNTs suspended in Dulbecco’s media and 0.1% pluronic were probe sonicated for 15 min before dosing. IEC-6 cells were plated in 96-well plate with 60K cells/well for 24 h before dosing. Media with 10% fetal bovine serum was the negative control and Triton X-100 (0.3%) was the positive control. Cells were then exposed to the MWCNTs at various concentrations (0.3-300 μg/ml) for 24 h. Following incubation, the cells were washed with media and cytotoxicity was assessed using a colorimetric method that measures mitochondrial activity. Only the <8 nm MWCNT displayed cytotoxic effects, inducing 50% cell death at a concentration of 300 μg/ml. All other MWCNTs tested were negative. The results suggest that the outside diameter of MWCNTs is an important factor in the cytotoxicity of these nanomaterials in rat IEC-6 cells. This abstract does not necessarily represent US EPA policy.

**2188** Differential Mitochondrial Perturbations among Primary, Cancerous, and Asthmatic Lung Cell-Types after Exposure to Engineered Nanomaterials

H. Lujan, and C. M. Sayes, Baylor University, Waco, TX.

The use of metallic nanoparticles as additives in consumer and industrial products is rapidly increasing. Specifically, zinc and aluminum are highly utilized as fuel additives and other automotive applications, thus increasing the risk of occupational, consumer, and environmental exposure to these engineered nanomaterials. Zinc (Zn) and aluminum (Al) have been shown to accumulate within mitochondria and perturb mitochondrial processes, however the specific mechanisms of toxic action remain unknown. There is a need to develop toxicological testing paradigms focused on the elucidation of Zn, ZnO, Al, and Al2O3 toxicities. The purpose of this study was to determine the effect of zinc and aluminum nanoparticles, as well as their oxide counterparts, on human mitochondrial health along the electron transport chain (ETC). To determine changes in mitochondrial health, three different epithelial cell-types from the upper airway with varying phenotypes were selected as a test system. The three phenotypes include primary cells (PTBE), cancer cells (AS49), and asthma cells (DHBE). These cell-types were selected to represent a healthy human population as well as two unique sensitive subpopulations. Our hypothesis is that the differential baseline mitochondrial health profiles will be key determinants of induced nanotoxicity. Specifically, the primary and asthma cells are more sensitive to the metal nanoparticle exposures when compared to the cancer cell-type because cancer cells as less susceptible to ETC perturbations through oxidative stress. The mitochondria in each cell-type was characterized before and after exposure to normalize mitochondrial health metrics. Characterization included, mitochondrial morphology, mitochondrial dehydrogenase activity, and gene/protein expression. Differential dose-response patterns in mitochondrial activity were seen in mitochondrial morphology assessments, degradation of cristae structure, decreased mitochondrial dehydrogenase activity, and increased antioxidant response. While all cell-types exhibited changes in mitochondrial health, the primary cells showed the most pronounced alteration of mitochondrial structures, while the asthma cell-type experienced increased proinflammatory responses. The changes in the mitochondrial structure and function in the cancer derived cell-type were minor compared to those observed in the other cells. These results give newfound insight that will influence safety testing guidelines by providing evidence to use more realistic healthy (PTBE) or compromised (DHBE) populations.

**2189** Biomimetic In Vitro/In Vivo Models for Assessment of Hazardous Pulmonary Effects of Nanoparticles

L. Wang Rojanasukul, T. Romberg, J. Coyle, X. He, C. Kiratipalboon, T. Stueckle, R. Derk, P. Demokritou, and T. Rojanasukul. NIOSH, Morgantown, WV; and West Virginia University, Morgantown, WV.

Potential human exposure to respirable nanoparticles (NPs) has become a major concern with increasing evidence showing that NP pulmonary exposure results in particle deposition in deep lung tissues and causes pathological changes. Such adverse health effects have not been well assessed partially because it is impossible to assess the toxicities of countless NPs using animal models, and limited relevance of in vitro models to evaluate specific toxicities of NPs. To address the challenges, we have developed multiple in vitro models to assess the biological and toxicological activities of well-characterized NPs with the identification of target lung cells of pulmonary exposed NPs from animal studies. Based on established in vivo doses that induce significant pulmonary disorders, physiologically relevant in vitro doses (i.e., 0.02 - 0.2 μg/cm²) of NPs, including carbon nanotubes (CNTs) and iron oxide NPs (Fe₃O₄), were used to evaluate their toxic effects on human lung cells under long-term exposure condition (up to 6.5 months). Present study data showed that NPs were able to induce dose- and time-dependent cytotoxicity, inflammation, fibrogenesis and neoplastic transformation of human lung cells, consistent with in vivo data. Our in vitro studies determined specific particle type- and cell type-dependent NP-induced cell proliferation, anchorage-independent growth, apoptosis evasion, and increased cell migration and invasion. Furthermore, by developing a fibroblast stem cells (FSC)-enriched fibroblast focus model to mimic in vivo fibrogenic response, we demonstrated a dose-dependent increase in fibroblast focus formation and collagen production by primary lung fibroblasts treated with multi-walled carbon nanotubes (MWCNTs). This result unveils a novel mechanism of nanotube-induced fibrogenesis through ALDH-dependent FSC activation. The described in vitro-vivo combination approach will support the utility of in vitro models as rapid screening and predictive tools for risk assessment of nanomaterials.
2191 Biointeractions of Aerospace Relevant Nanomaterials with Human Gut Microbiota in a Human Gut Simulator

R. Agans1, A. Gordon2, S. Hussain3, and O. Paliy4; 1Henry M. Jackson Foundation, Wright-Patterson AFB, OH; 2Wright State University, Fairborn, OH; and 4Air Force Research Laboratory, Wright-Patterson AFB, OH.

Broad inclusion and incorporation of engineered nanomaterials (ENMs) in consumer goods demands an understanding of the impact such products have on humans. Specific concern has risen regarding oral exposures to dietary ENMs and the subsequent impact on gastrointestinal health via microbial dysbiosis. Employing an in vitro Human Gut Simulator (HGS) system, we have examined interactions of dietary nano titanium dioxide (TiO2) with human gut microbiota. Following HGS seeding and community stabilization, we administered TiO2 over seven days, followed by a seven day recovery period. We measured changes to cell density, community structure, metabolic end products, and predicted community functional capacity. Addition of low dose TiO2 resulted in a modest loss of cell density only in the transverse region of the HGS. High dose TiO2, conversely, caused a rapid reduction in cell density as early as 24 hrs following exposure in the proximal vessel. Similarly, population density was also lost in the transverse and distal regions. Furthermore, cell density recovered to the original levels following cessation of TiO2 addition. Microbiota profiling via 16S rRNA gene based high-throughput sequencing did not reveal any specific susceptibilities to TiO2 exposure within individual HGS regions at the Class level. Comparison of the various ratios between bacterial abundance, and assessment of gram status differences during pre- TiO2, and post-exposure periods; indicated a broad effect of TiO2 on the microbiota. We also did not notice a specific change in measures of community diversity, with alpha diversity and evenness maintaining similar values during all measured periods. Predicted functional capacity of the microbiota also remained unchanged during TiO2 exposures. Interestingly, Scanning Transmission Electron Microscopy (STEM) indicated close association of TiO2 particles to bacterial cells, but no direct interaction. These results provide evidence for the negative impact of TiO2 on the whole gut microbiota community independent from the host following recurring exposures.

2192 Impact of Various Surface Coatings on In Vitro Cell Uptake and Cytotoxicity of Ultrasmall Superparamagnetic Iron Oxide Nanoparticles (USPION)

USPION are excellent candidates for medical applications, due to their unique physicochemical properties (e.g., nanoscale size, highly reactive surfaces, and superparamagnetism). However, the potential adverse health effects of USPION with different coatings, commonly employed to control their biological activity and stability, are not fully understood. Therefore, the goal of this study was to evaluate cellular uptake and cytotoxicity of carboxyl- and amino-coated USPION on human coronary artery endothelial cells (HCAEC) as a vascular cell model. Both types of USPION were spherical with average hydrodynamic diameter of ~100 nm as assessed by DLS, and negatively charged (-36.3 and -6.5 mV for carboxyl- and amino-coated USPION, respectively) according to zeta potential analyses. After heat sterilization, the deposited dose. After exposure, cell lines were assessed for cytotoxicity, ROS, and mitochondrial membrane potential (ΔΨm). BEAS-2B demonstrated significant dose-dependent sensitivity to iNECs than incinerated pristine counterparts. In pSAE cells, cytotoxicity, enhancement in ROS, and dissipation of ΔΨm caused by PC, PC-CNT, and PU-CNT were generally lower in magnitude compared to BEAS-2B cells at treatments examined, and is likely attributable to differences in depositional characteristics between the respective culture media for both respective cell lines. Whilst the effect of iNECs on the distal respiratory airway epithelia remains limited in interpretation, the current in vitro model of the respiratory bronchial epithelia demonstrated profound sensitivity to iNECs at depositional doses plausibly relevant for occupational cohorts, indicating potential risk to occupational cohorts with direct exposure to incinerated thermoplastics NECs during disposal.

2193 Incinerated Carbon Nanotube-Enabled Thermoplastics Enhance Cytotoxicity in Human Airway In Vitro Models

J. Coyle1, R. Derk1, T. Kornberg2,3, D. Singh4, T. Stueckle5, P. Demokritou6, Y. Rojanasakul7, and L. Rojanasakul7; 1NIOSH, Morgantown, WV; 2West Virginia University, Morgantown, WV; and 3Harvard University, Boston, MA.

Engineered nanomaterials (NMs) are increasingly being incorporated into synthetic materials as fillers and additives. However, the potential pulmonary exposure effects of NM-enabled composites (NECs) during recycling and disposal have not been adequately addressed. The current investigation aims to characterize the cytotoxicity of incinerated NM-enabled thermoplastic composites (iNECs) on two in vitro pulmonary models. Ultrafine particles released from thermally decomposed pristine PC and carbon nanotube-containing polycarbonate (PC/-CNT) and polyurethane (PU/-CNT) were captured on inline filters, extracted, and suspended in sterile water. Incinerated thermoplastics were ultrasonicated and diluted in culture medium for acute in vitro exposure to primary small airway epithelial (pSAE) and BEAS-2B cells. The Harvard DG model was utilized to estimate the particle settling into the cellular microenvironment to characterize in vitro deposited dose. After exposure, both cell lines were assessed for cytotoxicity, ROS, and mitochondrial membrane potential (ΔΨm). BEAS-2B demonstrated significant dose-dependent sensitivity to iNECs than incinerated pristine counterparts. In pSAE cells, cytotoxicity, enhancement in ROS, and dissipation of ΔΨm caused by PC, PC-CNT, and PU-CNT were generally lower in magnitude compared to BEAS-2B cells at treatments examined, and is likely attributable to differences in depositional characteristics between the respective culture media for both respective cell lines. Whilst the effect of iNECs on the distal respiratory airway epithelia remains limited in interpretation, the current in vitro model of the respiratory bronchial epithelia demonstrated profound sensitivity to iNECs at depositional doses plausibly relevant for occupational cohorts, indicating potential risk to occupational cohorts with direct exposure to incinerated thermoplastics NECs during disposal.

2194 The Influence of Fluid Dynamics on Nanomaterial Delivery and Toxicity: Elucidating the Roles of Particle Size and Cell Model

Colloidal silver nanoparticles (AgNPs) are being increasingly utilized in biomedical applications. However, the effectiveness of these procedures are dependent upon sustained, strong interactions between AgNPs and the surrounding environment. Therefore, prior to the development of effective NP-based therapeutics an accurate means of assessing NP delivery must be established. Both in vitro and in vivo methodologies are being utilized, however, limited correlation exists between these models. One way to overcome this limitation is through the development of enhanced in vitro environments that retain the advantages of cellular systems but more accurately mimic true physiology. In this work, a dynamic in vitro environment was utilized to characterize the AgNP deposition efficiency. Dynamic flow was generated through the use of a peristaltic pump, operating at a flowrate equivalent to known capillary rates. To better understand how dynamic flow impacted deposition, two cell models were utilized; an adherent lung epithelial model (A549) and a suspension monocyte model (U937). Additionally, as bio-transport mechanisms are a function of particle size we included two experimental, citrate-coated AgNPs - 5 and 50 nm. AgNP deposition was evaluated and found to vary as a function of flow environment, cell model, and primary particle size. Dynamic flow significantly decreased the delivered dose of AgNPs to the adherent lung cells; with the 5 nm AgNPs experiencing the greatest drop in deposition. However, AgNP delivery was increased within a dynamic environment for the monocytes, due to increased nano-cellular interactions. For both cell models, the subsequent cytotoxicity, stress, and inflammatory responses correlated to delivered NP dosages, as assessed via reactive oxygen species production, p53 levels, and cytokine secretion. This work highlights the need for NP deposition and safety evaluations to be carried out in a physiologically relevant exposure system.
2195 Label-Free 3D Raman Imaging of Carbon Nanotubes in Mammalian Cells

M. Huynh, C. Mikoryak, P. Pantano, and R. Draper. University of Texas at Dallas, Richardson, TX.

Multi-walled carbon nanotubes (MWCNTs) pose a respiratory hazard because they can cause pulmonary fibrosis, which may lead to mesothelioma. The Bionanosciences Group at UT Dallas is interested in understanding the interactions of triloblock polymer Pluronic F-108-coated MWCNTs with macrophages that are the first responders to nanoparticles encountered in the body. This information is relevant for improving the biomedical efficacy of MWCNT therapeutics, for understanding mechanisms of MWCNT biocompatibility, and for developing methods to monitor MWCNT toxicity. To better understand mechanisms of MWCNT toxicity, it is important to know whether MWCNTs physically enter cells and where they locate inside cells. We have developed procedures to detect internalized MWCNTs and reconstruct 3D images of RAW 264.7 mouse macrophages with cell-associated MWCNTs by laser scanning confocal Raman microscopy. Images of cells are reconstructed with stacks of optical sections from confocal planes to place the subcellular MWCNT locations in the context of the intact cell. The 3D MWNT Raman images demonstrated that Pluronic F-108-coated pristine MWCNTs (P-MWNTs) and carboxylated MWNTs (C-MWNTs) exposed to RAW 264.7 cells for 24 h at 37 °C accumulated inside the cells within punctate vesicles, most likely in the endosome/lysosome system, but not in the cytoplasm. These results are consistent with our previous observations that RAW 264.7 cells accumulate ~100 times more C-MWNTs suspended in the surfactant Pluronic F-108 than corresponding P-MWNTs during a 24 h incubation at 37 °C (Wang et al., 2018). Future work will involve assessing the intracellular distributions of various functionalized MWCNTs and evaluating their fate after internalization, and whether they are degraded, secreted, or if they persist within cells. Also, Raman imaging with live cells will be used to access whether accumulation of MWNTs induce the release of cytokines that may cause lysosomal membrane damage and result in the redistribution of MWNTs to the cytoplasm. A better understanding of the mechanisms by which MWNTs interact with macrophages should lead to better rational designs of safer carbon nanomaterials. Wang et al., “Quantitation of cell-associated carbon nanotubes: Selective binding and accumulation of carboxylated carbon nanotubes by macrophages.” Nanotoxicology (2018): 1-22.

2196 Titanium Dioxide Nanoparticle Induced AP-1 Activation via ERKs and p38 Kinase

M. Ding, T. Barber, S. Leonard, and J. Aldinger. NIOSH, Morgantown, WV. Sponsor: Y. Yuan

Titanium dioxide (TiO2) is a white mineral used in the manufacturing of paint, paper, plastics, sun tan lotion, and other products. Recent studies indicated that TiO2 nanoparticles cause chronic inflammation and lung tumor formation in rats. It is believed that the toxicity and carcinogenesis of TiO2 is associated with particle size. Since activator protein-1 (AP-1) is known to play an important role in the induction of neoplastic transformation and regulation of multiple genes involved in cell proliferation and inflammation, we investigate the potential of TiO2 nanoparticles on reactive oxygen species (ROS) generation and AP-1 signaling in a mouse epithelial cell line, JB6 cells. Incubation of JB6 cells with TiO2 nanoparticles resulted in a dose dependent generation of -OH radicals. TiO2 nanoparticles caused a 3-fold increase in AP-1 activity in the cells. The induction of AP-1 activity in cultured cells was dose-dependent. The signal transduction pathways for AP-1 activation were also investigated and the results demonstrate that TiO2 stimulates mitogen-activated protein kinase (MAPK) family members, including extracellular signal-regulated protein kinases (ERKs), p38 kinase, and C-Jun N-terminal kinase (JNKs). Inhibition of ERKs, p38 kinase, but not JNKs with specific inhibitors SB203580, PD98059, and SP600125, inhibited TiO2 nanoparticles-induced AP-1 activation, respectively. These findings demonstrate that TiO2 nanoparticles stimulate the generation of -OH radicals and induces AP-1 activation, which may be mediated through p38 kinase and ERKs pathways.

2197 Particle Size and Surface Charge Dependent Toxicity of PAMAM Dendrimers in Cultured Endothelial Cells

M. Patel, S. De Paoli, O. Elhelu, S. Farooq, and J. Simak. US FDA, Silver Spring, MD.

Different nanomaterials are under development for various biomedical applications in which nanoparticles contact blood and vasculature. Therefore, investigating the interactions between nanomaterials and vascular endothelial cells is of great importance. Here, we show the effects of polyamidoamine (PAMAM) dendrimers of different two sizes, generation 2 (G2; approximately 3 nm diameter) and generation 7 (G7; 9 nm), with neutral (OH-terminated), anionic (COOH-terminated) and cationic (NH3-terminated) surface modifications on cultured human umbilical vein endothelial cells (HUVECs). HUVECs and extracellular membrane vesicles (EVs) were characterized by flow cytometry (FC), nanoparticle tracking analysis (NTA), laser scanning confocal microscopy (LSCM) and electron microscopy (SEM, TEM). We found that only cationic dendrimers (G2 & G7) induced significant HUVEC apoptosis. G7-NH3 interacted strongly with HUVEC plasma membranes and mitochondrial membranes, and phospholipid vesicles containing G7-NH3, formed, which resulted in extensive plasma membrane blebbing and disintegration. Furthermore, flow cytometric analysis showed that G7-NH3-treated HUVECs released large numbers of extracellular vesicles (EVs) positive for CD105 and PS. A notable population of EVs positive for the mitochondrial marker TOM20 but negative for the autophagosome marker LC3 was found. In summary, large cationic PAMAM dendrimers (G7-NH3) showed both proinflammatory and proapoptotic effects in endothelial cells; at high dendrimer concentrations, these effects were accompanied by necrotic cytotoxicity. G7-NH3 caused plasma and mitochondrial membrane disintegration and the release of EVs, including EVs of mitochondrial origin that were not associated with mitophagy. The findings and conclusions in this study have not been formally disseminated by the US FDA and should not be construed to represent any Agency determination or policy.

2198 Developing a Protocol for Observing the Effects of Sex Differences on Macrophage Polarization

M. Lyons1, J. Ray2, and A. Hollian2. 1Troy University, Troy, AL; 2University of Montana, Missoula, MT.

Macrophages are the primary innate immune cells in the lungs. They protect the lungs by phagocytosing inhaled foreign particles and organisms. Macrophages exhibit several different phenotypes with distinct functions—the “classically activated” M1 phenotype, which is associated with inflammation, or the “alternatively activated” M2s, which can be divided into a variety of subsets. There is evidence that estrogen receptor alpha (ERα) signaling promotes M2 macrophage development, contributing to sex differences seen in human respiratory disease prevalence. For example, it may help explain why asthma, an M2-driven disease, occurs more often in women than in men. However, the exact role that sex hormones play in respiratory pathophysiology is still unknown. Understanding how sex hormones influence macrophage phenotype development in the lungs will help us address this gap of knowledge. The goal of this project was to develop a protocol for macrophage phenotype and ERα expression analysis via flow cytometry. Developing an effective protocol for cytometric assessment of these proteins is challenging due to our need to simultaneously assess both cytoplasmic and nuclear proteins, as well as extracellular markers. Murine bone marrow-derived macrophages and alveolar macrophages (AMs) were polarized into M1 and M2 pheno- types and analyzed for ERα, M1 markers CD38 and Ly6C, and the M2 marker YM1. After establishing that our fixation and permeabilization protocol was suited for all markers of interest, we determined effective concentrations for all markers of interest, we determined effective concentrations for all markers of interest, we determined effective concentrations for all markers of interest. Expression of the M1 and M2 phenotype markers corresponded appropriately to the M1- and M2-polarized macrophages, respectively. ELISA measurement of cytokines was used to corroborate our cytometric results. Overall, this project improved our protocols for studying macrophages in order to better understand how sex hormones affect macrophage phenotype development. In the future, we will apply these protocols to in vivo studies assessing sex differences in the immune response to inhaled particles. This project was supported by NIH grants R25 ES022866 and R01 ES023209.

2199 Evaluating the Toxicity of Silver Nanoparticles in ARPE-19 Cells through High-Content Morphometric Analysis

Efficient methods are needed to evaluate the human and environmental health effects of silver nanoparticle (AgNP) exposure. A high content imaging-based phenotypic profiling approach was used to determine the effects
of 12 types (40, 60, 80 and 100 nm coated with citrate, polyvinylpyrrolidone (PVP), and branched polyethyleneimine (BPEI)) of AgNPs on organelle morphology in human retinal pigmented epithelial (ARPE-19) cells. AgNPs (0.1-30 µg/ml) were applied to the cells seeded in a 384-well format, with silver nitrate acting as silver ionization control. The Distorted Grid (DG) model was used to estimate the cellular delivered dose. After 24 hrs of treatment, cells were live-labeled with MitoTracker (mitochondria), fixed, permeabilized and labeled with Hoechst-33342 (nuclei), SYTO14 (nucleoli) and fluorescent conjugates of concanavalin A (ER), phalloidin (actin cytoskeleton), and wheat germ agglutinin (Golgi/plasma membrane). A multiplexed cell viability and apoptosis assay was run in parallel. Cells were imaged using an Opera Phenix High Content Screening System and profiled using Harmony High Content Analysis software. Approximately 1200 morphological features were measured per cell and summarized to the well level for analysis. The DG model predicted that the fraction of AgNP deposited on cells increased with particle size and differed based on coating (BPEI > citrate > PVP). Phenotypic profiling showed that all AgNP types affected the organelle morphology in a concentration-dependent manner, with over 600 features having benchmark doses below the threshold for cytotoxicity. The pattern of changes in cell morphology differed across coating agents and silver nitrate. Citrate coated AgNPs showed the most pronounced effects below the cytotoxic threshold. 60 nm PVP had fewer effects on cell morphology than other coatings, yet apoptosis was observed at an estimated delivered dose as low as 1.45 µg/ml. This screening method may inform subsequent assay selection by highlighting the intracellular regions affected by AgNPs of interest. This abstract does not necessarily reflect US EPA policy.

Potential Role of Thioredoxin-Interacting Protein in Silver Nanoparticle-Mediated Mast Cell Degranulation

R. Mendoza, and J. Brown, University of Colorado Denver, Aurora, CO.

Silver nanoparticles (AgNPs) are being incorporated into a variety of consumer and medical products primarily due to their antimicrobial properties. This will lead to a significant rise in exposure to the general population; however, our understanding of the potential risks is still minimal. We have previously demonstrated that AgNPs induce a non-IgE mediated degranulation of mast cells. Importantly, we have also shown a strong genetic contribution to AgNP driven mast cell degranulation. RNA sequencing performed on bone marrow-derived mast cells (BMMCs) from high-responding (C57BL/6) and low-responding (LP/J) strains of mice demonstrated a significant increase in thioredoxin-interacting protein (txnip) in the low-responding strain after exposure to 20nm AgNP. We therefore explored the role of TXNIP in mast cells to determine its potential regulatory role in AgNP-mediated degranulation. The following exposure to AgNP, txnip mRNA levels were increased in LP/J BMMCs at six hours post-exposure while protein levels were significantly decreased in C57BL/6 BMMCs. siRNA knockdown of TXNIP resulted in a trend towards increased degranulation. Using a Seahorse XF analyzer, we found that BMMCs from low- and high-responding strains possess varying glycolytic capacities in response to AgNP exposure possibly implicating TXNIP as a regulatory protein for cellular metabolism during mast cell degranulation. Our data suggests that TXNIP plays a role in non-IgE mediated mast cell degranulation initiated by exposure to 20nm AgNP and may possibly modulate cellular metabolism.

Amorphous Silica Coating Protects against Iron Oxide Nanoparticle-Induced Cell Transformation and Genotoxicity

T. Kornberg,1 T. Stueckel2, J. Coyle3, R. Derk4, P. Demokritou5, Y. Rojanasakul1, and L. Rojanasakul1. 1West Virginia University, Morgantown, WV; 2NIOSH, Morgantown, WV; and 3Harvard University, Boston, MA.

Iron oxide nanoparticles (IONP) have a wide range of uses in biotechnology, medicine, and transportation. However, very little is known about their potential adverse health effects following human exposure. Some evidence suggests that dissolution of IONP following endocytosis into cells may disrupt iron homeostasis, resulting in genotoxicity and neoplastic-like cellular transformation. Surface modification of IONP, such as an amorphous silica coating, may impact subsequent adverse outcomes by reducing particle dissolution. The main objective of this study was to assess IONP low dose, long term exposure effects, including carcinogenic potential, as well as the utility of an amorphous silica coating in reducing or preventing these outcomes. Human bronchial epithelial cells (Beas2B) were continuously exposed to nFeO3 or nano-SiO2 coated nFeO3 (SiO2 : nFeO3) for up to 6.5 months at an occupationally relevant low dose (0.65 µg/cm2 or 2.88 µg/ml) and evaluated over time for indications of neoplastic-like transformation and its underlying mechanism. Transformation was compared to that induced by gas metal arc mild steel welding fumes (GMA-WF), which were recently re-classified as a Group 1 total human carcinogen and are comprised of roughly 80% iron/iron oxide. Our results showed that beginning at four months, nFeO3-exposed Beas2B underwent neoplastic-like transformation, as indicated by increased cell proliferation and attachment-independent colony formation. These outcomes correlated with nFeO3 dissolution, increased intracellular iron, and genotoxicity, as well as significant changes in pathways related to DNA damage repair and autophagic processes. nFeO3-induced transformation also closely matched that of GMA-WF induced transformation SiO2 : nFeO3 treatment, however, did not induce any changes in the above parameters. Overall, our results indicated potential carcinogenic risk of nFeO3 associated with particle dissolution, iron homeostasis disruption, and changes in autophagy and DNA damage repair pathways, which were reduced with an amorphous silica surface coating. This study shows the potential utility of a “safe by design” hazard reduction strategy, to alter particle physicochemical properties based on mode of toxicity to reduce risk.

In Vitro Dermal Toxicity of Redox-Active Metal Nanocatalysts

E. Kisim,1 S. Guppi1, N. Yanamala1, and A. Shvedova1,2, 1NIOSH, Morgantown, WV; and 2West Virginia University, Morgantown, WV.

Nanocatalysts (NCT) represent the convergence of catalysts, a mature technology with a new one, nanotechnology. NCT is a rapidly growing field that involves the use of nanomaterials as catalysts for a variety of catalytic applications. Since metal nanoparticles (MeNPs) have a large surface-to-volume ratio compared to bulk materials, they are attractive candidates for use as catalysts. A number of redox-active MeNPs and their oxides (MeO) including nickel (Ni) and cobalt (Co) are widely used. The physical nature and reactive surface properties of some of these may affect their ability to induce dermal toxicity thus causing adverse skin reactions. We hypothesize that toxicity of Me/MeO NP occurs via their ability to initiate oxidative stress, thereby inducing redox-sensitive transcription factors and triggering inflammation. Moreover, due to the skin’s susceptibility to UV radiation, it is important to evaluate whether Me/MeO NP enhance the adverse effects of UVB. To test these hypotheses, the effects of Ni, Co, NiO, CoO, Co3O4 and CoO alone (0-26 µg/cm2) and co-exposed with UVB (4KJ/m²) were studied in vitro and in situ using murine epidermal cells (B6P+) and an engineered human skin construct (EpiDerm FT). Cell exposure to Me/MeO NP resulted in a dose- and time-dependent loss of cell viability, cell damage, oxidative stress and activation of AP-1/NF-kB. Co-exposure of Me/MeO NP with UVB ensued in amplification of the observed effects. Exposure of EpiDerm FT to Me/MeO NP caused tissue damage, oxidative stress and accumulation of inflammatory mediators. Hierarchical cluster analysis resulted in two major clusters separating cytokines productions related to inflammatory cell recruitment (more intense) and T2-type/ regulatory immune responses (dimmed). UVB exposure alone induced significant tissue damage and secretion of cytokines/chemokines. Ni compounds drastically enhanced the percutaneous LDH and UVB across the whole cytokine spectrum, while Co oxides prompted much weaker reaction. Interestingly, inflammatory cytokine/chemokine levels upon exposure to Me/MeO NPs, with or without UVB pre-treatment, followed similar trends compared to cell/tissue damage i.e., NiO > NiO3-CoO > CoO and correlated with their similar effects on UVB in both in vitro and in vivo settings. Ligation of human and the adverse effects of Me/MeO NP could induce cytotoxicity, oxidative stress and inflammation, and may potentially enhance response caused by UVB pre-treatment. Disclaimer: The findings and conclusions of this report are those of the authors and do not necessarily reflect those of National Institute for Occupational Safety and Health.

 Comparative In Vitro Study of Adverse Pro-neoplastic Potential of Tremolite Asbestos and its Cleaveage Fragments in Human Epithelial (BEAS-2B) and Mesothelial (MET-5A) Cells

A. Shvedova1,2, S. Guppi1, T. Khalilullin1,2, N. Yanamala1, and E. Kisim1.

1NIOSH, Morgantown, WV; and 2West Virginia University, Morgantown, WV.

The fibrous form of tremolite is one of the six recognized types of asbestos. It is known that inhalation of respirable tremolite fibers (TF) can cause asbestosis, lung cancer and both pleural and peritoneal mesothelioma. Tremolite also occurs in a non-fibrous habitat that can be mechanically broken into cleavage fragments (CF) which can meet the criteria for fibers. Despite the considerable amount of work showing that CF are less potent in their carcinogenic effects compared to TF, they may play a role in the process of mesothelioma development. Using a Seahorse XF analyzer, we found that CFs have a significant impact on cell metabolism and growth while not inducing cell death. Using a Seahorse Galaxy platform, we found that CFs induce a strong metabolic shift in MET-5A cells including decreased metabolism and increased oxidative stress. These results coupled with the finding that CFs are present in the lungs of patients diagnosed with mesothelioma indicate that CFs may be a potential factor in the etiology of this malignancy independently of the TF exposure. These findings and implications may prove helpful for future research.
ing CF (with similar median length but different width/aspect ratio) using in vitro models. Sub-chronic exposures of human epithelial (BEAS-2B) and mesothelial (MET-5A) cells - both target cells of the respective lung cancer and malignant mesothelioma - to TF and CF were employed in the current study. Cells were evaluated for the presence of several cancer hallmarks indicating the neoplastic transformation following continuous exposure to the sub-toxic concentration of TF and CF for 5 weeks. TF-exposed cells, both BEAS-2B and MET-5A, revealed a neoplastic-like transformation phenotype characterized by significant increase in proliferation, morphological transformation, invasion/migration and anchorage-independent growth compared to controls. In contrast, no anchorage-independent growth was observed in CF-exposed cells although an increase in proliferation, morphological transformation and migration/invasion was detected albeit at lower intensity compared to TF. Additionally, CF had no impact on apoptosis susceptibility while TF caused increased apoptosis in MET-5A cells and its inhibition in BEAS-2B cells. Both TF and CF induced oxidative DNA damage albeit with a stronger effect in TF-exposed cells. Analysis of inflammatory responses using a cytokines/chemokines clustering approach suggested cell-type specific effects to TF and CF exposures as well as treatment related differences. Overall, our data are compatible with the interpretation that tremolite asbestos fibers demonstrated higher neoplastic transformation potential compared to CF (at the same mass dose) in both epithelial and mesothelial cells. Disclaimer: The findings and conclusions of this report are those of the authors and do not necessarily reflect those of National Institute for Occupational Safety and Health.

2204 Effects of Multiwalled Carbon Nanotube Accumulation on Macrophage Cell Viability and Proliferation In Vitro

E. Chow, R. Wang, and R. Draper, University of Texas at Dallas, Richardson, TX.

The range of applications for multi-walled carbon nanotubes (MWNTs), from electronics to medicine, is increasing their global production despite an incomplete understanding of their toxicological potential. A recent study reported that more than 99% of all nanoparticles administered in vivo are sequestered by macrophages, but the types and severity of effects induced by MWNT accumulation in macrophage cells is not well understood. Our previous work showed that macrophages preferentially accumulate a~100X more Pluronic® F108-coated carboxylated MWNTs (cMWNTs) than non-functionalized pristine MWNTs (pMWNTs) (Wang et. al., Nanotoxicology, 2018, DOI: 10.1080/17435390.2018.1472309). Furthermore, cMWNT accumulation in RAW 264.7 cells after a 20h exposure impaired subsequent phagocytic function. Our recent work focuses on the effects of cMWNTs on other macrophage cell functions, specifically cell proliferation and viability. To assess cell proliferation, RAW 264.7 cells were treated with varying concentrations of cMWNTs or pMWNTs and incubated at 37°C for 24, 48, or 72 hours. The cells were then washed to remove MWNTs in the media and proliferation was measured with a crystal violet assay. The results showed that neither cMWNT nor pMWNT accumulation significantly affected cell proliferation after a 24h exposure, but cell proliferation was reduced by as much as 88% and 95% after exposure to cMWNTs at 200 µg/mL for 48h and 72h, respectively. The severity by which cell proliferation decreased between 24h and 72h of exposure raised the question of whether 24h exposure to cMWNTs affected cell viability in ways undetected by the cell proliferation assay. Consequently, colony formation assays were conducted in which RAW 264.7 cells were treated either with pMWNTs at 100 or 200µg/mL, or with cMWNTs at concentrations ranging from 25 to 200µg/mL and incubated at 37°C for 24h. The cells were then washed, harvested, seeded at a density of 1000 cells per plate, and incubated at 37°C in media free of MWNTs for 10 days, after which the colonies were stained and counted. There were 371 ± 22, 248 ± 27, and 187 ± 13 colonies per plate for the control, pMWNT-treated, and cMWNT-treated cells, respectively, which suggested that cMWNT accumulation over 24h impaired cell viability by 49.6%. Additional experiments will explore the effects of cMWNTs on reactive oxygen species and apoptosis.

2205 Evaluation of Cytotoxicity Potential of 6-Thioguanine Loaded Chitosan Nanoparticles with or without Curcumin

CANCER is the second leading cause of mortality in the world. Cancer nanotherapeutics are rapidly progressing and being implemented to overcome several limitations of conventional drug delivery systems. The objective of the study was to synthesize 6-thioguanine (6-TG) loaded chitosan nanoparticles (CNPs) and to evaluate the cytotoxicity with or without curcumin (CUR) on two cancer cell lines viz. Breast adenocarcinoma (MCF-7) and Ovarian teratocarcinoma (PA-1). 6-TG loaded CNPs were formulated by ionic-gelation method. Morphologically the 6-TG loaded CNPs were spherical in shape and showed mean size, PDI, zeta potential and Entrapment efficiency of 261.63 ± 6.01 nm, 0.35 ± 0.10, 15.97 ± 0.46 mV and 44.27% respectively. MTT [3-(4, 5- dimethylthiazolyl)-2]-2, 5- diphenyltetrazolium bromide] assay was conducted on MCF-7 and PA-1 cell lines at 48 h incubation for cytotoxic evaluation. IC₅₀ values of 6-TG, 6-TG loaded CNPs and CUR for MCF-7 were 23.09 µM, 17.82 µM, 11.48 µM and 15.73 µM respectively. Likewise, IC₅₀ values of 6-TG, 6-TG loaded CNPs and CUR for PA-1 were 5.81 µM, 3.92 µM and 12.89 µM respectively. Combination of 6-TG loaded CNPs (IC₅₀) with CUR (IC₅₀) on PA-1 and MCF-7 showed percent cell viability of 43.67 ± 0.02 and 49.77 ± 0.05 respectively. This study suggests that the cytotoxicity of 6-TG and 6-TG loaded CNPs is dose-dependent and 6-TG loaded CNPs proved to be significantly more effective (~1.5-fold high anticanicancer efficacy) than that of 6-TG against PA-1 cells. Further, combination of 6-TG loaded CNPs with CUR showed synergistic cytotoxicity i.e. enhanced anticancer efficacy on PA-1 cancer cells.

2206 Bioactivity of Multiwalled Carbon Nanotube Mixtures with Multiple Aspect Ratios

J. Hubczak, T. Stueckle, A. Erdely, J. Roberts, A. Stefaniak, J. Hubczak, and V. Kodal, West Virginia University, Morgantown, WV; and NIOSH, Morgantown, WV.

Multi-walled carbon nanotube (MWCNT) composites have vastly superior mechanical and structural properties compared to conventional materials. In order to be cost effective and to improve the distribution in the composite matrix, MWCNTs produced in large volume with multi-aspect ratios are utilized. Past research identified pulmonary health effects and the molecular mechanisms associated with exposure to mostly uniformed dimensional tubes; however, much is unknown concerning exposure associated with mixtures containing multi-aspect ratio tubes. In order to investigate this concern, we evaluated the toxicity profile of two multi-aspect-ratio MWCNT mixtures (MWCNT-1 and MWCNT-2) and compared them with the toxicity profile of more uniform and well-characterized MWCNT (Mitsui-7) and carbon black (CB, Printex-90) samples. Automated field emission scanning electron microscopic analysis showed that the MWCNT mixtures had a wide distribution of lengths from a few nanometers up to 20 µm and diameters that change according to length. The Mitsui-7 were more uniform with a diameter ~50 nm and the CB had a diameter of ~20 nm. Cytotoxicity and cell proliferation was assessed in human monocytic cells (THP-1) at 0 - 120 µg/mL and in primary human fibroblast cells (PHF) at 0 - 16 µg/mL NFkB (nuclear factor kappa-light-chain-enhancer of activated B cells)-induced inflammatory potential was screened using THP-1 reporter cells. THP-1 WT and NLRP3-deficient cells were used to screen for inflammasome activation. Acellular oxidative stress potential of the material correlated with the fold increase in vitro NFkB activation and oxidative stress induction, measured using a dichlorofluorescin-diacetate assay. The extracellular remodeling and fibroblast transformation potential was evaluated by measuring collagen I, α-smooth muscle actin, and TGF-B in PHF cells. Given the toxicity and the metric for molecular initiating events, the MWCNT-2 mixture was the most bioactive material followed by Mitsui-7 > CB > MWCNT-1. We conclude that it was not possible to fit all multi-aspect-ratio MWCNTs into a universal toxicity profile. Ongoing extensive physiochemical characterization could elucidate the key confounders influencing the toxicity profiles of such a multi-aspect-ratio MWCNT mixture.
Silver nanoparticles (AgNP) are found in a range of applications but are primarily used as antimicrobial agents in consumer and medical products. Many studies have assessed the in vitro and in vivo effects of AgNP using airway models, but none have directly studied how their impacts are modified by individual differences in genetic and acquired susceptibility, or gene x environment interactions (GxE). In this study, we derived airway epithelium organotypic culture models from murine tracheal epithelial cells to assess determinants of susceptibility to AgNP toxicity. We compared dosimetrically adjusted dose-response relationships for AgNP on barrier dysfunction, glutathione (GSH) depletion, reactive oxygen species (ROS) production, lipid peroxidation, and cytotoxicity across genetic strains (A/J and C57BL/6), differentiation conditions (normal and “Th2-skewed” conditions) and several exposure durations (a single exposure of 24 hours and a repeated exposure of 4 hours, every other day, over 5 days (5×4 hours)). In this study, we found that organotypic cultures differentiated under “Th2-skewed” conditions are a model for allergic airway diseases, such as asthma. Using a benchmark dose (BMD) approach, we found the most sensitive adverse cellular responses to be ROS production and lipid peroxidation at 5×4 hours conditions in organotypic cultures differentiated under “Th2-skewed” conditions. This study highlights the importance of using multiple genetic strains and differentiation conditions to identify determinants of susceptibility. Such in vitro assessments can be used to inform regulatory policy aimed at special protections for susceptible populations.

Engineered nanomaterials (ENM) are becoming increasingly prevalent, both in consumer products and in medical applications. The proliferation of this technology increases the likelihood of human respiratory exposure to ENM. Studies have shown that ENMs can induce permeabilization of lipid membranes in cells. For example, when ENMs are phagocytosed by macrophages, ENMs can interact with phagolysosome membranes. These ENMs can destabilize these membranes, resulting in the release of cathepsin B from the phagolysosome and subsequent interleukin 1β release. Lanthanum titania oxide (LTO) is of interest because of its wide spread use in electronics, magnets, and batteries. The objective of this work was to evaluate the behavior of pristine (pLTO) and N-doped (nLTO) nanoparticles in macrophages and the mechanism of particle-induced lysosomal membrane permeabilization (LMP) using multiple membrane models. It was hypothesized that pLTO would cause membrane disruption by increasing lipid order, creating tighter packing and decreased membrane fluidity. Bone marrow derived macrophages (BMDM) were used for LMP assay. Human red blood cell (RBCs) and liposomes (DOPS and POPC) were used as a simplified surrogate for internal cellular membranes. RBCs and liposomes were exposed to the LTO particles and changes in membrane order were measured using fluorescence lifetime and anisotropy on a custom-built fluorometer with the fluorescence probe Di-4-ANEPPDHQ. Additionally, ENM-induced membrane leakage in RBCs was measured using a hemolysis assay. We saw greater LMP from pLTO exposed A549 cells than from nLTO exposed A549 cells. It was hypothesized that pLTO-exposed nanoceria, attributed to C=O groups from milk components, and suggestion of loss of, or overcoating of, citrate after exposure to each SBF. FeGF exposure increased the isoelectric point from pH 2.5 (citrate-coated nanoceria) to 3.0. Exposure to the other SBFs had less effect. Surface charge was more negative after exposure to all SBFs, except FeGF. A549 cells were incubated for 2 h with SLF and Caco-2 cells with 75% FaGF or FeGF:25% cell culture medium or 90% FaIF or FeIF:10% cell culture medium containing 0, 1, 5, 20, or 100 µg/cm² SBF exposed nanoceria. SBF dilution with cell culture medium was necessary because cells did not survive exposure to these undiluted SBFs. The resazurin assay quantified cell metabolism. Exposure to SBFs below 100 mcg/cm² non-significantly increased cell metabolism in many cases. A decrease of cell metabolism (non-significant) was only seen after exposure to 100 mcg/cm² FaGF, FeGF, and FeIF. The increased hydrodynamic size (that would reduce uptake/absorption) and lack of reduced cell metabolism below 100 mcg/cm² (orders of magnitude above the reported environmental aerosol concentration), suggest SBF-induced corona formation does not increase nanoceria adverse effect risk. Support: NSF REU EEC-14604861 and NIH R01GM101995.

Mitochondria have several important functions in eukaryotic cells including ATP production, reactive oxygen species regulation, and programmed cell death. These functions are intimately tied to mitochondrial structure as dysfunctional mitochondria often display structural defects. Given how important mitochondria are to cell health, it is surprising that mitochondrial structure and function are understudied areas in nanotoxicology. Silver nanoparticles (AgNPs) have antibacterial properties and have been incorporated into unilamellar liposomes (DOPS and POPC) have antibacterial properties and have been incorporated into unilamellar liposomes. For example, AgNP coated liposomes were found to be more toxic than pristine liposomes. The objective was to determine if simulated body fluid (SBF) exposure changes its surface properties and toxicity. Crystalline citrate-coated nanoceria (primary particles ~30 nm) was incubated with simulated lung (SLF) for 3 h, fasting- (FaGF) or fed-gastric (FeGF) for 2 h, and fasting- (FaIF) or fed-intestinal fluid (FeIF) for 6 h, water washed, and dried. Exposure to each SBF increased the hydrodynamic diameter. Thermogravimetric analysis indicated organic coating on the FeGF- and (to lesser extent) FeF-exposed nanoceria. FTIR showed organic coating on the FeGF-exposed nanoceria, attributed to C=O groups from milk components, and suggestion of loss of, or overcoating of, citrate after exposure to each SBF. FaGF exposure increased the isoelectric point from pH 2.5 (citrate-coated nanoceria) to 3.0. Exposure to the other SBFs had less effect. Surface charge was more negative after exposure to all SBFs, except FeGF. A549 cells were incubated for 2 h with SLF and Caco-2 cells with 75% FaGF or FeGF:25% cell culture medium or 90% FaIF or FeIF:10% cell culture medium containing 0, 1, 5, 20, or 100 µg/cm² SBF exposed nanoceria. SBF dilution with cell culture medium was necessary because cells did not survive exposure to these undiluted SBFs. The resazurin assay quantified cell metabolism. Exposure to SBFs below 100 mcg/cm² non-significantly increased cell metabolism in many cases. A decrease of cell metabolism (non-significant) was only seen after exposure to 100 mcg/cm² FaGF, FeGF, and FeIF. The increased hydrodynamic size (that would reduce uptake/absorption) and lack of reduced cell metabolism below 100 mcg/cm² (orders of magnitude above the reported environmental aerosol concentration), suggest SBF-induced corona formation does not increase nanoceria adverse effect risk. Support: NSF REU EEC-14604861 and NIH R01GM101995.
2212 Effect of Particle Size on the Cytotoxicity of Zinc Oxide Nanoparticles in Rat and Human Intestinal Cell Models

Zinc oxide nanoparticles (NPs) have several commercial applications ranging from catalysts to semiconductors. ZnO NPs are toxic to bacteria, aquatic organisms and human cells. There is a potential for human oral exposure to ZnO NPs following accidental or intentional ingestion, hand-to-mouth activity, or mucociliary transport following inhalation. This study assessed the cytotoxic effects of ZnO NPs (10 and 150 nm) in rat and human intestinal cells. The rat cells are a 2-dimensional model (IEC-6) while the human cells are a 3-dimensional highly differentiated model. Three-dimensional cell cultures offer greater predictability of in vivo toxicity than comparable 2-dimensional cell cultures because of their complexity and their overall functions are more similar to native tissues. The effect of dose (0.1 - 100 μg/mL rat; 1-100 μg/mL human), time (4 and 24 hr) and particle size were evaluated. ZnSO₄ (0.1-100 μg Zn/mL) was tested for 4 and 24 hr to assess Zn ion toxicity. IEC-6 cells were plated at 60k/well in a 96 well plate 24 hr before dosing. Media with 10% fetal bovine serum was the negative control. Triton X-100 (0.3%) was the positive control. ZnO NPs were suspended in media and probe sonicated before dosing. Following incubation, the cells were washed with media. Cytotoxicity was assessed using a colorimetric method that measures mitochondrial activity (MTS; rat; MTT, human). In IEC-6 cells, a significant dose-dependent (p<0.0001) decrease in viability was observed after 4- and 24-hr incubation of the 10 and 130 nm ZnO NPs. For both particles in IEC-6 cells, at 4 hr, viability decreased ~50% at ≥ 50 μg/mL; at 24 hr, viability decreased ~75% at ≥ 25 μg/mL. In human cells, viability was significantly decreased, but no greater than 10% at 4 or 24 hr, for both ZnO NPs. For ZnSO₄, similar results to the ZnO NPs were observed in both tissues at 4 and 24 hr. Particle size does not appear to have a role in the cytotoxicity of ZnO NPs in these cells. In addition, the similar cytotoxicity profile of ZnO NPs and Zn²⁺ ions suggests dissolution of the NPs may have a greater impact than particle size. This abstract does not necessarily represent US EPA policy.

2213 Effects of Surface Modification of Graphene Quantum Dots on Differentiated THP-1 Human Macrophages

Due to their unique chemical and physical properties, graphene quantum dots (GQDs; <10 nm in diam) are attractive for biomedical applications such as bio-imaging and drug delivery. Previous studies show that bare GQDs cause DNA damage and significantly increase the expression of proinflammatory cytokines (including TNF-α and IL-8) in macrophages at concentrations where no significant toxicity is observed (<50 μg/mL). However, these studies have been limited to bare GQDs without taking surface modification effects into consideration, which has the potential to passivate the GQDs surface and minimize toxicity. The objective of this study was to investigate the effects of bare, carboxyl- and amino-coated GQDs on differentiated THP-1 human macrophages. Nanoparticle size distribution was assessed by transmission electron microscopy, atomic force microscopy, and dynamic light scattering in water and cell culture medium. GQDs exhibited an average diameter (TEM) of 5-10 nm and surface charges of -22 mV and +19 mV for carboxyl- and amine-coated GQDs, respectively. Aggregation was observed when GQDs were dispersed in the serum-rich cell culture medium, which is probably associated with protein corona formation. Cells were exposed to bare, carboxyl-, and amino-coated GQDs at concentrations of 15, 100, or 250 μg/mL for 24 and 48 hr. No significant cytotoxicity was observed for bare and carboxyl-coated GQDs at all concentrations. For amino-coated particles, a decrease of 40% in cell viability was observed at concentrations >100 μg/mL after 48 hr. The cytotoxicity pathway (e.g., apoptosis vs. necrosis) and release of cytokines were also assessed by flow cytometry and ELISA, respectively. Our findings indicate that the surface coating of GQDs significantly affects particle uptake and toxicity in human macrophages. Further studies are needed to build the toxicological profile of GQDs before use in biomedical applications.

2214 Molecular Toxicity Analysis of Citrate Gold Nanoparticle-Treated Human Intestinal CaCo-2 Cells by Array Gene Expression Profiling

A. D. Wusu, N. R. Sibuyi, A. S. Skepu, A. A. Madiehe, and M. Meyer. 1University of the Western Cape, Cape Town, South Africa; and 2DST/Mintek NIC Biobalms Unit, Johannesburg, South Africa.

Some in vitro studies have shown citrate gold nanoparticles (cAuNPs) to be safe for nanomedicine applications (not toxic) via viability assay, while some have shown that toxicity is size-dependent. Meanwhile, in a previous study (Sibuyi et al., 2017), the application of peptide functionalised cAuNPs was established for selective induction of apoptosis in CaCo-2 cells. Unfunctionalized cAuNPs were shown to accumulate inside the cells with no discernible toxicity. However, very little is known about how the uptake of cAuNPs may affect gene expression patterns within cells. Any adverse effects of cAuNPs on gene expression may hamper the use of AuNP in nanomedicine. Consequently, this study aimed to investigate the effects of cAuNPs on gene expression in CaCo-2 cells. Monodisperse, 14 nm spherical cAuNPs were synthesised using the Turkevich method. CaCo-2 cells were treated for 24 hrs with 12.5 nM cAuNPs. The viability and uptake of cAuNPs in CaCo-2 cells were monitored using WST-1 assay and ICP-OES, respectively, and the expression levels of a panel of 84 genes that are related to molecular toxicity were evaluated using quantitative RT-PCR and the RT2 Profiler PCR array. Although the WST-1 assay shows no toxicity of cAuNPs to CaCo-2 cells, gene expression profiling revealed that internalisation of cAuNPs affects the expression of several genes associated with endoplasmic reticulum stress, DNA damage and repair, immunotoxicity, oxidative stress and antioxidant and mitochondrial energy metabolism pathways.

2215 Evaluation of the Skin Sensitizing Potential of Gold Nanomaterials and the Impact of Established Dermal Sensitivity to Gold on the Pulmonary Immune Response with Respect to Dose Mass and Surface Area

K. A. Roach, S. E. Anderson, A. B. Stefanikia, H. L. Shane, and J. R. Roberts. NIOSH, Morgantown, WV.

The easily-manipulated physico-chemical properties of gold nanomaterials (AuNM) have proven useful in many biomedical applications. However, the historical use of gold for the treatment of rheumatoid arthritis and the known sensitizing capacity of gold salts suggest that AuNM may exhibit immuno-modulatory properties. To address this, three studies were performed using female C57BL/6 mice. First, the skin sensitizing capacity of different forms of gold was assessed in the Local Lymph Node Assay (LLNA) using soluble gold salt (AuCl₃, 10%) and increasing concentrations (2.5, 5, 10%) of gold particles (Au, 12.1 um) and spherical AuNM (30 nm). Next, the pulmonary immune effects of AuNM (10, 30, or 90 ug) were assessed 1 d, 4 d, and 8 d post-aspiration. Finally, the impact of existing dermal sensitivity to gold on the pulmonary immune response to different forms of gold was assessed. Mice were dermally sensitized to gold by three dermal exposures (1 d, 2 d, 3 d) to 10% AuCl₃ or vehicle control (VC). Mice were then aspirated once (10 d), twice (10 and 14 d), or three times (10, 14, and 18 d) with VC, 30 μg Au, or a dose of AuNM normalized to the mass or surface area of the 30 μg Au (30 μg Au or 0.2 μg, respectively) and euthanized 1 d later. In the LLNA study, AuCl₃ had a stimulation index (SI) of 10.9, in accordance with its known potent sensitizing capacity. Although the SI of AuNM (2.3) was higher than that of Au (1.1), a three-fold increase in lymphocyte proliferation was not observed for either particle, indicating minimal risk for dermal sensitization. In the dose response study, AuNM induced only minimal lung injury and inflammation. However, exposure to the 90 ug dose did induce a significant increase in total number and percent activated CD4⁺+ T-cells and B-cells in the mediastinal lymph nodes at 4 and 8 d. In the alergy study, after two and three aspirations, mice sensitized to gold exhibited elevated lung lymphocyte numbers which correlated to dose surface area. Moreover, serum IgE levels were significantly increased only in dermally-sensitized mice aspirated with AuNM, irrespective of dose, indicating a potential for increased susceptibility to the development of an IgE-mediated adaptive immune response following respiratory exposure. Collectively, the results from these studies suggest existing dermal sensitivity to gold may exacerbate the pulmonary immune effects resulting from AuNM inhalation.
2216 Gender-Specific Biological Responses in Juvenile Rats Orally Exposed to Three Engineered Nanomaterials

N. P. Mortensen1, M. C. Moreno1, P. R. Patel1, R. W. Snyder1, S. L. Watson1, S. R. Black1, S. J. Sumner1, and T. R. Fennell1. 1RTI International, Research Triangle Park, NC; and 2University of North Carolina at Chapel Hill, Kannapolis, NC.

Engineered nanomaterials (ENMs) are widely used in medicine, food, and agriculture, as well as general household applications, and exposure to them is ubiquitous. Children represent a vulnerable population because perturbations in cell growth and signaling can disrupt temporally-sequenced developmental processes leading to long-term functional deficits. Little is known about the behavior, and biological responses of ENMs and their toxicity in developing animals. In this study three nanoparticles (NPs) provided by The NIHEHS Consortium for Nanotechnology Health Implications Research were tested: TiO2, P25, 30 nm Al2O3, and 50 nm ZnO. Three litters (five males and five females) of juvenile Sprague-Dawley rats were daily administered 10 mg/kg NP or vehicle control (water) by oral gavage between postnatal day (PND) 17-20. Basic neurobehavioral (acoustic startle response, locomotor activity, and rotarod) and cardiac (ECGenie) assessment were performed 4 hours post administration of the final dose. Animals were sacrificed on PND 21, and selected tissues were collected, weighted, and processed for histopathology or biochemical analysis. Neurotransmitter concentrations in brain tissues were quantified by HPLC with electrochemical detection. No change was observed for body weight (b.w.) or brain-to-b.w. ratio for pups. Liver-to-b.w. ratio were significantly increased for male pups receiving TiO2 (0.0417±0.0028) and Al2O3 NP and (0.0409±0.0021) and for female pups administered TiO2, P25 (0.0420±0.0040) compared to control (male: 0.0389±0.0025; female: 0.0393±0.0021). No neurobehavioral effects were found. Heart rate was significantly decreased for female pups administered TiO2, P25 (441±43.3 beats per minute (bpm)) compared to vehicle control (512±46.0 bpm). No significant changes were observed for neurotransmitter levels in brain tissue. Enhanced Darkfield and Hyperspectral imaging (CytoViva) are being used to evaluate the presence of NPs in tissue sections of the intestine, liver, spleen, kidney, and lymph nodes. The microscopy analysis is in progress, we have located Al2O3 in the liver. Gender-specific responses were observed in juvenile rats orally administered TiO2, P25 and Al2O3 NP. These data suggest that the developing animal represents a valuable model for oral ENM exposure.

2217 Long-Term Effects of Inhaled Nanoparticles in Rats: Ceriumdioxide and Bariumsulphate

R. Landsiedel1, L. Ma-Hock1, K. Wiench1, S. Gröters1, B. van Ravenzwaay1, H. Ernst2, and D. Schaudien2. 1BASF SE, Ludwigshafen am Rhein, Germany; and 2Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany.

Ceriumdioxide (NM212) and bariumsulphate (NM220) nanoparticles were tested according to the OECD test guideline no. 453; additions were made to the standard protocol to find evidence of inflammation and potential lung tumours with high sensitivity. Aerosol concentrations were concentrations 0.1, 0.3, 1 and 3 mg/mL and 50 mg/m³ was tested, respectively. Levels of cerium measured in the organs increased with higher exposure concentrations and over time. However, the accumulation only reached a very low level. Lung burdens of barium were unexpectedly low during the first three months of exposure, due to fast clearance most probably by dissolution measured in the organs increased with higher exposure concentrations and tested according to the OECD test guideline no. 453; additions were made to H. Ernst the Federal Institute for Risk Assessment. Toxiology and Experimental Medicine and the biodistribution was analysed by the Federal Institute for Risk Assessment.

2218 Comparative In Vivo Assessment of Alveolar Fibrosis, Histopathology, and Systemic Translocation Induced by Carbon Nanotubes and Nanofibers from US Facilities

K. Fraser1, V. K. Kodali1, L. Bishop1, T. Eye1, J. Hubczak2, S. Foster3, N. Yanamala1, D. Schweger-Berry1, S. Friend1, A. Stefanis1, M. M. Dahm2, M. K. Schubauer-Berigan3, E. M. Birch1, D. E. Evans1, N. Q. Wu4, G. Casuccio5, K. Bunker6, M. S. Orandle7, A. F. Hubbs1, R. R. Mercer1, and A. Erdely1. 1NIOSH, Morgantown, WV; 2NIOSH, Cincinnati, OH; 3West Virginia University, Morgantown, WV; and 4R/J Lee Group, Monroeville, PA.

Pulmonary exposure to carbon nanotubes or nanofibers (CNT/F) is known to induce inflammation, toxicity, or tumorigenesis, and is a concern in the occupational setting. CNT/F represent a large class of materials and it is unclear if all confer similar toxicity. Our aim was to use ENM-TED to test the pulmonary effects induced by CNT/F with variable physicochemical properties obtained from U.S. facilities. Seven different multi-walled CNT and two CNF were characterized and evaluated for alveolar fibrosis, translocation, and histopathological changes in mice at 1, 7, 28, and 84 d following oropharyngeal aspiration to 4 or 40 µg of each material. Lung sections at 84 d post-exposure to 40 µg were microscopically evaluated to measure changes in histopathology. Moderate and multifocal granulomatous bronchopneumonia, bronchiolitis obliterans, bronchiolar epithelial hypertrophy, and peribronchiolar fibrosis were observed in most, but not all, high dose exposures. Variances in incidence and severity between the CNT/F correlate to physicochemical properties (e.g., particle agglomeration state, nominal tube diameter, etc.). Alveolar fibrosis was measured using morphometric point and intercept counting, and was generally increased in 7 of the 9 materials reaching significance in materials with nominal tube diameter greater than or equal to 50 nm. Tracheo-bronchial lymph node (TBLN) and liver sections at 84 d post-exposure were microscopically evaluated for particle accumulation. A range of TBLN and lung accumulation patterns were observed, which reflect the ability of macrophages to phagocytose and clear particles dependent on size and agglomeration. Systemic translocation was limited to single tubes or fibers rather than agglomerates, meaning less systemic accumulation for smaller diameter, more agglomerated material. The lower dose of MWCNT did not exceed a lung to blood distribution, even though nanofibrous material was measured using morphometric point and intercept counting, and was generally increased in 7 of the 9 materials reaching significance in materials with nominal tube diameter greater than or equal to 50 nm. Tracheo-bronchial lymph node (TBLN) and liver sections at 84 d post-exposure were microscopically evaluated for particle accumulation. A range of TBLN and lung accumulation patterns were observed, which reflect the ability of macrophages to phagocytose and clear particles dependent on size and agglomeration. Systemic translocation was limited to single tubes or fibers rather than agglomerates, meaning less systemic accumulation for smaller diameter, more agglomerated material. In conclusion, histopathologic changes and translocation were dependent upon physicochemical properties such as particle agglomeration size and morphology. Ongoing research and modeling techniques will elucidate relationships between physicochemical characteristics and toxicities of various CNT/F.

2219 Multiwalled Carbon Nanotubes Modulate Immune Responses and Pulmonary Injury without Increasing Influenza A Virus Titers in Infected Mice

H. Chen1, S. T. Humes1, M. Rose1, S. E. Robinson1, J. C. Loeb1, L. C. Smith1, I. V. Sabaraya1, N. B. Saleh2, L. W. Castlemale1, J. A. Lednicky1, and T. Sabo-Attwood1. 1University of Florida, Gainesville, FL; and 2University of Texas at Austin, Austin, TX.

Extensive development and use of nanomaterials (NMs) have garnered concerns regarding their potential exposure and adverse health effects. Many toxicological investigations have particularly focused on pulmonary injury that include fibrosis, asthma, and possibly lung cancer, but only a few reports have explored how exposure to NMs can affect host’s susceptibility to pathogenic infections. Previously, we have found exposure of mice to pristine single-walled carbon nanotubes (SWCNTs) can significantly increase viral titers to influenza A virus (IAV) in mice in concert with repressed antiviral and pro inflammatory immune responses. In the present study, we investigated if pre-exposure to a different type of carbon nanotube, hydroxylated multi-walled carbon nanotubes (MWCNTs), would impact immune mechanisms and viral titers similarly. Male mice were randomly assigned to control, MWCNTs, IAV, and MWCNTs+IAV groups and exposed to either 20 µg of MWCNTs or control vehicle (pluronic) by pharyngeal aspiration. On day 3, animals were then given 3.14×10⁵ TCID₅⁰ IAV or PBS by intranasal instillation. All animals were euthanized on day 7 and endpoints including immune cell profiles and cytokine and chemokine levels in bronchioalveolar fluid (BALF), lung histopathology and mRNA expression of innate immune and oxidative stress-related genes, were measured. Our results showed minimal lung tissue damage when mice were exposed to MWCNTs alone. Compared with mice that were exposed to IAV only, MWCNTs didn’t significantly alter viral titers or immune cell profiles in BALF in the co-exposed group, but significantly increased cytokine and chemokine levels (IL-1β, TNFα, GM-CSF, KC, MIP-1α, MIP-1β, MIP-2, and RANTES), and inhibited expression of antiviral genes (Ifn-γ, Rgp-1, Mda5, and Ifn-2). Unlike pristine SWCNTs, hydroxyl functionalized MWCNTs do not increase viral titers to IAV infection, however they do cause molecular changes related to the immune response that are similar between CNT types.
Silver nanoparticles (AgNPs) are, largely due to their antimicrobial properties, one of the most commonly used nanomaterials in consumer products such as cosmetics, clothing, household products and even in food products and biomedical purposes, including drug delivery and tumor targeting applications. Although reports of human exposure via several routes have been rapidly increasing owing to increases in the manufacture and utilization of AgNPs, few reports exist on the acute toxicity associated with different sizes of AgNPs. Recently, we reported that intraperitoneally administered AgNPs in 10 nm diameter showed acute toxicity in BALB/c mice, e.g., reduced activity and piloterection at 5 hours post-administration, lowered body temperatures at 6 hours post-administration and death within 24 hours post-administration with histopathological lesions mainly in liver, but the same amount of AgNPs in 60 and 100 nm diameter did not. This study aimed to evaluate the effects of antioxidants on acute toxicity of intraperitoneally administrated AgNPs in BALB/c mice. One hour after the administration of AgN-acetyl-L-cysteine (NAC, 2000 mg/kg bw, i.g.), Vitamin C (200 mg/kg bw, i.g.), Vitamin E (100 mg/kg bw, i.g.) or L-buthionine-(S,R)-sulfoximine (1.6 g/kg bw, i.p.), 10 nm AgNPs (0.2 mg/mouse) was intraperitoneally administered to 7-week-old female BALB/c mice (5 mice/group) and then sacrificed 6 and 24 hours after AgNPs treatment. In biochemistry, glucose was increased in all AgNP treated groups, except for NAC + AgNPs group. In histopathology, the lesions observed in AgNPs only group, congestion, vacuolation in the liver, increased cellular components in the liver sinusoid and apoptosis in white pulp of the spleen were found at 6 hours, while these lesions were eliminated by NAC pre-treatment but not by others. These lesions were remained until 24 hours. Acute toxicity of intraperitoneally administered 10 nm AgNPs was reduced by only NAC of pre-treated antioxidant.

Cytogenotoxic and Mitodepressive Effects Induced by Silver and Copper Oxide Nanoparticles, and Their Mixture in Allium cepa L.  
O. Ogunsusi1, O. Fadoju1, O. Alabi2, C. Alimba1, S. Cambier2, S. Eswara1, A. Gutieb3, and A. Bakare1. 1University of Ibadan, Ibadan, Nigeria; 2Federal University of Technology Akure, Akure, Nigeria; and 3Luxembourg Institute of Science and Technology, Belvaux, Luxembourg.

Silver (Ag) and copper oxide (CuO) nanoparticles (NPs) are utilised in the manufacture of numerous consumer products because of their antimicrobial properties. However, there are scientific concerns that their potential release and coexistence in the environment may lead to genotoxic consequences in the ecosystem. Therefore, sufficient information on the cytogenotoxicity of both NPs and none on their mixture. Therefore, we investigated the cytotoxic and genotoxic effects of AgNPs, CuONPs and their mixture (1:1) using the Allium cepa chromosome aberration assay. The nanoparticles were characterised using Transmission Electron Microscopy and Dynamic Light Scattering. Allium cepa roots were exposed to five concentrations (5 - 80 mg/l) of each NP and their mixture for 24 h; and the recovery effect was examined after another cell cycle in distilled water. Both NPs were spherical in shape. AgNPs, CuONPs and their mixture respectively had hydrodynamic sizes of 219.40 nm, 2260 nm, and 282.50 nm; and zeta potentials of -25.30 mV, 5.29 mV and -16.40 mV. AgNPs significantly (P < 0.05) increased Mitotic Index (MI) while CuONPs and their mixture significantly (P < 0.05) decreased the MI. Chromosomal aberrations such as sticky chromosomes, disturbed spindles, anaphase bridges were significantly (P < 0.05) increased in A. cepa exposed to both NPs and mixture compared with the negative control. Partial recovery effect (36 %) was observed in the root cells exposed to AgNPs only. Interaction factor analysis of the mixture showed that the AgNPs and CuONPs interacted antagonistically to induce cytogenotoxicity. These results show that exposure to AgNPs, CuONPs and their mixture are capable of inducing chromosomal anomalies in Allium cepa; and may be of environmental and public health importance.

Changes in Lung and Blood Transcriptomes Following Exposure to Multi-walled Carbon Nanotubes in Mice  
T. O. Khaliullin1,2, M. S. Newman3, E. R. Kisin2, K. A. Suleimanova1, L. M. Fatkhutdinova1, N. Yanamala2, and A. A. Shvedova1,2. 1West Virginia University, Morgantown, WV; 2NIOSH, Morgantown, WV; and 3Kazan State Medical University, Kazan, Russian Federation.

Pulmonary exposure to multi-walled carbon nanotubes (MWCNT) has been shown to cause local acute and chronic inflammation, fibroproliferation, and immunotoxicity in small animal studies. However, the search for representative biomarkers of exposure is an ongoing endeavor. Whole blood gene expression profiling is a promising approach to identification of novel biomarkers for tissues over traditional histopathology. This study was to look for correlates between RNA expression in lung tissue and in whole blood after MWCNT exposure. Mice were administrated 40 µg of MWCNT or USP-grade phosphate buffered saline via pharyngeal aspiration and sacrificed 56 days after treatment. RNA microarray (Agilent 2100) studies were performed alongside histopathology of lung sections. Analysis of lung tissue RNA using Ingenuity Pathway Analysis (IPA) indicated trends in inflammatory response and connective tissue organization markers, with an emphasis on immune cell trafficking, phagocytosis, and adaptive immune responses. At the same time, many innate immunity-related transcripts (plunc, bpi1, reg3g) were significantly downregulated. Activation of cancer-related disorders and functions was mostly decreased. IPA analysis of the 280 significantly differentially expressed genes in the whole blood was suggestive of increased hematopoiesis and cell development, activation of cancer/tumor development pathways, and atopy. Additionally, gene expression changes in the blood were indicative of ER-stress and mTOR pathway. The goal of this study was to identify common, upregulated genes between whole blood and lungs, important for the adaptive immune responses: ccx1r, cd72, sharpin, and s1cl1a1. Trim24, important for T,2 cell effector function, was downregulated in both datasets. Hla-dqa1 (MHC-I1) mRNA was upregulated in the lungs and downregulated in the blood, as was ilr4b, which controls intracellular response. The only common disorder between lungs and blood was “hypersensitivity.” In conclusion, our studies have shown that transcription changes occurring in the lungs of MWCNT-exposed mice do not necessarily produce a completely replicable pattern in the whole blood, however, specific systemic responses may be shared between transcriptomic profiles.

Development of Whole Body Inhalation System for Well-Dispersed Nanomaterials Toxicity Testing (Taquann Direct-Injection Whole Body Inhalation System)  
Y. Taquahashi1, S. Yokota2, K. Morita1, M. Tsuji1, Y. Hirabayashi1, A. Hirose2, and J. Kanno1,2. 1National Institute of Health Sciences, Kawasaki, Japan; and 2Japan Bioassay Research Center, Japan Organization of Occupational Health and Safety, Hadano, Japan.

Inhalation is a primary route of exposure to nanomaterials (NMs) and therefore the whole-body inhalation exposure studies are most important for their toxicity testing. In designing inhalation toxicity studies for NMs, it is important to control the status of aggregate and agglomerates (AA) to be consistent with the status presumed in human exposure. For example, a multiwalled carbon nanotube (MWCNT) such as Mitsui MWNT-7 is a mixture of single fibers (SF) and their AA. Human ambient air, in general, is less agitated; the AA may sediment away faster, single fibers may suspend longer in the air and be inhaled by humans. On the other hand, the air for experimental animals is rigorously agitated in most studies, which could control the reactivity of the aerosol: when the aerosol is a mixture of SF and AA, the AA could be trapped by the upper respiratory tract and impede the SF to reach the alveolar region and consequently induce AA-specific proximal lesions. Taking all into account, we considered that it is essential to make a well-dispersed aerosol without AA for the human-relevant exposure scenario. To realize this condition, we developed a simple and reproducible dispersion method (Taquann Method) and an optimized aerosol generator system for this dispersed samples, designated as Taquann Direct-Injection Whole Body Inhalation System (Taquann Method). Using this system, we conducted a study to demonstrate its performance. C57BL/6 mice were exposed to pristine MWNT-7 (U-CNT) or Taquann-dispersed MWNT-7 (T-CNT) aerosol at a concentration of 2 mg/m3 for 2 hours per day for 5 days. Lung burden of mice exposed to U-CNT was half of those exposed to T-CNT (approx. 4 and 8 micro-gm per animal, respectively). AA were found trapped by the nasal cavity mucosa in U-CNT group, explaining its lower lung burden. Our preliminary short-term inhalation toxicology tests confirmed that this Taquann method and Taquann inhalation system is applicable to various types of NMs with minimal sample-dependent pre-treatment/pre-adjustment. The latest version is less expensive, and fully
2224 Pulmonary Toxicity Associated with Different Zinc Nanoparticles after Intratracheal Instillation in Rats

X. Xin1, M. Barger1, K. Roach3, G. Boyce1, M. Dulini1, A. Stefanaki1,2, S. Leonard1,2, and J. Roberts1,2. NIOSH, Morgantown, WV; and West Virginia University, Morgantown, WV.

Zinc nanoparticles (Zn NPs) are used extensively in various products including cosmetics, personal hygiene products, paints, food additives, and cancer therapeutic agents. As Zn NPs production increases, pulmonary toxicity related to occupational exposure becomes a concern. The goal of this study was to assess pulmonary toxicity of Zn NPs of different size, shape, solubility, and composition. In the first study, 2 doses (0.05 and 0.125 mg) of 6 particles were examined: fine-sized ZnO (FZnO), nano-sized elemental Zn (EZn), nano-sized ZnO (NZnO), ZnO nanowire (WNZnO), and comparable nano-sized TiO2 (NTiO2) and TiO2 nanowire (WTiO2) as highly insoluble control materials. Male Sprague-Dawley rats were exposed by intratracheal instillation (II) to 0.05 or 0.125 mg of particles or vehicle control DM (dispersion medium) following a 5 min sonication on day 0. Body weights were recorded throughout the study. Parameters of lung injury and inflammation were measured in bronchoalveolar lavage (BAL) at 1, 7, 14, 21, and 28 day post-exposure. In a second study, 5 doses of TIO2 FZnO and EZn were exposed orally (PO) at 0.05 to 0.0 or 0.125 mg of particles or vehicle control DM (dispersion medium) following a 30 sec sonication that resulted in less release of soluble Zn prior to II. The same time points and endpoints as in the first study were analyzed. In the first study, NZnO had the greatest specific surface area (SSA) and solubility prior to II. FZnO and NZnO agglomerates were smaller than the other samples, and consistent across studies. Study 1 showed the high dose of FZnO and NZnO caused decreased body weight on 1-3 D, which gradually increased by 1 M, followed by normal weight gain up to 3 M. All particles caused transient lung injury and inflammation at 1 D post-exposure except NTiO2, with NZnO>FZnO>EZn>WNZnO>WTiO2. At 7 D, lung injury and inflammation remained increased in the groups exposed to Zn NPs only. Inflammation persisted up to 3 M post-exposure to the greatest degree in the NZnO group followed by FZnO then EZn, while there was recovery in the groups exposed to TiO2 and WTiO2. Eosinophils were increased to the greatest degree in the NZnO>FZnO>EZn groups at 1 and 7 D. Study 2 showed a similar trend as the first study in changes of body weight, lung injury, and inflammation, although the difference between the NZnO and FZnO was not as pronounced. Material characterization studies suggested differences in toxicity may be associated with increased solubility as a function of composition (oxide vs elemental) and increased SSA.

2225 Bioactivity of Boron Nitride Nanotube Preparations That Differ in Purity In Vitro and In Vivo

J. Roberts1,2, V. Kodali1, X. Xin1, M. Barger1, K. Roach3, A. Stefanaki1,2, T. Eye1, M. Wolfarth1, S. Leonard1, D. Porter1,2, and A. Erdely1,2. NIOSH, Morgantown, WV; and West Virginia University, Morgantown, WV.

Boron nitride nanotubes (BNNTs), due to their wide band gap and thermal and chemical stability, are expected to be incorporated into a myriad of industrial applications. Currently, commercial production of BNNTs occurs through different processes including a pressurized vapor/high temperature process (PVTH) or an induction thermal plasma process (plasma), both resulting in 30-60 % residual compounds and impurities. In the current work, we evaluated the pulmonary and systemic toxicity arising due to acute exposure of BNNTs from the plasma process. Four BNNTs with a gradient of purity (from 50% to 90% tubes) were used to assess toxicity and evaluate bioactivity. Hexagonal boron nitride (less than 100 nm in diameter) was used as a reference material. All BNNTs tested were agglomerated bundles of few multi-walled tubes (~3 to 5 walls/tube). Electron microscopy (EM) confirmed a visible decrease in impurities and an increase in tubular structures across the gradient samples. In vitro and in vivo experiments were performed following sonication of BNNTs in dispersion media (DM). Preliminary EM sizing showed that the BNNTs dispersed in DM had a length of ~0.5 - 1.5 µm and a diameter of ~5 - 30 nm. Electrocardiographic and magnetic resonance measurements showed no change in surface hydroxyl radicals among the BNNTs with various purities. In vitro, the toxicity was evaluated in human monocye cells (THP-1) wild-type and NLRP3-deficient cells at a concentration range of 0-100 µg/mL. At the high doses, there was a small but statistically significant increase in lactate dehydrogenase (LDH) released in the highest purity BNNT exposures. This increase in toxicity was attenuated in NLRP3-deficient cells. In vivo toxicity was evaluated in male C57BL/6 mice exposed by oropharyngeal aspiration to 4 or 40 µg of BNNT sample/mouse. Animals were euthanized 1 and 7 d post-exposure and lung lavage was performed to evaluate lung injury and inflammation. At day 1 there was a significant influx in neutrophils, a marker for lung inflammation, as well as an increase in LDH activity in particle-exposed groups. The response was highest in animals exposed to the high dose of the highest purity BNNT mixture. Inflammation and injury began to resolve by 7 d. These results indicate that BNNTs made by plasma processes induce acute toxicity and inflammation only at high concentrations and ongoing studies will evaluate histopathological changes and clearance up to 3 mo post-exposure.

2226 Activities of Mitochondrial Enzymes in Heart and Brain of Rats Exposed to Titanium Dioxide Nanoparticles

O. Ademuyiwa1, S. A. Kehinde1, O. G. Adelesi1, R. N. Ugba1a, E. O. Dare1, D. O. Babayemi1, and A. D. Wus2. Federal University of Agriculture, Abeokuta, Nigeria; and Lagos State University, Ojo, Lagos, Nigeria.

Titanium dioxide Nanoparticles (TiO2 NPs) have found wide application in various products making exposure to this metal oxide nanoparticle inevitable. Information about toxic effects of TiO2 NPs after oral exposure are extremely limited. Since mitochondrionopathies are being recognized as subtle and insidious biochemical events in the toxicity associated with various toxicants, this study determined the activities of mitochondrial enzymes (Malate dehydrogenase, MDH; Succinate dehydrogenase, SDH; Complexes Complete III+III, CIII+III, Complexo IV-IV, CVIP) in rats exposed to TiO2 FZnO and EZn NPs at oral doses (50, 150 and 250mg/kg body weight) for 4, 8 and 12 weeks. Control rats (n=18) received distilled water for the same period. At the end of TiO2 NPs exposure, brain and heart were removed from the rats and activities of mitochondrial enzymes determined. Enzymes in the two organs exhibited different patterns on exposure to TiO2 NPs. While cardiac MDH was down-regulated throughout the study, brain MDH increased at 4 and 8 weeks of 50 and 12 weeks of 150mg/kg body weight doses respectively. In both organs, SDH activity was up-regulated at 4 weeks. While the up-regulation in cardiac SDH was dose-dependent, brain SDH did not show any dose dependency. In contrast however, CPII+III in both organs was down-regulated, except at 4weeks of 150- and 12weeks of 50mg/kg body weight where increases ranging between 2 and 7 folds were observed. While cardiac CIII+ was decreased at 8 weeks of 150mg/kg body weight dose, the brain enzyme was up-regulated by 50 and 250mg/kg body weight doses of TiO2 NPs. Unsystematic changes characterized the response in brain CVIP, whereas the cardiac enzyme was down-regulated, except at 8weeks of 50 and 250mg/kg body weight doses of TiO2 NPs. Our findings indicate that TiO2 NP-induced alterations in cardiac and brain mitochondrial energy metabolism might be important in pathologies associated with exposure to TiO2 NPs.

2227 Crystalline Nanocellulose-Induced Lung Toxicity and Global Gene Expression Changes in the Rat

Crystalline nanocellulose (CNC) is an emerging nanomaterial with multiple commercial and industrial applications. Occupational exposure to CNC during the production and/or use of products containing the nanomaterial potentially resulting in adverse health effects among workers is possible. Therefore, there is an immediate need to determine the toxicity potential and mechanisms underlying CNC toxicity. Male Fischer rats were exposed by whole body inhalation exposure to air or CNC (20 mg/m³, 6 hours/day, 14 days), and pulmonary toxicity and lung gene expression changes were determined one day following the last exposure. CNC particles were detected in the lung alveoli of the exposed rats. Compared with the air-only exposed controls, significant increases (p<0.05) in the incidence of bi-nucleated alveolar macrophages (AM), lactate dehydrogenase activity, pro-inflammatory cytokine levels, phagocyte oxidant production, and AM and neutrophil counts were detected in the bronchoalveolar lavage of the CNC exposed rats. Mild lung histological changes, such as the accumulation of AM and neutrophils, were observed in the CNC exposed rats. Global gene expression profiling by next generation sequencing identified 573 genes whose expressions were significantly different (FDR p<0.05) in the lungs of the CNC exposed rats, compared with the controls. Bioinformatic analysis of the lung gene expression data identified significant enrichment of several biological functions and canonical pathways related to inflammation (cellular movement, immune cell trafficking, inflammatory diseases and response, respiratory disease, and free radical scavenging, complement system, acute phase response, leukocyte extravasation signaling, granulocyte and agranulocyte adhesion and diapedesis, IL-10 signaling, phagosome formation and matu-
2228 The Impact of Neuroinflammatory Disease and Environmental Exposures on Gold Nanoparticle Accumulation in the Mouse Brain

Epidemiological studies correlate air pollution exposure with increased incidence of Alzheimer’s Disease (AD). We postulate that translocation of inhaled ultrafine particles (UFP, <100 nm) to secondary target organs, including the brain, is one mechanism by which airborne UFP can cause adverse effects. The biodistribution of nanoparticles, particularly to the brain, is still a question that needs to be thoroughly investigated. In young, healthy C57 mice (n=7) that were exposed for 4hrs via whole body inhalation (WBI) to gold nanoparticle aerosols (AuNP; count median diameter (CMD), 20nm, geometric standard deviation (GSD), 1.5), AuNP did not readily accumulate in the brain following an inhalation exposure. We hypothesize that inflammatory insults, such as environmental exposures or neuroinflammatory diseases, can change barrier permeability and ultimately alter NP biodistribution. Aged 3xTgAD mice - which mimic human AD-related pathologies and exhibit progressive neuroinflammation - and non-transgenic (NTg) mice (16 mo males, n=7-8) were exposed via WBI to AuNP aerosol for 4 hrs (CMD, 27 nm, GSD, 1.5). Tissues were harvested 24 hrs post-exposure and analyzed for Au using inductive-coupled plasma mass spectrometry. There was no significant difference of Au accumulation by genotype in the brain regions measured. Separate groups of aged 3xTgAD and NTg mice were also exposed to ambient UFP-enriched aerosols for 4hrs/day for 8 days (CMD, 88 nm, GSD, 1.5) as a purported air-blood barrier insult prior to AuNP aerosol exposure to characterize exposure-related changes in AuNP accumulation in the brain. UFP-enriched aerosol exposures did not induce acute lung inflammation nor significantly affect AuNP accumulation in the brain regions measured. However, when 3xTgAD and NTg mice (3, 19, and 23 mo males, n=7-11) were injected intravenously with colloidal AuNP (primary particle size 20 nm, 45-49 μg per mouse), there was a significant age x genotype interaction effect (p=0.006) found in the whole brain, as well as in areas of the brain that are particularly affected by AD, such as the hippocampus (p<0.05). This suggests that as the pathology progresses, the brain becomes more permeable to vascular accumulation of AuNPs, but that stronger insults are needed to see any differences in brain accumulation of inhaled AuNP. Funding: R01ES020332, T32ES007026, 3P30ES001247.

2229 Limited Neurotoxicity from Neonatal Inhalation Exposure to Ultrafine Carbon Particles or Diesel Particulate in C57Bl/6

Epidemiological studies have shown exposure to anthropogenic fine particulate matter is associated with adverse neurodevelopmental outcomes in children. Complementary studies using rodent models have shown that developmental exposure to ambient nanoscale particulate matter can lead to sex-specific neurotoxicity and learning deficits. However it is still unclear about the direct sources and particulate matter constituents that contribute to these deleterious outcomes. To better evaluate potential particulate matter contributors to developmental neurotoxicity, two studies were conducted to assess the potential developmental effects of pure ultrafine carbon particles (UFCP; median aerodynamic diameter: <40 nm) and nanoscale diesel particles (median aerodynamic diameter: <100 nm) on brain pathology and behavior in C57Bl/6 mice. The UFCP aerosol was generated from a spark-discharge setup and the diesel particles were generated from ultrasonic nebulization of dissolved National Institute of Standards and Technology Standard Reference Material 1650b (SRM 1650b). Separate inhalation exposure of each material with neonatal mice occurred on postnatal days 4-7 and 10-13 for 4hrs/day, 4 days/week at a mass concentration of 50 μg/m3 for UFCP and 100 μg/m3 for SRM 1650b. Assessments of central nervous system pathology 24 hours following exposure showed no gross inflammation or injury following pure ultrafine carbon exposure, while SRM 1650b did increase glial fibrillary acidic protein (GFAP) immunodensity in the corpus callosum and cortex, suggestive of inflammation. To assess learning deficits, behavior on a fixed-interval schedule of reinforcement, a paradigm that involves temporal learning and is historically effective at detecting the protracted effects of low-dose neurotoxicants such as lead, was utilized in exposed adult. No significant treatment-related learning differences were found in the adult mice. The lack of extended effect from the developmental particulate matter exposures, even at relatively high mass concentrations, suggests neither ultrafine elemental carbon nor diesel particle exposure alone are sufficient contributors to adverse developmental neurotoxicity. Further research on more reactive constituents of particulate matter including volatile organic species, reactive metals, and gases need to be done to better clarify specific toxic contributors.

2230 Activities of Glycolytic Enzymes in Rats Exposed to Titanium Dioxide (TiO2) Nanoparticles (NPs)

Titanium dioxide nanoparticles (TiO2, NPs) have been applied widely in various products such as food, packaging, electronics, sunscreens, paints, drugs and cosmetics. Safety of TiO2 NPs remains unclear because data on absorption, distribution, elimination or any adverse effects after oral exposure are extremely limited. Since disorders of energy metabolism are being recognized as incipient biochemical events in the toxicity associated with various toxicants, this study determined the activities of glycolytic enzymes in rats exposed to TiO2, NPs. Male albino rats were exposed orally to TiO2, NPs (8-12nm) (50, 150 and 250mg/kg body weight) for 4, 8 and 12 weeks. Control rats (n=18) received distilled water for the same period. Tissues were received at the end of TiO2, NPs exposure, blood and liver were removed from the rats. Activities of glycolytic enzymes (Hexokinase [HK], Aldolase [ALD] and Lactate dehydrogenase [LDH]) were then determined. In the lymphocytes (with the exception of 50mg/kg body weight, 8 weeks and 150mg/kg body weight, 12 weeks), exposure to TiO2, NPs up-regulated HK activity. Plasma LDH activity was also up-regulated except at 12 weeks of 150mg/kg body weight dose where 40 and 30% decreases were observed in the plasma and erythrocytes respectively. Hexokinase followed the same pattern as that of the lymphocytes. In a similar vein, both hepatic and lymphocyte ALD followed the same pattern and exocytosed to TiO2, NPs. Their activities was assessed in the brain regions except at 8 and 12 weeks of 50 and 150mg/kg body weight where slight decreases were observed. While plasma ALD also increased (except at 12 weeks of 150mg/kg body weight), erythrocyte ALD increased only at 4 and 8 weeks, but decreased throughout the 12 week exposure period. Compared to erythrocyte LDH that decreased on exposure to TiO2, NPs, a common signature was observed for the lymphocyte, plasma and hepatic enzymes. LDH in these compartments was down-regulated at 8 and 12 weeks of 50 and 150mg/kg body weight doses of TiO2, NPs, whereas at other doses and time intervals, LDH was up-regulated. Our findings indicate that while exposure to TiO2, NPs inhibited erythrocyte glycolytic pathway at the level of ALD and LDH, it enhanced the flux through the plasma, lymphocyte and hepatic glycolytic pathways.

2231 Effects of Multi-Walled Carbon Nanotube Exposure on Brain Oxidative Stress and Inflammation in C57BL/6 Mice

T. L. Young1, G. Herbert1, S. Lucas1, B. Sanchez1, J. Begay1, A. K. Ottens2, A. Erdely1, and M. Campen1. 1University of New Mexico, Albuquerque, NM; 2Virginia Commonwealth University, Richmond, VA; and 3NIOSH, Morgantown, WV.

In vivo models demonstrate increased brain and lung inflammatory activation, disrupted blood-brain barrier (BBB) integrity, increased oxidative stress, serum profile changes, impaired endothelial function, and vasodilatory insufficiencies following multi-walled carbon nanotube (MWCNT) exposure. The mechanism by which oxidative stress and inflammation are explored in this study. We hypothesized that the MWCNT exposure induces serum peptide composition modifications that mediate pro-inflammatory and pro-oxidative stress changes in the brain, likely delivered via exosomes. To test this hypothesis, male wild-type C57BL/6 mice (6-8 weeks) exposed to vehicle (dispersion media), 3, 10 or 40 μg MWCNT via oropharyngeal aspiration were euthanized at various time points post exposure. Pulmonary inflammation was assessed via bronchoalveolar lavage fluid (BALF) cell and protein quantification and inflammatory cytokine/chemokine expression was determined by electrochemiluminescence. Serum bioactivity of whole plasma MWCNT was significantly decreased in MWCNT-exposed mice. While plasma ALD also increased (except at 12 weeks of 150mg/kg body weight), erythrocyte ALD increased only at 4 and 8 weeks, but decreased throughout the 12 week exposure period. Compared to erythrocyte LDH that decreased on exposure to TiO2, NPs, a common signature was observed for the lymphocyte, plasma and hepatic enzymes. LDH in these compartments was down-regulated at 8 and 12 weeks of 50 and 150mg/kg body weight doses of TiO2, NPs, whereas at other doses and time intervals, LDH was up-regulated. Our findings indicate that while exposure to TiO2, NPs inhibited erythrocyte glycolytic pathway at the level of ALD and LDH, it enhanced the flux through the plasma, lymphocyte and hepatic glycolytic pathways.
staining revealed increased albumin staining in extravascular spaces of exposed mice compared to controls. Studies to evaluate oxidative stress, neuroinflammation, and exosomal contributions are ongoing. These preliminary findings suggest that MWCNT exposure induced a pro-inflammatory milieu that may disrupt the BBB.

**2232 ICONS - Integrated Testing Strategy for Mechanistically Assessing the Respiratory Toxicity of Functionalized MWCNT**

O. H. Creuzenet1,* D. Lison2, S. Van Den Brule2, S. Simon2, J. Bonner1, and C. Ziemann1, 1Fraunhofer ITEM, Hannover, Germany; 2LTAP, Louvain, Belgium; 3BIBU, Cluj, Romania; and 4North Carolina State University, Raleigh, NC.

Multiwalled carbon nanotubes (MWNT) show promising technical properties (e.g., composite reinforcement; electrical conductivity). MWNT, meeting WHO criteria, exhibit straight or curved/tangled morphology, depending on length and diameter. Evident fiber toxicity was observed for the rigid fiber type, i.e. carcinogenicity in the rat model after intratracheal injection. Tangled type MWNT (not carcinogenic) may show an altered toxic potential regarding fibrogenic or genotoxic effects following surface modification with functional groups such as -NH2 or -COOH. The ERA-NET SIINN project ICONS (International Collaboration On Nanotube Safety) aimed at mechanistically evaluating and ranking the pro-fibrotic and genotoxic potential of tangled MWNT, focusing on impact of core purification and surface functionalization. A batch of industrially relevant Nanonyl NC7000 was therefore chemically or thermally purified and surface functionalized (-COOH and -NH2). At Fraunhofer ITEM, the eight resulting MWNT (pristine, milled, purified, and functionalized) were tested for sterility and endotoxin. For in vitro use, they were dispersed using an ultrasound-based protocol, and characterized by light and scanning electron microscopy. Subsequent in vitro (gene)toxicity testing with MRC-5 primary human lung fibroblasts revealed differential induction of proliferation (RICK, mitotic index), induction of membrane damage and micronuclei, and loss of chromosomes. Based on these results and existing in vivo data (generated by LTAP and NCSU; oro-pharyngeal aspiration tests), two functionalized MWNT will be selected for a 4-wk inhalation test in rats (based on OECD TG 412), including a 4-wk recovery (validation test). Completed pre-trials demonstrated feasibility of generating respirable MWNT aerosols by dry dispersion with pressurized air. This project is funded by the German BMBF (FKZ: 03XP0063).

**2233 Analyzing the Mechanism of Amorphous Silica Nanoparticle-Induced Immunosuppression in a Mouse Model of Allergic Contact Dermatitis**

Over the last few decades, the field of nanotechnology has grown swiftly, and nanoparticles (NP) based consumer goods are now widely available. Specifically, amorphous silica NPs are approved anti-caking agents in both foods and cosmetics. Furthermore, additional research suggests a potential role for silica NPs in drug delivery and bio-sensing applications. The ubiquitous nature of NP enabled technology increases the need for comprehensive toxicological evaluation of NPs. Our lab is interested in the effects of topical exposure of silica NPs on both healthy skin and skin models of allergic contact dermatitis (ACD). For this study, hairless C57BL/6 mice were either challenged with vehicle or 2, 4-dinitrofluorobenzene (DNFB), after DNFB sensitization. Topical exposure of only 4 μg/ear of 20 nm silica NPs decreases the DNFB induced ear swelling response, and this effect is associated with decreased inflammatory cytokine expression (IL-1β and MIP-2) and reduced cytotoxic T cell skin infiltration, after 24 hours. Importantly, we have also identified that silica microparticles (400 nm) do not reduce the DNFB induced ear swelling response, even with equivalent surface area doses. This suggests that reductions in DNFB bioavailability in the skin, due to particle binding, is an unlikely mechanism of action. To evaluate the upstream signaling events in the silica NP treated skin, we performed a global RNA sequencing study to assess NP induced transcriptome changes in whole skin samples. Over 3400 genes were differentially expressed in DNFB treated skin, compared to control; however, the expression of only 28 genes were significantly altered by 20 nm silica NP exposure in DNFB treated skin. Genes associated with lipid synthesis, extracellular matrix based signaling, activator protein-1 signaling, and anti-oxidant activity were all upregulated by silica NP exposure. While additional studies are required to identify whether these changes in the transcriptome lead to functional changes, these genes represent a potential mechanism by which silica NPs reduce skin inflammation. Supported by: NIH Training Grant ES-05026, R01 ES014299.

**2234 Nickel Nanoparticles-Induced Lung Injury and Fibrosis: The Role of miR-21**

Y. Mo, and Q. Zhang. University of Louisville, Louisville, KY.

In previous studies, we and other groups have demonstrated that exposure to nickel nanoparticles (Nano-Ni) causes severe and persistent lung inflammation and fibrosis. Although it is well-known that Nano-Ni induces oxidative stress, it is unclear which mechanisms contribute to lung fibrosis. Here, we propose that miR-21 may play an important role in Nano-Ni-induced lung inflammation, injury, and fibrosis. miR-21 knock-out (miR-21 KO) and their wild-type (WT) (C57BL/6) mice were used for our in vivo comparative studies. Mice were intratracheally instilled with 50 μg per mouse of Nano-Ni. At day 3 post-exposure, bronchoalveolar lavage (BAL) was performed and the neutrophil count, CXCL1/KC level, LDH activity, total protein concentration, and MMP-2/9 protein levels and activities in the BALF were determined. In addition, mouse lung tissues were collected for determination of MMP-2/9 activities by gelatin zymography assay and for histology study by H&E staining. At 6 weeks post-exposure, mouse right lungs were collected for determination of hydroxyproline content. At day 3 post-exposure, 50 μg per mouse of Nano-Ni caused severe acute lung inflammation and injury that were reflected by increased neutrophil count, CXCL1/KC level, LDH activity, total protein concentration, and MMP-2/9 protein levels and activities in the BALF from WT mice. Nano-Ni exposure also caused increased MMP-2/9 activities in the mouse lung tissues from WT mice. Although Nano-Ni also caused above effects in miR-21 KO mice, their levels were significantly lower than those in the WT mice. Histologically, infiltration of a large number of neutrophils and macrophages in the alveolar space and interstitial tissues was observed in lungs from WT mice exposed to Nano-Ni. However, exposure of miR-21 KO mice to Nano-Ni only caused mild acute lung inflammation and injury. At 6 weeks post-exposure, in the WT mice, Nano-Ni caused extensive interstitial fibrosis and proliferation of interstitial cells with inflammatory cells infiltrating the alveolar septa and alveolar space. However, exposure of miR-21 KO mice to Nano-Ni only caused slight lung fibrosis. Our results demonstrate that short-term Nano-Ni exposure causes less acute lung inflammation and injury in miR-21 KO than WT mice. In addition, long-term Nano-Ni exposure in miR-21 KO mice causes much milder chronic lung inflammation and fibrosis than that in WT mice. Our results suggest that miR-21 may be involved in Nano-Ni-induced lung injury and fibrosis.

**2235 Pharmacokinetics Relates to Safety of a Gadolinium-Containing Metallofullerene**

M. Ehrich1, R. Council-Troche1, J. Hinckley1, S. Werre1, J. Jortner2, and Z. Zhou2. 1Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA; and 2Luna Nanoworks, Danville, VA.

The pharmacokinetic studies used male rats given IV doses of 2 mg/kg of a gadolinium-containing metallofullerene proposed for use in diagnostic imaging. Gadolinium content in a 2 mg/kg dose of the dosing solution was 0.53 mg/kg, as determined by ICP-MS, using a method with a detection limit <0.05 ng/ml in solution. Gadolinium concentrations in whole blood samples taken 15 to 24 h after Gd-metallofullerene administration showed rapid depletion of the quantity of the test agent (half life < 2 h), with levels at 16 h less than 5% of what they were at 1 h. Gd contents in liver samples measured 16 h after dosing (n=3) were 217, 145 and 233 ng/g of liver. These levels were higher than levels in blood at that time and approximated those levels measured in blood at 0.5 hr. The test agent also underwent comprehensive safety evaluation after intravenous administration to male and to female rats at the same dose used for pharmacokinetic studies (2 mg/kg of the gadolinium-containing metallofullerene) as well as a dose 5-fold higher (10 mg/kg). Evaluation endpoints included multiple physiological, behavioral and neurological observations done in intact animals before and up to 14 days after test agent administration. In addition, blood samples were taken for clinical pathology and multiple tissues collected for detailed histopathology 2, 4, 8 and 14 days after administration. No agent-induced effects of toxicological significance were noted at any endpoint at either dose in either gender of rats. Results suggest that, at the doses tested, this fullerene was safe but would have higher levels in liver than in blood at 16 h after administration. Supported by NIH to Luna Nanoworks with subaward to Virginia Tech.
We recently reported that modeled acute exposure to multi-walled carbon nanotubes (MWCNT) increased systemic inflammation, induced vascular dysfunction, disrupted the blood-brain barrier (BBB) and induced neuroinflammation. We further identified a dramatic shift in circulating peptides, found to be mediators of systemic bioactivity and a promising source of health-effect biomarkers. Here, we assessed the burden of repeated MWCNT exposure in inciting a peptidomic response, its association with MMP-9 proteolysis, and longer term neuroinflammatory ramifications. Male C57BL/6 wild-type (WT) and MMP-9 <sup>-/-</sup> knockout (KO) mice were exposed to MWCNT-7 by oropharyngeal aspiration (n=7/group): 0 µg control vehicle (0.6 mg/ml albumin, 0.01 mg/ml DPPC) once per week, 10 µg once per week, and 40 µg at week-1 followed by 0 µg once per week until collecting serum and brains at 28 days after the initial treatment (7 days after the last aspiration). An enriched-peptide fraction was extracted and assessed by untargeted data-independent mass spectrometry while brains were assessed by immunofluorescence microscopy. In WT mice, 1613 (34%) of 4759 reproducibly quantified serum peptide factors were significantly responsive across all exposures (5% FDR) with half (785) directly dependent on MMP-9, speaking to the sizeable, though non-exclusive, role of MMP-9 in production of the MWCNT-responsive peptidome. Repeated 10 µg exposure significantly induced 957 (59%) of the peptidomic responses, highlighting the significance of repeated lower dose exposures. Separately, 1119 (69%) peptide factors were significantly shifted a full 4-weeks after the larger 40 µg bolus dose, supporting a prolonged impact to circulating factors. Likewise, albumin leakage across the BBB and pronounced microglial activation proximal to impacted vessels were observed after repeated low dose exposures as well as after 4-week recovery from high dose MWCNT. These effects were strikingly muted in brains of MMP-9 KO animals. Overall findings affirm significant MWCNT effects on the circulating peptidome, a sustained neurotoxicological burden of exposure, and a dependence on MMP-9 proteolytic function, together substantiating a prolonged impact of exposure.

### Systematic Comparative Assessment of the Cellular Stress Response Pathway Activation by Various Valproic Acid Analogues to Support Biological Read Across

N. G. Vrijenhoek¹, M. J. Moné², R. Gräpel¹, S. E. Escher², and B. van de Water¹. \^1LACDR, Leiden, Netherlands; and \^2ITEM, Hannover, Germany.

Chemical read across is commonly evaluated without considering mechanistic biological knowledge. Here we used a large panel of valproic acid (VPA) analogues to include detailed mode-of-action (MoA) data as a proof-of-concept for read across. VPA is used as an anticonvulsant, but can induce liver steatosis. In rodents, VPA and some of its analogues cause hepatic steatosis, whereas other analogues do not. Since hepatotoxicity is linked to cellular stress pathway activation, we anticipated that VPA analogues that cause steatosis would activate similar stress response pathways, whereas in vivo negative compounds do not. Therefore, we deployed a panel of cellular stress response HepG2 BAC-GFP reporter cell lines, and performed high throughput transcriptomics analysis of cellular stress pathways. We measured stress response pathway activity at high throughput in the reporter cell lines with SRXN1 as target protein for oxidative stress, BiP for unfolded protein response, and p21 for DNA damage response. Cells were treated with a concentration range of 18 different VPA analogues for 24 h, and then imaged by confocal microscopy followed by quantitative image analysis. We were able to largely predict the steatosis in vivo potential of VPA analogues based on the expression of SRXN1-GFP and p21-GFP. Subsequently, we checked whether VPA analogues that cause liver steatosis yield similar transcriptional perturbations. Tempô-Seq analysis of ~3000 genes involved in stress pathway responses for different VPA analogues in a concentration range over 24 h confirmed the concentration response activation of both oxidative stress and p53 downstream targets as well as additional stress pathways, supporting the application of Tempô-Seq technology. Further comparative analysis among all VPA analogues in both HepG2 and primary human hepatocytes will be discussed. Thus, by monitoring adaptive stress response pathways at both the protein and the transcription level, we anticipate to support risk assessment by providing quantitative and mechanistic biological information to corroborate a robust read-across approach. This work was part of the EU-ToxRisk project and received funding of the European Union’s Horizon 2020 research and innovation program under grant agreement No 681002.
Mitotoxicity perturbation has been recognised as a key event in the process of chemical-induced organ toxicity. Nowadays the assessment of the mitochondrial functioning in early toxicity screens is based on static measurements of various mitochondrial processes. Here we focused on the integration of concentration- and time-resolved imaging-based mitochondrial injury data and subsequent transcriptionomics-related cellular perturbations information. We used a panel of ~20 agrochemicals that specifically target mitochondrial respiratory complex (MRC) I, II or III. Effects of the various inhibitors on mitochondrial functioning were monitored using time-resolved high content confocal imaging of mitochondrial membrane potential (MMP) and cell viability in HepG2 cells. A phenomenological computational model was used to describe the observed MMP dynamics. To link the mitochondrial perturbation to subsequent cellular stress responses, we used TempO-Seq targeted RNAseq assessing >3000 genes that capture the genome wide variations in gene expression upon MRC inhibitor exposure. In addition, BAC-GFP cellular stress response reporter imaging was used to validate the observed mitochondrial and cell injury-related changes in gene and related protein expression. The various CI and CIII inhibitors, but not CII inhibitors, were effective in depleting the MMP. The MMP dynamics were quantified by fitting sets of time constants, which could distinguish the effects of MRC inhibitor treatment. Potency of MMP depletion by MRC inhibitors was related to cell death only when glycolysis was inhibited. In repeat dosing regimens of HepG2 3D spheroids demonstrated the intrinsic mitotoxicity-induced cell death of CI and CIII inhibitors. The TempO-Seq data revealed activation of cellular stress response pathways that typically paralleled the potency of onset of MMP depletion by the MRC inhibitors. Transcriptional induction of stress response markers, as identified by TempO-Seq, could be validated using HepG2 GFP-reporters. In summary, the integrated assessment the dynamics of mitochondrial dysfunction and cellular stress response activation provides a novel approach to quantitatively in-depth assess mitotoxicity liability. This work was part of the EU-ToxRisk project and received funding from the EU’s Horizon 2020 programme under grant agreement No 681002.

Acute kidney injury (AKI) is associated with substantial morbidity and mortality and is recognized as a leading cause of chronic kidney disease. The death of epithelial cells in the proximal tubules is thought to be the primary cause of AKI, but epithelial cells that survive kidney injury have a remarkable ability to proliferate. Because proximal tubular epithelial cells play a predominant role in kidney regeneration after damage, a potential approach to treat AKI involves targeting the epithelial cell proliferation following acute damage in vitro. This compound may provide a path for new therapies toward kidney tubule repair after damage.

The adverse effects of Environmental estrogen, bisphenol A (BPA), are multifaceted; this study was to identify the biological pathways perturbed by BPA that potentially influences the immune response system. Tandem-MS-Tag (TMT)-Liquid Chromatography Tandem Mass Spectrometry (LC-MS/MS) quantitative proteomic analysis of the proteome of BPA-treated caco-2 cells. Label-Free-Quantification (LFQ) of the proteome of BPA (10 µg/mL) infected mouse CD4+ T cells. Co-immunoprecipitation (Co-IP) with STimulator of Interferon Genes (STING) and ZDHHC1. Cellular stress, phagosome maturation and especially the Siruin signaling pathways were identified, using both IPA and STRING analysis, as the major protein pathways perturbed by BPA in both human caco-2 cells and mouse CD4+ cells. IPA-Upstream regulator analysis indicated that the pro-inflammatory cytokines including IL-4 and IL-5 typically enriched in type 2 T helper cell (T_{h2}) and Arylhydrocarbon Receptor (AhR), were activated in BPA-infected mouse CD4+ T cells. CD38/ cyclic ADP ribose hydrolase or cyclase was another BPA-activated upstream regulator indicated by the proteomics data. A protein palmitoyltransferase, ZDHHC1, was identified by mass spectrometry as one of the top proteins upregulated by BPA. Results from co-immunoprecipitation (Co-IP) demonstrated that ZDHHC1 and STING form a heteromultimeric complex. Through proteomics analysis of BPA-treated or infected cells, we identified the major protein pathways that are regulated by BPA. Typically, the up-regulated oxidative-stress pathway as well as the protein expression of CD38 suggested an increased consumption of NAD+ and the reciprocal down-regulation of Sirt1 that increase histone acetylation and gene activation. Upstream regulator analysis indicated BPA-infected CD4+ T cells presented a pro-inflammatory state of type 2 helper cell (T_{h2}). We found that the expression of ZDHHC1 is up-regulated additively by BPA and vitamin D.

AhR is a nuclear receptor that responds to xenobiotics by induction of genes BPA and CYP1A2, Sustained AhR activation has been associated with carcinogenicity and other toxicities in rodents and humans. Thus, identification of this liability is important to ensure patient safety. We assessed the transcriptional response of AhR genes in liver and lung in a 1-month rat study with 5 and 8-day peel-offs with an AhR-activating carcinogen (PCB-126) at doses with and without treatment to carcinogens (1000 ng/kg/day or 500 nkd) and non-carcinogenic (150 nkd) in 2-y rat studies. For liver, Cyp1a1 demonstrated dose and time-dependent increases with the 1000 nkd dose yielding a median response of 8000-fold in males and females. At the non-carcinogenic dose of 150 nkd, the median at 1 month was 2430-fold for females and 1370-fold for males. Cyp1a2 showed dose and time-dependent increases with the greatest median response of 20-fold at 1000 nkd, while 150 nkd had a response of approximately 8-fold. Cyp1b1 had the greatest response at 1000 nkd at 1 month, with a median response of 2060-fold for females and 1420-fold for males, while at 150 nkd the response was 132-fold in females and 20-fold in males. The response for lung was more variable than in liver, with Cyp1a1, AhR and Cyp1b1 demonstrating informative dose and time-dependent increases. This study characterized transcriptional responses for AhR regulated genes in liver and lung for PCB-126 dosed at a non-carcinogenic (150 nkd) and carcinogenic dose (1500 nkd) for 5 days, 8 days and 1-month, demonstrating that transcriptional responses can also clearly separate these doses. The data from this study could be considered a benchmark for assessing dose-dependent AhR activation and subsequent utility for projecting tumorigenic doses for other compounds, when sustained AhR activation is seen in liver and/or lung.
Ingestion of or exposure to chemicals poses a serious health risk. Early detection of cellular changes induced by such events is vital to identify appropriate countermeasures to prevent organ damage. The aim of this study is to predict in vivo organ injuries in rats with the use of gene expression from in vitro primary liver and kidney cells exposed to thioacetamide, a known liver toxin that promotes fibrosis. A set of gene modules, associated with specific organ injuries, has been derived from gene expression levels in liver and kidney tissues from rats exposed to diverse chemical insults. First, the injury-associated gene modules were assessed and validated by analyzing gene expression data in liver, kidney, and heart tissues obtained from Sprague-Dawley rats exposed to thioacetamide. The rats were injected with low (25 mg/kg) or high (100 mg/kg) dose of thioacetamide for 6 or 24 hours. Finally, the modular approach was used on the gene expression data from primary liver cells (in vitro) exposed to thioacetamide to predict organ injuries observed in vivo. It was found that the most activated liver gene modules in vivo were those associated with cellular infiltration and fibrosis. Histological analyses supported these results, signifying the potential of aerosol gene expression data to identify organ injuries. It was also found that the in vitro to in vivo predictions correlated well with an R² value of 0.64. The top ranking liver injuries in vitro correctly identified known pathological changes such as fibrosis.
Metabolite Markers for Acetaminophen-Induced Liver Damage in the Laboratory Rat

V. Pannala1, K. Vinnakota1, K. Rawls1, S. Estes1, T. O’Brien1, R. Printz2, J. Papin2, J. Reifman1, M. Shiotla1, J. Young4, and A. Wallqvist1. 1US Army Medical Research and Materiel Command, Frederick, MD; 2University of Virginia, Charlottesville, VA; 3Vanderbilt University School of Medicine, Nashville, TN; and 4Vanderbilt University School of Engineering, Nashville, TN.

Acetaminophen (APAP) is the most commonly used analgesic and antipyretic drug in the world, yet poses a major risk of liver injury when taken in excess of the therapeutic dose. Current clinical markers do not detect the early onset of liver injury associated with excess APAP, information that is vital to reverse the injury progression through available therapeutic interventions. Hence, novel injury markers that can detect the onset of liver damages are desirable. Several studies have used transcriptomics, proteomics, and metabolomics technologies independently and in combination to discover potential markers of liver injury. However, the causal relationship between these observations and their relation to the APAP mechanism of liver toxicity is not clearly understood. Here, we used Sprague-Dawley rats orally gavaged with a single dose of 2 g/kg of APAP to collect tissue samples from the liver and kidney for transcriptomics and blood and urine samples for metabolomics analysis. We developed and used a multi-tissue, metabolism-based physiological modeling approach to integrate these data, characterizing the effect of excess APAP levels on liver metabolism, and identified a list of plasma and urine metabolites that are associated with APAP-induced liver toxicity. Our analysis indicated that the amino acid related pathways and nucleotide metabolism pathways in the liver were the major pathways impacted within 10 h post-APAP treatment and metabolites in these pathways could serve as potential markers for APAP-induced liver injury. The coupled multi-tissue modeling framework of in vivo metabolism provides both mechanistic insights and a capability to propose plasma and urine metabolites as potential early markers of toxicant-induced organ damage.

A Computational Biology Framework for Modeling Multisystem Adverse Outcome Pathways Initiated by Exposures to Ozone and Associated Air Pollutants

Exposure to ozone and associated photochemical air pollutants constitutes a persisting and widespread problem around the globe. In addition to causing respiratory effects, photochemical pollution impacts the cardiovascular, immune, integumentary and other physiological systems. Reactive contaminants such as ozone typically exert their detrimental effects via the generation of reactive oxygen species (ROS). For example, ROS result from reactions of ozone with skin lipids during dermal contact and from reactions with lung lining fluid components following inhalation. These secondary ROS initiate a series of cascading events, such as release of pro-inflammatory mediators, infiltration of immune cells, and activation of aryl hydrocarbon receptor (AhR) pathways. Multiple physiological systems are affected by these events; for example, respiratory-provoked pro-inflammatory mediators can enter the circulatory system, initiate neuroendocrine-immune crosstalk and subsequently affect heart rate variability. This work describes the development of interconnected computational simulation modules for the exposure biology of ozone and associated photochemical pollutants in the integumentary, respiratory and cardiovascular systems. These modules are designed as components of the MENTOR (Modeling Environment for Total Risk) modeling platform for whole-body human exposure, dosimetry, toxicokinetics and toxicodynamics. MENTOR employs a spectrum of systems dynamics modeling approaches, combining differential equation and agent-based methods to quantify overlapping Adverse Outcome Pathways (AOPs) involving multiple scales (biomolecular, cellular, histological, organ) and physiological systems and endpoints. Using this approach, results have been obtained for various case studies that demonstrate how our model mechanistically simulates events taking place at the molecular and cellular scale to predict and quantify outcomes at the tissue and organ scale; for example, the model reproduces changes in macroscopic lung function properties (elastance and resistance) that are initiated by reactions of ozone with phospholipids and proteins of the pulmonary lining fluid. Supported by NIH grants ES050522 and ES047483.

Systematic Transcriptomics-Based Comparison of Cellular Stress Response Pathways Activation in Different Human Liver Cell Test Systems

B. ter Braak1, M. Niemeijer1, R. Boon2, S. Huppelschoten1, S. Wink1, C. Verfaille2, and B. van de Water1. 1Leiden University, Leiden, Netherlands; and 2KU Leuven, Leuven, Belgium.

Drug-induced liver injury (DILI) remains a major burden on the economy and healthcare. Given the diversity of DILI types a improved mechanism-based testing strategy to evaluate DILI liability is essential. Previously we generated a large panel of BAC-GFP HepG2 hepatocyte reporter cell lines in which we can visualize and quantify the abundance and subcellular localization of cellular stress biomarkers. These HepG2 reporters can be used in a high content and throughput imaging-based screening approach to assess safety liabilities of new chemical entities. We applied BioSpyder targeted RNAseq to explore the expression profiles of ~3000 toxicity related genes. We evaluated the activation of four key cellular stress response pathways: oxidative stress (induced by exposures with di-ethyl maleate), unfolded protein response (by tunicamycin), DNA damage response (by cisplatin) and inflammation response (by TNF). In this study we investigated the hepatotoxic responses of 18 BAC-GFP reporters and compared these with wildtype HepG2 responses. We found that the GFP tags did not affect the stress response activation patterns. Next, we benchmarked these responses of HepG2 against other in vitro hepatotoxicity models: stem cell derived hepatocytes (hiPSC-Heps), undifferentiated stem cells (hiPSC) and primary human hepatocytes (PHHs) from 3 different donors. Interestingly, we found that although the hiPSC-heps were immature the stress response activation patterns had a high correlation with responses from PHHs. In general, HepG2 and hiPSC-heps seem more sensitive to cellular stress than PHHs, as their stress activation was already observed at lower concentrations. In terms of robustness the HepG2 outperformed hiPSC-heps and PHHs. Variability in PHHs was especially large for expression patterns of inflammation related genes, likely caused by the hepatocyte extraction process from the donor liver which is known to cause high intra-liver variability levels. To our knowledge this is the first study that systematically studied the expression patterns of different in vitro DILI models under conditions of dedicated cellular stress response activation in hepatotoxic conditions. Supported by EU-ToxRisk project (grant agreement No 681002).

Evaluation of Systemic and Microbiome-Derived Effects of Antibiotics on the Plasma Metabolome in Rats

V. de Brujin1, C. Behr1, S. Sperber1, T. Walk2, E. Fabian1, M. Slopianka2, K. Beekmann3, and B. van Ravenzwaay4. 1BASF SE, Ludwigshafen am Rhein, Germany; 2Metanomics GmbH, Berlin, Germany; and 3Wageningen University, Wageningen, Netherlands.

Xenobiotics can alter the gut microbiome’s composition and functionality and thereby modulate host health. Metabolomics is a promising tool to identify and evaluate the effects of xenobiotics on the gut microbiome. In previous research, indole derivatives, hippuric acid (HA) and bile acids have been identified as key metabolites affected by antibiotic treatment. This study aims to identify the role of the microbiome in these alterations of metabolic profile after oral and parenteral administration of antibiotics. In this project, two poorly bioavailable antibiotics (vancomycin and streptomycin) were either orally or parenterally administered to Wistar rats to distinguish between microbiome-derived and systemic changes in the plasma metabolome. These reference profiles were compared to the profiles of a third readily bioavailable antibiotic (roxithromycin). 250 defined metabolites were analyzed in plasma of orally and parenterally treated animals, as well as diet and vehicle controls after 7, 14 and 28 days. Indole-3-acetic acid (I3A) and HA were significantly downregulated after both parenteral and oral administration of all three antibiotics. Hereby, I3A and HA seem to be sensitive indicators of gut microbiome modulation, since it is assumed that a small amount of the parenterally administered dose of the antibiotic ends up in the intestinal tract via biliary excretion. Contrary, oral administration of all three antibiotics resulted in alterations in the bile acid pool, with taurocholic acid upregulated and glycochenodeoxycholic acid (GCDCA) downregulated. GCDCA was downregulated after intraperitoneal administration of vancomycin, but not after subcutaneous administration of streptomycin. As roxithromycin has a high bioavailability and is excreted in the feces after parenteral administration, it is in line with expectations that after both oral and subcutaneous roxithromycin treatment, taurocholic acid was upregulated and GCDCA was downregulated. These results show that modulation of the gut microbiome by the poorly bioavailable antibiotics leads to specific changes in especially the bile acid pool that cannot be found after parenteral administration of these anti-
Analysis of Metabolome Changes in the Bile Acid Pool in Feces and Plasma of Antibiotic-Treated Rats

C. Behr1, M. Slopianka2, V. Haake2, V. Strauss1, S. Sperber1, H. Kamp1, T. Walk2, K. Beekmann2, I. Rietjens2, and B. van Ravenzwaay1. 1BASF SE, Ludwigshafen am Rhein, Germany; 2Metanomics GmbH, Berlin, Germany; and Wageningen University, Wageningen, Netherlands.

The bile acid-liver-gut microbiota axis plays an important role in the host’s health. A change of the gut microbiota can impact on the bile acid pool, but also the bile acids themselves can influence the gut microbiota composition. In this study, six antibiotics from five different classes (lincosamides, glycopeptides, macrolides, fluoroquinolones, aminoglycosides) were used to modulate microbial communities of Wistar rats to elucidate changes in the bile acid metabolism and to identify key metabolites in the bile acid pool related to gut microbial changes. 20 primary and secondary bile acids were analyzed in both stool and feces of treated animals, vehicle control and diet control. After treatment, significant changes of primary and secondary bile acids in both matrices of treated animals could be observed. There was an increase of taurine-conjugated primary bile acids in both plasma and feces. Contrary, cholic acid and most of the analyzed secondary bile acids were found to be significantly downregulated in plasma whereas cholic acid accumulated in the feces. This accumulation was not seen for ursodeoxycholic acid indicating a different mode of action for the macrolide antibiotic. Although different classes of antibiotics with different activity spectra against gut microbiota were applied, the overall effect on the bile acid pool tended to be similar in both matrices except for streptomycin because it is not able to cross the intestinal barrier. The bile acid microbiome community affect the bile acid pool in plasma and feces of the host and that bile acid profiling can be indicative for an alteration of the gut microbiome. Further, this change in the bile acid pool could lead to secondary effects such as an altered absorption or excretion of metabolites or xenobiotics or activation or inactivation of nuclear receptors in the liver or intestine which might have implications for toxicological evaluations regarding the gut-liver axis, the immune system and other body functions known to be influenced by the gut microbiota.

Development of a Quantitative Systems Toxicology Model of Drug-Induced Cholangiocyte Injury in DILysim

G. Taneja1, S. Q. Siler1, B. A. Howell1, P. B. Watkins2, and J. L. Woodhead1.
1DILysim Services, Raleigh, NC; and 2University of North Carolina at Chapel Hill, Chapel Hill, NC.

Cholangiocyte injury accounts for a quarter of drug-induced liver injury (DILI) cases and is associated with higher rates of morbidity and mortality than other types of DILI (Chalasani et al., 2015). While there are many compounds known to cause cholangiocyte injury, there are currently no methods to screen drugs for this potential at the lead candidate selection phase. Inhibition of multi-drug resistance protein 3 (MDR3) has been shown to correlate with cholangiocyte injury and drug toxicity in humans. MDR3 mediates transport of phospholipids to the bile canaliculus. Inhibition of phospholipid transport reduces micelle formation resulting in naked bile acids that can damage cholangiocytes. Objective: The goal of our project was to develop a novel QST model for assessing and predicting drug-induced cholangiocyte injury in humans. Methods: We developed a cholangiocyte life cycle model as well as a model of phospholipid transport via MDR3. The parameterization of the model relied on experiments on the relationship between phospholipids and bile acids measured in liver transplant patients; specifically, results showing that increases of ALP, believed to reflect cholangiocyte injury, follow an increase in the ratio of bile acids to phospholipids following liver transplant. The submodel was then successfully integrated with DILysim, a QST model of drug-induced liver injury that is being developed by a public-private partnership (The DILysim Initiative). Results: In our submodel, with a simulated MDR3 inhibitor having a Ki of 1 µM, the bile acid to phospholipid ratio increased to ~20 from the baseline level of 10. Total cholangiocyte apoptotic flux increased to cause cholangiocyte injury and drug toxicity in humans. MDR3 mediates transport of phospholipids to the bile canaliculus. Inhibition of phospholipid transport reduces micelle formation resulting in naked bile acids that can damage cholangiocytes. This in silico model can be used to predict the effects of a potential therapeutic candi-
2256 Inter-individual Variability of Carcinogenic Metabolism in the Collaborative Cross Mouse Population

G. Boysen1, G. P. Miller1, E. Siegel1, I. Nookaew1, L. M. Hallberg2, and B. T. Ameredes2. 1University of Arkansas for Medical Sciences, Little Rock, AR; and 2University of Texas Medical Branch, Galveston, TX.

Human studies often reveal large inter-individual variation in response to chemical exposure, believed to be derived from social, racial, and regional differences. The Collaborative Cross (CC) mice were created to represent a genetically heterogeneous population covering all possible genotypes. We hypothesize that the variability in susceptibility derived from genetic diversity can be modeled in mice by combining the CC model with the 1,3-butanediol (BD) exposure model. BD is metabolized by CYP2E1 to three epoxides that form protein adducts. The BD-derived protein adducts are suitable biomarkers for BD uptake, metabolic activation, and detoxification. Mice from 60 CC inbred strains were exposed to BD and N-terminal valine adducts N-(2-hydroxy-3-buten-1-yl)-valine (HB-Val), N,N-(2,3-dihydroxy-1,4-butanediyl)-valine (pyr-Val) and 2,3,4-trihydroxybutyl-valine (THB-Val) were quantitated. CYP2E1 activity in liver microsomes were determined using P-nitrophenol as substrate. The distribution of N-terminal valine adducts were 5, 17, and 87% for HB-Val, pyr-Val and THB-Val, respectively. For individual exposure groups, CYP2E1 activities initially decreased and then increased with exposures. In contrast to the protein adducts, variation in CYP2E1 activities were less dramatic, and ranged from 5 to 13-fold. Together, these results provide evidence for up to 13-fold variation in CYP2E1 activity based solely on genetic diversity, which can translate in an up to 435-fold difference in formation of reactive metabolites. Thus, a small difference in baseline activity can be expected drive the risk phenotype. To our surprise, CYP2E1 activity did not correlate with protein adduct formation. In addition, QTL analyses did not reveal any association of protein adduct formation with certain genetic traits. Together these results show that BD uptake, distribution and metabolism is not limited by CYP2E1 activity and suggest that several other proteins are involved, such as other phase I and phase II or membrane transport proteins. Further, 60 inbred strains are insufficient to identify genetic loci that drive complex mechanism such as the toxicokinetics of carcinogens. In contrast, adduct formation in the relative small CC population was similar than reported for human exposure study of similar size, demonstrating that the complexity of populations can be investigated using the CC mouse model.

2257 A Multi-scale Stochastic Model Explains Zoned Cytochrome P450 Induction in the Liver Lobule

Y. Yang, N. Watee, and S. Bhattacharya. Michigan State University, East Lansing, MI.

2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD), one of the most potent environmental toxins, significantly induces cytochrome proteins, including Cyp1a1 and Cyp1a2, with a centrally localized spatial profile in the liver lobule. Besides toxin-induced zonal gene induction, metabolic functions in the liver lobule are also zonated along the central-portal axis. To investigate the roles of metabolic zonation in spatially restricted gene induction, we have developed a multi-scale, agent-based spatial model of a mouse liver lobule. The spatial location of hepatocytes in this model was calibrated from single-cell resolution imaging data. In each cell, a stochastic model was implemented to capture the switch-like Cyp1a1 induction by TCDD. The initial conditions for the model were determined from liver zonation experimental results. With this model, we investigated the role of the Wnt signaling pathway and the stochastic character of spatially-zonated Cyp1a1 gene induction. The results collected in this study reveal that endogenous Wnt signaling and activation of Cyp1a2, which binds and sequesters TCCD in the liver, together regulate the zonal hepatic induction of AhR target genes. Our model provides a more mechanistic understanding of low-dose toxic responses in the liver.

2258 Simulation of Macrophage Activation Dynamics under Various Microenvironment Signals Using an Agent-Based Modeling Approach

In this study we present a new multiscale Agent-Based Model (ABM) that spans molecular, cellular and tissue levels to provide a computational simulation framework aimed at reproducing and elucidating the dynamics of macrophage phenotypes under various complex activation signals, while considering system stochasticity and heterogeneity. Key factors in signaling cascades are included in the model, so that critical underlying regulatory controls influencing the activation process can be explored and quantified. Specifically, the model assumes that expression dynamics of pro- and anti-inflammatory cytokines are primarily regulated by activation of the following transcription factors: Nuclear factor-kappa B (NFkB), nuclear factor (erythroid-derived 2)-like 2 (Nrf2) signaling transducer of (STAT3) and STAT6. These factors were selected as representative controllers of transcriptional responses due to their essential role in inflammation. Activation of NFkB in macrophages induces transcription of pro-inflammatory cytokines, chemokines and other inflammatory mediators; the activity of NFKB is primarily modulated by the activity of its kinase (IKK) and its inhibitor (IκB) through the Toll-like receptor (TLR) signaling pathway. The activity of Nrf2 is mainly mediated by interactions with the Kelch-like ECH-associated protein 1 (Keap1) and activities of STAT3 and STAT6 are mainly mediated by the activity of Janus kinase 1 (JAK1), JAK3 and tyrosine kinase 2 (TYK2) following binding of anti-inflammatory cytokines to corresponding receptors. Crosstalk between the NFKB and Nrf2 pathways is also incorporated in the model. Model simulation results are presented and compared with available data from an in vitro system of mouse bone marrow-derived macrophages exposed to various doses of LPS/IFNγ and IL-4/IL-13. It is shown that our model has the ability to qualitatively reproduce dynamic patterns of macrophage phenotypes over time. A quantitative metric, i.e. a “macrophage activation (or polarization) ratio”, is defined to explore how cytokine signaling translates into polarization and to search for important regulatory components and model sensitivity analysis was performed to identify factors having large impacts on this metric. Supported by NIH grants E5050202, E5019584 and E5004738.

2259 Metabolome-Wide Association Study of Deployment to Balad, Iraq or Bagram, Afghanistan

D. P. Jones1, M. Ryan1, D. Walker1, K. Uppal1, P. Krahi1, P. Hopke1, M. UteI1, T. Mallon1, and Y. Go1. Emory University, Atlanta, GA; 1Uniformed Services University, Bethesda, MD; and 2Clarkson University, Potsdam, NY.

Concern about occupational exposures to military personnel and adverse health outcomes resulted in 2006 Department of Defense (DoD) Instruction 6490.03 requiring Military Services to perform comprehensive deployment health risk assessments that includes baseline, routine, and incident-related health surveillance and documentation of deployment-related exposures. To support this effort, we assembled a multidisciplinary research team to assess the utility of serum in the Department of Defense Serum Repository (DoDSR) for biomonitoring chemical exposures and identifying biomarkers associated with exposures. In the present study, we used high-resolution metabolomics (HRM) to identify metabolic changes in military personnel associated with deployment in Balad, Iraq, or Bagram, Afghanistan. The numbers in the current study consisted of paired pre- and post-deployment data for 373 individuals (n = 187 in Case group; n = 186 in Control group). HRM and bioinformatics were used to identify metabolic differences associated with deployment. The results show that differences at baseline (pre-deployment) between personnel deployed to Bagram compared to Balad or Controls included sex hormone and keratin sulfate metabolism. Differences associated with deployment to Balad included amino acid and lipid metabolism associated with inflammation and oxidative stress, and pathways linked to metabolic adaptation and repair. Difference associated with deployment to Bagram included lipid pathways linked to cell death and metabolism associated with innate immunity and keratin metabolism. Differences associated with deployment show that 26 of 271 environmental chemicals (ToxCast) differed in association with deployment to Balad, and 3 of these chemicals including trichlorfon metrifonate, dinitrofuram and ametryn clustered with metabolites that differed in association with deployment. In conclusion, metabolic differences in pre- and post-deployment are consistent with deployment-associated responses to air pollution and other environmental stressors.

2260 Neonatal Exposure to Environmental Chemicals BPA, BDE-99, and PCB Persistently Alters the Liver Transcriptome in Adult Mice

J. J. Lim1, J. L. Dempsey2, H. Lehmer3, J. McDonald1, T. Bammier1, T. J. Kavanagh1, and J. Y. Cui1. 1University of Washington, Seattle, WA; and 2University of Iowa, Iowa City, IA.

Persistent environmental chemicals such as bisphenol A (BPA), polybrominated diphenyl ethers (PBDEs), and polychlorinated biphenyls (PCBs) are linked to many human diseases. It is increasingly recognized that there is a life-long impact on disease risk. The goal of the present study was to test our hypothesis that neonatal exposure to these chemicals persistently dysregu-
lates the transcriptome of the liver, which is the major organ for xenobiotic metabolism and nutrient homeostasis. Two-day-old male and female C57BL/6 mice were suprapelinguously exposed to corn oil, BPA (250μg/kg), BDE-99 (an enriched PBDE congener in humans, 57mg/kg), or the Fox River Mixture (an environmentally relevant PCB preparation, 30mg/kg), once daily for three days. RNA-Seq was conducted in livers from 5- and 60-day old mice. Data were analyzed using Hsats2, Cufflinks, Ingenuity Pathway Analysis (IPA), and the R package topGO. Neonatal exposure to all three chemicals persistently altered the expression of genes involved in the metabolism of drugs, carbohydrates, and lipids, as well as epigenetic modifications, with males being more susceptible than females. BPA and BDE-99 had more prominent effects compared to PCBs. Top predicted upstream regulators included the tumor suppressor p53 (persistently down-regulated by BPA in females), the sterol biosynthesis regulator Scap (persistently regulated by both BDE-99 and PCBs), as well as the nuclear receptors that regulate lipids (PPARs) and drug metabolism (CYPs). The long non-coding RNA (IncRNA) H19, linked to hepatocellular carcinoma, was persistently increased by BPA and BDE-99. Within the imprinted Dlk1-Dio3 cluster, which expresses genes in a parent-specific manner and is known to promote liver tumor, BPA and BDE-99 persistently increased the paternal allele-specific IncRNAs Meg3 and Rian, whereas protein-coding genes from the maternal allele remained silent. Our results demonstrate that neonatal exposure to these environmental chemicals persistently regulates the liver transcriptome in adulthood, possibly due to cross-talk between epigenetic reprogramming and nuclear receptors.

2261 Metabolome Wide Association Study of Occupational Exposure to Benzene
D. I. Walker1, Q. Lam2, L. Zhang3, R. Vermeulen4, W. Hu5, G. Li6, S. M. Rappaport6, D. P. Jones7, M. T. Smith8, and N. Rothman9. 1Icahn School of Medicine at Mount Sinai, New York, NY; 2National Cancer Institute, Rockville, MD; 3University of California Berkeley, Berkeley, CA; 4Utrecht University, Utrecht, Netherlands; 5Chinese Center for Disease Control and Prevention, Beijing, China; and 6Emory University School of Medicine, Atlanta, GA.

Benzene is a recognized hematotoxin and leukemogen; however, its mechanisms of action in humans remain unclear. To provide insight into the processes underlying the relationship between benzene exposure and disease, we performed high-resolution metabolomics (HRM) profiling of plasma collected from a cross-sectional study of 33 healthy workers exposed to benzene (median 8-hr time-weighted average; 36 ppm), and 25 matched unexposed controls in Shanghai, China. Metabolic features associated with benzene were identified using a metabolome-wide association study (MWAS) framework that tested for the relationship between feature intensity and benzene exposure. Following correction for multiple testing, associated features were characterized for the presence of known and predicted benzene metabolites, and biological response by pathway enrichment. MWAS identified 478 mass spectral features associated with benzene exposure at FDR<20%. Comparison to a list of 13 known benzene metabolites and 86 metabolites predicted using a multi-component biotransformation algorithm showed five metabolites were detected, which included the known metabolites phenol and benzene dioxepoxide. Metabolic pathway enrichment identified 41 pathways associated with benzene exposure levels, with altered pathways including mitochondrial shuttle, fatty acid metabolism, sulfur amino acid metabolism, glycolysis, glutathione metabolism, and branched chain amino acid metabolism. These results, which suggest disruption to fatty acid uptake, energy metabolism and increased oxidative stress, point towards pathways related to insulin resistance and mitochondrial dysfunction, which has previously been linked to benzene exposure in animal models and human studies. In addition, fatty acid oxidation has been identified as a critical pathway for hematopoietic stem cells (HSCs) and controls stem cell self-renewal. Taken together, these results may suggest benzene exposure is associated with disruption of mitochondrial pathways, and provide a plausible mechanism underlying benzene-induced hematotoxicity in humans.

2262 Study of Hookah/Cigarette Constituents-Gene/Protein-Pathway-Disease Using Systems Biology Approach
W. Liu1, S. Huang2, Y. Luo1, Y. Tseng3, T. Gordon4, K. Galdanes5, A. Harrington6, M. Marshall7, E. Halzack8, M. Zhong9, L. Chen9, and J. Yang1. 1National Chiao Tung University, Hsinchu, Taiwan; and 2New York University School of Medicine, Tuxedo, NY.

Hookah smoking is becoming increasingly popular worldwide. Recent epidemiological studies have indicated that hookah smoking is significantly associated with respiratory diseases, and may contain more harmful constituents than cigarette smoking. In addition, gene expression alterations and mechanisms of disease development affected by the constituents of hookah smoking are still unclear. To address these issues, we propose the novel experimental design and analyzing strategy to study the effects and mechanisms of hookah smoking and its constituents (e.g., nicotine, CO and PAH). Here, we performed large-scale profiling (i.e., NGS) at 2 and 24 hours after exposing the human lung epithelial cells (BEAS-2B) to five different conditions of the hookah smoking (i.e., control, charcoal only, charcoal with tobacco, charcoal with herbal, and electronic heater with tobacco). Systematic analyzing strategy was used to compare our results with public hookah and cigarette smoking datasets. Firstly, we identified 271, 313 and 198 differentially expressed genes (DEGs) (* test p < 0.05 and FC > 1.5) from our hookah set (charcoal with tobacco vs. control), the public hookah dataset and public cigarette datasets, respectively. Our result shows that more infection-related pathways (e.g., Salmonella infection; hypergeometric test p < 0.05) were identified from the hookah datasets than from the cigarette datasets, which might result from polluted hookah device or used contaminated water filters. Next, we identified individual constituent in hookah smoking by genome-wide comparison between tobacco and herbal datasets (the nicotine dataset) and identified 89 DEGs related to nicotine. Interestingly, at 24 hours after exposure, the cardiovascular system development, dopaminergic synapse and fatty acid metabolism pathways were activated by nicotine. In addition, 645 DEGs are related to charcoal in comparison to electronic combustion (the CO and PAH dataset). The inflammation and diabetes mellitus related genes and pathways were activated at 2 and 24 hr after exposure in the CO and PAH dataset. Overall, our results show that hookah smoking may have higher risk in bacterial infection than cigarette smoking and link the hookah constituents to diseases. These results imply that frequent hookah smoking is more likely to harm people than cigarette smoking.

2263 Serum Metabolomics Reveals That Gut Microbiome Perturbation Mediates Arsenic Toxicity in Mice
J. Xue1, Y. Lai1, L. Chi2, P. Tu1, J. Leng1, C. Liu1, H. Ru1, and K. Lu1. 1University of North Carolina at Chapel Hill, Chapel Hill, NC; and 2North Carolina State University, Raleigh, NC.

Arsenic contamination in drinking water has been a global health concern over many years. Except for well-recognized carcinogenic effects, numerous studies have also linked arsenic exposure with a variety of chronic diseases such as diabetes, neurological effects, and cardiovascular diseases, although the etiology underlying is still unclear. Recently, increasing evidence have indicated that gut microbiome is an important risk factor in modulating the development of diseases. This study aims to investigate the role of gut microbiome perturbation in arsenic-induced diseases by coupling a high-resolution mass spectrometry-based global metabolomics approach and an animal model with altered gut microbiome induced by bacterial infection. Serum metabolic profiling revealed that when gut microbiome homeostasis was perturbed, both the number and regulation pattern of the metabolites with significant differences induced by arsenic exposure changed dramatically. Specifically, the metabolic pathways related with fatty acids, phospholipids, sphingolipids, cholesterol, and tryptophan changed dramatically, and these pathways were not or were less disrupted when gut microbiome stays normal. Our study suggested that gut microbiome perturbation can exacerbate or cause the metabolic disruption induced by arsenic exposure in mice.

2264 Use of an Alternative Vehicle in the Human Cell Line Activation Test (h-CLAT) to Broaden the Utility of the Test to Detect Dermal Sensitizers
A. Greninger1, P. Vij2, D. Sergeyev3, B. Varsho4, and G. DeGeorge1. 1ExxonMobil Biomedical Sciences Inc., Annandale, NJ; and 2MB Research Labs, Spinnerstown, PA.

The human Cell Line Activation Test (h-CLAT) was developed as an in vitro method of discriminating skin sensitizers from non-sensitizers and was promulgated by OECD as a testing guideline (OECD TG 442E) in the spirit of advancing the 3Rs (Replacement, Reduction, and Refinement). As part of an Integrated Approach to Testing and Assessment, this test method addresses the third key event of the skin sensitization Adverse Outcome Pathway by measuring the selective induction of the surface markers CD54 and CD86 in the human monocyte leukemia cell line THP-1, which functions as a dendritic (Langerhans) cell surrogate. This guideline test is hindered by the sanctioning of only two currently validated vehicles (DMISO and saline), precluding in vitro sensitization testing of a wide range of insoluble chemicals. One such insoluble test chemical, Tetrakis (2-ethyl butyl) Orthocarbonate, was evaluated in the h-CLAT using an alternative vehicle (i.e., 100% ethanol) in an effort to broaden
the utility of the test. Known reference chemicals representing strong, and moderate sensitizers such as 2,4-dinitrochlorobenzene (DNBC) and mercaptotobenzothiazole (MBT) (used as positive controls), as well as a non-sensitizer such as isopropanol (used as a negative control), were also included to evaluate the utility of ethanol as an alternative h-CLAT vehicle. In two replicate runs, DNBC and MBT induced positive responses for CD54 (RFI >200%) and CD86 (RFI >150%) expression as expected, whereas isopropanol resulted in negative responses for both cell-surface markers. Solvent-only controls confirmed that 100% ethanol itself did not cause cytotoxicity or produce positive responses in either CD54 or CD86. The test chemical did not induce positive responses for CD54 or CD86 in the modified assay; however, due to other limiting physical-chemical properties of such a test as LOG kow <3.5, the negative test result did not inform the ultimate determination of hazard classification. This work demonstrates that 100% ethanol is a suitable alternative solvent which may expand the applicability domain of the h-CLAT.

2265 Proteomic and Bioinformatic Analyses for the Identification of Proteins with Low Allergenic Potential for Use in Hazard Assessment

N. Krutz1, J. Winget2, C. Ryan3, R. Wimalasena4, S. Maurer-Stroh1, B. Dearman5, I. Kimber6, and G. Gerberick3. 1Procter & Gamble Company, Stroombeek-Bever, Belgium; 2Procter & Gamble Company, Mason, OH; 3Bioinformatics Institute, ASTAR, Singapore, Singapore; 4University of Manchester, Manchester, United Kingdom; and 5GF Consultancy LLC, West Chester, OH.

Use of botanicals and natural substances in consumer products has increased in recent years. Such extracts can contain protein that may theoretically represent a potential risk of IgE-mediated allergy. No method has yet been generally accepted or validated for assessment of the allergenic potential of proteins. For development of suitable methods the datasets of allergenic and non-allergenic (or low allergenic) proteins are required that can be compared, respectively, as positive and negative controls. However, data are unavailable on proteins that lack or have low allergenic potential. Here, low allergenic potential proteins are identified based upon the assumption that proteins with established human exposure, but with a lack of an association with allergy, possess low allergenic potential. Proteins were extracted from sources considered to have low allergenic potential (corn, potato, spinach, rice and tomatoes) as well as higher allergenic potential (wheat) regarding the most common allergenic foods. Proteins were identified and semi-quantified by label-free proteomics analysis conducted using mass spectrometry. Predicted allergenicity was determined using AllerCatPro (https://allercatpro.bii.a-star.edu.sg/). This in silico tool compares proteins on a sequence and 3D structure level with a dataset of >4,000 protein allergens and performs with 84% accuracy to predict allergens versus non-allergens. In summary, 9070 proteins were identified and semi-quantified from six protein sources. Within the top 10% of the most abundant proteins identified, 178 characterized proteins were found with no evidence for allergenicity predicted by AllerCatPro and were considered to have low allergenic potential. This panel of low allergenic potential proteins provides a pragmatic approach to aid the development of alternative methods for more robust testing strategies to distinguish between proteins of high and low allergenic potential to assess the risk of novel proteins of high and low allergenic potential to assess the risk of novel proteins.

2266 Efferocytosis of cSiO2-Induced Cell Corpses by the Max Planck Institute Alveolar Macrophage Model Is Potentiated by the Omega-3 Docosahexaenoic Acid (DHA)

L. D. Rajasinghe1, P. S. Chauhan1, A. Evered1, A. Peyman1, M. Gavrilin2, J. R. Harkema1, A. Hollian3, and J. J. Pestka4. 1Michigan State University, East Lansing, MI; 2Ohio State University, Columbus, OH; and 3University of Montana, Missoula, MT.

Occupational exposure to crystalline silica (cSiO2) has been ethnologically linked to autoimmune disease. We previously demonstrated that intranasal instillation of lupus-prone mice with cSiO2 markedly accelerates systemic autoimmunity and glomerulonephritis by promoting pulmonary ectopic lymphoid neogenesis. Rapidly, all of these effects were prevented when mice were fed with omega-3 docosahexaenoic acid (DHA) at translationally relevant concentrations. Alveolar macrophages (AMph) rapidly phagocytose cSiO2, ultimately resulting in their death. Inefficient removal of resultant cell corpses via a phagocytic process known as efferocytosis, can increase a host’s exposure to autophagosomes thereby contributing loss of tolerance and autoimmunity. Here we determined how DHA influences the ability of cSiO2-generated cell corpses to be recognized during efferocytosis and/or the efferocytic capacity of AMph. ASC-transfected RAW 264.7 cells (target) were pre-incubated with or without 25 µM DHA, labelled with CFSC, and their death induced by incubation with cSiO2. Resultant cell corpses were then incubated for up to 16 h with CytoTox™-labelled Max Planck Institute (MPI) cells (effector), an alveolar macrophage surrogate, that were also pre-incubated with or without DHA (25 µM). Amnis® imaging flow cytometry revealed that maximum efferocytosis occurred at 8 h with the highest clearance of death cell corpses when target cells were pre-incubated with DHA. Since the recognition of dying cells during efferocytosis depends on the externalization of phosphatidylserine (PS) on the cell membrane, total PS along and its externalization were measured in target cells after 24 h pre-incubation with/without 25 µM DHA. DHA pre-incubation not only increased total PS content but also increased PS externalization in cSiO2-induced dying target cells 4, 6 and 8 h after addition of the particles. Overall, this study suggests that DHA supplementation enhanced PS externalization during cSiO2-induced cell death and that this corresponded to functional improvement in recognition by AMph-like cells and consequent engulfment of cell corpses. These findings might explain, in part, reduced cSiO2-stimulated autoimmune nephritis observed in lupus-prone mice consuming DHA. Supported by NIHES grant ES027353, Lupus Foundation, and Dr. Robert and Carol Diebel Family Endowment.

2267 Impact of Trichloroethene Metabolite Dichloroacetyl Chloride on Nrf2/Keap/HO-1 Axis: Potential Role in Autoimmunity

N. B. Chakrabarty, H. Wang, G. Wang, and F. Khan. University of Texas Medical Branch Galveston, Galveston, TX.

Our previous studies have shown that trichloroethylene (TCE) and one of its reactive metabolites dichloroacetyl chloride (DCAC) are associated with the induction of autoimmunity response in MRL+/+ mice. Our studies also show that oxidative stress in TCE/DCAC-mediated autoimmunity. Nuclear factor (erythroid-derived 2)-like2 (Nrf2) is an antioxidant stress-related transcription factor that binds to antioxidant responsive element (ARE). The Nrf2-ARE pathways protect against reactive oxygen species by regulating a great number of cytoprotective and antioxidant gene expression. We used immortalized murine Kupffer cells (KCs) and human Jurkat T cells that were treated with an antioxidant and Nrf2-activator tert-butyldihydroquinone (tBHQ) one hour prior to incubation with 5mM of DCAC for 24 hours. Treatment with DCAC significantly inhibited Nrf2 and Nrf2 target genes HO-1 and Keap-1 mRNA expression, but elevated phospho-Nrf2 protein level. Furthermore, DCAC-mediated inhibition was associated with increased mRNA expression of Nrf2 downstream inflammatory target NF-kB (p65) and TNF-α mRNA. The results show that DCAC-mediated impairment of Nrf2 regulation could be critical in generating a pro-inflammatory response and could play a crucial role in the induction of DCAC-mediated autoimmunity. Further studies are required to fully understand the contribution of Nrf2/Keap/HO-1 axis in TCE/DCAC-mediated autoimmune response. Supported by NIH R01 grants E5026887 and E5016302.

2268 Contribution of Cytochrome P450 2E1 in Trichloroethene-Mediated Autoimmunity: Association with Oxidative Stress and Nrf2 Pathway

G. Wang, M. Wakamiya, J. Wang, S. Ansari, and F. Khan. University of Texas Medical Branch, Galveston, TX.

Reactive trichloroethene (TCE) metabolites and oxidative stress are involved in TCE-mediated autoimmunity, as evident from findings of our previous studies in MRL+/+ mice. However, molecular mechanisms underlying TCE-mediated autoimmunity remain largely unknown. Cytochrome P450 2E1 (CYP2E1), the major enzyme responsible for TCE metabolism, could contribute to TCE-mediated toxic response through free radical generation. The current study was, therefore, aimed to further evaluate the significance of TCE metabolism leading to oxidative stress and autoimmune response by using MRL+/+ mice that lack CYP2E1. The Cyp2e1-null MRL+/+ mice were generated by backcrossing Cyp2e1-null mice (B6N:129S4-Cyp2e1) to MRL+/+ mice. Female MRL+/+ and Cyp2e1-null MRL+/+ mice were given TCE (10 mmol/kg, i.p., every fourth day) for 6 weeks; their respective controls received corn oil only. TCE treatment in MRL+/+ mice induced oxidative stress, evident from significantly increased serum anti-malondialdehyde (MDA)- and anti-4-hydroxynonenal (HNE)-adducts antibodies and reduced liver GSH. TCE treatment also modulated Nrf2 pathway with decreased Nrf2, HO-1 and elevated NF-kB (p65) expression in the liver. TCE exposure also led to increases in serum anti-tdN nucleic acids (ANA) and anti-double stranded DNA antibodies (anti-dsDNA). Although TCE treatment in Cyp2e1-null MRL+/+ mice also led to increases in serum anti-MDA/HNE-adducts antibodies and changes in liver...
GSH, Nrf2, HO-1 and NF-κB along with increases in serum ANA, anti-dsDNA, the changes in the oxidative stress and autoimmunity markers in these mice were less pronounced compared to that in MRL+/+ mice. These findings support the contribution of CYP2E1-mediated TCE metabolism in autoimmune response and an important role of Nrf2 pathway in TCE-mediated autoimmunity. Supported by NIH ES0670 and ES026887.

Modulation of Trichloroethene-Mediated Hepatic Inflammamsonme Activation and Immune Dysregulation by Antioxidant N-Acetylcysteine

H. Wang, G. Wang, Y. Liang, J. Sun, and F. Khan, University of Texas Medical Branch, Galveston, TX.

Trichloroethene (TCE) exposure is associated with the development of various autoimmune diseases, including autoimmune hepatitis (Aih) and systemic lupus erythematosus (SLE), potentially through the generation of excessive reactive oxygen and nitrogen species (RONS; oxidative stress). However, the mechanisms by which oxidative stress contributes to these TCE-mediated autoimmune diseases are not fully understood, and are the focus of current investigation. Female MRL+/+ mice were treated with TCE and along with or without antioxidant N-acetylcysteine (NAC) for 6 weeks (TCE, 10 mmol/kg, i.p., every 4th day; NAC, 250 mg/kg/day via drinking water). TCE exposure resulted in activation of hepatic inflammasomes (NLRP3 and caspase-1) and up-regulation of pro-inflammatory cytokine IL-1β, and these changes were significantly reduced following NAC supplementation. TCE treatment also led to increased hepatic lymphocyte infiltration, including cytotoxic T cells (CD3+CD8+CD44+CD62L−), dendritic cells (CD11b+CD11c), NK cells (CD49b+), and activation of both hepatic and splenic B cells (B220+GL7+ cells). Furthermore, TCE treatment resulted in a reduction of the Treg to Th17 cell ratio. Interestingly, NAC-mediated but hepatic and splenic immune cells was effectively attenuated by NAC. More importantly, TCE exposure also induced an increase in anti-nuclear antibodies (ANA) in the serum, which was also significantly reduced following NAC supplementation. Taken together, our findings provide evidence for TCE-mediated inflamma- somes activation of various immune cells, and skewed balance of Treg and Th17 cells in the liver. The attenuation of TCE-mediated hepatic immune responses by NAC strongly supports the role of oxidative stress in TCE-mediated autoimmunity. These novel findings could help in designing therapeutic strategies for such autoimmune diseases. Supported by NIH R01 grants ES062887 and ES016302.

Percent n-3 in Highly Unsaturated Fatty Acids (HUFAs) Is Predictive of Disease Outcomes in Environmental Toxicant-Triggered Autoimmunity

Increased tissue content of n-3 highly unsaturated fatty acids (HUFAs, containing ≥20 carbons with ≥3 double bonds) at the expense of n-6 HUFAs may protect against environmental toxicant-triggered autoimmunity. Our laboratory currently uses the female NZBWF1 mouse to understand how consumption of docosahexaenoic acid (DHA, 22:6 n-3), a major HUFA in fish oil, can be used to prevent or treat lupus induced by crystalline silica (cSiO2), a known environmental trigger of human autoimmune disease. Previously, we found that supplementation with DHA dose-dependently decreased the magnitude of several pathogenesis endpoints of cSiO2-triggered lupus including pulmonary lymphocyte infiltration, B and T cell-containing ectopic lymphoid structures (ELS) in lung, and pulmonary and systemic inflammation and cytokines. Here, we related these cSiO2-induced disease endpoints to the %n-3 in HUFA in the red blood cells (RBC), lung, spleen, and kidney. The %n-3 in HUFA measures n-3 HUFA as percent of total HUFA rather than percent of total fatty acids, thereby decreasing variation by limiting analysis to the HUFA pool. Increased %n-3 in HIFA was associated with decreased autoim- mune biomarkers, such as anti-dsDNA IgG antibodies (R2=0.38, p=2E-5) and B-cell activating factor (R2=0.36, p=4E-4). Increased B-cell %n-3 in HUFA was also associated with less B and T cell infiltration in the lungs (R2=0.46, p=2E-6 and R2=0.49, p=1E-6, respectively), and decreased levels of pro-inflammatory cytokine TNF-α (R2=0.41, p=1E-5) and chemokine MCP-1 (R2=0.38, p=2E-5). Similar associations were found between these endpoints and %n-3 in HUFA in the lung, spleen, and kidney. These findings demonstrate that dis- ease phenotypes induced by cSiO2 exposure strongly correlate with %n-3 in HUFA in RBC and other tissues. This biomarker might therefore be useful in a precision medicine approach exploiting n-3 HUFA supplementation to prevent and/or treat lupus and other autoimmune diseases triggered by envi- ronmental toxins. In Situ Mapping of the Reactivity of Chemical Sensitizers in Reconstructed Human Epidermis Using High-Resolution Magic Angle Spinning (HRMAS) NMR Technique

H. Sour1, F. M. Moussallieh1, E. Elbayed1, E. Gimenez-Amam1, M. Klanick3, and J. P. Lepoittevin1. 1University of Strasbourg, Strasbourg, France; and 2Cosmetics Europe, Brussels, Belgium. Sponsor: A. Schepky.

Allergic contact dermatitis is a reaction of the immune system resulting from skin sensitization to an exogenous hazardous chemical. The prevalence of this disease (15-20%) has increased and, as there is no treatment other than symp- tomatic, the prevention relies on the evaluation of the sensitizing potency of chemicals prior to their introduction on the market. One of the alternatives to animal methods for risk assessment of chemicals is by measuring their reac- tivity towards epidermal proteins. So far, this was approached using isolated small reactive peptides in solution but these tests are far from reflecting the complex chemistry taking place in a living epidermis. With the aim of replac- ing animal tests while maintaining the most similar reaction conditions to the human epidermis, we have developed a new method based on the use of HRMAS NMR to monitor in situ the reactions of carbon 13 substituted chemi- cal sensitizers with nucleophilic amino acids in reconstructed human epidermis (RHE). RHE were treated with chemicals and spectra were acquired using HRMAS NMR and then analyzed using HRMAS NMR quantitave sequences. We were thus able to study the reactivity profile of chemicals in situ as a function of exposure time and dose. First, both MMS and CA were found to react rapidly in RHE with a maximum concentration of add- ucts between 5h and 8 h for MMS but already at 30 min for CA. Second, MMS was found to react mainly with Cys/His but also with Lys and Glu minor extent with Glu/Asp, Lys and Met, while CA was reacting only with Cys and Lys. Third, dose/ response studies have shown that the reactivity with Cys was easily saturable and therefore associated with GSH reaction. Fourth, the metabolism of CA to cinnamic acid and cinnamyl alcohol was observed and quantified. Therefore, using quantitative HRMAS NMR sequences and RHE we were able to study the reactivity of two sensitizing chemicals as a function of exposure time and dose and to monitor in situ broader aspects of reactivity like detoxication and metabolism processes which are not covered when using peptides in solu- tion.

Å6-Tetrahydrocannabinol Suppression of Monocyte-Mediated Astrocyte Production of MCP-1 and IL-6 in a Co-Culture Stimulated with TLR7 Agonist

M. Rizzo, R. Crawford, S. Sermet, and N. Kaminski, Michigan State University, East Lansing, MI.

Migration of monocytes to the brain has been implicated as a key event in chronic neuroinflammation and in the etiology of several central nervous sys- tem diseases including HIV-associated neurocognitive disorder. In the brain, activated monocytes have the potential to cause neuronal injury through pro-inflammatory interactions with astrocytes. This includes inducing as- trocyte secretion of cytokines and chemokines, which promotes a positive feedback loop of neuroinflammation. Cannabis is widely used by HIV-infected individuals with a prevalence of 20-37% in the United States and Canada. Å6- tetrahydrocannabinol (THC) and cannabidiol (CBD), two major constituents of cannabis, are known to have immune suppressive and anti-inflammatory properties. Previously, we developed a human co-culture system that demon- strates that monocytes, though secretion of IL-1β, promote astrocyte produc- tion of MCP-1 and IL-6 in response to toll-like receptor 7 (TLR7) stimulation (mimic HIV ssRNA). The objective of this study was to determine the effect of THC and CBD on monocyte-mediated astrocyte inflammation when stimu- lated through TLR7. THC treatment of the TLR7-stimulated co-culture resulted in decreased astrocyte production of MCP-1 and IL-6, while CBD increased IL-6 and had no effect on MCP-1. With the use of monocyte and astrocyte monocolonies, THC and CBD targeted both cell types. Interestingly, THC and CBD were both shown to decrease IL-6 and MCP-1 in astrocyte monoclonies, which for THC, is consistent with the co-culture observation. However, di- totoxicological effects were observed with CBD, as there was augmentation in the co-culture and suppression in the astrocyte monoculture. These findings were explained when THC and CBD were shown to suppress and augment monocyte production of IL-18, respectively. Furthermore, the CBD-mediated augmentation of monocyte-derived IL-18 superseded the direct CBD sup- pression on astrocytes. Collectively, this study demonstrates that THC but not 2019 SOT Annual Meeting
CBD, suppresses monocyte-provoked astrocyte inflammatory responses. In summary, cannabis use (high THC/low CBD) may decelerate monocyte processes that are implicated in HIV-associated neuroinflammation.

**2273** Resveratrol-Induced FoxP3-Regulatory T Cell Subset, Th3, Alleviates Acute Lung Injury Induced by Staphylococcal Enterotoxin-B (SEB)  
H. Alghetaa, A. Mohammed, M. Nagarkatti, and P. Nagarkatti, University of South Carolina School of Medicine, Columbia, SC.

It is well known that the intake of food enriched with resveratrol (RES), 3,5,4’-trihydroxy-trans-stilbene, is useful in protection or treatment of diseases such as diabetes and cancer. We have shown previously that resveratrol treatment led to survival of C3H mice from fatality following exposure to dual dose of Staphylococcal enterotoxin B (SEB) via activation of TGF-β signaling in T regulatory cells of CD4+ FoxP3+ lineage. In the current study, we investigated the role of RES in boosting the anti-inflammatory effects via induction of T-helper3 cells (Th3). To this end, C3H/HeJ mice were pretreated orally with 100 mg/kg of RES, 24 hrs and 90 minutes before induction of acute lung inflammation by SEB, a CDC select agent of bioterrorism. Infiltrating cells from broncho-alveolar fluid lavage (BALF) and spleenocytes were harvested to measure biological parameters. In addition, in vitro polarization of spleenocytes pretreated with 50 µM RES or with the tryptophan metabolite, kynurenine (Kyn) derived from RES-treated mice was carried out following 1µg/ml SEB activation for 48 hrs. Our findings revealed increase in Th3 population in vivo and in vitro by flow cytometry particularly IL10 expressing cells in RES-treated group. Furthermore, protein quantification by ELISA showed increase in IL10 levels in BALF and plasma of RES-treated mice as well as in cell culture supernatant of RES- and Kyn-treated groups. In addition, Th1 and Th17 cell populations and their related cytokines were reduced significantly in lungs, sera and cultured cells treated with RES. PCR analysis showed significant elevation in the expression of Kyn mRNA in lung infiltrating cells and alveolar epithelial cells isolated from mice treated with RES, while STAT1 mRNA expression was significantly ablated in lung infiltrating mononuclear cells. Immunofluorescence investigation showed significant increase in the regulatory protein, MUC5b, which is involved in mucociliary clearance mechanism in respiratory system of RES-treated mice. Together, RES treatment induced increase in Th3 population which led to a decrease in Th1 and Th17 responses following SEB exposure. Supported by NIH P01AT003961, P20GM103641, R01AI219788 and R01AI219347.

**2274** Protective Effects of Sodium Butyrate Resulted from Reconstruction of Altered Gut Microbiota Mediated by SEB-Induced Acute Lung Injury  
A. Mohammed, H. Alghetaa, P. Nagarkatti, and M. Nagarkatti, University of South Carolina, Columbia, SC.

Inhalation of Staphylococcal Enterotoxin B (SEB) is known to induce acute lung injury (ALI). Sodium butyrate has been shown to have anti-inflammatory effect in some studies. In the current study, we investigated the role of sodium butyrate in attenuating ALI. Thus, a dual-dose of SEB was given to C3H/HeJ mice, which were then treated either with vehicle or butyric acid. SEB-administration caused ALI and 100% mortality within 5 days, while all butyrate-treated mice survived and suppressed the inflammation in the lungs by increasing anti-inflammatory cells including T regulatory cell lineage and myeloid derived suppressor cells. Moreover, we investigated the regulatory genes and we found that sodium butyrate activates PPAR-gamma signaling pathway and Nos1, IL10 and decreases IFN-gamma. Furthermore, colon microbiota was collected and 16S rRNA sequencing was performed. The data were analyzed to determine the alpha and beta diversity. The major phylum was Firmicutes, class Clostridia and order was Clostridiales to the level of genus Ruminococcus in the colon of sodium butyrate-treated SEB group. Further, mouse transcriptome array shows decrease in genes of TNF and chemokines ccl12, ccl2, ccl26, and cxcr2, besides increasing claudin2, claudin34, defenses-alpha and defenses-beta. Together, our data suggests that butyrate attenuates SEB-induced mortality and ALI by reconstructing altered microbiota. Supported by NIH grants P01AT003961, R01AI219347, R01AI219788 and P20GM103641 to PN and MN, and MohESR fellowship for AKM.

**2275** TCDD Alters Microbiome and Induces Myeloid-Derived Suppressor Cells That Inhibit T Cell Activation by Depleting Cysteine  
W. Neamah, M. Nagarkatti, and P. Nagarkatti, University of South Carolina School of Medicine, Columbia, SC.

Myeloid-derived suppressor cells (MDSCs) are a heterogeneous population of cells that are defined by their myeloid origin, immature state, and ability to potently suppress T-cell and B-cell responses. Murine MDSCs are characterized by the expression of CD11b and GR1 cell markers and can be subdivided into two groups, Monocytic and Granulocytic based on the expression of Ly6C and Ly6G molecules. Previously, we found that one persistent environmental pollutant that induces MDSCs and MDSC subset expansion was 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD). In the current study, we observed that injecting C57BL/6 mice with 10µg/kg TCDD alters gut microbiome by increasing of Lactobacillus abundance when compared to vehicle after three days. Increase in Lactobacillus is related to T-reg and MDSC induction. After fecal transplantation, we found mice that received feces from TCDD-treated mice have higher peritoneal MDSCs and MDSCs subset compared to mice that received feces from vehicle-treated mice. TCDD-induced MDSCs and Monocytic MDSCs led to reduction in splenic IL-17 and IFN-γ levels of these mice. Furthermore, 16S rRNA analysis of gut microbiota reveals reduction in cysteine metabolism pathway in the microbiome of treated mice. It is known that MDSCs block T cell activation by sequestering cystine and limiting the availability of cysteine. Our results from 3H-thymidine assay shows TCDD-induced MDSCs inhibit ConA-activated T cell activation when cultured with MDSCs whereas culturing with cysteine enhances T cell activation. Also, we found that TCDD-induced MDSCs have less ASC expression, neutral amino acid transporter that is important to export cysteine as well as less cystathionase, which converts methionine to cysteine when compared to vehicle. In summary, our data shows TCDD alters microbiome by increasing Lactobacillus enrichment that induced MDSCs. MDSCs suppress T cell activation through depleting cysteine in the environment. Supported by NIH P01AI039361, P20GM103641, R01AI219788, R01AI219347 and MOHESR/Iraq.

**2276** Immunomodulatory Activity of N-Butylbenzenesulfonamide in Female B6C3F1/N Mice  
R. Frawley1, C. Rider1, V. Johnson2, G. Burleson3, K. Shockley1, C. Willson1, T. Steinbach4, and D. Germolec1.  
1NIHES, Research Triangle Park, NC; 2Burleson Research Technologies, Morrisville, NC; 3Integrated Laboratory Systems, Inc., Research Triangle Park, NC; and 4Experimental Pathology Laboratories, Inc., Durham, NC.

N-Butylbenzenesulfonamide (NBBS) is a high production volume plasticizer used in polyamide commercial and consumer products. NBBS has been detected in environmental water samples, and in leachate from polyamide cooking utensils, making oral exposure the likely route for human exposure. Distribution studies in rodents demonstrated that NBBS was rapidly absorbed into tissues, and eliminated rapidly, with little indication of accumulation. NBBS is reported to induce alterations in hematological parameters, and androgen and progesterone receptor mediated transactivation in adult rodents, and to adversely affect implantation and pregnancy in gestation studies. However, little is known regarding the impact of NBBS on the immune system. The objective of this study was to evaluate the potential immunomodulatory effects of NBBS in adult female B6C3F1/N mice, using a standard panel of innate, cell-mediated, and humoral-mediated immunity endpoints. Mice were exposed to 0-5000 ppm NBBS by dosed feeding for 28 days. Under the conditions of the study, NBBS exposure had little or no effect on body and organ weights, hematology, relative or absolute numbers of lymphocyte sub-populations in the spleen, or histopathology of lymphoid or selected non-lymphoid organs. In contrast to the lack of effects on structural and cellular immune functions, androgenic and progesterone receptor mediated transactivation in adult rodents, and to adversely affect implantation and pregnancy in gestation studies. However, little is known regarding the impact of NBBS on the immune system. The objective of this study was to evaluate the potential immunomodulatory effects of NBBS in adult female B6C3F1/N mice, using a standard panel of innate, cell-mediated, and humoral-mediated immunity endpoints. Mice were exposed to 0-5000 ppm NBBS by dosed feeding for 28 days. Alterations in the Mouse Skin and Gut Microbiome following Dermal Exposure to the Antimicrobial Chemical Triclosan

R. Baur, N. Marshall; E. Lukomska; L. Weatherly; H. Shane; S. Anderson. West Virginia University, Morgantown, WV; and \textsuperscript{2}NIOSH, Morgantown, WV.

It is increasingly being recognized that the microbiome plays an important role in human health. Dysbiosis of the microbiome has been shown to alter immune responses and has been associated with increased risk of allergic disease. Triclosan is an antimicrobial chemical used in the healthcare field as a high level disinfectant. In humans, triclosan exposure has been associated with an increase in food and aeroallergy and asthma exacerbation. Although not directly sensitizing, dermal exposure to triclosan has been shown to augment allergic responses to experimental allergens in mouse models. However, the impact of dermal exposure to antimicrobials, such as triclosan, on the microbiome is unknown. This study investigated the impact of dermal exposure to triclosan on the skin and gut microbiome in mice. Mice were dermally exposed to 2–3% triclosan or acetone vehicle control for either 7 or 28 consecutive days. Swabs were used to collect skin commensal bacteria prior to exposure and over the course of the exposure period and fecal pellets were collected following the last triclosan exposure to assess gut commensal bacteria. Following bacterial DNA extraction from skin swabs and fecal pellets, composition of the skin and gut microbiota was determined by 16S ribosomal RNA sequencing. Sequences were grouped into operational taxonomic units and given taxonomic assignments. Analysis of changes in relative abundance identified decreased Proteobacteria and increased Firmicutes in the triclosan exposed group compared to the vehicle control. The skin and gut diverged on the class taxonomic level; Clostridia increased in skin samples, whereas Bacilli increased in the fecal pellet samples. Within the class of Clostridia, Lachnospiraceae and Ruminococcaceae were both increased in relative abundance in the skin swab samples. Lactobacillaceae within the class Bacilli was increased in abundance in the gut. Taken together, dermal exposure to triclosan altered the composition of commensal bacteria in both the skin and gut of mice, suggesting that triclosan can induce dysbiosis of the microbiome and this may contribute to the observed alternations in immune function.

Investigation on the Possible Role of microRNAs in the Regulation of Chemical Allergen Potency

V. Galbiati, M. Pisapia, M. Marinovich, C. L. Galli, and E. Corsini. Università degli Studi di Milano, Milan, Italy.

Allergic contact dermatitis (ACD) is an immunological mediated inflammatory disease and is one of the most common occupational diseases in industrialized countries. ACD is a T-cell mediated skin inflammation caused by repeated skin exposure to low molecular weight chemicals. Chemical allergy is of considerable importance to the toxicologist, who has the responsibility of identifying and characterizing the allergenic potential of chemicals. While incredible progresses have been made in the development of non-animal tests, currently it is not possible to estimate the sensitizing potency of chemical allergens. Using THP-1 cell line, a model for primary human monocytes, and assuming that the extent of chemical allergen-induced dendritic cells activation/maturity and lifespan may drive the quality and magnitude of T cell activation, we have conducted a study using allergens of different potency to verify this hypothesis. Up-regulation of CD80, CD86 and HLA-DR, and the release of several cytokines were evaluated in THP-1 cells. Results indicate that extreme allergens of different potency differently activate DCs, with extreme allergen induction/maturation and lifespan may drive the quality and magnitude of T cell activation. We have conducted a study using allergens of different potency to verify this hypothesis. Up-regulation of CD80, CD86 and HLA-DR, and the release of several cytokines were evaluated in THP-1 cells. Results indicate that extreme allergens induce a more rapid CD86 up-regulation (24h) compared to the moderate and weak allergens. Furthermore, HLA-DR was up regulated at 72h only by the extreme sensitizers. Overall, results suggest that allergens of different potency differently activate DCs, with extreme allergen inducing a higher degree of maturation compared to moderate and weak allergens. Based on these results, we moved to the analysis of miRNAs expression in response to chemical allergens as valuable explanation to understand allergenic potency. MVs release by immune system cells may be induced by soluble agonists or in response to physical or chemical stress. MicroRNAs are non-coding RNA molecules that regulate gene expression at the post-transcriptional level. Recent findings indicate that miRNAs contained in MVs may determine reprogramming of gene expression in target cells. Although ACD has been studied extensively, there are few studies conducted to investigate miRNA expression. Using miScript miRNA PCR Array (Qiagen) we identified few miRNAs involved in ACD. These include let-7, miR-142 and miR-155. We are currently investigating the possible correlation between the miRNA expression observed with the screening and the effective potency of selected contact allergens tested. Acknowledgements: This study was supported by funding from Colgate-Palmolive Grant for Alternative Research (SOT Award 2017–2018).

The Effects of Pristine and Carboxylated Multiwalled Carbon Nanotubes on Phagocytic Function of Macrophages

R. Lohray, R. Wang, E. Chow, and B. Draper. University of Texas at Dallas, Richardson, TX.

The global production and applications of multi-walled carbon nanotubes (MWCNTs) have increased in recent years despite evidence that MWCNTs cause pulmonary fibrosis in lab animals that may lead to mesothelioma. Studies to understand the pathological mechanisms of MWCNTs often focus on macrophages as they are first responders to invaders in the body. Recent work in our lab shows that both human and mouse macrophages preferentially accumulate ~100X more carboxylated MWCNTs (C-MWCNTs) than pristine MWCNTs (P-MWCNTs). Also, Class A scavenger receptors expressed in macrophages may be involved in the selective accumulation of C-MWCNTs (Wang et al., Nanotoxicology, 2018, DOI: 10.1080/17435390.2018.1472309). To investigate the potential impacts of accumulated C-MWCNTs and P-MWCNTs on phagocytic function of macrophages, this study focused on two approaches: 1. Mouse macrophage RAW 264.7 cells were pre-exposed to C-MWCNTs or P-MWCNTs at 37° C for 2h and 24h, washed and challenged with 1 μm fluorescent polystyrene beads to monitor the phagocytic activity of the cells. This was done quantitatively through flow cytometry and qualitatively using confocal fluorescence microscopy. The fluorescent intensities of the cells treated with either C-MWCNTs or P-MWCNTs were compared to that of the control cells. The results demonstrated that 24h exposure to C-MWCNTs reduced phagocytosis of beads by 30-40% versus the control while exposure to P-MWCNTs did not suggest that 24h pre-exposure to C MWCNTs impaired phagocytic function. 2. To further investigate the impact of C MWCNTs on macrophages, the second approach will employ GFP expressing E. coli as a phagocytic marker. Cells treated with C-MWCNTs or P-MWCNTs will be washed and then challenged with E. coli. The phagocytosed bacteria will be detected using confocal fluorescence microscopy. The difference in bacteria uptake with and without pre-exposure to either C-MWCNTs or P-MWCNTs will be quantitatively measured using flow cytometry. The approaches developed in this study will facilitate the assessment of potential impacts of various MWCNTs on macrophages' defensive function to phagocytose pathogenic bacteria.

Development of a Zebrafish Larvae-Screening Assay to Identify Compounds with Immunotoxicity and Anti-inflammatory Activity

Zebrafish is a unique model for pharmacological manipulation of the innate and adaptive immune response. They are small and permeable to many small compounds and there are several transgenic lines available to visualize cells from the innate immunity (neutrophils and macrophages) and adaptive immunity (B and T cells). Taking advantage of zebrafish embryo transparency, we can test the toxicity of pharmacological, agrochemical and cosmetic compounds to the immune system by quantifying these cell populations. Additionally, this model can also be used to identify new anti-inflammatory compounds by following leukocyte recruitment to inflammation induced by sterile tissue injury. We have developed an assay in zebrafish larvae to detect compounds with specific toxicity for the immune system and to screen and identify new anti-inflammatory drugs. For these purposes two transgenic lines have been used: neutrophil-specific Tg (mpx:GFP)/114 and macrophage specific Tg (mpeg:mcherry). Different reference compounds with known anti-inflammatory effect were chosen and their doses selected after an MTC (Maximum Tolerated Concentration) assay carried out in 3 days post fertilization (dpf) embryos (when the innate immune system is already in place). To determine compounds toxicity at the innate immune system level, embryos were exposed to fresh dose for 48 h and the population of neutrophils and macrophages was quantified by fluorescence microscopy. Inflammation was induced by sterile injury of the tail fin and neutrophil recruitment to the wound site was assessed at 4, 6 and 12 h post injury in the presence of reference compounds using a partially automated platform. The ability of the compounds to suppress the expression of inflammatory genes (Il1b, Inf-a) was also evaluated by quantitative PCR. This zebrafish assay shows to be a cost-effective assay over mammalian models for the identification of new anti-inflammatory compounds and there are several transgenic lines available to visualize cells from the innate immunity (neutrophils and macrophages) and adaptive immunity (B and T cells). Taking advantage of zebrafish embryo transparency, we can test the toxicity of pharmacological, agrochemical and cosmetic compounds to the immune system by quantifying these cell populations. Additionally, this model can also be used to identify new anti-inflammatory compounds by following leukocyte recruitment to inflammation induced by sterile tissue injury. We have developed an assay in zebrafish larvae to detect compounds with specific toxicity for the immune system and to screen and identify new anti-inflammatory drugs. For these purposes two transgenic lines have been used: neutrophil-specific Tg (mpx:GFP)/114 and macrophage specific Tg (mpeg:mcherry). Different reference compounds with known anti-inflammatory effect were chosen and their doses selected after an MTC (Maximum Tolerated Concentration) assay carried out in 3 days post fertilization (dpf) embryos (when the innate immune system is already in place). To determine compounds toxicity at the innate immune system level, embryos were exposed to fresh dose for 48 h and the population of neutrophils and macrophages was quantified by fluorescence microscopy. Inflammation was induced by sterile injury of the tail fin and neutrophil recruitment to the wound site was assessed at 4, 6 and 12 h post injury in the presence of reference compounds using a partially automated platform. The ability of the compounds to suppress the expression of inflammatory genes (Il1b, Inf-a) was also evaluated by quantitative PCR. This zebrafish assay shows to be a cost-effective assay over mammalian models for the identification of new anti-inflammatory drugs as well as for the evaluation of immunotoxicity.
Neutropenia is a dose-limiting toxicity associated with immunomodulatory anticaner agents. One mechanism of drug-induced neutropenia is the inhibition of maturation of neutrophil blasts in bone marrow. We developed an in vitro assay to differentiate bone-marrow-derived CD34+ hematopoietic stem cells (HSCs) into mature neutrophils from cyonmolus monkeys for which in vitro neutrophil maturation has not been described. Commercially available CD34+ HSCs from cyonmolus monkeys were cultured in media supplemented with growth factors to induce expansion and myeloid commitment followed by neutrophil maturation. Examination of May-Grunwald Giemsa stained cells suggested that morphological changes were consistent with differentiation of CD34+ HSCs into mature neutrophils. The staining further revealed that mature neutrophils appeared in cyonmolus monkey CD34+ HSC cultures 5-6 days earlier than from cultures of human CD34+ HSCs under similar conditions. Neutrophil maturation was also evaluated by flow cytometry for cell surface markers: CD34 for early progenitor cells; CD33 for myeloblasts, promyelocytes, myelocytes, and metamyelocytes; and CD11b for metamyelocytes, band, and mature neutrophils. During the expansion and commitment phase, CD34 expression decreased and CD33 expression increased, consistent with the appearance of committed neutrophils. CD33 levels began decreasing and CD11b began increasing, consistent with the presence of mature and hyper-segmented neutrophils. These results demonstrate that CD34+ HSCs from cyonmolus monkeys differentiate into mature neutrophils in vitro. This assay will be useful for evaluating the potential of immunomodulatory compounds to induce neutropenia and for comparing nonclinical toxicity study findings to potential risk for humans.
Enzyme-linked immunosorbent assay (ELISA) is an extremely sensitive cell-based assay for detection of secreted effector molecules from immune cells. Here, we investigated the detection of IFNγ secreted from cynomolgus macaque peripheral blood mononuclear cells (PBMC) in response to cytomegalovirus (CMV) via the use of a UL-83 (pp65) peptide pool. Inherent variability in this highly sensitive assay means that acceptance criteria common to ELISA validation may not readily apply to all aspects of a validation effort for this type of assay. Additionally, significant variability in the execution of the assay can be introduced by small changes in input material processing. Further, the use of ELISpot assay in support of drug development requires bespoke validation per test article or antigen and therefore a robust validation study design to successfully optimize and execute in support of a standard toxicology study is needed. Here, we investigated critical parameters for successful ELISpot assay execution including: 1) optimal conditions and cell density for isolation, cryopreservation and thawing of PBMCs; 2) IFNγ responses from fresh and frozen PBMCs; 3) precision (intra-assay, inter-assay); 4) sensitivity and linearity; 5) antigen-specific spot count settings, detection, and sensitivity optimization for a given ELISpot reader system. We share lessons learned in our efforts to validate this assay and discuss the appropriate strategy to rigorously investigate the development of a test article, or antigen-, specific deployment of this assay in a GLP laboratory space.

Development of a Full-Thickness 3D Autologous Skin Equivalent Model to Determine Immunogenicity of Therapeutics

There is growing demand for human-based assays to test compounds/therapeutics for adverse immune reactions prior to entering clinical trials. Human skin equivalent models are useful in vitro testing platforms. We describe a unique full-thickness 3D autologous skin equivalent model made from primary human tissue which is representative of normal human skin and an autologous platform for testing therapeutics under development. Primary human fibroblasts and keratinocytes were grown from healthy volunteer tissue. The full-thickness skin equivalent model was generated by first forming a dermal equivalent by culturing fibroblasts on a scaffold before adding donor-matched keratinocytes and culturing at the air-liquid interface. Histology and immunofluorescence for protein markers of epidermal differentiation (involucrin and cytokeratin 14) and for dermal collagen (Picro Sirius red) was completed and compared to normal skin. We co-cultured the model with activated peripheral blood mononuclear cells (PBMCs) and observed similar immune damage to that in our skin explant assay. Immunofluorescence staining for heat shock protein 70 (HSP70) as a marker of apoptosis was used to confirm these findings. We also used the model to screen for adverse immune events to known positive and negative control therapeutic monoclonal antibodies, similar to our skin explant assay, but replacing the skin explant with the 3D autologous skin equivalent model. Our model was representative of normal human skin, showing similar structure observed by haematoxylin and eosin staining and positive immunofluorescence staining for protein markers of epidermal differentiation and skin structure (involucrin, cytokeratin 14 and Picro Sirius red). Our data also suggest this model could be used to detect adverse immune events to positive control therapeutic monoclonal antibodies with damage in the model as shown by positive HSP70 staining. No HSP70 staining was observed in the 3D skin model treated with negative control monoclonal antibody. We have generated an autologous 3D skin equivalent model, representative of normal human skin. Our data has shown this to be a useful platform for the detection of adverse immune events when testing biologics under development.
Dosage Scaling in Mouse Models for Binge Drinking: An Empirical Approach

S. B. Pruett, W. Tan, B. Nanduri, and G. Howell III. Mississippi State University, Mississippi State, MS.

Allometric dosage scaling between mouse and human is often done by expressing the dosage as dose per meter squared of body surface area rather than dose per body weight. This allometric conversion requires multiplying the dosage in humans by 12.3 on the basis of dose per body weight to obtain a biologically equivalent dosage in mice. However, this was derived from studies using one class of toxicants, chemotherapeutic agents for cancer. Subsequent work has shown that the conversion factor required to achieve biologically equivalent dosages varies considerably from one drug or chemical to another. Therefore, we sought to determine biologically equivalent dosages of ethanol in mice and humans using an empirical approach. We compared dosage (g/kg) to area under the blood ethanol concentration vs. time curve (AUC) for data from the literature for humans and from our own data (plus data from another lab for confirmation) for mice. We calculated the AUC using our original results that showed ethanol concentrations over time at various ethanol dosages. The results indicate that the linear relationship between dosage and AUC is similar for mice and humans (the lines are parallel). However, the x-intercepts are highly significantly different with 2.5-S fold higher dosages required in mice to achieve the same AUC as compared to humans. We also observed that both AUC and peak blood ethanol concentrations correlated significantly with induction of a corticosterone response in mice, indicating that AUC is a good indicator of biological effects. The results demonstrate that a dosage of 2 g/kg in humans produces similar AUC values as a dosage of 5 g/kg in mice, and a dosage of 1 g/kg in humans produced similar AUC values as 4 g/kg in mice. Thus, concerns in the ethanol research community about high ethanol dosages (5-6 g/kg) used in binge drinking experiments in mice seem to be unfounded. In fact, to match biological effects of ethanol in humans and mice, dosages must be greater for mice than for humans. This work was supported by R01 AA095505. S. Pruett is supported by P20 GM103646.

Immune Effects of Inorganic Arsenic Exposure on Mouse Bone Marrow-Derived Macrophages

In many parts of the world, including the United States, inorganic arsenic (iAs) contaminates groundwater used for drinking, food production, and irrigation. The World Health Organization set a 10 μg/L safety limit for arsenic in drinking water. Yet still as many as 140 million people worldwide may be exposed to drinking water with arsenic contamination at levels above that threshold. Elicits a broad range of adverse health effects, arsenic is a confirmed carcinogen by the IARC and also causes increased susceptibility to infectious diseases such as tuberculosis, indicating that arsenic affects the immune system. The purpose of this study is to elucidate the effects of arsenic on the developing immune system with an in vitro mouse bone marrow-derived macrophages exposure paradigm. Briefly, macrophages were cultured from larval rat bone marrow harvested from day 17 pups. The rats were dosed with different levels of iAs (0.0001 - 1 μM) either during or after macrophage differentiation, and stimulated with either LPS or PamCyS (Toll-like receptor 4 and 2 ligands, respectively). Culture supernatant was analyzed for cytokines and NO production. S2-plex cytokine analysis revealed differences between iAs-treated and untreated macrophages, with and without stimulation by LPS or PamCyS. For example, MCP-1, a cytokine that regulates chemotaxis of monocytes and basophils, is downregulated with increasing iAs doses applied after macrophage differentiation. Additionally, exposure to iAs alters macrophage nitric oxide (NO) production in a sex-dependent manner. Stimulated female samples yielded a U-shaped response with increased levels with by iAs, while male samples exhibited a negative linear trend. NO has been shown to produce both antimicrobial and antitumor activity. Therefore, for the host, disruption or alteration of macrophage NO production together with a suppressed proinflammatory cytokine response could lead to increased susceptibility to infectious agents and cancer. Further mechanistic investigation and pathway analysis may explain how arsenic specifically targets macrophages in a sex-dependent manner and alters downstream events, such as activation of immune cells essential for host protection. Research such as this contributes to our understanding of the full spectrum of adverse health effects of arsenic exposure and may help inform future policies on drinking water standards. Supported by NIHES R00ES024808 (FS) and T32ES07141 (EL KR).

Cigarette Smoke Extract May Induce Lysosomal Storage Disease-Like Adverse Health Effects

E. Park1, Y. Park1, S. Lee2, C. Yoon3, and K. Lee.1 1Kyung Hee University, Yongin-si, Korea, Republic of; 2Korea Institute of Toxicology, Jeonggup-si, Korea, Republic of; and 3Korea Basic Science Institute, Seoul, Korea, Republic of. Sponsor: A. Shvedova.

Cigarette smoke is known to be associated with the incidence of a variety of pulmonary diseases, and alveolar macrophages are a key player in the defense mechanism against inhalable toxicants. Herein, we found that a hydrophilic fraction in smoke extracts from 3R4F reference cigarettes (CSE) contains high concentrations of volatile substances compared to cigarette smoke condensate (amphoretic fraction). We also identified the toxic mechanism of CSE using MH-S, a mouse alveolar macrophage cell line. CSE decreased cell viability accompanying increased LDH release. Additionally, mitochondrial volume was decreased, and a decrease of catalase activity and intracellular calcium concentration and decrease of ER and lysosome volume at the highest dose. More interestingly, damaged organelles accumulated in the cytosol, and CSE-containing particles specifically penetrated to mitochondria. Meanwhile, any significant change in autophagy-related protein expression was not found in CSE-treated cells. Following, we evaluated the effects of CSE on secretion of inflammatory-related cytokines and chemokines, considering the relationship between organelle damage and the disturbed immune response. Very importantly, we found that expression of innate and adaptive immunity-mediated mediators is disrupted following CSE exposure. Taken together, we suggest that CSE may cause the accumulation of damaged organelles in the cytoplasm by impairing selective autophagic function. In addition, this accumulation is responsible for the inadequate ability of immune cells to repair damage of lung tissue following exposure to CSE.

IL-4 Administration or Zinc Supplementation Mitigates Aggravated Thymus Atrophy in Zinc-Deficient Rats

T. Kido1, M. Suka1, M. Tsuno2, and H. Yanagisawa1. 1Jikei University School of Medicine, Tokyo, Japan; and 2National Defense Medical College, Saitama, Japan.

Nutritional zinc deficiency leads to immune dysfunction, including inflammatory diseases. We previously showed that inflammation induced by zinc deficiency can be inhibited by IL-4 administration or recovered by zinc supplementation. Furthermore, mitigation of thymus atrophy was observed by IL-4 administration or zinc supplementation. Here, we investigated whether the macrophage subtype is involved in mitigating thymus atrophy in zinc-deficient rats. Five-week-old male rats were fed a standard diet (17 g/day), and two groups were fed a zinc-deficient diet (n = 7 each). Each group was also injected with saline or IL-4 (zinc-deficient/IL-4 i.p.). Another group of rats were treated and untreated macrophages, with and without stimulation by LPS or PamCyS. For example, MCP-1, a cytokine that regulates chemotaxis of monocytes and basophils, is downregulated with increasing iAs doses applied after macrophage differentiation. Additionally, exposure to iAs alters macrophage nitric oxide (NO) production in a sex-dependent manner. Stimulated female samples yielded a U-shaped response with increased levels with by iAs, while male samples exhibited a negative linear trend. NO has been shown to produce both antimicrobial and antitumor activity. Therefore, for the host, disruption or alteration of macrophage NO production together with a suppressed proinflammatory cytokine response could lead to increased susceptibility to infectious agents and cancer. Further mechanistic investigation and pathway analysis may explain how arsenic specifically targets macrophages in a sex-dependent manner and alters downstream events, such as activation of immune cells essential for host protection. Taken together, we suggest that CSE may cause the accumulation of damaged organelles in the cytoplasm by impairing selective autophagic function. In addition, this accumulation is responsible for the inadequate ability of immune cells to repair damage of lung tissue following exposure to CSE.
supplementation groups, thymus structure was recovered by intake of the standard diet. Therefore, there was no significant change in total macrophage and CD4+CD8+ double-positive cell numbers in the thymus.

### 2293 Effects of the Food Additive tBHQ on OVA-Elicited Food Allergy in Mice
Michigan State University, East Lansing, MI.

Immune-mediated adverse reactions to food allergens are rising at an alarming rate, globally, for reasons that are not completely understood. Although many factors such as microbiota, diet, obesity, and environmental chemical exposure have been proposed to contribute to this marked increase, the identification of specific causative factors has remained elusive. Previous data from our lab demonstrated that tert-butylhydroquinone (tBHQ), a food additive present in many processed foods, promotes polarization of T cells towards a Th2 lineage, a key step in the development of allergy. Here we tested the hypothesis that tBHQ, at concentrations relevant to human exposure, exacerbates the allergic response in ovalbumin (OVA) sensitized mice. Female Balb/c mice (4 weeks old) were provided control diet or diet with 0.001% tBHQ for the duration of these studies. Mice were exposed to OVA once per week for 4 weeks during the sensitization phase. Sensitization to OVA was assessed by the rise in OVA-specific IgE and IgG1. Upon oral challenge, mice were monitored for hypothermia shock response (HSR) and mast cell protease (mMCP-1) response. Although sensitization with OVA elicited a robust OVA-specific IgE antibody response in both the control and tBHQ diet groups, IgE levels were markedly higher in the mice on the tBHQ diet as compared to control diet. Likewise, in response to OVA challenge, a greater decrease in body temperature was observed in the mice on the tBHQ diet compared to control animals. Furthermore, the mMCP-1 response to OVA challenge was 3-fold greater in the mice on the tBHQ diet as compared to control diet. In addition, flow cytometry showed both mast cell population (CD117+ FcεRI+) and T helper 2 (Th2) cells (CD4+ GATA-3- IL-4+) population in splenocytes from the tBHQ-treated group were increased compared to control. Lastly, induction of IL-4, IL-5 and IL-13 was greater in splenocytes derived from mice on the tBHQ diet in an ex vivo recall response assay. Taken together, these data suggest that exposure to tBHQ through the diet promotes OVA sensitization and exacerbates anaphylactic response to OVA challenge in a mouse model of food allergy.

### 2294 In Situ Immunization with a TLR9-Agonist Enhances Survival in HNSCC
University of Iowa, Iowa City, IA.

Immunotherapy involving immune checkpoint inhibitors anti-PD1 and anti-CTLA4 antibody has shown promise for the treatment of head and neck squamous cell carcinoma (HNSCC). However, only a subset of HNSCC patients respond to these therapies. Therefore the identification of alternative immunotherapeutic strategies is necessary to improve HNSCC patient outcomes. CMP-001 is a novel toll-like receptor-9 (TLR9) agonist that consists of an unmethylated CpG motif-rich G10 oligonucleotide encapsulated in virus-like particles. In situ vaccination of CMP-001 is believed to activate tumor-associated plasmacytoid dendritic cells (pDCs) leading to tumor antigen presentation to T cells and anti-tumor T cell responses. This study is designed to investigate the therapeutic and abscopal effect of CMP-001. C57BL/6 mice were subcutaneously inoculated with murine mEERL HNSCC cells on both left and right flanks of each mouse. Three doses of CMP-001 was administered intratumorally into the left tumor. Tumor (injected and distant) growth, abscopal response, and survival were monitored. Results indicate that in situ vaccination of CMP-001 can significantly prolong mice survival, as well as suppress tumor growth on injected and distant sites over three weeks. The regression of CMP-001-injected tumors was durable. However, distant site tumors relapsed after the completion of treatment. In an ex vivo study we found an increase of CD4+ T cell infiltration at both injected and distant tumors in CMP-001-treated mice compared with controls. These results demonstrate the anti-tumor efficacy of CMP-001 and warrants further study of CMP-001 and other TLR9 agonists as a novel immunotherapeutic strategy for the treatment of HNSCC.

### 2295 E-cigarettes Adverse Effects and Nutrition Prevention
Southern University and A&M College, Baton Rouge, LA.

Chronic obstructive pulmonary disease (COPD) is one of the leading cause of death in United States. Cigarette smoking is one of the leading cause of COPD. Tobacco smoke contains more than 4500 chemicals, several of which are known carcinogens and/or can cause toxic effects leading to excessive inflammation and pathogenesis. With more than 7000 unique flavors and 450 brands commercially available, there has been recent surge in the sales of Electronic cigarettes (e-cigs), marketed as a safe alternative of conventional smoking. E-cigarettes are battery-operated devices which are used for heating e-liquids to produce vapors. Recent scientific reports present a controversial picture about this claim for e-cigs as safe alternatives. Studies now demonstrate that e-cigs can induce inflammatory responses almost similar to those by conventional cigarettes which may contribute to lung pathologies. On these lines, we investigated the effect of tobacco flavored e-cig vapor condensate (TF-ECVC; w/o nicotine) on immune related genes using human alveolar epithelial II cells (A549). Our findings revealed that AECII cells when exposed to the concentration of 2% or higher of TF-ECVC, show significantly reduced viability. We also observed TF-ECVC mediated increase in the production of cytokines and chemokines (CCL2, CXCL8, IL-1β and IL-6). Additionally, increased expression of the cystosolic receptor NOD-1; the membrane bound receptor TLR4; and Caveolin-1 (the protein associated with caveolae, a type of membrane raft) in TF-ECVC challenged cells provides further insights into signaling pathways regulated in A549 cells. Results obtained so far suggests for the possible regulatory role of lipid rafts (caveolae) in TL4/NOD1 signal-ing in TF-ECVC challenged A549. We also observed anti-inflammatory role of Urolithin A and Urolithin B in TF-ECVC challenged A549 cells in terms of cyto-kine/chemokine production and rescue of protein homeostatic mechanism. Further studies are in progress to determine detailed molecular mechanisms regulated by TF-ECVC and the role of Urolithins in mitigating the observed adverse effects.

### 2296 d-Limonene Modulates B Lymphocyte Activity and Viability
C. M. Lappas, and K. R. Patrick.
Lebanon Valley College, Annville, PA.

Sponsor: C. Lappas, American Association of Immunologists

The cyclic terpene, d-limonene, which is a major component of several plant essential oils, is used widely as an additive in perfumes, soaps, foods and beverages, has been used clinically to dissolve cholesterol-containing gallstones, to relieve gastric acid-induced heartburn, and has been shown to possess chemopreventative and chemotherapeutic activity. Given the widespread use and clinical relevancy of the compound, it is surprising that only limited studies have investigated the effects of d-limonene on immune system function. It has been shown previously that d-limonene inhibits T cell activity and induces cell death at high concentrations. We show that d-limonene also modulates B lymphocyte activity and viability. B lymphocytes were purified from the spleens of C57BL/6 mice and activated by incubation with F(ab')2 goat anti-mouse IgM secondary antibody, IL-4 and anti-CD40 mAb for 24 hours at 37°C in 5% CO2. Cells were co-cultured with 0.5-8 mM d-limonene or vehicle control. Activation marker expression was measured by flow cytometry and cell viability was measured via trypan blue and annexin V and propidium iodide staining. The activation-induced expression of CD69 was inhibited by up to 72% as a result of exposure to d-limonene, the expression of CD68 was inhibited by up to 60%, while no significant effect on MHCII expression was observed. Treatment with 8 mM d-limonene induced B lymphocyte cell death, with lower doses having no significant effect on cell viability. These data indicate that d-limonene possesses immunosuppressant and cytotoxic activity. These immunomodulatory activities must be considered when evaluating therapeutic and commercial applications of the compound.

### 2297 Microcystin Exposure in Non-alcoholic Fatty Liver Disease Links Ectopic Intestinal Fibrotic Lesions: Role of Liver-Gut Crosstalk
S. Sarkar1, D. Kimono1, M. Albadrani1, R. K. Seth1, G. Scott1, D. E. Porter1, P. Nagarkatti2, M. Nagarkatti2, and S. Chatterjee1.
1. University of South Carolina, Columbia, SC; and 2. University of South Carolina School of Medicine, Columbia, SC.

Intestinal fibrosis is a common complication of Inflammatory Bowel Disease (IBD) and in Crohn’s Disease globally, though it may remain subclinical without any intestinal obstruction. Studies also reveal that chronic inflammation such as non-alcoholic fatty liver disease (NAFLD) increases the risk of intes-
2299 High Dimension Biological Analysis Pipeline for Assessing the Immunotoxicity of Carbon Nanotubes

D. Sariqiannis1, S. Karikitsos1, A. Tsatsakis1, and K. Golokhvast1. 1 Aristotle University of Thessaloniki, Thessaloniki, Greece; 2 University of Crete, Heraklion, Greece; and 3 Far Eastern Federal University, Vladivostok, Russian Federation.

The toxic effects of multi-walled carbon nanotubes (MWCNTs) are often associated with intracellular oxidative processes related to the generation of reactive oxygen species (ROS). In order to identify the effects of exposure to purified and unpurified MWCNTs on different biological targets, immunological, biochemical, and computational pathway analyses were carried out on samples from health human volunteers and in vitro models. MWCNTs with higher amount of metallic impurities caused a 1.8-fold increase in lipid hydroperoxide levels, while the number of mature T lymphocytes with reduced potential underwent more than a 3-fold increase. Whole genome transcriptomics in lung epithelium cells (A549) and keratinocytes (HaCaT) showed that gene expression is significantly modulated after exposure to purified and unpurified MWCNTs. 48-hour exposure resulted in approximately 500 genes expressed differentially in the case of MWCNTs with different levels of impurities. Similar results were found when we analyzed the data isolating the 25 genes involved in the molecular pathway associated to oxidative stress. The persistence of the induction of genes driving chemokine and cytokine-signaling-mediated inflammation showed the importance of the inflammatory effects of MWCNTs, and in particular the unpurified ones. Pathway analysis showed significant modulation of genes related to the NFκB pathway after exposure to unpurified MWCNTs, resulting from oxidative stress induction. This may serve as a parameter of the season’s circulating strains of virus. Despite improvement in capabilities to predict prevalent strains and rising yearly vaccinations, millions of Americans continue to suffer from influenza infection each year. Thus, it is important to consider the factors which may be decreasing the effectiveness of vaccines. We previously showed that a common food preservative, tert-butyldihydroquinone (tBHQ), impairs human CD4+ T cell activation and shifts murine CD4+ T cell polarization away from an antiviral phenotype. Accordingly, we hypothesized that consumption of tBHQ would impair the memory response to viral infection. To test this, we fed mice a diet containing 0.0014% tBHQ or a tBHQ-free diet. The mice were first infected with influenza x31 (H3N2), and 28 days later the mice were subjected to a heterosubtypic infection with influenza A/PR/8/34 (H1N1). After seven days, tissues were collected and effects of dietary tBHQ on immune cells were studied. tBHQ consumption resulted in increased expression of CD25 and CD69 in T cells, indicating greater cellular activation. Further, the effector function of T cells was heightened in the tBHQ group, characterized by increased CD107a and granzyme B expression. Likewise, tBHQ-exposed mice demonstrated lower levels of T cells which recognized influenza antigens, suggesting a robust immune response which lacked pathogen specificity, characteristic of a primary infection response as opposed to a memory response. The mice fed tBHQ also demonstrated higher mRNA expression of inhibitory proteins, CTLA-4 and IL-10, and more regulatory T cells known to suppress the immune response during influenza infection. Notably, this is the first study to show these effects. Lastly, after secondary infection the tBHQ-exposed mice experienced more severe weight loss and prolonged recovery compared to the control mice. Taken together, our data suggest that consumption of physiologically relevant doses of tBHQ results in impaired heterosubtypic immunity to influenza infection. This work was supported by NIH grants ES024966 and GM092715.
Nitro-oleic fatty acid (NOA) is formed by the nitration of the olefinic carbon to yield a potent electrophilic compound. NOA can modify cytostatic residues via Michael addition to alter protein function. It has been shown to reduce inflammatory cell activation within the cardiovascular system, but it has not been studied within the lung. Intratracheal bleomycin (ITB) administration is a well-established model of pulmonary inflammation and acute lung injury; therefore, in this study we examined whether intratracheal administration of NOA reduced bleomycin-mediated pulmonary inflammation. C57BL/6 male mice were administered bleomycin (3U/kg) or control (PBS) intratracheally. Half of the bleomycin or control animals received NOA (50μg) in the same volume as bleomycin 72 hours later. All animals were given in a total volume of 50μl. Bronchoalveolar lavage (BAL) and lung tissue were collected 7 days post ITB. As previously seen, mice treated with ITB lost a significant amount of body weight; however, addition of NOA mitigated this loss (-2.3±0.94 vs -4.0±1.83 g). ITB treatment increased lung leak as shown by increased BAL protein (67±22.2 vs 413±54.7 mg/mL), which was also reduced by NOA (50±35.1 vs 355±43.4 mg/mL). Histology revealed cell infiltration and tissue injury in ITB mice that was not reduced with the NOA. Flow cytometry of BAL cells demonstrated loss of Siglec F-+/F4/80-+/CD45-+/CD115-+ macrophages with ITB (95±3.3 vs 37±6.6%). Analysis of CD11b+/Gr1+ cells showed an increase in non-resident macrophages (4±5.8 vs 19±0.9%, p=0.1%) that was decreased by NOA (34±3.8%). To measure the effects of bleomycin and NOA on interstitial cells a lung digest was performed. Mesenchymal cells (CD31-, CD45-, Sca-1+) demonstrated an increase in CD44 and CD90 expression in response to ITB (3±2.0 vs 23±1.0%; 43±2.3 vs 74±2.6%) which was significantly reduced by NOA (19±0.9%; 70±2.3%). Single cell analysis of mesenchymal and perivascular endothelial cells (CD31+,-; CD45-,+) showed expression of the profibrotic protein ZEB1 was induced by ITB and that OANO significantly decreased ZEB1 by 3±0.94% vs 23±1.0%; 43±2.3 vs 74±2.6%) which was reduced by OANO (19±0.9%; 70±2.3%). To measure the effects of bleomycin and NOA within the lung lining at baseline. These findings suggest that treatment with NOA opposes ITB-mediated pro-inflammatory cellular activation and may do so by altering resident cell function and favoring resolution.

Manipulating the immune system to achieve therapeutic efficacy in cancer treatment has led to a new class of drugs that brought lasting remissions to many patients who had run out of options. The development of new drug candidates. Therefore, the goal of this study was to develop an NHP vaccination model that specifically elicits a CTL response, in order to evaluate the efficacy of the cytokotoxic T lymphocyte (CTL) response. To achieve this, MHC-genotyped Mauritian cynomolgus macaques (MCMs) were immunized with 3 replication incompetent recombinant adenovirus serotype 5 (Ad5) vectors, each containing the coding sequence for mesenchymal and perivascular endothelial cells (CD31+,-; CD45-,+) showed expression of the profibrotic protein ZEB1 was induced by ITB and that OANO significantly decreased ZEB1 by 3±0.94% vs 23±1.0%; 43±2.3 vs 74±2.6%) which was reduced by OANO (19±0.9%; 70±2.3%). To measure the effects of bleomycin and NOA within the lung lining at baseline. These findings suggest that treatment with NOA opposes ITB-mediated pro-inflammatory cellular activation and may do so by altering resident cell function and favoring resolution.

During an innate immune event B-cells are activated to produce immunoglobulins (Ig). Functional Ig production is partially controlled by the immunoglobulin heavy chain locus (IGH) which contains two 3'regulatory regions (3'IGHR). Three enhancers (hs3, h1, h2, hs4) are contained within each 3'IGHR and are thought to influence transcription, Ig class switch recombination (CSR) events. During CSR B-cells switch into different Ig isotypes (IgG1, IgA1-2, IgM, IgE). The human hs1 enhancer within the 3'IGHR is polymorphic in that it contains a 53bp invariant sequence (IS) that can be repeated one to four times in tandem. Multiple autoimmune disorders have been associated with the hs1.2 polymorphism as well as a sensitivity to xenogenous chemicals, such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). Previous work in mouse models has shown TCDD-induced inhibition of the hs1.2 enhancer and 3'IGHR are correlated with inhibition of secreted Ig. However, TCDD has been shown to activate the human hs1 enhancer and produce differential effects on Ig secretion, i.e. decreased IgG but increased IgE. These results highlight the potential species differences in the hs1.2 activity and 3'IGHR function. Our objective is to understand the role of the hs1.2 polymorphism in the expression and production of different Ig isotypes and sensitivity to TCDD. Utilizing CRISPR/Cas9 gene editing within a human B-cell line (CL-01) that can be induced to express the different Ig isotypes, we targeted the polymorphic IS in the hs1.2 enhancers to induce a deletion in the number of IS repeats. We identified several clones with an altered hs1.2 genotype that corresponded to changes in basal and stimulated IgM and IgG secretion, as well as changes in the mRNA expression of the different Ig isotypes. To measure the effects of bleomycin and NOA within the lung lining at baseline. These findings suggest that treatment with NOA opposes ITB-mediated pro-inflammatory cellular activation and may do so by altering resident cell function and favoring resolution.

Type 1 diabetes (T1D) is an autoimmune disease characterized by T-cell mediated destruction of insulin-producing pancreatic beta cells. Both genetic and environmental factors have been shown to contribute to T1D development. One candidate environmental factor implicated in T1D susceptibility is the diet. A potential connection between the diet and regulation of immune function is the aryl hydrocarbon receptor (AhR), a ligand activated transcription factor that modulates the expression of metabolizing enzymes (e.g. Cyp1a1) as well as immune genes. Previous studies with the high affinity synthetic AhR ligand, 11-CBQ, demonstrated that strong AhR activation leads to reduced severity of insulin. The working hypothesis for this study is that AhR activation by the dietary ligand, indole-3-carbinol (I3C) will suppress development of T1D. I3C is found in cruciferous vegetables such as broccoli, kale, and Brussels sprouts. Mice were fed a synthetic plant-free diet (AIN93M) supplemented with 2000ppm I3C. Based on the average measured food consumption of 2.5 g/day, the dose of I3C was equivalent to 250 mg/kg/day. Initially, a 1-week pilot study was conducted to determine the extent by which dietary I3C activates AhR. AhR was highly activated in the small intestine as measured by Cyp1a1 induction (5475±4205-fold increase in the duodenum, 650±269-fold in the jejunum, and 26810±25939-fold in the ileum). Cyp1a1 was also induced systemically, although to a much lower extent (10.1±3.2-fold in the liver, and 2.8±0.5-fold in the PLN). In a follow-up study, mice were fed an I3C supplemented diet starting at 7 weeks of age and insulitis was scored at 12 weeks of age. Surprisingly, dietary I3C significantly increased insulitis, which diverges from our findings with 11-CIBQ. One explanation for this finding could be that 2000ppm I3C suboptimally activated AhR. In our studies with 11-CIBQ (45 mg/kg), AhR was activated systemically resulting in hepatic Cyp1a1 induction three orders of magnitude higher than in mice treated with I3C. Our finding that inadequate AhR activation worsened insulitis is consistent with our previous findings that low levels of AhR activation promotes hyperinflammatory responses, whereas high levels of of mesenchymal and perivascular endothelial cells (CD31+,-; CD45-,+) showed expression of the profibrotic protein ZEB1 was induced by ITB and that OANO significantly decreased ZEB1 by 3±0.94% vs 23±1.0%; 43±2.3 vs 74±2.6%) which was reduced by OANO (19±0.9%; 70±2.3%). To measure the effects of bleomycin and NOA within the lung lining at baseline. These findings suggest that treatment with NOA opposes ITB-mediated pro-inflammatory cellular activation and may do so by altering resident cell function and favoring resolution.
AhR activation suppresses the immune response. In future studies, we will use AhR knockout mice on the NOD background to demonstrate that I3C acts through AhR to alter insults severity.

**2307** Breaking Tolerance: A Case of Immune-Mediated Thrombocytopenia after Administration of BMS-986156 An Anti-GITR Antibody to Cynomolgus Monkey

Glucocorticoid-induced TNFR-related protein (GITR), is a co-stimulatory immune receptor expressed on activated T cells, with highest expression observed on regulatory T cells. BMS-986156, an agonistic IgG1 monoclonal antibody specific for GITR, enhances T effector and regulatory functional markers in vivo via activation of NFKB and increased cell survival and by depleting regulatory T cells via antibody-dependent cellular cytotoxicity (ADCC) or antibody-dependent cellular phagocytosis (ADCP). In a 3-month intermittent intravenous (QW) toxicity study with a 10 week post-dose recovery, cynomolgus monkeys (up to 6 sex/group) were administered 0, 10, 40, or 150 mg/kg BMS-986156. One female monkey administered 150 mg/kg BMS-986156 (AUC [0 - 168] 593,000 µg • h / mL, approximately 75× the steady state exposure at clinical dose of 240 mg Q2W, well above the clinically administered dose) had substantial decreases in platelets at the end of dose and during the recovery period. One monkey administered 150 mg/kg BMS-986156 was negative for a potential immune-mediated cause. Serum from the female monkey with thrombocytopenia had increased platelet-specific antibodies relative to concurrent vehicle control treated female monkeys and relative to other female monkeys administered 150 mg/kg BMS-986156 (up to 23×). The presence of platelet-specific antibodies in the serum of this female monkey provides a potential mechanism of the observed thrombocytopenia. Given the agonistic potential of anti-GITR immunotherapy in enhancing immune responses, the presence of autoantibodies to endogenous platelet surface proteins was considered likely due to pharmacology.

**2308** Neuroimmunotoxicological Perspectives of Gulf War Illness

M. V. Brahmagoti, and M. B. Abou-Donia. Duke University Medical Center, Durham, NC.

Gulf War Illness is a systemic, multi-symptom condition affecting veterans of the Gulf War who have been exposed to chemical warfare agents such as rockets filled with sarin and cyclosarin, both of which are nerve agents that are extremely toxic. Symptoms can include neurological dysfunction, mental illnesses such as PTSD, depression and anxiety, gastrointestinal bleeding and severe upset, as well as disorders affecting other systems in the body, but the immune system, in particular, is placed under extreme stress by these neurotoxins due to the cascades activated within the complement component of the immune system; this complement component serves as a crucial piece in host defense, providing innate and acquired immunity for the body. When it is affected by these neurotoxins, the inflammatory response is activated and this increases the likelihood for conditions like Parkinson’s, AMD and Alzheimer’s Disease, as well as a plethora of other conditions that are unexplainable by the patient’s family medical history. Our previous studies have indicated a higher level of autoantibodies, compared to neuronal specific proteins. The consistent presence of such autoantibodies in the systemic circulation can result in activation of other immunological factors. The main objective of this study is to compare the complement component of the healthy and ill GW veterans. Although complement plays a major role in host defense, its role in inflammatory responses is alarming. During normal healthy conditions, the complement is regulated by membrane-associated and soluble cytotoxic proteins, and when dysregulated, it induces damage to the host cells leading to pathological conditions initiating an autoimmune response. The activation of complement cascade is by the classical, alternative, or lectin pathways. The alternative pathway is continuously activated in vivo through spontaneous C3 thioester bond hydrolysis, resulting in the formation of C3 convertase, generating C3b, which in turn activates several proteins. Factor H is one of the main regulators of the activation of the alternative pathway, which promotes dissociation by preventing the formation of the C3 convertase enzyme. Our preliminary results on complement component C3 by ELISA showed an increased level in GW veterans compared to healthy GW veterans (p-value less than 0.001) and our forthcoming results will indicate the comparative levels of other complement components and C reactive protein to that of the autoantibodies. Supported by DOD W81XWH-18-1-0454.

**2309** Development and Validation of Assays for Detection of Anti-HPV Antibodies and Neutralization of HPV Viruses

M. Lindeblad, F. Kabirov, Y. Chen, U. Bhat, E. Glaze, R. Shoemaker, and A. Lyubimov. 1University of Illinois at Chicago, Chicago, IL; and 2National Cancer Institute, Bethesda, MD.

Immunoassays were developed for detection of anti-HPV antibodies and HPV virus neutralization in rabbit serum after IM administration of HPV16L1-16GSI synthetic peptide vaccine (Kinzbaier et al., 1992; Roden and Wu, 2006). The validated mouse ELISA assay was then modiﬁed to measure the L1 and L2 (17-35) Abs titers simultaneously in a single serum sample (5 µL) using a multiplex assay. The standard curves for L1 and L2 were linear (delta > 30%) for at least seven 2-fold consecutive dilutions from 12,800X to 819,200X. All curves provided excellent inter-plate precision (CVs from 2.16% to 11.98% for L1 and 5.61% to 9.19% for L2). Following testing of 10 blank matrix samples from different sources, the maximum matrix interference was seen at the level of 0.0078 EU/ml for L1 and 0.0231 EU/ml for L2. The high level quality controls (1 EU/ml) for L1 and L2 at 12,800X dilution and 25,600X dilution showed very good intra-plate and inter-plate precision (L1 - CVs from 2.0% to 12% for intra-plate and 16.4% to 19.2% for inter-plate assay; L2 - CVs from 1.2% to 10.2% for intra-plate and 11.9% to 16.0% for inter-plate assay). The screening cut points were established at 12,800X dilution for signals at 192 and 223 for L1 and L2, respectively. The neutralization assay in rabbit and human plasma was developed to detect neutralizing antibodies. Several batches of furin-cleaved HPV18-Luc were prepared and analyzed by gel electrophoresis and neutralization assays. Plasmid plasmid and pLucfLuc plasmid were co-transfected into 293T cells and the cells were collected after 48 hours. The cells were subjected to lysis buffer and incubated for 48 hours at 37°C for virus maturation. The lysate was collected and subjected to Opti-prep density-gradient ultracentrifugation. More batches of furin-cleaved HPV18-Luc were prepared and viral activity and neutralization studies with rabbit sera were performed using different batches of the psuedovirus as well as from the combined stock of fcPsV18 from all the batches. The neutralization assay will be validated using the combined stock and will be used for future GLP rabbit studies with the HPV vaccine. This assay showed high titers of HPV antibodies induction and sufficient virus neutralization by Day 45 in two pilot rabbit studies. This work was funded by National Cancer Institute, contract number: HHSN261201500261.

**2310** In Vitro Skin Tests for the Detection of Sensitization, Immunotoxicity, and Assessment of Relative Potency

Sensitization to chemicals and cosmetics resulting in allergy is an important health issue. Until recently, the most favorable method to test compounds for sensitization was the mouse local lymph node assay (LLNA). Here we describe a human in vitro skin explant test for identification of sensitization hazards and the assessment of relative skin sensitizing potency. This method uses a human autologous system to test for sensitivity and adverse reactions to compounds, in which activity is measured as histopathological grading of skin damage, caused by induced immune sensitization response, which correlates with T cell proliferation and IFN-γ production. Using this approach we have measured responses to 44 chemicals including skin sensitizers, pre/pro-haptens, respiratory sensitizers, non-sensitizing chemicals (including skin-irritants) and previously LLNA misclassified compounds (e.g. Nickel Sulphate). The skin explant test gave 95% specificity, 95% sensitivity, 95% concordance with the LLNA and a correlation coefficient of r=0.9 (p<0.0001). Additionally, it has proven to be a sensitive method for predicting allergy responses to cosmetics and can be used to determine adverse effects of repeat dosing. The assay was modified to aid preclinical prediction of immunotoxicity of therapeutic drugs such as monoclonal antibodies or small molecule drugs. We tested 17 commercial biologics in the skin explant assay (n=10) and correlated the results with clinical occurrence of adverse reactions. Results showed a statistically significant positive correlation between adverse clinical occurrences and a positive response in the skin explant test (r=0.815, p<0.0001). An analogue of the TGN1412 drug, which caused the Northwick Park trial disaster in 2006, was tested and gave an extreme positive response.
Role of Lymphocyte-Specific Protein Tyrosine Kinase (LCK) in Suppression of the Immunoglobulin M (IgM) Response in Human CDS$^+$ Innate-Like B Cells (ILBs)

J. Zhou, L. Blevis, R. Crawford, and N. Kaminski. Michigan State University, East Lansing, MI.

LCK is a well-characterized kinase involved in T cell receptor signaling but the role of LCK in human B cells is poorly understood. Recent studies have demonstrated that AhR-mediated suppression of the IgM response in human B cells involves upregulation of LCK. Interestingly, human ILBs, a heterogeneous population within the total B cell pool, express high levels of LCK. ILBs also express a high basal level of program cell death protein-1 (PD-1), an immune checkpoint inhibitor, which can suppress the IgM response, and is especially sensitive to stimulation by interferon gamma (IFNγ). Therefore, studies were conducted to determine the sensitivity of ILBs to AhR-mediated suppression of the IgM response and determine whether stimulation of ILB with IFNγ alters the levels of LCK, PD-1, and suppression of the IgM response by AhR activation. From these studies, AhR activation significantly upregulated total LCK and PD-1 proteins in ILBs, which correlated with significant suppression of IgM. In addition, IFNγ treatment significantly reduced the total LCK protein levels and increased AhR-mediated IgM suppression in ILBs. Collectively, results from these studies support the role of LCK in AhR-mediated suppression of IgM responses in human CDS$^+$ ILBs. In addition, ILBs are particularly sensitive to the effects of TCDD, likely due to their high expression of LCK. Supported in part by NIH ES002520 and ES004911.

Sex-Specific Effects of Chronic Arsenic Exposure on Influenza Pathology in Adult C57BL/6 Mice

S. Attreede$^1$, C. Kashwiagi$^1$, K. Ryblik$^1$, E. Illingworth$^2$, H. Zhang$^1$, A. Fink$^3$, S. Klein$^1$, C. Heaney$^1$, and F. Sillé$^2$. Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; and College of Saint Benedict and Saint John’s University, Collegeville, MN.

Inorganic arsenic (iAs) is a common drinking water contaminant, known immunotoxicant and is associated with increased risk of respiratory infection. About 200 million people globally are exposed to iAs in their drinking water at levels exceeding the World Health Organization’s safety standard of 10 ppb. Respiratory infections like influenza A virus (IAV) remain among the top causes of death worldwide. While a few previous studies demonstrate increased IAV susceptibility in iAs-exposed mice, none to date have assessed the role sex and iAs dose play in immunotoxicity and IAV pathogenesis. The aim of this study is to determine those sex- and dose-dependent immunotoxic mechanisms of iAs exposure on IAV disease susceptibility and pathogenesis in a mouse model. We hypothesize that exposure to iAs skews the immune response in a dose- and sex-specific manner, resulting in increased pathology and mortality in males and females. Exposed seven-week-old C57BL/6 male and female mice to iAs (sodium meta-arsenate) at 0, 10, 100 or 1000 ppb chronically via ad libitum drinking water. At 5 wk-of exposure, mice were intranasally infected with 10$^5$ 50% tissue culture infective dose (TCID$_{50}$) of mouse-adapted A/California/4/2009 (H1N1) (ma2009). Results demonstrate that exposure to all doses of iAs in female mice and 100 and 1000 ppb in male mice significantly increases clinical signs of disease pathology (ANOVA, p=0.0025) and mortality (log-rank survival analysis, p=0.0033) at 12 days post-challenge (DPC). Analysis of bronchoalveolar lavage fluid at 3 DPC reveals that IL-2 expression is reduced in males and females exposed to iAs, while many proinflammatory cytokines and chemokines were significantly increased at all doses in females and in males exposed to 1000 ppb iAs compared to control. We are currently investigating the source of the exacerbated innate inflammatory response and how iAs exposure leads to higher mortality in females compared to males. We are assessing lung viral titers and histopathology, and performing flow cytometric immune cell profiling in the lung and mediastinal lymph nodes following infection. Our data suggest the sex- and dose-dependent immunomodulatory effects of iAs in drinking water on influenza infection response and pathology. These results help shed light on the increased respiratory pathology seen in epidemiological studies of individuals exposed to high levels of drinking water iAs. Funding: ST32HL070534-35.

Hunting for Goldilocks: Trying to Identify a “Just Right” Dose for an OX40-Activating Antibody in Cynomolgus Toxicology Studies

J. Game$^1$, W. Freebern$^1$, R. Haynes II$^1$, M. Koepfing$^1$, M. Quigley$^2$, C. Gao$^2$, C. Milburn$^2$, Z. Chen$^1$, E. Sahin$^1$, H. Haggerty$^1$, M. Graziano$^1$, and R. T. Bunch$^1$. Bristol-Myers Squibb, New Brunswick, NJ; and Bristol-Myers Squibb, Redwood City, CA.

BMS-986178 is a fully human immunoglobulin G1 agonist monoclonal antibody that binds to human OX40, a co-stimulatory receptor expressed primarily on activated effector T cells and regulatory T cells. In preclinical studies, OX40 agonism has been shown to increase cytotoxic T-cell activity and enhance the antitumor immune response. Administration of a BMS-986178 mouse monoclonal antibody in mice with CT26 tumors demonstrated an inverted U-shaped curve, with increased antitumor activity at doses of ≤3 mg/kg but decreased antitumor activity at 10 mg/kg. Similarly, in vitro data with human T cells showed increasing T-cell activation as BMS-986178 increased to a certain concentration, after which T-cell activation decreased. Toxicology studies of BMS-986178 performed in cynomolgus monkeys were consistent with an inverted-U-shaped dose-response curve relating to immunostimulation. High doses of BMS-986178 (≥30 mg/kg intravenously weekly for 1 month) in cynomolgus monkeys showed immune suppression instead of stimulation as assessed by T-cell-dependent antibody and ex vivo recall responses to keyhole limpet hemocyanin (KLH), suggesting that high doses are in the immune-suppressing range of the inverted U-shaped curve. To identify a dose of BMS-986178 that can elicit the intended immune-stimulating pharmacological effects in cynomolgus monkeys, a second 1-month pharmacodynamics and toxicology study was conducted with weekly doses of BMS-986178 from 0.1 to 10 mg/kg to total of 5 doses (day 1 AUC$_{0-168}$ = 0.1 to 20× the 80-mq Q2W clinical AUC). BMS-986178-clearing antidrug antibodies (ADAs) formed after the second dose at ≤1 mg/kg; at 1 mg/kg, ADAs were associated with hypersensitivity reactions (transient tremors, redness, and/or swelling after the third and/or fourth dose). Furthermore, suppression of the T-cell-dependent antibody and ex vivo recall response to KLH were observed at ≥1 mg/kg. Therefore, these data indicate that there is no BMS-986178 dose in cynomolgus monkeys that allows for both the intended pharmacology and sustained exposure for ≥1 month and suggest that the cynomolgus monkey is not an optimal model for safety evaluation of BMS-986178.

Nickel Nanoparticles Enhance LPS-Induced Pro-Inflammatory Cytokine Production via a NF-κB-Dependent Pathway in Human Lung Epithelial Cells In Vitro and Promote Acute Lung Inflammation in Mice In Vivo

D. You, A. Taylor-Just, and J. Bonner. North Carolina State University, Raleigh, NC.

Nickel nanoparticles (NINPs) are widely used in various industrial applications such as catalysts for the production of multiwalled carbon nanotubes. Thus, the toxicity of NINPs after inhalation exposure is a major concern for occupational lung diseases. Pre-existing respiratory disease or the sex of the individual, may influence one’s susceptibility toward exposure to NINPs. Pre-existing lung inflammation can be induced by lipopolysaccharide (LPS), a ubiquitous component of gram-negative bacteria. Both LPS and NINPs activate the toll-like receptor, TLR4. We hypothesized that NINPs would exacerbate LPS-induced lung inflammation through amplification of TLR4 signaling intermediates (e.g., NF-κB, MyD88) to enhance cytokine production and lung inflammation. In vitro: an immortalized human bronchial epithelial cell line (BEAS-2B) was stimulated with LPS, NINPs, or both. Cell supernatants and mRNAs were collected after 24 and 48hrs after the treatment to measure IL-6 and IL-8 mRNA and secreted protein by RT-PCR and ELISA, respectively. The lcb kinase inhibitor, 2-(aminobenzotriamino)-5- (4-fluorophenyl)-3-thiophencarboxamide (TPCA-1), was used to inhibit activation of NF-κB. To determine whether NF-κB plays a role in NINP exacerbation of LPS-induced inflammation, BEAS-2B cells were treated with TPCA-1 (5μM or 10μM) 30 minutes prior to LPS and NINP stimulation. In vivo: 8-week old male and female mice were treated by intranasal instillation with vehicle (0.1% Pluronic in PBS), LPS (Sug/kg), NINPs (4mg/kg), or both LPS and NINPs. Necropsy was performed 24hrs post-exposure. NINPs and LPS synergistically increased IL-6 and IL-8 production both at the mRNA and protein level in BEAS-2B cells. TPCA-1 blocked the synergistic increase of IL-6 and IL-8 caused by LPS and NINP co-exposure in BEAS-2B cells. The in vivo study also revealed that male mice were more susceptible to acute lung inflammation caused by either LPS and NINPs compared to female mice. Both LPS and NINPs co-exposure to NINPs and LPS would result in more severe lung inflammation in humans compared to either agent alone, especially in males. Funding: Supported by NIHES grant R01-ES020897, NIEHS Training Grant T32ES007046, and NSF Grant T5-022.
Industrialized countries are facing a significant increase in immune-mediated disorders, including allergy, autoimmunity and cancer, for which exposure to environmental factors, includingendocrine disrupting chemicals, may provide plausible explanation. RACK1 is a scaffolding protein involved in several signaling pathways, controlling essential cellular processes and important biological events, including immune response, and cancer. Our published data supports the existence of a complex hormonal balance, between glucocorticoids and androgens, in the control of RACK1 expression and immune cells activation, suggesting that RACK1 can be targeted by endocrine active compounds. This study aimed to investigate the regulation of RACK1 expression following exposure to selected estrogen active compounds, namely 17β-estradiol, diethylstilbestrol (DES), bisphenol A (BPA) and zearalenone, to define whether and to what extent they can modulate the transcriptional regulation of RACK1, and its implication in the modulation of innate immune responses. The human promyelocytic cell line THP-1 was used for all experiments. Cells were treated with increasing concentrations (highest concentration tested CV80) of the selected compounds for 6 and 16 h for the RACK1 promoter activity in transiently transfected with Δ1 luciferase reporter construct of the human RACK1 gene, 16 h for the mRNA expression and for 24 h for the protein expression. For functional testing, after 24 h of incubation with the selected compounds LPS (10 ng/ml) was added, and pro-inflammatory cytokine release assessed 24 h later by ELISA. All compounds modulated RACK1 expression and the response to LPS, confirming our working hypothesis. However, the results showed a different behavior of the analyzed substances. While 17β-estradiol and DES increased at low doses (1-2 nM) and reduced at higher doses (> 1 μM), BPA and zearalenone showed an increase at higher concentrations (> 1 μM) in the expression of RACK1, suggesting that different mechanisms are in place, not directly attributable to the estrogenic activity.

### 2316 Applying the Appropriate Assay Format for Cytokine Release Assays to Deliver the Appropriate Interpretation of Safety Risks

J. Munday, S. Buchie1, and C. Cooper. Covance, Harrogate, United Kingdom; and Covance, Madison, WI.

Following the serious adverse events that resulted in severe cytokine storm responses in individuals dosed with TGN1412, it has been a health authority regulatory expectation that any compound that has the potential to modulate immune activation status is assessed with in vitro assays to predict the potential for activation of a cytokine release mechanisms. Over the last 10 years many investigators have assessed a variety of in vitro cellular assays for evaluation of this response but these do not always reflect the true biologic mechanisms taking place. This poster will review data generated for liquid phase, solid phase, and co-culture assay formats with positive controls (Anti-CD3 Monoclonal antibody, Anti-CD28 Monoclonal antibody, Anti-Her2 Monoclonal antibody and CD19/CD3 bi-specific T-cell engager) which are known to have different modes of action for induction of cytokine release. This data will be used to highlight the importance of choosing an appropriate assay format for characterisation of cytokine release. It will discuss how target biology considerations and test article structural considerations need to be considered for choosing the appropriate cytokine release assay format. Details of how the Fc region of a monoclonal antibody will govern the choice for a solid phase format and how co-culture systems with PBMCs and endothelial cells can be used for a greater physiological understanding will be presented. Utilising these data the poster will show how applying the appropriate assay format can be used to accurately predict the potential for cytokine storm for novel biologics.

### 2317 Epicutaneous Sensitization with Protein Allergens Differentiates Naïve T Cells into Not Only Th2 but Also Th17 Cells, Which Differs from the Sensitization with Chemical Allergens

It is well known that the sensitization with chemical allergens differentiates naïve T cells into TH1 cells in draining lymph nodes, which elicits delayed-type hypersensitivity reactions. IFN-gamma secreted by Th1 cells plays an important role in this process. Conversely, what types of effector T cells are differentiated in draining lymph nodes of mice sensitized by protein allergens such as enzyme is not well known. Furthermore, the types of hypersensitivity reactions elicited by protein allergens remain unclear. To address these issues, we investigated mice sensitized by papain enzyme as a protein allergen. Mice were sensitized by 24hrs exposure to papain twice a week for one month. The draining lymph node cells were then isolated and re-stimulated by papain. ELISA and FACS analyses of the cytokines synthesized in lymph node cells revealed that CD4+ IL-4+ Th(2) and CD4+ IFN-γ+ T(17) cells were differenti-ated in the draining lymph nodes of the mice sensitized by papain. However, CD4+ IFN-gamma+ T cells (Th1) were not detected. The sensitized mice were elicited by applying papain onto the ear to address the role of Th2 and Th17 cells differentiated in the papain-sensitized mice, and the allergic reactions in the ear were examined. Real-time PCR analyses revealed that IL-17 mRNA of Th17 marker was up-regulated in a time-dependent manner; however, IL-4 mRNA of Th2 maker was not detected at any time points. These phenomena were confirmed by immunofluorescent microscopy using a specific antibody for IL-17, suggesting that Th17, but not Th2, migrated into the ear after the elicitation. Additionally, the papain-sensitized mice possessed papain-specific IgE, and mast cell degranulation was observed after the elicitation. These findings reveal for the first time that the sensitization of papain enzyme differentiates naïve T cells into not only Th2 but also Th17 cells as effector T cells contributing to the allergic reactions. The generated Th2 produces IL-4 and is involved in IgE syntheses in the draining lymph nodes. Conversely, the generated Th17 cells migrate to the skin and produce IL-17 after elicitation.

### 2318 Effect of TCDD on B Cell Responses in the Spinal Cord in EAE

E. Kummar, and B. Kaplan. Mississippi State University, Mississippi State, MS.

Multiple Sclerosis (MS) is an autoimmune demyelinating degenerative disease of the central nervous system. A mouse model, experimental autoimmune encephalomyelitis (EAE), is most commonly used to study the pathogenicity of MS, which can be induced after administration of the self-peptide myelin oligodendrocyte glycoprotein (MOG35-55). The severity of EAE can be influenced by Th2 and Th17 cytokines. In our previous studies, TCDD upregulated FasL on B cells, especially the follicular B cells in the spleen and lymph nodes of EAE mice at day 18, suggesting that part of the mechanism for suppression of EAE is induction of a FasL-expressing regulatory B cell to induce apoptosis. The mechanisms by which TCDD upregulates FasL on B cells, especially the follicular B cells in the spleen and lymph nodes of EAE mice at day 18, are not well understood. To investigate the mechanism of TCDD on B cell responses in the spinal cord, we performed ELISA and FACS analyses of the cytokines synthesized in lymph node cells. We found that the number of infiltrating cells as well as CD4+ IFN-gamma+ T cells (Th1) were not detected. The sensitized mice were elicited by applying papain onto the ear to address the role of Th2 and Th17 cells differentiated in the papain-sensitized mice, and the allergic reactions in the ear were examined. Real-time PCR analyses revealed that IL-17 mRNA of Th17 marker was up-regulated in a time-dependent manner; however, IL-4 mRNA of Th2 maker was not detected at any time points. These phenomena were confirmed by immunofluorescent microscopy using a specific antibody for IL-17, suggesting that Th17, but not Th2, migrated into the ear after the elicitation. Additionally, the papain-sensitized mice possessed papain-specific IgE, and mast cell degranulation was observed after the elicitation. These findings reveal for the first time that the sensitization of papain enzyme differentiates naïve T cells into not only Th2 but also Th17 cells as effector T cells contributing to the allergic reactions. The generated Th2 produces IL-4 and is involved in IgE syntheses in the draining lymph nodes. Conversely, the generated Th17 cells migrate to the skin and produce IL-17 after elicitation.
2319 Low-Level Arsenic Exposure Impairs the In Vitro Differentiation of Mouse Bone Marrow Erythroid Progenitor Cells

S. Medina¹, X. Zhou¹, A. Bolt¹, H. Xu², F. Lauer¹, K. Liu¹, and S. Burchiel¹.
¹University of New Mexico, Albuquerque, NM; and ²East China University of Science and Technology, Shanghai, China.

Anemia is a hematological disorder that affects millions of people worldwide. The prevalence of anemia is disproportionately high in arsenic endemic regions. Despite strong epidemiological evidence for the association between arsenic exposure and anemia, a clear mechanistic understanding of how arsenic contributes to anemia remains unknown. The goal of this study was to evaluate the effects of arsenite (As³⁺) and the As³⁺ metabolite, monomethylarsonious acid (MMA³⁻) on the development of bone marrow erythroid progenitor cells. To determine the effects of As³⁺ and MMA³⁻ on erythroid progenitor cell differentiation, we developed an in vitro model of erythropoiesis using primary mouse bone marrow hematopoietic progenitor cells (HPC). The progression of HPC through the stages of erythropoiesis was assessed based on cell surface marker phenotype using flow cytometry. The percentage of megakaryocyte-erythroid progenitors and colony-forming-unit-erythroid cells was significantly reduced after 48 h exposure to 100 and 500 nM As³⁺. MMA³⁻ significantly suppressed all erythro-megakaryocytic progenitor subsets. Evaluation of later-stages of erythroid differentiation revealed a significant suppression of erythroblast subsets at 24 h that persisted through 72 h with the 500 nM As³⁺ and 100 and 500 nM MMA³⁻ exposures. Throughout the differentiation time course, a significant increase in the percentage of early myeloid progenitor cells as well as more mature myeloid cells was observed with both As³⁺ and MMA³⁻. Our results show that As³⁺ and MMA³⁻ suppress the differentiation of erythroid progenitor cells starting at very early stages of erythropoiesis, possibly by skewing HPC lineage commitment in favor of myelopoiesis. Future studies will focus on characterizing mechanisms responsible for arsenic-induced hematopoietic imbalance and impairment of erythropoiesis.

2320 Prolonged Exposure to Sodium Arsenite Initiates Epithelial-Mesenchymal Transition in Human Renal Proximal Tubule Epithelial Cells (RPTEC/HTERT)

A. Slusser¹, L. Fleming, S. Somji, D. Sens, and S. Garrett. University of North Dakota, Grand Forks, ND.

Renal fibrosis develops in the glomerulus and tubulointerstitium as a result of cellular injury. The progressive decline in renal function that occurs in kidney disease is correlated with the degree of tubolointerstitial fibrosis. These fibrotic lesions are the result of myofibroblast activation, and subsequent production of collagen matrix, however the origin of myofibroblasts in the tubular epithelia remains controversial. In this study, we evaluated the potential of renal proximal tubular epithelial cells (RPTEC/HTERT) to transition into myofibroblasts via epithelial-mesenchymal transition by subjecting cultures to prolonged sodium arsenite exposure. Here we report that RPTEC/HTERT chronically exposed to moderate concentrations of sodium arsenite (4.5 micromolar) have lost the ability to perform apical-basolateral transport, and display morphological features consistent with a transition from tubular epithelial cells to myofibroblasts including elongated spindle shape, cytoplasmic projections, and decreased intercellular contacts. Confocal microscopy revealed the acquisition of several mesenchymal characteristics, including the upregulation of N-cadherin, vimentin, and alpha-smooth muscle actin with a concomitant decrease in E-cadherin and Ksp-cadherin. Further, these cells have substantially decreased E-cadherin and beta-catenin localized to the membrane, indicating the dissolution of adherens junctions. Together, these results provide evidence supporting the capability of proximal tubule epithelial cell de-differentiation in to myofibroblasts, consistent with pathological type II EBPs that prolonged arsenite exposure can initiate this process in proximal tubule epithelial cells.

2321 Enrichment of Genes Associated with Squamous Differentiation in Cancer-Initiating Cells Isolated from Arsenite Transformed UROtsa Cell Lines

Urothelial cell carcinomas (UC) with basal characteristics particularly squamous differentiation are generally classified as being more aggressive with poor outcomes. Our laboratory has shown that the immortal urothelial cell line, UROtsa when transformed with the environmental carcinogen arsenite gives rise to tumors exhibiting prominent focal areas of squamous differentiation. Cancer initiating cells (CICs) isolated from these transformed cell lines also form tumors in immune compromised mice with a histology distinguishable from the originating cell lines, including focal areas of squamous differentiation. These observations suggest that the CICs may represent the cell population that is originally transformed by arsenite exposure. The goal of this study was to determine the degree of difference in the gene signature pattern between the arsenite-transformed cell line and the CICs isolated from the cell line and determine if the CICs gene signature was enhanced for the genes related to squamous differentiation or other pathways involved in the development of UC. Our results demonstrate that differential expression of genes between the arsenite-transformed cell line and isolated CICs totals 4,415 transcript clusters and 3,469 identifiable genes. In addition, the CICs were highly enriched for genes involved in squamous differentiation, which include genes for keratinization and formation of the cornified, envelop. These genes (AZM1, CERS, DSG1, SPRR3, SPRR2E, SPRR4, SPRR2D, SPRR1B, SPRR2A, SPRR2B, SULT2B1, KRT1, KRT10, KRT16, KRTDAP, SCEI, ZFP750, KRT14, KRT6a, and KRT6b) have a role in structure, function or development of the stratified squamous epithelium and are normally expressed in the skin or esophagus and not the urinary bladder. In conclusion, our study shows that the genes involved in squamous differentiation, a basal subtype of muscle invasive bladder cancer are enriched in arsenite-transformed CICs and these cells give rise to tumors that show focal areas of squamous differentiation.

2322 Oncogenic KRAS Occurs after Prolonged In Vitro Arsenite Exposure of Human Prostate Epithelial Cells

A. Merrick¹, D. Phadke², R. Shah², K. Pelch¹, S. Auerbach¹, R. Paules¹, M. DeVito¹, M. Waalkes¹, and E. Tokar¹. ¹NIHES, Research Triangle Park, NC; and ²Sciome, LLC, Research Triangle Park, NC.

Inorganic arsenic is an environmental human carcinogen of the urinary tract that includes the prostate gland, which may be among its many target organs. RWPE-1 cells are immortalized human prostate epithelial cells and are non-tumorigenic, not forming tumors in nude mice and showing contact inhibition and anchorage dependence in soft agar assay. The Case-PE cell line was derived from prolonged (29 weeks), continuous, in vitro exposure of RWPE-1 cells to 50uM sodium arsenite. Case-PE cells are malignantly transformed according to the above three criterion but the mechanism remains unclear. We performed RNA-seq for differential gene expression and targeted sequencing to gain insight into in vitro arsenite transformation. RNA-seq showed 7,265 significantly altered transcripts in Case-PE cells compared to RWPE-1 cells at greater than 2-fold change. There were 3,261 up-regulated transcripts and 4,044 transcripts down-regulated transcripts. Pathway analysis of altered transcripts supported increased cell growth, cell motility and survival pathways in Case-PE cells. Notably, KRAS was increased over 400-fold and PSA (KLK3) rose over 50-fold. Connectivity analysis showed 34 annotated KRAS downstream transcripts were increased more than 5-fold, as well as an up-regulation of several growth factors including IGF1, IGF2, EGR1, VEGFA, and IGFBP7. Whole genome DNA sequencing of the KRAS gene revealed an allelic imbalance with high expression of a mutated transcript carrying an oncogenic mutation at codon 12 and many silent mutations, accompanied by relatively low expression of a wild-type (wt) allele. Parallel cultures of RWPE-1 cells retained a wt KRAS genotype. Copy number analysis and sequencing did not support amplification of a large genomic region containing the KRAS gene. Additional studies using 454 Roche sequencing reads showed KRAS variant switching in Case-PE transformed cells, where KRAS-4b was found as the predominant transcript variant, compared to the KRAS-4a variant that was primarily expressed in RWPE-1 cells and in a normal prostate epithelium donor. These data are consistent with KRAS driven proliferation pathways found in spontaneous tumors and transformed cell lines. It is well known that arsenite is not a direct mutagen. Thus, further investigation of the molecular and genomic events underlying increased expression and mutation of KRAS might help explain the ability of arsenite to malignantly transform RWPE-1 cells in this in vitro model exposure system.
Impacts of Gut Bacteria on Oral Bioaccessibility of Arsenic in Soils Using a Multi-compartment In Vitro Gastrointestinal Model

University of North Carolina at Chapel Hill, Chapel Hill, NC, and 2US EPA, Research Triangle Park, NC.

The World Health Organization lists arsenic as one of the top 10 chemicals of major public health concern due to its high level of toxicity, worldwide prevalence, and exposure of millions of people around the world to elevated levels (>100 µg/L). Understanding the factors that regulate physiological absorption (i.e. bioavailability) of arsenic as well as arsenic effects on the gastrointestinal system upon oral ingestion can lend insight into exposure and potential ways to mitigate the potential for toxicity. For example, low pH of gastric fluids and metabolism of arsenic by gut bacteria have been found to decrease dissolution and absorption of inorganic arsenic in vitro. Different food consumptions of arsenic from food sources may cause different bioaccessibilities in the body, and after oral ingestion, the body’s response to these factors remains understudied. In this study, bioaccessibility of arsenic in two standard reference materials (i.e. sodium arsenate, hexavalent, and NIST 2710a) was assessed in a multi-compartment simulated gastrointestinal (GI) system consisting of a stomach, small intestine, and colon which contained gut bacteria sourced from the feces of female mice. For the arsenic bioaccessibility assay, soluble and insoluble arsenic were separated using a series of centrifugation and filtration steps. The concentrations of arsenic in each fraction were measured using neutron activation analysis. Colon bacteria from a mouse that had been exposed to arsenic before weaning were characterized using quantitative microbiology and 16S rRNA sequencing. For both reference materials, the bulk of the arsenic remained insoluble in all GI compartments. The gut bacteria community structure contained a host of microbes (e.g. Bacteroidetes, Firmicutes, Clostridia, Lactobacillus, and Proteobacteria), which was found in the human colon and the microbiota remained unchanged before and after acute arsenic exposure.

Chronic Exposure to Arsenic and High-Fat Diet Induces Sex-Dependent Renal Effects

Y. Zhang, J. Young, M. Kong, J. Freedman, and L. Cai.
University of Louisville, Louisville, KY; and 2Jilin University, Chang Chun, China.

Obesity is one of the most common public health problems and it increases the risk of renal disease. Exposure to arsenic, a well-known global contaminant, is also associated with kidney disease. Chronic exposure to arsenic causes various health effects which may induce oxidative stress. There is a paucity of data on the combined effects of whole life, low-dose arsenic exposure and high fat diet (HFD) on the kidney. Additionally, gender differences in this response have not been explored. The present study aimed to determine the effects of combined arsenic and HFD on markers of kidney disease and gender-specific differences in the response. C57BL/6J mice were exposed to the 100 ppm arsenic via drinking water from conception to sacrifice. Dam mice were continuously exposed to arsenic before weaning. After weaning, mice were divided into HFD (42% calorie as fat) and normal or low fat diet (LFD, 13% calorie as fat) groups. At 10 and 24 wks, mice were sacrificed and kidneys harvested. We found HFD feeding increased body-weight gain compared to control. Exposure to arsenic slightly reduced HFD-increased body-weight gain in male mice, but further increased HFD-increased weight gain in female mice. Blood arsenic levels were very low without significant differences among groups at both time-points. There was no difference for renal arsenic levels between control and HFD-fed groups. However, As feeding significantly reduced renal arsenic accumulation in both sex groups at both time-points. Histological analysis showed that arsenic aggravated obesity-induced glomerular area expansion, mesangial matrix accumulation, and fibrosis. HFD induced renal inflammation and fibrosis, reflected by increased IL-1β, Lactate dehydrogenase, fibronectin, and CTGF. Arsenic exposure caused significantly increases in HFD-induced inflammatory and fibrotic effects, which were more pronounced in male mice. In female mice, there was a transient increase in antioxidant levels at 10 wks time-point, but significantly decreased at 24 wks in arsenic/HFD group. Therefore, we concluded that arsenic exposure caused time and sex-dependent alterations in HFD-induced kidney damage. In general, male mice had more severe responses than female mice.

The Gut Microbiota Modulates As-Disrupted Lipid and Cholesterol Homeostasis

University of North Carolina at Chapel Hill, Chapel Hill, NC, and 2North Carolina State University, Raleigh, NC.

Arsenic (As)-induced LXR/RXR signaling inhibition is a potential mechanism underlying the cardiovascular effects caused by As. The gut microbiota can influence As toxic effects; however, whether it plays a role in As-induced LXR/RXR signaling inhibition and the subsequent lipid and cholesterol dysbiosis is still unknown. Here, we compared the As effects on the LXR/RXR signaling, lipid and cholesterol homeostasis in conventional mice and gut microbiota-disrupted mice. We investigated the hepatic gene expression by RNA-seq and we found As exposure significantly perturbed the LXR/RXR signaling axis and cholesterol synthesis pathway in conventional mice. After validated by qPCR, we found the expression of sreb1c, hmgcr, and cyp7a1 as well as that of cholesterol efflux genes, including abca1, abcg5, abcg8, and c63e, was inhibited by As exposure in conventional mice but not in AB-treated mice. Similarly, As exposure inhibited the hepatic expression of ldr and scarb1, which are involved in reverse cholesterol transport (RCT), in conventional mice. By contrast, 1 ppm As exposure increased the mRNA levels of ldr and scarb1 in AB-treated animals. Correspondingly, 1 ppm As exposure exerted opposite effects on the serum cholesterol levels in the two types of mice, increasing the serum cholesterol levels in conventional mice but decreasing these levels in AB-treated mice. Serum lipid levels, especially triglyceride (TG) levels, were increased in conventional mice exposed to 1 ppm As, while As exerted only minimal effects on the serum lipids in AB-treated mice. Liver lipid patterns were also differentially altered in the two types of mice exposed to 1 ppm As. In conclusion, gut microbiome disruption by antibiotics reverses the As-induced inhibition of the expression of downstream LXR/RXR signaling pathway genes and influences As-induced cholesterol and lipid homeostasis disorders. Therefore, the gut microbiota is a critical factor regulating As-induced LXR/RXR signaling perturbation, and modulation of the gut microbiota could be a promising intervention strategy to reduce the toxic effects of As on lipid and cholesterol homeostasis.

Building an Adverse Outcome Pathway Network for Arsenic-Induced Diseases

US EPA, Research Triangle Park, NC; 2US EPA, Cincinnati, OH; and 3US EPA, Washington, DC.

Arsenic exposure has been associated with numerous diseases ranging from cancers of the bladder, skin and lung, to metabolic diseases such as cardiovascular disease and diabetes mellitus, as well as adverse pregnancy outcomes such as spontaneous abortions, low birth weights, and cognitive impairments of young children exposed either in the womb and or in early life. Multiple epidemiologic as well as animal studies have provided evidence that arsenic exposure can increase the human health risk for these diseases; however, the molecular events by which arsenic contributes to these diverse disease states is yet to be fully elucidated. Adverse outcome pathways (AOPs) are data-informed constructs that illustrate series of biological events leading to adverse effects. Our goal was to use the AOP framework to organize the abundance of information about arsenic-related diseases and identify important key events and possible knowledge gaps, specifically using a cancer example (bladder cancer) and a noncancer example (diabetes). To construct AOPs for these independent disease states, we performed a literature search in PubMed and identified peer reviewed medical reviews that focused on the molecular events involved in these idiopathic diseases. Using these publications we identified key events and key event relationships in the progression of these diseases and built the AOPs. We then compared these AOPs against the idiopathic disease pathways in the Kyoto Encyclopedia of Genes and Genomes (KEGG), and observed that our AOP constructs aligned well with the pathways in the KEGG database. We then began overlaying information from published arsenic mechanistic studies, and in doing so, we identified key events in the progression and culmination of arsenic-induced bladder cancer and arsenic-induced diabetes. This approach was helpful in informing susceptibility and identifying key mechanistic steps and data gaps in the onset of these two arsenic-related diseases. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA. Mention of trade names or commercial products does not constitute endorsement or recommendations for use.
2327 The Role of O-GlcNAcylation in Driving Arsenic-Linked Metabolic Syndrome

M. Dodson, and D. Zhang. University of Arizona, Tucson, AZ.

Chronic exposure to inorganic arsenic (iAs), mainly via contaminated drinking water, is linked to an enhanced risk of developing cardiovascular, kidney, and respiratory diseases, as well as some cancers and type II diabetes. Importantly, chronic iAs exposure can affect populations worldwide, from the United States, Canada, and Mexico, to Taiwan, China, and Bangladesh, where in many cases the iAs concentrations in the water significantly exceed the World Health Organization (WHO) recommended limit of 10 μg/L. Among the pathologies linked to prolonged exposure to iAs is metabolic syndrome, which is defined by an increase in a specific subset of metabolic risk factors, including obesity, dyslipidemia, insulin resistance and inflammation, all of which are associated with cardiovascular disease and type II diabetes. Key to the progression of metabolic diseases is a shift from normal homeostatic metabolism to a new metabolic program that is pro-pathogenic. As such, understanding the metabolic reprogramming that occurs in tissues affected during the progression of metabolic syndrome, particularly upon exposure to environmental toxins, is vital to enhancing current and future patient therapies. One key metabolic pathway is the hexosamine biosynthesis pathway (HBP), which is responsible for utilizing ~2-5% of the cell’s glucose to produce UDP-GlcNac, a key metabolite used in the O-GlcNAcylation of target proteins. Altered HBP activity, as well as significant changes in protein O-GlcNAcylation, have both been shown to contribute to the progression of metabolic syndrome. Here, we show that iAs treatment enhances global protein O-GlcNAcylation both acutely and chronically, with mass spectrometry data revealing a number of critical targets involved in glucose metabolism, mitochondrial function, vesicle trafficking, and proteostasis, among others. Differentiated NIH-3T3L1 adipocytes exposed to arsenic demonstrated significant changes in adipogenesis and insulin signaling compared to their control counterparts, with knockdown of OGT, the enzyme responsible for adding protein O-GlcNAcylation to proteins, partially rescuing the arsenic phenotype, inferring a key role for altered protein O-GlcNAcylation in driving arsenic-induced metabolic changes. Because iAs exposure increases the prevalence of disease in human populations, the effects of arsenic on the molecular, cellular, and pathophysiologic mechanisms that contribute to disease progression will prove extremely valuable in the generation of preventive and therapeutic strategies, as well as in the identification of biomarkers, for the general populations at risk.

2328 Arsenic-Induced Perturbations of the GR Pathway in Trophoblasts: Implications for Placental Dysregulation

Exposure to inorganic arsenic (iAs) is a public health issue as prenatal exposures to iAs are associated with adverse cognitive outcomes, low birthweight, spontaneous abortion, and infant mortality, among others. Previous research in non-placental cells has shown that iAs dysregulates the glucocorticoid receptor (GR) pathway. As this pathway is a critical regulator of cell signaling in the placenta, such dysregulation may contribute to the observed effects of prenatal iAs exposure. In this project, we set out to investigate whether iAs exposure modulates the expression of the GR signaling pathway in placental cells and a potential mechanism involved in this modulation. To investigate disruption of the GR pathway by iAs exposure, JEG-3 placental trophoblasts were treated with non-cytotoxic, environmentally-relevant doses of iAs (0.5-3 μM) for 24 hours and assessed for changes to GR-associated genes mRNA expression, protein expression, and DNA methylation. Results demonstrated that iAs treatment alters the expression of 12 GR-associated genes that play a role in nutrient transport, placental growth, cell survival, and embryonic implantation. These genes include Aquaporin 1 (AQPI), Period Homolog 2 (PER2), Metallothionein 2A (MT2A) and Serum-GC-regulated kinase 1 (SGK1), among others. Interestingly, seven of these 12 genes displayed a biphasic dose-response relationship, with low doses (0.5 μM) induced expression and high doses (3 μM) repressed expression. Treatment with iAs was not associated with changes in total trophoblast GR protein expression at any dose as determined by Western blot. Lastly, CpG methylation levels were also measured in trophoblasts after iAs treatment using the EPIC 850 K Illumina platform. Changes in DNA methylation levels were observed in all 12 genes that displayed changes in mRNA expression as a result of iAs treatment, suggesting a role for the epigenome in this altered mRNA expression. This study therefore supports prior reports that iAs acts as an endocrine disruptor and provides evidence of a novel mechanism by which prenatal iAs exposure may induce adverse birth outcomes.

2329 Metabolism of Arsenic in Genetically Diverse Collaborative Cross Mice

Mice have been preferred animal models for laboratory studies focusing on adverse effects of chronic exposure to inorganic arsenic (iAs). Like humans, mice metabolize iAs to form monomethylated and dimethylated metabolites (MAs, DMAs). However, mice metabolize iAs more efficiently than humans, resulting in a faster clearance and lower tissue retention. This may explain why some of the effects of iAs reported in humans have been difficult to reproduce in mice. The goal of this study was to find a mouse strain in which the metabolism of iAs resembles that in humans. Epidemiologic data suggest that the efficiency of iAs methylation depends in part on polymorphisms in AS3MT. The Collaborative Cross (CC) is a panel of recombinant inbred mouse strains designed to model genetic diversity of human populations. We examined iAs metabolism in male mice from 12 CC strains with different As3mt haplotypes or different levels of As3mt expression in the liver. The mice were exposed to iAs in drinking water (0.1 or 50 ppm) for one week and As metabolites were analyzed in urine and livers. We found significant differences in sum of As species and proportions (%) of iAs, MAs and DMAs, which were more pronounced in the liver as compared to urine, particularly in mice exposed to 50 ppm As. At this exposure level, large variations among the strains were found in hepatic %iAs (15-48%), %MAs (16-29%), and %DMAs (29-66%). In urine, DMAs represented 90-99% of total As in all CC strains regardless of exposure. In addition, %DMAs in urine did not correlate with sum of As species in the liver. Thus, the proportions of As species in urine were not representative of the internal exposure. Notably, As3mt mRNA expression in the livers of the CC mice exposed to 50 ppm correlated negatively with %iAs (R²=-0.35, P=0.013) and positively with %DMAs (R²=0.44, P=0.0014) in the liver. No significant correlations were found between As3mt expression and the proportions of As species in livers of mice exposed to 0.1 ppm, or in urine regardless of exposure level. Thus, we have not found yet a mouse strain in which proportions of As species in urine match those reported in human studies (10-30 %iAs, 10-20% MAs, 60-70% DMAs). However, the CC strains in which we observed low %DMAs in the liver after exposure to 50 ppm As (suggesting inefficient iAs methylation) may serve as better models for studies aiming to reproduce effects of iAs described in humans.

2330 Using the Zebrafish Model System to Define Developmental Arsenic Toxicity

K. G. Kiper, and J. L. Freeman. Purdue University, West Lafayette, IN.

Arsenic (As) is an environmentally abundant environmental toxicant and in its inorganic form is highly toxic. High levels of As in soil can dissolve into water, contaminating ground water, the most common source for human exposure. Both the US EPA and the Department of Health and Human Services (DHHS) have determined that both acute and chronic exposure to high levels of inorganic As can cause cancer; however, evidence is increasing that chronic exposure to As in children may also be associated with disruption to cognitive development and function. While the mechanism of action of As is not completely understood, As at low levels can cause a range of cardiovascular and circulatory health effects that can directly and indirectly translate to insults of the brain. This study tests the hypothesis that embryonic exposure to As results in specific changes to survival, behavior, and morphology of larval zebrafish. Zebrafish embryos were treated with two concentration ranges of As (Sodium Arsenite) [0, 0.1, 0.5, 1, 5, 10 μM] or [0, 0.05, 0.1 mM] immediately after fertilization and exposed through 120 hours post fertilization (hpf). The higher concentration range was first used to calculate LC50s every 24 hours for As during the developmental time period through 120 hpf. The lower concentration range was then applied to assess impacts to behavior using the visual motor response (VMR) assay and morphology including total larval length, head length, head width, and brain length at 120 hpf. The LC50s were calculated at 3.2 mM, 3.4 mM, 2.5 mM, 1.1 mM, and 1.7 mM at 24, 48, 72, 96, and 120 hpf, respectively. The larval VMR results indicate that the 0.1 mM treated larvae were hypoactive (p<0.05). Significant differences were also observed at the morphological endpoints in the 0.1 mM treatment group (p<0.05). This study will set the stage for further exploration of the influence of As in mixtures with other metals.
2331 Metabolic Phenotype of Genetically Diverse Collaborative Cross Mice Exposed to Arsenic

Arsenic methyltransferase (As3mt) is the key enzyme in the pathway for methylation of inorganic (iAs) and organic arsenic. Alternative splicing pathways play an essential role in detoxification of iAs. As3mt converts iAs to mono- and dimethylated metabolites (MAs, DMAs) that are excreted mainly in urine. Polymorphisms in As3mt have been identified as the single most important genetic factor affecting iAs metabolism and susceptibility to adverse effects of iAs exposure in population studies. However, the relationship between As3mt polymorphism and the adverse outcomes of iAs exposure have never been examined in animal models. The goal of the present study was to examine effects of iAs exposure on metabolic phenotypes of mice from two Collaborative Cross strains, CC021/Unc (CC021) and CC027/ TauUnc (CC027), that have different As3mt haplotypes (NOD/ShiLtj and WSB/Eii, respectively) and different SNPs in As3mt gene. The patterns of iAs metabolism in these two strains, specifically the proportions of total arsenic present as iAs (%iAs) and DMAs (%DMAs) in the liver and urine, are also significantly different. Here, the male mice from the two strains were exposed to iAs in drinking water (0.1 or 50 ppm) for 11 weeks. Blood glucose and plasma insulin levels were measured after 6-hour fasting and 15 min after ip. injection of glucose (2 g/kg b.w). Body composition (%fat and %lean mass) were determined using MRI. Prior to iAs exposure, fasting glucose was higher and insulin lower in CC027 as compared to CC021 mice. iAs exposure had no statistically significant effects on either glucose or insulin measures. However, it affected the body composition and the effects differed between the strains. After exposure to 50 ppm iAs, %fat was ~3-fold higher in CC021 as compared to CC027 mice, while %lean mass was lower (p<0.05). Similar differences were found in mice exposed to 0.1 ppm iAs, but these differences did not reach statistical significance. No statistically significant differences were found in body composition of the unexposed CC021 and CC027 controls. CC021 mice had significantly higher fasting and 15-min plasma insulin levels than CC027 mice regardless of the treatment. These results suggest that iAs exposure influences adiposity of CC021 and CC027 mice, but the direction of these effects may depend on As3mt genotype and/or on other genetic characteristics of these mouse strains.

2332 Sexually Dimorphic Hepatic Responses to Environmental Arsenic Exposure in a Mouse Model of Non-alcoholic Fatty Liver Disease

W. H. Watson1, J. L. Young1, T. J. Burke1, T. Kalbfleisch1, L. Cai1, C. States1, G. E. Arteel1, and J. H. Freedman1. University of Louisville, Louisville, KY; and 2University of Pittsburgh, Pittsburgh, PA.

Obesity is a major risk factor for the development of non-alcoholic fatty liver disease (NAFLD), but progression of the disease is dependent on additional factors. Recent studies suggested that inorganic trivalent arsenic (arsenite) is such a factor. The purpose of the present study was to delineate pathways that are altered by arsenic in a mouse model of NAFLD. Male and female C57BL/6J mice were continuously exposed to 100 ppm arsenite in drinking water starting 2 weeks before conception, and this was combined with consumption of a Western-style high fat diet (HFD) after weaning for up to 6 months. Normal drinking water and defined low fat diet (LFD) were used as controls. Changes in liver pathology, redox status and gene expression were assessed at 10 and 24 weeks after weaning. Consumption of HFD for 6 months resulted in obesity and steatosis (fatty liver) in both male and female mice. In mice fed LFD, arsenite exposure had no observable effect in males or females. The HFD produced more severe liver injury in male mice than in female mice. Females gained more weight with the combination of arsenic and HFD than they did on HFD alone, an effect not seen in males. RNA-seq analysis was performed at 10 weeks after weaning. In female mice, 76 genes were differentially expressed in response to arsenite in the context of HFD. Of these, 12 (16%) encoded xenobiotic metabolizing enzymes. In male mice, 26 genes were differentially expressed. Five of these (19%) were genes involved in immunity and inflammation. There were no differences in antioxidant gene expression, hepatic glutathione/glutathione disulfide levels, or plasma cytokine/cytokine concentrations. Sex-specific differences in hepatic gene expression and consumption of different diets contributed to differences in the ways liver injury is manifested in response to whole-life exposure to environmental arsenic.

2333 Alternative Splicing Events and RT-PCR Analysis of SHC1 in Arsenic Exposed Human Keratinocytes

A. P. Ferragut Cardoso1, M. Banerjee1, L. Al-Eryani1, M. A. Sayed1, J. W. Park1, and J. C. States1. 1University of Louisville, Louisville, KY; and 2National Cancer Institute, Bethesda, MD.

Chronic arsenic exposure in drinking water is associated with an increased risk of developing skin, lung and urinary bladder cancer. The molecular etiology of arsenic induced cancer remains elusive. Pre-mRNAs are often subject to alternative splicing that either includes or excludes exons in the mature mRNA resulting in synthesis of functionally distinct protein isoforms. The imbalance in isoform species can result in pathogenic changes in critical signaling pathways. Arsenic exposure has been reported to induce differential mRNA splicing. Differential RNA splicing was investigated in a model of skin carcinogenesis to test the hypothesis that alternative splicing events induced by arsenite exposure play a role in skin carcinogenesis. Multiple cultures of HaCaT cells, 4 each with 0 (As-) or 100 (As+) nM NaAsO2, were maintained for 7 weeks. We mapped 100x2bp paired-end RNA-seq reads to the human genome (hg38) and transcriptome (Ensembl, release 82) using the software STAR (v2.5) allowing up to 3 nt mismatches per read and up to 2 nt mismatches per 25 nt seed. To identify differential arsenic events between the As- and As+ samples, we used rMATs v3.2.5 to identify differential alternative splicing events from strand specific RNA-seq data corresponding to five basic types of alternative splicing patterns. As+ group was compared to As- to identify differentially spliced events with an associated change in percent-spliced-in (ΔPSI) of these events. Skipped exons (SE) with > 10 event readings and mean ΔPSI > 30% were analyzed. Based on functional relevance, Src homology 2 domain containing adapter protein 1 (SHC1) was selected for validation by RT-PCR. 1,149 SE events were significantly different between As- and As+ 66 mRNA isoforms - and 61 genes - showed > 10 event readings and mean ΔPSI > 30%. For SHC1, RNA-seq predicted SE counts decreased in As+. However, the RT-PCR did not detect significant changes between the two isoforms. Arsenic exposure causes alternative splicing events that might impact disease pathology. Further SHC1 sequencing and protein validation, and investigation of other alternative spliced targets would be essential to elucidate the mechanisms involved in arsenic-induced skin carcinogenesis. Funding: NIH grants R01ES027778, R21ES023627, P20GM103436, R15GM126446.

2334 Investigating Cell Type Specific immune Responses to Acute Influenza A Infection in Adult Mice Exposed to Arsenic In Utero

B. C. Goodale1, K. S. Hsu1, K. E. Ely1, B. A. Stanton1, and R. I. Enelow1. 1Geisel School of Medicine at Dartmouth, Hanover, NH; and 2Dartmouth College, Hanover, NH.

Exposure to inorganic arsenic (iAs) via drinking water is associated with numerous adverse health effects, including lung disease, and impacts hundreds of millions of people worldwide. iAs exposure early in life is of particular concern and has been linked in epidemiological studies with increased respiratory infections during infancy, as well as increased morbidity and mortality from non-malignant lung diseases in adulthood. Studies in mouse have similarly found that iAs exposure increases morbidity from respiratory virus infection. We examined changes in immune cell populations and gene expression to investigate the effects of iAs exposure on cell-type specific gene expression and immunopathologic responses during adulthood. Pregnant dams were given Control or 100 µg/L iAs in drinking water ad libitum. Upon birth, iAs was removed from the drinking water and pups matured to adulthood (>7 weeks of age), when they were inoculated with a sublethal IAV infection. We examined changes in cell populations and gene expression in the lung using single cell RNA sequencing (sc-RNA-seq), and assessed inflammatory response and damage by measuring cytokines, immune cell infiltration, and albumin in bronchoalveolar lavage fluid (BALF). Mice exposed to iAs in utero had significantly altered immune cell populations in the lung, as detected by sc-RNA-seq, which correlated with significantly increased immune cells and IL1β in the BALF. We then used cell-type specific gene expression data to predict signaling networks that mediate the hyperinflammatory response. These data provide insight into molecular changes in immune cells that result from in utero iAs exposure and may mediate lasting predisposition to respiratory disease.
Differential Gene Expression Patterns in Subcutaneous and Intra-peritoneal Tumors Produced by Urotsa Cells Malignantly Transformed by Cadmium and Arsenite

Arsenite (As³⁺) and cadmium (Cd²⁺) are environmental toxicants that are associated with the development of various cancers, particularly urothelial cancers. These cancers spread locally requiring the ability of tumor cells to colonize the peritoneal organs following escape from the bladder. This laboratory has developed an in vitro model of bladder cancer by exposing the immortalized urothelial cell line, UROtsa, to As³⁺ and Cd²⁺ resulting in the generation of As³⁺- and Cd²⁺-transformed lines and seven Cd²⁺-transformed cell lines. Of these transformed cell lines three of them (As Name 1, As Name 2, and Cn Name 1) can form tumors in the peritoneal cavity (IP), whereas the rest of the transformed lines form only subcutaneous (SQ) tumors. The goal of this study was to determine if there was a difference in the gene expression patterns of the SQ tumors versus the IP tumors. The histology of the SQ and the IP tumors was similar with the exception of the degree of squamous differentiation, which was significantly lower in the IP tumors when compared to the SQ tumors. There was a decrease in the expression of the keratins (KRTs) 1, 6, 10, 14, 16, and 17 in the IP tumors when compared to the SQ tumors. However, the distribution of the expression of some of the keratins was different between the SQ and the IP tumors. KRT17 was mainly expressed in the well-differentiated areas of the SQ tumors, while expression in the IP tumors was found in the well-differentiated as well as the less-differentiated areas of the tumors. The expression of KRT19 was lower in the well-differentiated areas of the SQ tumors when compared to the IP tumors. In conclusion, the reduced expression of KRTs in the IP tumors suggests that KRTs may play a role in the metastatic spread of the tumors and their reduced expression may facilitate the process of metastasis.

The CD24⁺CD133⁺ Cells Isolated from Human Proximal Tubules Have Proliferative and Regenerative Potential in Response to Insult by the Environmental Toxicant Cadmium

The proximal tubules of the kidney are a major site of toxic insult, cell death and regeneration, and the development of renal tubular diseases. Toxic insult can result from exposure to heavy metals, pharmaceuticals, diabetic induced nephropathy and ischemia. Cadmium an environmental nephrotoxicant accumulates in the proximal tubule cells leading to overt renal damage. Previous studies from our laboratory have shown that the human proximal tubules contain a population of cells co-expressing the cell surface markers CD24 and CD133. This CD24⁺CD133⁺ double positive population is scattered throughout the kidney cortex and is capable of regenerating. Under cell culture conditions, these cells can be expanded and they retain their phenotype and their potential for self-renewal as well as the capacity to differentiate. The goal of this study was to determine the response of this progenitor population to the environmental toxicant cadmium and determine their ability to regenerate and differentiate. Our results suggest that the CD24⁺CD133⁺ proximal tubule cells are more resistant to the toxic effects of cadmium with increased ability to proliferate and regenerate in response to cadmium exposure when compared to the cells that only express CD24, which are more sensitive and lack the proliferative capacity. In addition, the CD24⁺CD133⁺ cells show in vitro tubulogenic, osteogenic, adipogenic and neurogenic differentiation, whereas the CD24⁺ cells lack the ability to differentiate. In conclusion, our study demonstrates that the CD24⁺CD133⁺ cells are the progenitor/stem cells that have proliferative and regenerative capabilities and exhibit multi-lineage differentiation potential, whereas the CD24⁺ cells are the differentiated cells that are sensitive to toxic insults and lack proliferative and regenerative capacities.

Environmental Cadmium Exposure Causes Lung Injury by Dysregulation of Mitochondrial Mechanisms

Y. Go, X. Hu, J. Fernandez, M. Smith, M. Orr, K. Uppal, and D. Jones. Emory University, Atlanta, GA.

Activation of oxidative stress mechanism is commonly associated with toxicity from environmental metals yet delineation of effects of low-dose metal exposures is complicated by positive and negative interactions with dietary factors, infection and other factors. Our previous study showed low-dose cadmium (Cd) toxicity in lung with potentiation of adverse Cd-dependent mechanisms following viral infection, and prevention of low dose Cd toxicity through nutritional selenium supplementation. In the present study, we examined the impacts of Cd burden at a low environmental level on lung metabolism, redox proteome, and inflammation in mice given Cd by drinking water (3.3 mg/L) for 16 weeks. The results showed that mice accumulated lung Cd comparable to non-smoking humans and showed increased levels of lipids in the lung, accompanied by disruption in mitochondrial energy metabolism. In addition, targeted metabolomic analysis showed that Cd-treated mice had increased accumulation of mitochondrial carnitine and citric acid cycle intermediates. The results of redox proteomics showed that Cd-stimulated oxidation of isocitrate dehydrogenase, malate dehydrogenase and ATP synthase. Taken together, our study shows that low dose Cd-enhanced lung inflammation is mediated by the mechanism involving impaired mitochondrial function and oxidative stress. These findings suggest that dietary Cd intake relevant to non-smokers without occupational exposures could be an important variable contributing to human pulmonary disorders.

Prenatal Exposure to Cadmium (Cd) and Postnatal Exposure to Cd and High-Fat Diet (HFD) Impairs Spermatogenesis and Increases Testicular Apoptosis

B. Zhou¹,², A. Gentry³, K. Pagidas¹, J. Young¹, M. Kong⁴, L. Cai⁵, and J. H. Freedman¹. ¹University of Louisville, Louisville, KY; ²Children’s Hospital of JiangXi Province, Nanchang, China; ³China; and ⁴Obstetrics/Gynecology and Women’s Health, Louisville, KY.

Obesity is a global health problem that negatively impacts testosterone levels and the quality of sperm production. The persistent environmental toxicant Cd also affects testicular tissues. The effects of prenatal and postnatal Cd exposure on spermatogenesis and the ability of HFD to further disrupt this process were evaluated. C57BL/6J mice were exposed to the low-dose (L-Cd, 0.5 ppm) or high-dose (H-Cd, 5 ppm) Cd via drinking water from conception to sacrifice. Offspring were continuously given two doses of Cd and fed either normal (NFD, 13% calorie as fat) or HFD (42% calorie as fat) once weaned for 10 and 24 wks and then sacrificed. Testes were harvested, weighted and then processed for metal analysis and histopathology. All round seminiferous tubules per animal were examined for germ cell degeneration and spermatogenesis. Apoptotic death in seminiferous tubules was analyzed by TUNEL staining. Data were analyzed by ANOVA. Exposure to H-Cd and HFD alone caused a significant increase in Cd content in testis. There was also a significant Cd-diet interaction. There was no difference in the number of round seminiferous tubules among animals fed NFD exposed to L-Cd or H-Cd. HFD induced high incidence of seminiferous tubule sloughing. There was an age effect on the incidence of multinucleated large cells within the lumen (24 > 10 wks old mice), which was not affected by Cd or diet. There were significant increases in apoptotic testicular cell death and detached seminiferous tubules, as well as decreased spermatogenesis in animals exposed to H-Cd at 24 wks. HFD caused central germ cell degeneration. These results suggest that chronic exposure to Cd impairs spermatogenesis in mice independent of diet, which may link environmental Cd exposure to ongoing unexplained male infertility.

SPARC Expression at Tumor Initiation and after Tumor Formation in a Bladder Urothelial Carcinoma Model System

Bladder cancer has a strong link to environmental exposure to toxicants. Our system uses this link to model urothelial carcinoma due to heavy metal cadmium (Cd) exposure to examine potential biomarkers. UROtsa bladder cells exposed to long-term, low doses of Cd were studied in 7 independently malignantly transformed cell lines. The resulting microarray analysis identified SPARC as the most repressed gene. SPARC, a secreted protein, has both oncogene as well as tumor suppressor actions depending upon the cancer studied with its role in bladder cancer remaining unclear. Previous lab results indicate significant SPARC repression following even short-term exposure to Cd and SPARC mRNA and protein is barely detectable, if at all, in the 7 Cd-transformed cell lines. Therefore, SPARC was transfected back into the Cd-transformed lines and their ability to form heterotransplant tumors was determined. SPARC was again repressed to undetectable limits in tumor heterotransplants. However, when corresponding stem cell UROospheres were injected, some SPARC expression was maintained in a small percentage of the tumor. In this study,
serial heterotransplant tumors were generated and results showed SPARC expression was not maintained nor increased within the tumor cells, even with successive tumor inoculations of the UROsphere generated tumors. However, stromal SPARC expression was found to increase. Therefore, we hypothesize that SPARC is inhibited within the tumor cells themselves and possibly by high stromal SPARC expression. The origin of SPARC stromal expression in heterotransplants was determined using RT-PCR with human or mouse specific primers. Results show that nearly all the SPARC in the heterotransplants was of mouse and not human origin, indicating that the mouse tumor stroma and not the human tumor cells were responsible for the SPARC expression. Further in vitro experiments showed that SPARC expression in the cell lines was repressed when exposed to exogenous human or mouse SPARC. Additional studies include examining transcription factors in SPARC repression and the role of SPARC in cell attachment and spreading. Overall, SPARC expression appears to play a vital role in tumor formation where high stromal SPARC may repress expression by tumor cells.

2340 Disposition and Toxicity of Cadmium in Wild-Type and BCRP-Null Mice Following Acute Exposure

Cadmium (Cd) is a highly toxic, present in tobacco smoke, paint pigments, Cd-Ni batteries, and fertilizers. Upon exposure, the metal accumulates in multiple tissues including the liver, kidney, testes, and placenta where it induces cellular stress and interferes with hormone production and nutrient homeostasis. The breast cancer resistance protein (BCRP) is an efflux transporter expressed in liver, kidneys, testes, and placenta. Our laboratory has demonstrated that Cd exerts an in vitro overexpression of the human BCRP gene down-regulation. In order to study the effects of Cd on enzymes involved in the detoxification process, the activities of enzymes catalase (CAT) and superoxide dismutase (SOD) were examined by Pearson’s method, revealed positive association between CAT, and SOD triglyceride concentrations compared to control. Correlation, as calculated by Pearson’s method, revealed positive association between CAT, and SOD triglyceride; SOD and plasma triglyceride; as well as ALP and ALT, respectively. The antioxidant enzymes catalase (CAT) and superoxide dismutase (SOD) activities were significantly (p < 0.05) decreased in rat exposed to the toxicants. Induction of Cd2+-cytotoxicity, a response attenuated by pharmacologic inhibition of BCRP. However, it is unknown whether a similar relationship between BCRP and Cd2+ toxicity occurs in vivo. In the current study, we sought to assess the disposition and toxicity of Cd2+ following acute exposure. A single dose of vehicle or CdCl2 (5.5 mg/kg ip) was administered to adult male and female wild-type (WT) and Bcrp-null mice (n=3-6). Tissues were collected at 24 hr for histopathologic evaluation and ICP/MS quantification of Cd levels. There were no noteworthy histopathologic findings in the kidneys or testes from WT and Bcrp-null mice. However, evidence of Cd-induced apoptosis was observed in the livers of Bcrp-null mice. Cd was detectable in all tissue samples from CdCl2-treated mice. At 24 hr, concentrations of Cd were highest in the liver and lowest in the testes with liver and kidney concentrations similar between male and female mice. Interestingly, there was a 30% higher accumulation of Cd (p=0.05) in the kidneys of male Bcrp-null mice compared to WT mice. Additional dose-response and time course studies are being conducted to further determine whether Cd2+ exposure and toxicity differ between WT and Bcrp-null mice. Supported by R01 ES029275, T32 ES007148, and P30 ES005022.

2341 Exposure to Lead and Cadmium Contaminating Metals: A Biochemical, Oxidative Stress and Lipid Profile Study in a Rat Model
O. O. Ogunrinola1, B. B. Sogunwa1, O. A. Ogunrinola2, and O. Ademuyiwa3. 1Lagos State University, Lagos, Nigeria; 2Babcock University, Lagos-Idishin-Remo, Nigeria; and 3Federal University of Agriculture, Abeokuta, Nigeria.

Heavy metals are dangerous environmental bio-accumulative pollutants that affect many organs in human and animals leading to a broad range of physiological, biochemical, and neurological dysfunctions. The study investigated the effect of 0.1 ml per body weight cadmium (cadmium chloride) and lead (lead nitrate) via drinking water on oxidative stress, lipid profile and biochemical parameters of four groups of male rat for thirty days. Control animals received distilled water for the same period. Alanine aminotransferase (ALT), aspartate aminotransferase and alkaline phosphatase concentrations were significantly (p < 0.05) increased by the treatment of cadmium (Cd), lead (Pb) and mixture of both cadmium-lead (Cd-Pb) respectively. The antioxidant enzymes catalase (CAT) and superoxide dismutase (SOD) activities were significantly (p < 0.05) decreased in rat exposed to the toxicants. Induction of Cd and Pb reduced significantly (p < 0.05) the plasma cholesterol and triglyceride concentrations compared to control. Correlation, as calculated by Pearson’s method, revealed positive association between CAT, SOD and plasma triglyceride; SOD and plasma triglyceride; as well as ALP and ALT, AST and plasma cholesterol; while negative association exists between CAT and AST activities. These results demonstrate that Cd, Pb and Cd-Pb induces oxidative and metabolic disturbance which might lead to potential risk of cellular dysfunctions.

2342 Systematic Review on the Effects of a 0.5 μg/dL Blood Lead Level in Children and Pregnant Women
L. Dolan, B. Flannery, and S. Fitzpatrick. US FDA, College Park, MD.

Presently, no safe blood lead level (BLL) in children has been identified. We conducted a systematic review of published, peer-reviewed epidemiological studies to determine whether a BLL of 0.5 μg/dL, which corresponds to dietary lead intake of 3 μg/day in children (aged 0-6) and 12.5 μg/dL in women of childbearing age, is associated with adverse health effects in pregnant women, their offspring or children of all ages. A review article from Health Canada provided the basis for literature prior to 2010, and PubMed and Web of Science were utilized to search from 2010 to February, 2018. We limited our review to studies examining study populations with mean BLL ≤ 20 μg/dL to reduce the influence of high BLL on the results. Review articles, occupational, inhalation, or dermal exposure, neurodevelopmental, in vivo animal, in vitro, in silico, or foreign language studies were excluded. Studies examined the relationship of BLL with several different outcomes, including, but not limited to anthropometric measurements, APGAR score, blood lipids, blood pressure, cardiovascular function, caries, cytogenetic damage, gestational age, hearing loss, hemoglobin, hormone levels, insulin resistance/blood glucose, kidney function, oxidative stress or pertubal onset of children; maternal pregnancy outcome, blood pressure, cardiovascular function, or mental status; and placental weight. Although some studies reported associations between ranges of BLL that included 0.5 μg/dL and changes in endpoints, none clearly identified a BLL of 0.5 μg/dL as an adverse effect level.

2343 Comparing the Relative Bioavailability (RBA) of Lead (Pb) in Soil and Dust

Soil and dust are the predominant sources of Pb exposure for children in the United States. Although quantitation of the intake of Pb from soil and dust ingestion is problematic, the importance of these sources is emphasized by studies that show that reducing levels of Pb in soil and dust lowers blood Pb levels in children. Here, we have used a mouse assay to estimate the RBA for Pb in urban soil and dust. These studies used NIST Standard Reference Materials (SRM) with certified mass fraction values for Pb as test materials. SRMs tested were 2584 (indoor dust), 2587 (soil containing Pb from paint), and 2710a (Montana I soil). Pb acetate (PbAc) was used as a source of highly soluble Pb. The test materials were used to amend AIN-93G rodent diet that was consumed by adult female C57BL/6 mice in an established assay for estimation of Pb bioavailability. Final levels of Pb in test diets ranged from about 1 to 30 parts per million. RBA estimates for Pb in different test materials were derived from linear regression analysis of the relation between cumulative Pb intake from amended diet and the concentration of Pb in skeleton or blood, two tissue biomarkers of Pb exposure. For blood, the rank order of slopes of regression lines from highest to lowest was 2584 > PbAc > 2587 > 2710a. For soil, the rank order of slopes of regression lines from highest to lowest was PbAc > 2584 > 2587 > 2710a. Thus, the rank order of RBA estimates derived from blood is 2584 > 2587 > 2710a. The rank order of RBA estimates derived from skeleton is 2584 > 2587 > 2710a. Differences in the RBA for Pb in different soil and dust samples may reflect differences in the speciation of Pb present in these materials or modifying effects of constituents that are present in some environmental media. Continuing studies of matched soil and dust samples collected from individual homes will provide new insights into the relation between sample composition, Pb speciation, and bioavailability. This abstract does not reflect US EPA policy.

2344 A Rare Case of Severe Life-Threatening Lead Poisoning Due to Accidental Exposure: Diagnosis, Treatment, and Prognosis
X. Du1, W. Zheng2, and Y. Ye1. 1Beijing Chaoyang Hospital, Beijing, China; and 2Purdue University, West Lafayette, IN.

Chronic long-term, low-dose environmental exposure to lead (Pb) has been extensively studied in large cohorts throughout the world. Clinical cases of occupational Pb exposure have also been reported among miners, smelters and battery workers. However, acute and severe Pb intoxications due to accident
exposure that threaten human life are rarely seen in literature. Here we report one clinical case administered to the emergency room in Beijing Chaoyang Hospital with life-threatening Pb intoxication. A 27-year-old woman initially complained menstrual pain and was prescribed a powdered Chinese medicine. The woman, however, was instead mistakenly provided with the pure Pb powder. Two hours after taking 12 grams Pb powder, she suffered from abdominal pain, vomiting, and diarrhea. Laboratory examinations revealed high lead levels in blood and urine. She was treated with hemofiltration, followed by EDTA chelation for six courses (3-day EDTA/4-day pause). After treatment, anemia and liver dysfunction were recovered, BLL and ULL turned to normal, and majority clinical symptoms relieved. In another case, a 42-year-old man worked in a lead and manganese (Mn) smelting factory for 5 years. He was brought to the emergency room with severe nausea, vomiting, colic, and irritability. He presented chronic encephalopathy, anemia look and accompanied with the right shoulder pain. BLL and ULL were 64.8 μg/dL and 0.383 mg/L, respectively; however, both blood and urinary Mn were normal. EDTA chelation increased urinary Pb excretion and improved clinical symptoms at 1 day. Yet high patients signed an informed consent and completed a health survey. This study was approved by the Ethics Committee of the University of Cartagena. The K-BIT intelligence test was administered to measure the IQ; blood Pb levels (BLL) were evaluated by graphite furnace atomic absorption spectroscopy; whole blood was used for hematology; gene expression was quantified from blood mRNA using RT-PCR; The ALAD polymorphism (rs 1800435) was characterized by PCR-RFLP. The BLL average was 3.3±0.2 μg/dL; BLLs above the CDC reference level (5 μg/dL) were found in 15.3% of studied samples. The highest BLL were detected in the fishing community of Tasajera, where the 97.5th percentile was 22.1-fold greater than the national value reported for the US. Being male, maternal breastfeeding and natural childbirth were associated with greater BLLs. Spearman correlation analysis showed negative associations between BLL and IQ, weight, stature, BMI, neutrophil-basophil and neutrophil-eosinophil ratios, whereas positive correlations appeared for BLL and platelets, monocytes and neutrophil-monoocyte ratio. The expression of ADAM, SOD, p53 and INF-γ mRNA decreased with Pb exposure, whereas TNF-α mRNA increased. BLL were not significantly different with respect to the ALAD genotypes. In short, Pb exposure impacts IQ, physical development, hematological markers and cytokine gene expression in children from the Colombian Caribbean. Here, we present evidence that these techniques produce results equivalent to the colony filter lift assay. And that the intensity of the blue color is related to the concentration of lead. Previously, we relied on replica plating to propagate yeast colonies. However, in this study we bloated and dried yeast two-hybrid colonies onto filter paper. Despite the stresses placed on the yeast, once the filters were placed on normal media, they experienced a full recovery with the system intact. Traditionally, the use of liquid nitrogen is required for the colorimetric system to function. We provide two different methods instead: the use of a standard freezer or dry ice combined with ethanol. This allows for ease of use of the system for those without specialized equipment or technical knowledge. Furthermore, the system can be grown on lead concentrations as high as 10,000 ppm without loss of function.

2345 Lead Impairs Intellectual and Physical Development, Platelet Number, Gene Expression of Cytokines, and Oxidative Stress Status in Children from the Colombian Caribbean
University of Cartagena, Cartagena, Colombia.

Lead (Pb) is a neurotoxic element that affects children health, especially those living under poverty. The objective of this research was to evaluate Pb exposure and its relationship with IQ, hematological markers and gene expression in children from the Colombian Caribbean. A total of 908 blood samples were collected from participants between 5 and 16 years of age. Yet high levels of Pb were found. The ALAD polymorphism (rs 1800435) was characterized by PCR-RFLP. The BLL average was 3.3±0.2 μg/dL; BLLs above the CDC reference level (5 μg/dL) were found in 15.3% of studied samples. The highest BLL were detected in the fishing community of Tasajera, where the 97.5th percentile was 22.1-fold greater than the national value reported for the US. Being male, maternal breastfeeding and natural childbirth were associated with greater BLLs. Spearman correlation analysis showed negative associations between BLL and IQ, weight, stature, BMI, neutrophil-basophil and neutrophil-eosinophil ratios, whereas positive correlations appeared for BLL and platelets, monocytes and neutrophil-monocyte ratio. The expression of ADAM, SOD, p53 and INF-γ mRNA decreased with Pb exposure, whereas TNF-α mRNA increased. BLL were not significantly different with respect to the ALAD genotypes. In short, Pb exposure impacts IQ, physical development, hematological markers and cytokine gene expression in children from the Colombian Caribbean. Here, we present evidence that these techniques produce results equivalent to the colony filter lift assay. And that the intensity of the blue color is related to the concentration of lead. Previously, we relied on replica plating to propagate yeast colonies. However, in this study we bloated and dried yeast two-hybrid colonies onto filter paper. Despite the stresses placed on the yeast, once the filters were placed on normal media, they experienced a full recovery with the system intact. Traditionally, the use of liquid nitrogen is required for the colorimetric system to function. We provide two different methods instead: the use of a standard freezer or dry ice combined with ethanol. This allows for ease of use of the system for those without specialized equipment or technical knowledge. Furthermore, the system can be grown on lead concentrations as high as 10,000 ppm without loss of function.

2346 Use of Zea mays Cob (Corn cob) as an Economic Adsorbent for the Adsorption of Lead (II) Ions from Aqueous Solution
C. Onwoodi, C. Uche and L. Petrik
1University of the Western Cape, Cape Town, South Africa; and 2Lagos State University, Lagos, Nigeria.

The increase in industrial activity is contributing to the significant upswing of potential toxic metals (PTMs) pollution in water resources. The PTMs thereby constitute a threat on the land and aquatic life. This study entails the use of corncob (CC), a biopolymer to absorb lead (II) ions from aqueous medium by batch process. The CC was characterised using analytical techniques: Fourier transform infrared (FTIR), scanning electron microscopy (SEM), thermogravi- metry analysis (TGA), x-ray diffraction (XRD) and point of zero charge (PZC). The pH, CC dosage, initial Pb (II) ions concentration, contact time, and temperature were optimized. The optimum pH was achieved at 3.00, with adsorp- tion of 4.64 mg/g. The kinetic data fitted better to pseudo-second order, and the accuracy was tested by three statistical tools: sum of square error, Chi-square and normalized standard deviation. The experimental data was applied to five isotherm model: Langmuir, Freundlich, Temkin, Dubinin- Kaganer-Raduskevich (DKR) and Halsey. DKR and Temkin best described the equilibrium adsorption data with regression coefficient (R2> 0.80). The ther- modynamic parameters values of standard enthalpy (ΔH°) 4.00 KJ/mol, standard entropy (ΔS°) 4.10 J/mol K and the Gibb free energy change revealed that the adsorption process was endothermic, spontaneous and feasible in nature. The results highlight the potential capability of corn cob in the effective removal of lead ions from aqueous solution.

2347 Development and Use of a Yeast Two Hybrid System to Detect Lead
D. Bianculli and M. E. Gillespie
St. John’s University, Jamaica, NY.

Despite advances, lead contamination continues to be an issue. This includes industrial sectors and perhaps more impactfully, lead contamination in residential areas which includes schools. We propose a methodology of lead detection using yeast as a living biodetector; a simple organism that can be easily grown and maintained in multiple environments. Here we use yeast strains that contain the yeast-two hybrid system, first developed by Fields and Song. In brief, this system is used to identify new protein-protein interactions. The system has been altered to be used as colorimetric biological detector of lead. With properly implemented controls, one can identify the presence of lead (Pb) in a simple media mixture through a visual readout. Here, we use a LacZ reporter system to facilitate the colorimetric indicator. The colorimetric indicator used in the system changes yeast colonies from blue to white when lead is present in the yeast. Here, we present evidence that these techniques produce results equivalent to the colony filter lift assay. And that the intensity of the blue color is related to the concentration of lead. Previously, we relied on replica plating to propagate yeast colonies. However, in this study we bloated and dried yeast two-hybrid colonies onto filter paper. Despite the stresses placed on the yeast, once the filters were placed on normal media, they experienced a full recovery with the system intact. Traditionally, the use of liquid nitrogen is required for the colorimetric system to function. We provide two different methods instead: the use of a standard freezer or dry ice combined with ethanol. This allows for ease of use of the system for those without specialized equipment or technical knowledge. Furthermore, the system can be grown on lead concentrations as high as 10,000 ppm without loss of function.

2348 Inhibition of Insulin Secretion by As, Cd, and Mn Is Associated with Metal-Specific Shifts in miRNA Profiles
R. Beck1, M. Chandi1, M. Styblo1, and P. Sethupathy2
1University of North Carolina at Chapel Hill, Chapel Hill, NC; and 2Cornell University, Ithaca, NY.

Type 2 diabetes (T2D) is a complex metabolic disorder characterized by hyperglycemia. While diet and exercise can influence the risk of T2D, chemical exposures have also been shown to impair mechanisms regulating glucose homeostasis and thereby increase T2D prevalence. Laboratory and population studies have shown that exposure to inorganic arsenic (iAs) impairs insulin secretion from pancreatic β-cells and leads to fasting hyperglycemia and/ or impaired glucose tolerance. Exposures to other metals, including cadmium (Cd) and manganese (Mn), have also been linked to T2D phenotypes, but data on the effects of these metals on insulin secretion from pancreatic β-cells is limited. In this study, we used a reporter system to monitor the secretion of insulin from yeast strains that contain the yeast-two hybrid system, first developed by Fields and Song. In brief, this system is used to identify new protein-protein interactions. The system has been altered to be used as colorimetric biological detector of lead. With properly implemented controls, one can identify the presence of lead (Pb) in a simple media mixture through a visual readout. Here, we use a LacZ reporter system to facilitate the colorimetric indicator. The colorimetric indicator used in the system changes yeast colonies from blue to white when lead is present in the yeast. Here, we present evidence that these techniques produce results equivalent to the colony filter lift assay. And that the intensity of the blue color is related to the concentration of lead. Previously, we relied on replica plating to propagate yeast colonies. However, in this study we bloated and dried yeast two-hybrid colonies onto filter paper. Despite the stresses placed on the yeast, once the filters were placed on normal media, they experienced a full recovery with the system intact. Traditionally, the use of liquid nitrogen is required for the colorimetric system to function. We provide two different methods instead: the use of a standard freezer or dry ice combined with ethanol. This allows for ease of use of the system for those without specialized equipment or technical knowledge. Furthermore, the system can be grown on lead concentrations as high as 10,000 ppm without loss of function.
context of IAs treatment is mir-146a (nearly 2-fold), a known transcriptional target of Nuclear factor xB (NF-xB). Cd and Mm exposure both disrupt the expression of miRNAs shown to be involved in oxidative stress responses. We propose that dysregulation of these miRNAs may be partially responsible for the inhibition of GSIS after metal exposure. We are currently performing studies in INS-1 B2/23 cells to determine whether miRNA over-expression or suppression can mitigate the negative effect of metal exposure on GSIS. Results of this study will help characterize the roles of miRNAs in metal-induced beta cell dysfunction and potentially differentiate these from the mechanisms involved in obesity-associated T2D.

**2349** Manganese Transport and Toxicity in CRISPR-Cas9-Mediated SLCO3A10 Knock-Out Hep3b Cells

M. Prajapati, C. Mercadante, H. Conboy, and T. Bartnikas. Brown University, Providence, RI.

Manganese (Mn), an essential metal, can be toxic at elevated levels. Mn toxicity can arise from occupational/environmental exposure, parenteral nutrition, hepatic conditions and certain genetic risks. Earlier this decade, such genetic risk was reported in the patients due to mutations in SLCO3A10, a Mn efflux transporter, leading to aberrant systemic Mn levels. Recent studies of genetically altered mouse model offered a better understanding of its importance in Mn homeostasis. To explore the function of SLCO3A10 in vitro, the current study employs a SLCO3A10 knockout Hep3b cell line (KO) designed using CRISPR-Cas9 gene editing tool. The mutations (in-deletion) leading to loss of function were confirmed by Sanger sequencing of target DNA. Nucleotide sequences showed a 5-BPs deletion and a T insertion in exon 1 of SLCO3A10 gene confirming the viable clone as a compound heterozygous (biallelic). qPCR analyses showed >70% reduction in SLCO3A10 expression of the KO engineered cells without any evident alteration in morphology or cell-growth pattern. Intracellular Mn concentrations measured using atomic absorption spectroscopy (AAS) indicated 1.7-fold and 3.6-fold (p<0.01) increases in KO cells (118 ±36 and 293 ±71 µM Mn/g protein) compared to WT cells (69 ±14 and 81 ±11 µM Mn/g protein) upon 24-hour exposure to 0.5 and 1 mM MnCl2, respectively. Cytotoxicity studies carried out using a series of concentrations of MnCl2 indicated the KO cells were susceptible to a short (24 hours) and a long-term (7 days) MnCl2 exposure when compared to wild-types. Such a difference may be attributed by intracellular Mn accumulation measured using AAS. Results from cytotoxicity studies carried out using series of concentration of ZnSO4 and CuSO4 showed a much smaller increase when compared to wild-type cells, suggesting the KO cells are susceptible to Mn toxicity, not to Zn and Cu. Transport studies carried out using radio-labeled Mn indicated a statistically significant reduction of 790% Mn import and export by KO cells when compared to wild-types. While the impaired Mn export was hypothesized, the impaired Mn import in these KO cells is currently under investigation. Such impaired import may result from suppression mutation/s leading to synthesis of a truncated inadequate Mn transporter. To address this, we generated a global Slc30a10 deficient (Slc30a10 KO/KO) mouse model using CRISPR/Cas9 to determine the localization of Slc30a10. Fluorescent images from Slc30a10 mice indicated Slc30a10 expression along the apical membrane of hepatocytes and enterocytes. Overall, our Slc30a10 KO/KO and Slc30a10 mice line suggest Slc30a10 is essential for early maintenance of Mn homeostasis.

**2535** Understanding the Role of the Manganese Transporter Slc30a10 in Developing Mice

Manganese (Mm) is an essential trace metal acquired through the diet. It is essential to regulate Mm levels as Mm can be toxic in excess. Mm excess leads to a Parkinson’s-like disorder which is often seen in industrial workers inhaling Mn-rich particles or fumes. Young individuals are believed to be particularly susceptible to the irreversible damages of Mn excess due to immature regulatory pathways of absorption and excretion. Therefore it is important to better understand early mechanisms of Mn metabolism to prevent Mn toxicity. In 2012, the first case of inherited Mn excess was identified. Patients exhibited systemic Mn excess, liver cirrhosis, a Parkinson’s-like disorder, and polycthemia (increased red blood cell counts). Mutations were identified in SLCO3A10, a protein previously thought to transport zinc. In this study we evaluate the potential role of SLCO3A10 in Mn homeostasis during development. We generate global Slc30a10-deficient (Slc30a10 KO/KO) mouse line. Slc30a10 KO/KO mice are smaller when compared to wildtype littermates, suggestive of early Mn toxicity. Metal analysis indicates postnatal day (PND) 14 Slc30a10 KO/KO mice exhibit comparable Mn levels when compared to Slc30a10+/- mice. However, by PND21 Slc30a10 KO/KO mice exhibit a 10-fold increase in brain Mn and a 2-fold increase in liver Mn levels. Interestingly Mn levels in Slc30a10 KO/KO mice decrease in the liver by PND28, suggesting the development of other Mn excretion pathways. Slc30a10 KO/KO mice also develop polycthemia between PND21 and PND28. Mn excretion studies also indicated PND21 Slc30a10 KO/KO mice excrete 40% less Mn than wildtype mice. In order to better understand the role of Slc30a10 in development, we also created an Slc30a10 W5F/W5F mouse line using CRISPR/Cas9 to determine the localization of Slc30a10. Fluorescent images from Slc30a10 W5F/W5F mice indicated Slc30a10 expression along the apical membrane of hepatocytes and enterocytes. Overall, our Slc30a10 KO/KO and Slc30a10 W5F/W5F mouse line suggest Slc30a10 is essential for early maintenance of Mn homeostasis.

**2352** Tungsten Enhances RANKL-Induced Differentiation of Osteoclasts in Bone

H. Chou1, A. M. Bolt2, M. P. Grant1, D. Plourde1, F. Mwale1, and K. K. Mann1.1. Lady Davis Institute, McGill University, Montreal, QC, Canada; and 2University of New Mexico, Albuquerque, NM.

Tungsten’s increasing presence in electronics, medical devices, and military applications position it as an emerging environmental toxicant, yet its potential health consequences are not well understood. As a contaminant in the environment, tungsten may become bioaccessible as tungstate, which can lead to exposure through water and soil. Like many metals, the highest concentration of tungsten accumulates in the bone, making the bone a long-term storage site and a source of chronic exposure. The bone is a dynamic organ that constantly undergoes intricate remodeling processes to balance bone formation, driven by the osteoblasts, and bone resorption, driven by the osteoclasts. Osteoblasts, like many other cell types, are derived from mesenchymal stem cells (MSCs). We report a global Slc30a10 deficient (Slc30a10 KO) mouse line using CRISPR/Cas9 to determine the localization of Slc30a10. Fluorescent images from Slc30a10 KO mice indicated Slc30a10 expression along the apical membrane of hepatocytes and enterocytes. Overall, our Slc30a10 KO and Slc30a10 W5F/W5F mouse line suggest Slc30a10 is essential for early maintenance of Mn homeostasis.
Tungsten is a ubiquitous metal that is used as an alloy in many different applications. Concerns about W toxicity have arisen after using tungsten in military ammunition instead of lead and depleted uranium. Tungsten is prevalent in commercial products due to its high density and malleability. Tungsten-nickel (W-Ni) is a developing alloy of interest in the aerospace industry due to its high resistance to corrosive environments. Other applications include orthopedic implants, magnetic heads for data storage, and military applications.

The harmful effects of tungsten toxicity have received considerable attention since the late 1990s. While the first studies limited to the analysis of toxicity in laboratory animals, the recent studies have focused on understanding the importance of tungsten in diseases related to cancer development. Tungsten toxicity has been shown to be a cause of cancer, and tungsten has been used as an ingredient in military ammunition instead of lead and depleted uranium. Tungsten is present in many commercial products due to its high density and malleability. Tungsten-nickel (W-Ni) is a developing alloy of interest in the aerospace industry due to its high resistance to corrosive environments. Other applications include orthopedic implants, magnetic heads for data storage, and military applications.

2357 Associations between Mercury Levels in Hair and Fish Consumption among Children in the South Area of Wakayama Prefecture, Japan

M. Yamamoto1, M. Itatani1, M. Nakamura1, C. Koriyama1, and M. Sakamoto1,2. 1National Institute for Minamata Disease, Minamata, Japan; and 2Kagoshima University, Kagoshima, Japan.

People are mainly exposed to methylmercury (MeHg) through fish consumption. Evaluation of the relationship between mercury (Hg) levels in hair and fish consumption is important for risk assessment of MeHg exposure. Marine mammals such as whales and tunas are known to contain high concentrations of Hg. In the south area of Wakayama Prefecture, Taiji residents traditionally eat whale and Nachikatsuura residents frequently eat tuna compared with other areas. Therefore, some of these residents may be exposed to higher levels of Hg. Assessments of MeHg exposure through fish consumption have been conducted for adult residents in this area, but no studies have estimated MeHg exposure in children who are highly susceptible to MeHg. The present study examined the associations (Spearman’s rank correlation coefficients) between Hg levels in hair in 106 children (Taiji residents: 29; Nachikatsuura residents: 77) at 7 years of age and their fish consumption, including marine mammals, using a food frequency questionnaire (FFQ) and food model for assessing MeHg exposure. The Hg levels in the hair of all 106 study subjects had a median of 2.7 µg/g, maximum of 21.3 µg/g, and minimum of 0.6 µg/g. The correlations between Hg levels in hair and consumption of whale, tuna, and 12 other fish species among the 29 subjects in Taiji were whale (r=0.71), tuna (r=0.21), and 12 other fish species (r=0.27). The correlations between Hg levels in hair and consumption of whale, tuna, and 12 other fish species among the 77 subjects in Nachikatsuura were whale (r=0.17), tuna (r=0.36), and 12 other fish species (r=0.09). The correlations between Hg levels in hair and consumption of tuna and 12 other fish species in the subjects who did not eat whale were tuna (r=0.39) and 12 other fish species (r=0.17). These findings indicate significant positive correlations between Hg levels in hair and areas with specific eating habits such as consumption of whale in Taiji or consumption of tuna in Nachikatsuura. The FFQ with food model used in this study and resulting information will be useful for future assessments of the health risks of MeHg exposure through fish consumption in children.

2358 Methylmercury Exposure Impacts Cell-Cycle Progression of Myoblasts

Methylmercury (MeHg) is a pervasive environmental toxicant, well-established to affect the nervous system. Recent evidence, however, has identified muscle as a novel target of MeHg toxicity. This is an attractive target owing to the characteristic muscle weakness observed in MeHg intoxicated humans. There is minimal evidence, however, on the direct effect of MeHg on muscle development. A previous study demonstrated MeHg decreases myogenin (MyoG) expression in C2C12 myoblasts induced to differentiate. MyoG is a transcription factor, which is normally upregulated within 24 hours (hr) of myoblast differentiation induction. It promotes expression of several factors important to myoblast muscle development. Here, we aim to explore the potential mechanism by which MeHg alters normal differentiation of myoblasts. It is our hypothesis MeHg perturbs myoblast differentiation, and maintains the undifferentiated state even under differentiation conditions. For our experiments, we also used C2C12 myoblasts. This in vitro model allows straightforward differentiation of myoblasts, immature, single-nucleated muscle cells, to myotubes, mature, multi-nucleated muscle fibers. We treated C2C12 with MeHg (0.5 or 2.5 µM) in growth media (myoblasts continue to proliferate) for 24 hr, then switched to low serum media (myoblasts induced to differentiate) without MeHg for another 24 hr. RNA and protein were isolated post-exposure for quantitative PCR and whole-cell western blot, respectively. We detected a significant decrease in MyoG expression at 2.5 µM, which translated to decreased MyoG protein as well at 0.5 and 2.5 µM. To elucidate further the effects of MeHg on cell-cycle, we examined p21, a cyclin-dependent kinase that is upregulated in myoblasts to signal terminal differentiation. We observed a significant decrease in p21 protein at both 0.5 and 2.5 µM. Moreover, we detected a persistent undifferentiated state; MyoG is downregulated and unable to promote muscle development, and p21 decreases, impacting terminal differentiation signals. It is necessary, however, to assess relative proportion of myoblasts to myotubes, as well as cell proliferative capacity under this culture condition, to confirm maintenance of the myoblast state. Supported by NIEHS R01ES025721 and T32ES007026.

2359 Tissue-Specific Role of Nrf2 (Nrf2) in Methylmercury-Induced Toxicity during Drosophila melanogaster Metamorphosis

J. Gunderson, M. Culbreth, and M. D. Rand. University of Rochester School of Medicine and Dentistry, Rochester, NY.

Methylmercury (MeHg) is a ubiquitous environmental toxicant known to target the developing nervous system. However, recent evidence implicates that MeHg also targets developing muscles, which may explain motor deficits seen in developmentally exposed children. Previous work in Drosophila melanogaster has indicated that developmental exposure to MeHg can inhibit eclosion, a stereotypic muscle-dependent behavior required for emergence of the adult fly from the pupal case. Normal eclosion behavior is thought to require the dorsal internal oblique muscles (DIOMs), a larval-derived muscle group that persists through metamorphosis. Thus, we hypothesized that perturbation of these muscles by MeHg could underlie the failure to eclose. MeHg can elicit toxicity at the cellular level by reacting with sulfhydryl groups on proteins or via oxidative stress induction. Moreover, MeHg has been shown to activate the Nfr2 antioxidant response pathway. Nfr2 is a transcription factor which, under basal conditions, is constitutively degraded. Exposure to MeHg prompts Nfr2 activation, and promotes expression of anti-oxidant genes. The Nfr2 pathway has primarily been studied in regard to xenobiotic defense, aging, and cancer in mature organisms. Less is known about the developmental role of Nfr2. Using the Drosophila model, we investigated the impact of developmental MeHg exposure on CncC, the Nfr2 homolog, in function in developing muscle. We hypothesized that CncC protects developing muscles from MeHg toxicity via enhanced transcription of antioxidant genes. To validate this, we show that the Nfr2 pathway is activated in Drosophila after exposure to MeHg in both adults and pupa by qPCR and Western blot. Further, we observe MeHg induces a collapsed myosporid phenotype, observed by fluorescence microscopy, in the DIOMs consistent with a parallel decrease in eclosion ability. Attempts to rescue eclosion with targeted overexpression of CncC reveals unexpected and distinct activity in muscles and neuro-muscular connective tissue, whereby overexpression in muscles was highly deleterious and lethal, and overexpression in neurons successfully rescued eclosion ability after developmental exposure to MeHg. Interestingly, CncC is seen to be endogenously expressed in developing DIOMs, which may be required for the proper function of the muscles in development and metamorphosis. Our data demonstrates a potential tissue specific activity for Nfr2 signaling during development that can directly differential toxic effects of MeHg. Supported by RO1ES025721 and T32ES007026.
the worms fed the high fat diets. Taken together, our data suggest a diet by
toxicant interaction in *C. elegans*, where dietary fat levels directly influence
the nematode’s response to MeHg exposure.

### 2361 Disposition and Toxicity of Cyanide-Mercury Complexes in Target Organs

C. C. Bridges, T. N. Mathis, M. C. Barnes, J. T. Buchanan, A. M. Kiefer, C.
S. Seney, O. Uchakina, and R. J. McKallip, Mercer University School of
Medicine, Macon, GA.

Mercury (Hg) is an environmental toxicant that is prevalent throughout the
world. Humans may be exposed Hg via inhalation, consumption of contami-
nated food, and/or exposure to Hg-containing substances. A major source of
environmental Hg is artisanal and small-scale gold mining (ASGM). Hg is
used to extract gold from ore; however, this process is very inefficient and a
large percentage of gold remains in the tailings. Cyanidation is used to extract
additional gold from processed ores. Because these ores are contaminated with
Hg from initial extraction attempts, there is significant concern that Hg
interacts with cyanide (CN) to form a Hg-CN complex. Humans may be ex-
posed to Hg-CN complexes via the ingestion of contaminated fish, ingestion of
fruits and vegetables irrigated with contaminated water, and ingestion of
shrimp from farms utilizing contaminated water. The purpose of the current
study was to determine where Hg-CN complexes accumulate in mammalian
organs/tissues and to determine the toxicity associated with exposure to
these complexes. Rats were injected with mercury(I)cyanide (0.1, 0.2, 0.3, and
0.4 mg/kg), containing radioactive mercury. The accumulation of Hg-CN was
measured in blood, kidney, liver, spleen, brain, urine, and feces. Histological
analyses of kidney and liver revealed injury even at lower doses. Immune re-
sponses in the spleen were suppressed by exposure to Hg-CN. Exposure to
Hg-CN has significant toxicological effects on mammalian systems and thus,
the presence of Hg-CN complexes in the environment is a significant human
health problem.

### 2362 Suppression of E2F1 and RAD51 in Chromate-Induced Failure of Homologous Recombination

R. Speer,1 C. Browning,2 and J. Wise Sr.1 1University of Louisville, Louisville,
KY; and 2Brown University, Providence, RI.

Lung cancer is a leading cause of cancer death, however while this disease is
largely attributed to smoking approximately 1 in 5 people with lung can-
cer never smoked. The mechanisms of how lung carcinogens cause cancer
are poorly understood. Studies show that chromosome instability is an early
event in lung cancer and contributes to this end point. Many metals including
hexavalent chromium (Cr(VI)) are known to induce chromosome instability.
Additionally, we have shown particulate Cr(V) causes DNA double strand
breaks and prolonged exposure impairs the effector step of the high fidelity
repair pathway, homologous recombination. The homologous recombin-
ation pathway is crucial in preserving genomic stability and preventing car-
cinogenesis. Data in our human lung cell model show longer exposures to
particulate Cr(VI) lead to loss of the critical effector step in the homologous
recombination pathway through impaired RAD51 function while preceding
steps remain functional. It is currently unknown how Cr(VI) impacts RAD51
function. The transcription factor E2F1 has previously been shown to be in-
olved in homologous recombination through transcription of DNA repair
proteins and also plays a role in the homologous recombination response to
DSBs. The objective of this study was to show prolonged exposure to par-
ticulate Cr(VI) inhibits the RAD51 response through E2F1 affecting mRNA ex-
pression and protein levels and localization. We found exposure to particulate
Cr(VI) reduced RAD51 and E2F1 mRNA and protein levels at all exposures. We
also observed alteration in protein half-life, but inhibited protein focus
formation in response to prolonged particulate Cr(VI) exposure. These results
provide mechanistic insight into the carcinogenesis of particulate Cr(VI) in
human lung cells and indicate a role of the transcription factor E2F1 in the loss
of the homologous recombination response. These data further build a foun-
dation to directly investigate how E2F1 is modulating the RAD51 response to
particulate Cr(VI) exposure. This work was supported by the National Institute
of Environmental Health Sciences [ES016893 to J.P.W] and the Jewish Heritage
Foundation for Excellence.

### 2363 Homologous Recombination Repair Protects against Genomic Instability in Bowhead
Whale Lung Cells after Prolonged Particulate Chromate Exposure

H. Lu1, C. Browning,2 S. Wise1, J. Toyoda1, R. Speer, S. Raph1, and J.
Wise Sr.1 1University of Louisville, Louisville, KY; and 2Brown University,
Providence, RI.

Particulate hexavalent chromium (Cr(VI)) is a well-established human lung
carcinogen, however its carcinogenic mechanism is poorly understood. Cr(VI)
induces DNA double strand breaks leading to genomic instability and carcino-
genesis in human lung cells. Homologous recombination (HR) repair protects
against genomic instability by maintaining high genomic fidelity during the
repair of DNA double strand breaks. Prolonged particulate Cr(VI) suppresses
HR repair while simultaneously inducing DNA double strand breaks in human
lung cells. Whales are long lived species living in a complex environment that
puts them at risk for long-term exposure and accumulation of environmental
contaminants. However, they have low cancer rates, which may be due to
better DNA protective mechanisms. How whales evade carcinogenesis is
unknown. This study focuses on the effect of particulate Cr(VI) exposure in
whale lung cells to determine if they exhibit protective mechanisms against
Cr(VI)-induced chromosome instability. Our study shows zinc chromate in-
duces concentration-dependent increases in cytotoxicity, chromosome dam-
age and DNA double strand breaks after both acute (24 h) and prolonged (120
h) exposure in whale lung cells. In response to zinc chromate-induced breaks,
HR was increased after both acute (24 h) and prolonged (120 h) zinc chromate
exposure. Our results indicate the response to prolonged Cr(VI)-induced cyto-
xicity, genotoxicity and HR repair activity are different between whale and
human lung cells. Future investigation of the differences in how human and
whale cells respond to chemical carcinogens may provide valuable insight
into mechanisms of preventing chemical carcinogenesis. The work was sup-
ported by the National Institute of Environmental Health Sciences [ES016893 to
J.P.W].

### 2364 Do Dysregulated Cellular Energetics Play a Role in Hexavalent Chromium-Induced
Human Lung Carcinogenesis?

J. Wise, L. Wang, M. Alstott, N. Ngalame, J. Hitron, Z. Zhang, and X. Shi
University of Kentucky, Lexington, KY.

Hexavalent chromium, Cr(VI), is a known human carcinogen that is a world-
wide environmental health concern. It is established that reactive oxygen
species, genomic instability, and DNA damage repair deficiency are import-
ant contributors to Cr(VI)-induced carcinogenesis mechanism. Some cancer
hallmarks remain understudied for the mechanism of Cr(VI)-induced carcino-
genesis. Increased de novo lipogenesis and the ‘Warburg Effect’ are an im-
portant in the mechanism of carcinogenesis and tumorigenesis in multiple
types of cancer. We recently reported that Mitochondrial respiratory dys-
function occurs after tumor development and not during the initial Cr(VI)-
induced carcinogenesis. Continuing this work we investigated the changes in
lipid metabolism and the ‘Warburg Effect’ in Cr(VI)-transformed human lung
cells. We used three human lung cell lines (human lung epithelial cells (BEAS-2B
and BEP2D cells) and human lung fibroblasts (WTHBF-6 cells)). Our results
showed an increased lipogenesis (palmitic acid levels) and Cr(VI) and
increased expression of lipogenesis proteins [ATP citrate lyase (ACLY), and
fatty acid synthase (FASN) expressions]. Using a drug (C75) for inhibition of
FASN, we found that C75 treated Cr(VI)-transformed cells had decreased
proliferation and loss of colony formation in soft agar. Interestingly, we also
found that Cr(VI)-transformed cells had no major changes in their glycolytic
function as measured by the Seahorse Analyzer when compared to their pas-
sage matched control cells and there were no observed increases in Cr(VI)-
transformed cells’ extracellular L-lactate levels. In conclusion, these data show
that Cr(VI)-transformation in vitro caused increases in lipid metabolism and
this increase is important for Cr(VI)-transformed cell cancer properties. In con-
trast, Cr(VI)-transformed cells did not exhibit increased anaerobic glycolysis
(‘Warburg Effect’). Therefore, future work is aimed at elucidating the mecha-
nism that is increasing lipogenesis and not increasing anaerobic glycolysis in
Cr(VI)-transformed human lung epithelial cells and lung fibroblasts.
Hexavalent chromium (Cr(VI)) compounds are known human lung carcinogens; but the carcinogenic mechanism is poorly understood. Cr(VI) induces DNA damage which normally leads to apoptotic responses to avoid transformation and carcinogenesis. Evasion of apoptosis is a hallmark of carcinogenesis, but it is unknown how Cr(VI)-damaged cells are able to escape cell death. We exposed human lung cells to low concentrations of zinc chorate for 6 months. During treatment we observed cell death using a colony forming assay. We also monitored changes in chromosome number and structure. In the middle, and at the end of treatment, cells were tested for anchorage independence. We found Cr(VI) induced cell death during the first 25 days of exposure with lower concentrations (0.0125 and 0.025 µg/cm²) while the highest concentration, 0.05 µg/cm², caused significant cell death initially, followed by a period of delayed survival at day 70 of treatment, and then decreased plating efficiency after day 120 which remained throughout exposure. Although plating efficiency decreased, cell growth was accelerated with the high treatment. Additionally, cells that escaped particular Cr(VI)-induced cell death exhibited significant amounts of structural and numerical changes. Control cells at all time points showed normal karyotypes. For treated cells, on day 5, 24, 26, and 30 percent of cells had abnormal karyotypes at 0.0125, 0.025 and 0.05 µg/cm² zinc chorate, respectively. On day 70, 46, 52, and 48 percent of cells had abnormal karyotypes at the same concentrations. On day 180, 18, 72, and 84 percent of cells had abnormal karyotypes at the same concentrations. Treatment-induced aneuploidy were observed at early time points compared to structural changes. None of the mass treated cells grew colonies in soft agar, however, clonal cell lines developed after 180 days of treatment indicated that 30% exhibited neoplastic transformation with a high degree of numerical and structural chromosome instability. These data support a hypothesis that Cr(VI)-treated cells can evade apoptosis and transform into chromosomally unstable cells that continue to survive and grow. This work was supported by NIHES grant ES016893 (J.P.W.) and the University of Louisville School of Medicine Basic Grant Program (S.S.W.).

Hexavalent chromium compounds are well-established respiratory carcinogens used in industrial processes. While inhalation exposure constitutes an occupational risk affecting mostly chromium workers, environmental exposure from drinking water or a widespread survival at day 70 of treatment, affecting millions of people throughout the world. Cr(VI) is genotoxic, forming protein-Cr-DNA adducts and silencing tumor suppressor genes, but its mechanism of action at the molecular level is poorly understood. Our prior work using FAIRE showed that Cr(VI) disrupted the binding of transcription factors CTCF and AP-1 to their cognate chromatin sites. Here, we used two complementary approaches to test the hypothesis that chromium perturbs chromatin organization and dynamics. DAmPOS2 analyses of MNase-seq data identified several chromatin alterations induced by Cr(VI) affecting nucleosome architecture, including occupancy changes at specific genome locations; position shifts of 10 nucleotides or more; and changes in position amplitude or fuzziness. ATAC-seq analysis revealed that Cr(VI) disrupted the accessibility of chromatin regions enriched for CTCF and AP-1 binding motifs, with a significant co-occurrence of binding sites for both factors in the same region. Cr(VI)-enriched CTCF sites were confirmed by ChIPseq and found to correlate with evolutionarily conserved sites occupied by CTFC in vivo, as determined by comparison with ENCODE-validated CTFC datasets from mouse liver. In addition, more than 30% of the Cr(VI)-enriched CTFC sites were located in promoters of genes differentially expressed from chromium treatment. We propose that Cr(VI) disrupts 3-dimensional chromatin organization and boundary formation between topologically associated domains in chromosomes, destroying the interactions between transcription regulatory sequences. Our results support the conclusion that Cr(VI) exposure promotes broad changes in chromatin accessibility and suggest that the subsequent effects on transcription regulation may result from disruption of CTFC binding and nucleosome spacing, implicating transcription regulatory mechanisms as primary Cr(VI) targets. Supported by NIERS R01 ES010907.

**2368 The Effect of GMDC in Overcoming Cisplatin-Induced Systemic Toxicity**

Cisplatin is a platinum-based chemotherapeutic drug widely used in the treatment of various cancers such as testicular, ovarian, lung, bladder, and cervical cancers. However, its use and the dosage range applied have been limited by severe side effects (e.g., nephrotoxicity and ototoxicity) and by the acquired resistance to cisplatin of patients during treatment. Metal-chelating agents have shown promising potentials in overcoming these problems associated with platinum drugs. We developed a new chelating chemical, sodium (S) 2, (dithiocarbamylato) (2S,3R,4R,5R)-2,3,4,5,6 pentahydroxyhexyl) (aminol) - and (dithiocarbamylato) butanoate (GMDC). In this study, we examined the effects of GMDC in modifying the cisplatin-caused systemic adverse effects in vitro and in vivo. GMDC exposure showed no cytotoxic effects on normal human kidney HK2 cells following 24h exposure at levels up to 1000 µM, and can dramatically reduce cisplatin-induced apoptosis and ototoxicity in HK2 cells. Results also showed a decreased amount of platinum in cells co-treated with GMDC in cisplatin rescue experiments. In 4T1 breast cancer xenograft mice model, it was shown that GMDC reduced cisplatin-induced nephrotoxicity by reducing cisplatin deposition in the kidney and attenuating cisplatin-induced elevations in BUN and plasma CRE. GMDC also ameliorated renal tubular dilation and vacuolation, and necrosis of glomeruli and renal tubule cells. Auditory brainstem response (ABR) test showed that cisplatin treatment decreased the hearing sensitivity of mice at all frequencies of stimulus, but GMDC reduced the hearing sensitivity loss, therefore alleviating the ototoxicity caused by cisplatin. Furthermore, cisplatin-induced other systemic toxicities were improved by GMDC as supported by the increased body weight and reduced hematotoxicity and hepatotoxicity. Importantly, co-treatment of cisplatin with GMDC does not affect cisplatin’s antitumor efficacy. The tumor growth, size, and metastasis were all comparable between cisplatin only treatment group and cisplatin and GMDC co-treatment group. In conclusion, our study suggests that GMDC reduces cisplatin-induced toxicity by preventing the accumulation and as well as the reduction of intracellular cisplatin, without compromising cisplatin therapeutic activity, supporting the further development of GMDC as a clinical agent in overcoming cisplatin’s toxicity and resistance.

**2369 Leaving Ligand Effects on Cytotoxicity, Solubility, and Reactivity of Monofunctional Platinum(II) Complexes**

H. L. Millay, B. B. Williams, and K. M. Williams. Western Kentucky University, Bowling Green, KY.

Monofunctional platinum(II) complexes, such as phenanthroplatin and pyriplatin, have notably different characteristics from the bifunctional anticancer complexes, such as cisplatin and oxaliplatin. The traditional bifunctional complexes covalently bind to DNA and predominantly form a 1,2-GG-intrastrand crosslink which leads to DNA distortion, transcriptional inhibition, and ultimately apoptosis. The monofunctional complexes bind to DNA at a single
guanine residue, without causing the DNA helix to distort, resulting in RNA polymerase II transcribing complex stalling at the platinum-DNA adduct and inhibition of transcription. This difference in DNA binding leads to different mechanisms of transcription inhibition, which correlates to cytotoxic effect. Monofunctional platinum(II) complexes have unique properties that may be exploited to target cancer cells without producing the toxic side effects associated with the currently approved platinum anticancer drugs. To advance the understanding of these monofunctional platinum(II) complexes, this study replaced the chloride leaving ligand with an acetate group, which should increase solubility and alter the rate of reactivity with key amino acid and nucleotide targets. Phenanthriplatin and pyriplatin compounds were reacted with silver acetate to form insoluble silver chloride and the desired compound. Proton nuclear magnetic resonance (1H NMR) spectroscopy was utilized to characterize the new compounds and conduct kinetic assays with guanosine 5′-monophosphate (5′-GMP). Rate constants of 2.9 x 10^{-4} M^{-1} s^{-1} and 1.6 x 10^{-5} M^{-1} s^{-1} were determined for pyriplatin and phenanthriplatin with 5′-GMP, respectively. A preliminary rate constant of 7.0 x 10^{-6} M^{-1} s^{-1} was determined for the newly synthesized pyriplatin-acetate complex. Ligand exchange kinetics directly influences the anticancer activity and toxicity of platinum drugs. Initial results indicate that the solubility is increased, and the rate of reaction is decreased by the acetate ligand. Further studies are currently being conducted to determine the cytotoxic effect of these novel platinum(II) compounds in mammalian cellular models (HEK293 and NTERA-2).

2370 The Effectiveness of a Monofunctional, Novel Platinum (II) Compound on Mammalian Cell Viability

J. Ko, L. B. Freeman, B. W. Williams, and K. M. Williams. Western Kentucky University, Bowling Green, KY.

For decades, platinum containing compounds have been used for the treatment of different types of cancer. In the United States, there are currently three different platinum compounds approved by the US FDA for use in the treatment of cancer: cisplatin, carboplatin, and oxaliplatin, all bifunctional compounds. These bifunctional compounds have two leaving groups, thus attached at two sites on the DNA molecule inducing interstrand cross-links and distorting the DNA. Phenanthriplatin, a cisplatin derivative, is one of several platinum compounds currently being considered as a treatment for cancer. Unlike cisplatin, phenanthriplatin is monofunctional, having only one leaving group to attach to the DNA without distortion the macromolecule. Bifunctional and monofunctional platinum(II) complexes bind to DNA by different mechanisms but ultimately lead to cell death. Here, Chloro-[2-(4-methyl-1,4-diazepan-1-yl)ethanamine] platinum(II) chloride (compound 1), a platinum compound with a similar steric profile to phenanthriplatin was reacted with both nucleotide, 5′-Guanosine monophosphate (5′-GMP), and the amino acid, N-Acetyl-L-methionine (N-AcMet). In the competition, N-AcMet products were formed from 24 hours, but 5′-GMP remained unreacted until several days. However, with time, 5′-GMP can replace N-AcMet. Thus, compound 1 shows a more traditional small molecule reactivity than other sterically hindered trinuclear compounds studied in the lab. Current studies have explored the cytotoxicity the compound in a cellular model of prostate cancer (NTERA-2) and control cells (HEK293). Current MTT data suggests that this compound, unlike phenanthriplatin, does not have higher toxicity than cisplatin.

2371 Development and Validation of an Analytical Method for Total Thallium in Rodent Plasma and Tissues by ICP-MS

Thallium (Tl) is a naturally occurring element and exists in +1 or +3 state. Thallium (Tl) is a heavy metal that naturally occurs in the earth's crust. Thallium has been used as a poising agent and induces a spectrum of adverse health effects, including nervous system and neurotoxicity. Chronic human exposure to thallium compounds occurs due to its presence as a contaminant in drinking water. Currently, there is insufficient toxicological data to support derivation of a human reference dose for thallium compounds. To address this data-gap, the National Toxicology Program (NTP) performed both perinatal rat range-finding and 14-day adult mouse toxicity studies of thallium (I) sulfate. Time-mated SD rats (n=12-20 per group) and offspring were exposed from gestational day 6 (GD 6) to postnatal day 28 (PND 28) via dosed drinking water containing 0, 3.13, 6.25, 12.5, 25, or 50 mg/L thallium (I) sulfate. All 25 and 50 mg/L groups were removed from study by PND 0 due to morbidity observations. Thallium exposure concentrations ≤ 2.5 mg/L did not impact dam fecundity or offspring survivability (PND 4-28); however, whole-body alopecia was observed in all offspring exposed to 12.5 mg/L thallium. Exposure to 12.5 mg/L also resulted in lower PND 28 bodyweights in males (-12%) and female (-9%) offspring, relative to controls. Total thallium concentration in maternal plasma, amniotic fluid (GD 18), fetal hematocrit (GD 18), and pup plasma (PND 4) provide evidence of placental and fetal transfer of thallium. Adult B6C3F1 mice (n=5 per sex/group) were exposed for 14 days via dosed drinking water containing 0, 6.25, 12.5, 25, 50, or 100 mg/L thallium (I) sulfate. Observed mortality led to the removal of the 100 mg/L group by study day 9. At study conclusion, mice exposed to 50 mg/L and > 100 mg/L displayed 20% (5/25) and 15.2% (3/19) (males) and 23.3% (11/47) (females) lower bodyweights relative to controls, respectively. Plasma thallium concentrations ranged from 0.3-2.734 ng/mL in male mice and 0.1-0.1998 ng/mL in female mice. Evidence of thallium toxicity was observed in two rodent species following subchronic drinking water exposure; these results will inform future studies to further characterize thallium hazard and safeguard public health.
production and the activation of JNK. Pretreatment with the antioxidant NAC and SP600125 (JNK inhibitor) effectively reversed Sb−−−induced β-cell apoptosis and related signals. In conclusion, these results suggest that Sb exerts its cytotoxicity on pancreatic β-cells by inducing the apoptosis through ROS generation-induced JNK activation downstream-triggered apoptosis pathway and provide further evidence to confirm the possible role of Sb as an environmental risk factor for diabetes.

3-Month Toxicity Studies of Tetravalent and Pentavalent Vanadium Compounds in Hsd:Sprague-Dawley SD Rats and B6C3F1/N Rice via Drinking Water Exposure

G. Roberts1, K. Elias2, D. Fallacara2, K. Levine1, J. Harrington3, S. Waidyanatha1, M. Hoth1, V. Godfrey-Robinson1, B. Sparrow1, and M. Stout1. 1. NIEHS/NTep, Research Triangle Park, NC; 2. Battelle Memorial, Columbus, OH; and 3. RTI International, Research Triangle Park, NC.

The National Toxicology Program performed 3-month toxicity studies of tetravalent (vanadyl sulfate; VS) and pentavalent (sodium metavanadate; SM) vanadium compounds in drinking water, due to potential human exposure and lack of robust toxicity data. Time-mated Hsd:Sprague Dawley SD rats were exposed via dosed drinking water during gestation (beginning GD6) and lactation. Pups were exposed in utero, during lactation, and continued exposure for 3 months post-weaning. Adult B6C3F1/N mice were exposed for 3 months. Animals were exposed to VS at 0, 21, 41.9, 83.8, 167.5, or 335 mg/L, or to SM at 0, 3.13, 6.25, 12.5, 250, or 500 mg/L. There was higher morbidity in the 500 mg/L SM dams and pups throughout the postnatal period. There were lower percent live pups at birth (-25%), lower number of viable pups at PND4 (-45%; pre-standardization) and throughout lactation after litter standardization (-28%; PND4-28) compared to controls. There were no effects on littering or pup survival in VS exposed dams or pups. For both compounds, in rats and mice, water consumption (g/day) was lower in male and female pups exposed to SM, compared to controls. In male and female mice exposed to SM, there were consistent increases in erythrocytes and reticulocytes and decreases in hematocrit and hemoglobin; changes in rats and in VS exposed animals were sporadic. In general, organ weight effects were attributed to body weight increases, except for treatment-related decreases in thymus weights for SM mice. Histopathological findings were limited for both sex/species, exposed to either compound. Based on plasma and urine total vanadium levels, and estimated vanadium consumption from water consumption data, the exposure to vanadium from SM appears to be higher than from VS. For both SM and VS, internal exposure increased proportionally with increasing estimated vanadium consumption. In general, effects were more frequently observed in SM exposed animals which may be attributable to higher systemic exposure to vanadium at similar compound concentrations.

Application and Safety Concern of Bismuth Materials and the Role of Autophagy in Bismuth Induced Nephrotoxicity Associated Mechanisms

L. Zhang, Soochow University, Suzhou, China.

Bismuth is widely used in metallurgy, cosmetics industry and medical diagnostics and recently, bismuth nanoparticles (BiNP) have been made and proved to be excellent CT imaging agents. We have synthesized bovine serum albumin based BiNP for CT imaging but we find a temporary kidney injury by BiNP. Due to the previous reported risk of bismuth on human health, we extended our studies on the mechanisms for BiNP induced nephrotoxicity. First, we found that BiNP can induce autophagy in human embryonic kidney cells, shown by the increase of monodansylcadaverine fluorescence staining and the amount of LC3II that can be inhibited by 3-MA. BiNP were capable of entering cells in a dose and time dependent manner by fluorescence, transmission electron microscopy and element detection methods. Blood biochemical analysis for in vivo studies indicated (g/day) was lower in control and blood nitrogen associated with cell apoptosis/necrosis and intraluminal cast formation in proximal convoluted tubules, indicating BiNP induced acute kidney injury (AKI) in mice. During AKI, we found an increase in LC3II, while the autophagic flux indicator p62 remained unchanged. Chloroquine and rapamycin was used to activate autophagy in AKI caused by BiNP. The results showed that BiNP induced AKI was significantly attenuated when autophagy was further promoted by rapamycin and AKI became severe when chloroquine was applied. In vitro studies also indicated BiNP induced autophagy, evident in autophagic vacuole formation, and increased level of autophagy related proteins including LC3II, Beclin1 and Atg12. Specifically, reactive oxygen species (ROS) generated by BiNP could be the major inducer of autophagy, because the ROS blocking attenuated autophagy. Autophagy induced by BiNP was primarily regulated by AMPK/mTOR signal pathway and partially regulated by Akt/mTOR. We also extended our findings by selecting five bismuth compounds and the results showed that bismuth nitrate, bismuth oxychloride, bismuth citrate, colloidal bismuth subcitrate and bismuth nanomaterials all induced slight cytotoxicity accompanied with autophagy. Our study provides fundamental theory to bismuth induced toxicity and the safety concern of bismuth metal needs to be emphasized.

Pulmonary Function in Veterans Exposed to Depleted Uranium

D. Glick1, S. Hines1, P. Gucer1, J. Gaitens1, M. Cloeren2, M. Condon3, M. Oliver1, T. Roth1, B. Weiler1, and M. McDarmid2. 1. University of Maryland School of Medicine, Baltimore, MD; and 2. VA Medical Center, Baltimore, MD.

In 1991, a group of Gulf War I (GWI) Veterans was exposed to depleted uranium (DU) during friendly fire incidents. A cohort of them underwent biennial surveillance at the Baltimore VA for potential DU-related health effects. The primary exposure in this cohort was via inhalation, but a subset have retained fragments and persistently elevated uranium urine (U) levels suggesting ongoing systemic exposure. Potential airways toxicity from exposure to DU oxides, particulates, and blast impact have prompted respiratory health monitoring, although no U-specific differences have been identified. We continue to follow this cohort with the hypothesis that those with higher DU body burdens may display a higher frequency of pulmonary abnormalities as measured by impulse oscillometry (IO) and spirometry when compared to those with lower DU levels. Between April and June of 2017, 42 of a dynamic cohort of 80 DU-exposed GWI Veterans were evaluated during a 3-day visit. Medical history and exposure questionnaires, 24-hour urine U (uU) collections, IOs, and spirometry testing were obtained. The mean percent of spirometry and uU values were compared between Veterans with high vs low uU values for forced expiratory volume in 1 second (FEV1), forced vital capacity (FVC), and the ratio of FEV1/FVC and airways resistance at 5 Hz (R5). Overall, mean spirometry and IOs values fell within the normal range. On spirometry, the mean percent predicted values for flow (low lung volume): FEV1, 90.9% vs 86.1%; FVC, 93.4% vs 91.2%. The mean FEV1/FVC ratios for both groups were above the 70% threshold for obstructive abnormality and were similar at 76.4% (high) and 73.5% (low). On IOs testing, the mean percent predicted values for total airways resistance (R5) were below the threshold for obstruction of 150% (112% high U, 123% low U). Higher DU body burden was not associated with worsening spirometric or lung function impaired by spirometry or IOs testing. Mean values obtained on both tests indicate that lung function remains normal in the cohort overall, now 26 years after the initial insult and without evidence of effect from the U burden.

Minimal Uranium Immunotoxicity following a 60-Day Drinking Water Exposure to Uranyl Acetate in Male and Female C57BL/6J Mice

High levels of uranium exist in air, water, and soil in the Navajo Nation, due in part to ~500 abandoned uranium mines located in the rural southwestern United States. In a recent report evaluating metal concentrations in unregulated water sources within the Navajo Nation, 75% had detectable levels of uranium, with 12.5% having levels above the regulated limit of 30 ppb. In addition, uranium was found to co-occur with other metals, including arsenic, which could magnify negative health effects in this population. Human exposures in the Navajo Nation are associated with increased prevalence of metal-associated diseases, including some evidence of immune dysfunction. However, little is known about the accumulation of uranium in immune organs or the immunotoxicity of uranium. We recently published, that oral exposure to uranium, in the form of uranyl acetate, results in overall low tissue retention of uranium (<0.01%), with very little accumulation in immune organs (blood, bone marrow, spleen, and thymus) of male and female mice. In the present study, we characterized the immunotoxicity of uranium, in the form of uranyl acetate (UA), following a 60-day drinking water exposure to 5 and 50 ppm in male and female C57BL/6J mice. The following immunotoxicity endpoints were evaluated: hematology, immunophenotyping of the bone marrow, spleen, and thymus, and immune cell function (lymphocyte mitogenesis and T-dependent antibody response). Uranium exposure had subtle impacts on the immune endpoints evaluated, likely as a result of low uranium accumulation at these sites. The only significant immunological alterations were a slight decrease in the numbers of splenic NK T-cells and macrophages of exposed male mice. Future work will focus on the immunotoxicity of uranium and arsenic co-exposures as well as on how changes in dietary conditions, such as supplemental iron, may affect uranium immune tissue.
Recent reports have demonstrated the association between heavy metal exposure and preterm birth. Preterm births are classified as early and late, depending on the duration of pregnancy, and are associated with increased risk of congenital illnesses such as heart failure, asthma, etc. Particularly, early preterm births carry a higher risk of mortality; however, the differential effects of heavy metal exposure on early and late preterm births are unknown. Objectives: To analyze the association between maternal whole blood concentrations of heavy metals, such as cadmium (Cd), lead (Pb), mercury (Hg), selenium (Se), and manganese (Mn) that are common toxicants in Japan, and early and late preterm births. The data of 14,847 pregnant women who were participants of the Japan Environment and Children’s Study were used. Data of the self-questionnaire pertaining to the first trimester (T1), second/third trimester (T2), and medical records after delivery were analyzed. Women were divided into two groups: early preterm (22 to < 34 weeks) and late preterm (34 to < 37 weeks). Maternal blood samples for measuring heavy metal concentrations were collected in T2 (pregnancy weeks: 14-39). The participants were classified into four quartiles (Q1-Q4) according to increasing heavy metal levels. The rate of preterm birth was 4.5%. After controlling for confounding factors such as age, pre-pregnancy body mass index, smoking, partner’s smoking, drinking habits, gravidity, parity, number of cesarean deliveries, uterine infections, household income, educational levels, and sex of infant, Cd levels were found, by multivariable logistic regression analysis, to be significantly associated with early preterm birth (p = 0.002), with odds ratio for early preterm birth of 1.91 (95% confidence interval: 1.12-3.27, P = 0.018) in subjects of Q4 compared with in subjects with term birth (≥ 37 weeks). Maternal blood Cd levels during pregnancy are positively associated with the risk of early preterm birth among Japanese women. Identification of the main source of maternal Cd exposure may contribute to the prevention of early preterm births and health maintenance of mothers and their infants in the future.

Effects of Model, Method of Collection, and Topography on Chemical Elements and Metals in the Aerosol of Tank-Style Electronic Cigarettes

M. Williams, K. Bozhilov, J. Li, and P. Talbot, University of California Riverside, Riverside, CA.

Over the past decade, electronic cigarettes (EC) have evolved from the classic 3-piece model to a cartomizer style, to a disposable unit, and finally to the tank style. These modified EC come in a variety of styles and shapes consisting of larger, more powerful batteries, replaceable atomizing units, and large volume tanks. The purpose of this study was to examine the effect of puffing topography and method of collection on 19 elements/metals in aero.

Improvement of Organotypic Slice Culture of Mouse Cerebral Cortex to Evaluate M1-Type Microglial Activation

T. Hoshi, T. Toyama, A. Naganuma, and G. Hwang, Tohoku University, Sendai, Japan.

Microglia (M0) at resting state sense microscopic changes in brain environments and activate to neurotoxic microglia (M1), which release inflammatory cytokines that are involved in neuronal cell death. It has been focused that M1-activation in cerebral cortex is implicated in various neurodegenerative diseases. Although organotypic slice culture of hippocampus of rats is widely used to study the crosstalk between microglia and neurons, little is known about the properties of microglia in the slices of cerebral cortex from mice with high applicability of the transgenic techniques. In this study, we aimed to establish a modified method for organotypic slice culture of mouse cerebral cortex that can accurately evaluates M1-activation. A few groups reported that cerebral cortices of embryonic day (E) 14 - postnatal day (P) 3 mice are available for organotypic slice culture, however microglia undergo proliferation and migrate to the cerebral cortex at P7 - P15, acquiring their mature phenotype. Thus, there is a possibility that the M1 phenotype cannot be evaluated correctly in slices prepared by conventional method, since the microglia are immature. To confirm the point, we examined the effect of postnatal day on the M1-activation by lipopolysaccharide (LPS), a classic inducer of the M1-activation. We prepared the slices using P2, P7 and P14 mice, however the slices made from P14 mice were failed to culture, but slices of P2 and P7 mice could be cultured. In this condition, induction of M1-markers (CD16, CD32, TNF-α and IL-β) by LPS in the slices of P7 mice are significantly higher than slices of P2 mice. The results indicate that the slices made from P7 mice are suitable for evaluate M1-activation. We next investigated the effects of various neurotoxic metals (arsenic(III), triethyltin, lead(II), aluminium(III), manganese(II) and methylmercury) on M1-activation using the improved-organotypic slice culture. Lead(II) and methylmercury increased the expressions of M1-markers, but other metals did not affect. These results suggest that M1-activation may be involved in neurotoxicity induced by Lead(II) and methylmercury. Taken together, the organotypic slice culture of mouse cerebral cortex improved by us can be a useful tool for screening of chemical substances that show neurotoxicity via M1-activation.
Correlations in Metal Concentrations between a Spot and 24-Hour Urine Collection

J. Gaitens1, M. Condon1, H. Xu1, M. Lewin-Smith1, F. Strathmann4, M. Velez-Quinones1, C. Brown1, and M. McDermid1,2. 1University of Maryland School of Medicine, Baltimore, MD; 2US Department of Veterans Affairs Medical Center, Baltimore, MD; 3Joint Pathology Center, Silver Spring, MD; and 4NMS Labs, Willow Grove, PA.

The US Department of Veterans Affairs’ (VA) Toxic Embedded Fragment Surveillance Center (TEFSC) uses urine biomonitoring to assess fragment-related metal exposure in war-injured Veterans. While a 24-hour urine collection has long been considered the gold standard for assessing systemic metal exposure, difficulties in obtaining a 24-hour sample, with the potential for external contamination from handling multiple voids during collection in an uncontrolled environment prompted the TEFSC to consider shifting from a 24-hour to a spot urine collection and to conduct an assessment of correlations between the two specimen types. 24 Veterans collected each void over a 24-hour period in separate containers. Concentrations of Al, As, Cd, Co, Cr, Cu, Fe, Pb, Mn, Mo, Ni, W and Zn were measured in each void and a pooled 24-hour sample using inductively coupled plasma-mass spectrometry. Spearman correlations for creatinine-adjusted metal concentrations were determined between each void and the 24-hour sample. Summary correlations were also calculated for each metal across each participant’s observations. On average Veterans submitted 6 samples over a 24-hour period (range: 2-8). Most metal concentrations were within ‘normal’ range. Correlation coefficients between each spot and 24-hour metal concentrations varied greatly according to sample collection time and by metal, with the strongest correlation noted for As (r=0.94, p<0.0001) and the weakest for Cu (r=-0.01, p=0.90). Summary correlations were >0.6 for 7 of the 13 metals. Overall, there were reasonable correlations between spot and 24-hour samples for half of the metals measured, but lack of stronger associations may be partly explained by the relatively low (normal) metal concentrations observed and the expected variability in exposure that can occur over the course of the day from diet and other sources. Evidence suggests that stronger correlations may be observed when urine metal concentrations are elevated above background. Beyond correlation of metal results, other factors suggesting the utility of a spot vs 24-hour sample in surveillance studies include the burden to the Veteran participant, risk for increased contamination, and the range of urine metal concentrations observed.

Neurodevelopmental Aspects of In Utero Exposure to Heavy Metals

D. Sarigiannis1, N. Papaoanou1, M. Fafouti1, M. Horvat2, J. Snoj Trtnik2, and S. Karakitsios1. 1Aristotle University of Thessaloniki, Thessaloniki, Greece; and 2Josef Stefan Institute, Ljubljana, Slovenia.

The effects of exposure to heavy metals on child neurodevelopment was evaluated in a Mediterranean cohort of mother-infant pairs. Heavy metals prenatal exposure included mercury, cadmium, lead, and arsenic, as well as essential elements (selenium, zinc, copper) at birth. Cognitive function, language, and motor development were assessed in children at the age of 18 months using the Bayley Scale. Individual metabolic profiles were characterized for untargeted urinary and plasma metabolomics analysis. Integrated pathway analysis and exposome-wide association algorithms were used to identify putative associations between in utero exposure to metals and metabolic pathway dysregulation, as well as between metabolic pathway perturbations and clinical neurodevelopmental indices. Metabolomics analysis revealed the presence of oxoglutaric acid, oxaloacetic acid, succinate, 2-oxoglutarate, formate, isocitrate, oxoglutaric acid, glycerol, L-carnitine, glutathione, methionine, cysteine, pyruvate, N-acetylglutamic acid, β-alanine, serine, and arginine. Pathway analysis revealed that the most perturbed metabolic pathways from exposure to heavy metals were related to the tricarboxylic acid (TCA) cycle; the metabolism of purine, pyrimidine, phospholipids and carnitine; and glycolysis. In addition, in children diagnosed with autism spectrum disorder (ASD), L-arginine of the child, L-tryptophan and acetate of the mother were above the 95th percentile, (5)-Lactate of the child was below the 5th percentile, while child blood levels of As and Hg were above the 95th percentile. Overall, the study provides additional mechanistic evidence on the effect of heavy metals in language, motor and cognitive development (including ASD), through major disturbances to cell biochemistry, which resulted in (a) energy deficiency to developing neurons and (b) the impairment of antioxidant defense mechanisms.

Heavy Metals Contamination in Eye Cosmetics in Alkhjar, Saudi Arabia: A Comparative Study

K. M. Alhathy1, A. Aljuaidi2, and R. Almutairi. Prince Sattam bin Abdulaziz University, Alkhjar, Saudi Arabia.

Cosmetic products, including eye liner and eye shadow, are widely used for beautification, body care and health purposes. Many countries regulate heavy metals, including cadmium (Cd), lead (Pb), nickel (Ni), cobalt (Co), or chromium (Cr), have been found in all kinds of cosmetics. These metals are known for their toxicity, such as neurotoxic, carcinogenic, mutagenic or teratogenic effects. Continuous assessment and monitoring of heavy metal contamination in cosmetics are needed. This study assessed the heavy metal concentrations in different low-cost brands of eye cosmetics (eye liner and eye shadow) that are sold in local markets in Alkhjar, Saudi Arabia, and compared with them with the heavy metals content in pricey and well-known brands of eye cosmetics. The samples were purchased and prepared in triplicate for analysis then assessed by using inductively coupled plasma mass spectrometry ICP-MS. The experimental results showed that lead (Pb) levels in six different low cost eye-liner and three low cost eye shadow brands ranged from 43 - 547153 ppm and 21 - 104 ppm, respectively, exceeded the maximum acceptable level for Pb as an impurity in cosmetics products based on US FDA and Canadian guidance which is set at 10 ppm, while Pb levels in well-known eye liner brands ranged from only 1 to 2 ppm (within the acceptable range limit). In addition, some analyzed low-cost eye shadow and eye liner cosmetics have high concentration of aluminum, cadmium and barium. In conclusion, there is a potential risk of heavy metal poisoning, particularly Pb poisoning in low-cost eye cosmetic products that are currently available in Alkhjar’s markets. Therefore, it is recommended that further assessment of cosmetics products such as eye liner and eye shadow should be carried out regularly to ensure these particular cosmetics follow international regulations of levels of heavy metals used in their ingredients.

Cytokine Expression Profiles and Metals Exposure Cluster Analysis within a Population Study

J. Ong1, S. McClain1, J. Hoover1, E. Erdei1, J. Lewis1, and D. MacKenzie. University of New Mexico, Albuquerque, NM.

The Navajo Birth Cohort Study (NBCS) was established to address community health concerns about chronic exposure to metals from abandoned uranium mines and waste sites. Many tribal populations experience health disparities, including increased rates of infection, kidney disease, diabetes and cancer; the immune system plays a role in all of these. Based on past and ongoing work with Navajo Nation and other tribes, we hypothesize that chronic low-level environmental exposure to metal mixtures from mine waste results in immune dysregulation. In this study, we used population samples to look for associations between metal exposure profiles and serum cytokine expression. Samples of whole blood and urine were collected from NBCS participants and analyzed for a panel of 35 metals and for expression of 17 cytokines using multiplex technology. Multiple linear regression revealed significant (p<0.05) associations between concentrations of total arsenic, blood cadmium, and serum copper measured in participants with single cytokines (IFNgamma, IL4, IL5, IL6, and IL13). To begin to better understand exposure patterns and the effects of mixed metals, we used PReMiuM, an R package for Bayesian clustering using Dirichlet processes, to group participants by exposure profiles based on detected metal concentrations. Participants cluster into four distinct groups: low levels of nearly all metals; middling metal values; and two groups in which multiple metals are elevated. In these “high” exposure groups, participants’ metal concentrations measure in the third and fourth quartiles, but the elevated metals differ between the groups. We observe distinct differences in cytokine profiles across the groups, suggesting that metals exposure profiles can influence cytokine expression profiles on a population level. Particularly striking are changes in IL17, IFNalpha, IL29 and IL1beta between the exposure groups. To better understand the potential health effects related to this exposure, it will be important to understand the relationships between chronic mixed metal exposures and potential immune dysregulation.
Absence of Embryofetal Malformations in Rats and Rabbits and Pre/Postnatal Developmental Toxicity in Rats following Oral Dosing with Bictegravir

C. McMahon	extsuperscript{1}, T. White	extsuperscript{1}, S. Moore	extsuperscript{3}, V. Sharper	extsuperscript{4}, J. Charlap	extsuperscript{3}, and L. Burns-Naas	extsuperscript{1}. \textsuperscript{1}Gilead Sciences Inc., Foster City, CA; \textsuperscript{2}Aclario Pharmaceutical Development Group, Inc., Vienna, VA; \textsuperscript{3}Charles River, Harsham, PA; and \textsuperscript{4}Charles River, Ashland, OH.

Bictegravir (BIC), a potent integrase strand transfer inhibitor (INSTI) with a high barrier to resistance, was first approved in a single tablet regimen BIKTARVY for HIV-1 infection in adults. The potential for BIC to produce developmental toxicity was evaluated in embryofetal development (EFD) studies. A pre/postnatal time point study was conducted to determine the potential effects on maternal pregnancy, parturition, and lactation, and on growth, viability, postnatal development, and reproductive performance of F₀ offspring. In EFD studies, BIC was given orally to pregnant rats (22/group) up to 300 mg/kg/day from gestation day (GD) 7 to 19, and pregnant rabbits (22/group) up to 1000 mg/kg/day from GD 7 to 19. In the PPND study, BIC was given orally to female rats (25/group) up to 250 mg/kg/day from GD 6 to lactation day 20. Clinical observations, body weights, food consumption, and Cesarean, fetal, reproductive and/or postnatal developmental parameters were evaluated.

In the rat EFD study, there was no maternal toxicity and no fetal malformations, including any neural tube defects (NTDs) or developmental toxicity up to the high dose (36-fold AUC exposure margin of 50 mg BIC clinical dose). In rabbits, maternal toxicity occurred at the high dose (1.4-fold AUC exposure margin). No fetal malformations, including NTDs, or increased embryolethality occurred in rabbits; developmental toxicity was limited to fetal weight reductions at the high dose, likely related to maternal toxicity. No overt toxicity as was seen in rabbits has been observed in humans at the clinical dose. In the rat PPND study, the NOEL was the high dose for F₀ maternal toxicity, F₁ pre/postnatal developmental toxicity (including behavior and reproduction), and F₂ early postnatal toxicity, and maternal and pup BIC exposures were 30- and 11-fold, respectively, higher than the clinical dose exposure. Taken together, these data show no direct BIC-related nonclinical developmental or reproductive toxicities.

Diphenyl Phosphate-Induced Toxicity during Embryonic Development

Diphenyl phosphate (DPPH) is an aryl phosphate ester (APE) that is used as an industrial catalyst and chemical additive, and is the primary metabolite of flame retardant APEs, including triphenyl phosphate (TPH). DPPH has been detected within urine of pregnant women, underscoring the need for developmental toxicity data. The objective of this study was to determine the potential in-UTR-induced toxicity during embryonic development. Using zebrafish as a model, we relied on phenotyping, hemoglobin quantification in situ, and mRNA-sequencing to determine the potential impacts of DPHP on cardiac morphogenesis, red blood cell formation, and the transcriptome, respectively, following whole-embryo exposures from 24-72 h post-fertilization (hpf). As DPHP and TPHP co-occur within environmental media, we also conducted a bivariate mixture experiment to determine if exposure to DPHP (250, 500, or 1000 µM) in the presence or absence of TPHP (5, 10, or 20 µM) - a cardiotoxic APE - in developing zebrafish - resulted in additive or synergistic toxicity. While exposure to DPHP from either 24-72 or 30-72 hpf resulted in a significant decrease in red blood cells (RBC) in the distance between the sinus venosus and bulbus arteriosus (SVBA), the magnitude of this effect was significantly decreased following initiation of exposure at 48 hpf - a developmental stage that follows cardiac looping. Based on mRNA-sequencing, exposure to 1000 µM DPHP from either 24-30 or 48-48 hpf resulted in significant alterations in mitochondrial function and heme-binding pathways relative to controls. Indeed, hemoglobin quantification in situ revealed that DPHP exposure from 24-72 hpf resulted in a significant decrease in hemoglobin relative to controls, suggesting that DPHP may suppress proliferation and/or maturation of erythroid precursors into erythrocytes. Co-exposure of embryos to DPHP and TPHP from 24-92 hpf resulted in a significant increase in SVBA length relative to DPHP or TPHP alone, suggesting that exposure to DPHP-TPHP mixtures may lead to additive effects on cardiac development. Overall, our findings to date demonstrate that DPHP is biologically active during embryogenesis, albeit the potency of DPHP is ~100-fold less than TPHP based on whole-embryo expression exposures - a finding that is consistent with the US EPA’s ToxCast data and likely due to DPHP’s high water solubility (log Kow = 1.4) and, as such, limited uptake into developing embryos.

Snus Smokeless Tobacco Impacts Osteotoxicity by Repressing Cellular Stress Mechanisms through the AKT-Signaling Network

L. Walker, N. Sparks, S. Sera, J. Carreon, E. Dominguez, and N. zur Nieden. University of California Riverside, Riverside, CA.

In the last 20 years, tobacco-related health disparity concerns have shifted focus from smoking to other forms of tobacco use. Pregnant women struggling with nicotine addiction may switch to harm-reduction tobacco products (HRTPs) as HRTPs are marketed as less harmful to users. Contrarily, epidemiological studies suggest that HRTPs may hinder infant bone mineral density. While current research indicates HRTP exposure directs targeted osteogenesis as gestational exposure of mouse embryos reduced skull mineralization by a presently unknown mechanism. To model osteoblocytopathy, human embryonic stem cells were differentiated into osteoblasts and consequently exposed to conventional sidestream cigarette (CSC) or a commercial Snus smokeless tobacco extract. Snus exposure decreased osteocalcin differentiation at subtoxic levels, while CSC exposure inhibited osteogenesis at cytotoxic levels. Both showed significantly increased cellular reactive oxygen species at inhibitory doses. Notably, dosing cultures with H2O2 alone inhibited osteogenesis only when dosing occurred during early differentiation. Cellular stress assessment found CSC cultures featured more apoptotic cells while Snus cultures had more injured cells without active apoptosis. Mechanistic analysis revealed higher activation of the survival kinase AKT exclusively in Snus-treated cultures. Activity of the stress rescue kinase, JNK, was also reduced in Snus cultures. Rescue experiments found concurrent AKT inhibitor or JNK activator treatment to rescue osteocenesis in Snus-treated cultures implicating mis-regulation of these kinases in Snus inhibitory outcomes. Global proteomic analysis of AKT signaling pathway targets identified hyperphosphorylation of FOXO transcription factors—responsible for bone homeostasis in adult cells—exclusively in Snus cultures marking them for nuclear exclusion. Taken together, our data suggests that Snus products impart normal osteogenesis through distinct mechanisms with Snus potentially operating through a mechanism specific to early osteogenic commitment.

Adverse Developmental Effects in Progeny of Zebrafish That Were Exposed to Atrazine during Embryogenesis

J. Akinchin Chin Tai, K. Horzmann, and J. Freeman, Purdue University, West Lafayette, IN.

Atrazine (ATZ) is an herbicide that is commonly used on crops in the Midwestern US. ATZ has a long half-life and is a common contaminant of drinking water sources. Although the US EPA set the maximum contaminant level at 3 parts per billion (ppb), water sources often exceed this limit. ATZ has been implicated as an endocrine disrupting chemical in multiple species. The current study used the zebrafish model system and tested the hypothesis that an embryonic parental ATZ exposure altered protein expression, morphology and behavior in developing progeny. Zebrafish embryos were collected from adults that were exposed to 0, 0.3, or 30 ppb ATZ during embryogenesis. Protein, morphology, and behavior analysis was completed with offspring from each chemical treatment group aged 120 hours. The offspring received no additional chemical treatment. Proteomic analysis found that parental exposure to ATZ, regardless of dose led to differential expression of proteins involved in pathways of cancer; neurological disease; and morphology of tissue, and muscular development. Morphology measurements of total length, head width, and brain length were not significantly different (p>0.05). Head length was found to be significantly different between the control group and parental exposure groups, with increasing exposure leading to increasing head length (p<0.05). The light/dark behavioral test detected no significant differences in swimming distance, velocity, or time spent moving/not moving (p>0.05). These findings suggest that a single embryonic parental exposure can alter proteomic expression and morphology in progeny supporting further assessment of adverse impacts in this generation.

Role of the Transcription Factor Nfe2 and Pro-oxidant Exposure in Inner Ear Development in Zebrafish

A. Bowsher, M. Mait, and L. Williams, Bates College, Lewiston, ME.

Millions of people worldwide suffer from hearing loss. While several mechanisms have been associated this loss, the role of oxidative stress remains underexplored. Nfe2, a transcription factor in zebrafish and other vertebrates, is localized to the otic vesicle during development and has been shown to me-
2391 Chemical-Induced Craniofacial Abnormalities Share a Conserved Molecular Mechanism with Neural Crest Development in Zebrafish and Mammals

Alternative methods for testing the developmental toxicity of chemicals have been developed worldwide. Zebrafish embryos represent a promising model for assessing teratogenicity owing to their rapid development and transpar-

ency. Many craniofacial abnormalities is a critical endpoint for eval-

uating chemical-induced teratogenicity, the common ontogenic pro-

cess disturbed by teratogens in zebrafish and mammals has not been wel-

l studied. In the current study, we exposed zebrafish embryos to 13 recog-

nized teratogens (retinoic acid, methotrexate, salicylic acid, valproic acid, caffeine, warfarin, methanol, aspirin, isoniazid, dexamethasone, 5-fluouracil, phenytoin, thalidomide, boric acid, and imatinib) and then performed cartilage staining using Alcian blue to examine detailed craniofacial morphological changes induced by the teratogens. Most of the teratogens induced craniofacial mal-

formations, which were found in both the neurocranial cartilage and pharyn-

gal skeleton. Retinoic acid, methotrexate, salicylic acid, and valproic acid severely abrogated the development of the ethmoid plate, mandible, and skull base. Caffeine, warfarin, hydroxyurea, and dexamethasone resulted in moderate phenotypes, namely obvious separated ethmoid plate and short-

ening of Meckel’s cartilage. The other compounds induced slight craniofacial mal-

formations of the lower jaw and skull base. Notably, these observations partly corresponded to the abnormalities reported in mammals, suggesting that the mechanism by which teratogens disrupt cranial neural crest (CNC) development in zebrafish and mammals is common. Comprehensive and semi-quantitative analyses were performed to examine the conserved biol-

genetic pathway involved in CNC development between zebrafish and mammals. We elucidated that the disruption of CNC development is the target biological pathway underlying chemical-induced craniofacial mal-

formations, and this finding represents a promising molecular endpoint for mechanism-based teratogenicity evaluation.

2392 Filling Gaps by New Approach Methods: A Case Study for Teratogenicity Prediction of VPA Analogs

T. Waldmann, and M. Leist. University of Konstanz, Konstanz, Germany.

In the last years new approach methods (NAM) have been developed to allow animal-free hazard assessment. They are often based on human cell cultures and they measure fundamental biological processes, such as neurite outgrowth, neural differentiation or cell migration. NAM are useful to assess whether chemicals affect key event (KE) as part of an adverse outcome path-

way (AOP). The regulatory use of data generated from NAMs represents the next big challenge in the field of in vitro toxicology and a first step may be the use of NAM for readacross (RAX) purposes. Here, we present a RAX case study using 8 structural analogs of valproic acid (VPA), an anticonvulsant drug with known in vivo teratogenic activity. Literature research revealed that 3 compounds are in vivo positive, 3 show no teratogenic in vivo effects. 2 com-

pounds have an unknown in vivo activity. This shows that a simple structural similarity may not be sufficient to conclude on teratogenicity. To improve RAX, we considered activity-activity relationships within an overall QSAR ap-

proach, added data on the mode of action (MoA), and complemented this information with data from NAM that measure disturbed embryonic devel-

opment. For the latter we used the zebrafish embryo test (ZET), the mouse embryonic stem cell test (mEST) and a recently developed induced pluripo-
tent stem cells (iPSC)-based neurodevelopmental model (UKN1). One MoA of VPA is the inhibition of histone deacetylases (HDAC). We found that the compounds showing a strong HDAC inhibition correlate with positive hits in our NAM. The UKN1 assay is an in vitro test method that models early neu-

rodevelopmental changes on human iPSC differentiating into neuroectodermal progenitor cells. These cell culture allows the measurement of 3 important endpoints; cell viability; gene expression and the formation of neural rosettes as a functional differentiation endpoint. With this combination of our end-

points we have identified all in vivo positive compounds and 2 out of 3 negative compounds. With the approach we applied the application of NAM for RAX studies, and point to a strategy that uses (i) existing in vivo and in vitro data; (ii) incorporates QSAR and (iii) and also provides new data to fill prediction gaps. The combination of these three aspects delivered a good prediction of teratogenicity of the investigated VPA analogs.

2393 Placental Transfer of 125I-Labeled Humanized Immunoglobulin G2ΔA in the Cynomolgus Monkey

Antibody-like biopharmaceuticals cross the placenta by utilizing existing transport pathways (e.g., FcRn receptor) for transfer of maternal antibodies to the conceptus. There are limited data evaluating this transfer during organogenesis in any species. Understanding placental transfer of antibody-like biopharmaceuticals can help predict risk of developmental toxicity across species, including humans. To complement previously published placental transfer data in the rat with humanized IgG2ΔA (hIgG2ΔA), the timing and magni-

tude of transfer in the cynomolgus monkey and embryo/fetal biodistribution of maternally administered 125I-radioiodinated hIgG2 was quantified on gesta-

tion days (GD) 35, 40, 50, 70 and 140 using gamma counting and whole body autoradiography 24 hours following intravenous injection. Chorallantoic or placental tissues were collected at all time points for Western Blot analysis with anti-FcRn antibody. Maternally administered 125I-hIgG2 was found in monkey embryo/fetal tissues at all time points, including during organo-

genesis (until GD 50). Due to embryo size, embryonic blood samples were not available at GD 35, but 125I-hIgG2 was detectable from GD 40 onwards. Embryo/fetal plasma 125I-hIgG2 concentration increased during gestation, but only increased slightly up to GD 70 in embryo/fetal tissues, with hIgG2 tissue concentrations generally similar between GD 70 and 140. The embryo/fetal/maternal 125I-hIgG2 plasma concentration ratio was approximately 2.3 fold higher on GD 140, in comparison to ratios on GD 40. Importantly, pla-

cental FcRn protein expression was confirmed at all timepoints. These data demonstrate placental transfer of hIgG2 in a nonhuman primate model, and at levels comparable to the rat model. Hence, rats also represent a biologically and clinically relevant species for placental transfer of hIgG2. Antibody was measured in the nonhuman primate and rat embryo/fetus during specific de-

velopmental windows, including organogenesis. Thus, direct antibody bind-

ing to biological targets present in the developing conceptus is conceivable, raising the potential for adverse developmental outcomes.

2394 Identifying the Molecular Mechanisms Responsible for Persistent Effects of Developmental Exposure to Chlorpyrifos on Behavior

N. Alugubelly, A. N. Mohammad, and R. L. Carr. Mississippi State

University, Starkville, MS.

Chlorpyrifos (CPF) is one of the most widely used organophosphorus insec-

cides (OPs). Developmental exposure to OPs has long-lasting negative im-

pacts, including abnormal emotional behavior. These negative impacts are observed at levels that cause only minimum inhibition of acetylcholinester-

ase, the canonical target of OPs. However, exposure to these levels results in the inhibition of the endocannabinoid metabolizing enzyme fatty acid amide hydrolase (FAAH) and altered emotional behavior specifically increased so-

cial play. However, the molecular mechanisms responsible for this increased social play are not known. In this study, male rat pups were exposed orally to either corn oil, 0.75 mg/kg CPF, or 0.02 mg/kg PF-04457845 (PF; a specific

hydrolase (FAAH) and altered emotional behavior specifically increased so-

cial play are not known. In this study, male rat pups were exposed orally to either corn oil, 0.75 mg/kg CPF, or 0.02 mg/kg PF-04457845 (PF; a specific
testing, the amygdala was collected from each cohort and protein expression was determined using a label-free shotgun proteomic approach. The obtained differentially expressed proteins from the different cohorts were analyzed by DAVID and Ingenuity Pathway Analysis software. The data from the non-behavior group of rats suggest that FAAH inhibition by development- tial exposure to CPF and PF persistently affects glutamatergic and GABAergic signaling. These data also suggest that there is a similar pattern of protein expression between CPF and PF suggesting that these long-term effects are due to the inhibition of FAAH. The data from the behavioral group of rats suggest that alterations in the glutamatergic and GABAergic signaling and activation of opioid signaling could be responsible for the increased social play behav- ior. These alterations in neurotransmitter signaling were observed in both CPF and PF treated rats. Overall, the data suggest that FAAH inhibition by CPF leads to an alteration in the opioid, glutamatergic, and GABAergic signaling that could be responsible for increased levels of social play.

Assessing the Toxicological Response of Placenta to PFAS Using “Placentox”—A Novel High-Throughput mRNA Biomarker Platform

J. Bangma, J. T. Szilagyi, and R. C. Fry. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Per- and poly-fluoroalkyl substances (PFAS), also known as fluorosurfactants, are a group of chemicals that have been widely used in stain repellents, paints, polishes, protective coatings, and firefighting foams. While some of these chemicals, including perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), have been discontinued in the United States, their persistence in the environment and continued use internationally make them a toxicological concern. Moreover, GenX, a modern fluorosurfactant replace- ment for PFOA, has recently contaminated drinking water in the Cape Fear River in the Wilmington area, warranting immediate evaluation of the risks associated. The USEPA acknowledges that certain PFAS can cause reproductive, developmental, liver, kidney, and immunological toxicity and may even be carcinogenic. While prior reports have shown that PFAS can cross the pla- centa, there is little understanding of how this class of compounds can impact placental function itself. We therefore developed the “PLACENTOX”-a mRNA biomarker panel designed to comprehensively examine potential changes in placental homeostasis, development, and function as a result of PFAS exposure. This panel includes 90 well-established mRNA markers of trophoblast fusion, invasion, nutrient and drug transport, apoptosis, proliferation, inflam- mation, oxidative stress, hormones production, and unfolded protein response in tandem with the Fluidigm Biomark HD platform for high-throughput qPCR analysis. JEG-3 cells, an in vitro trophoblast cell line, and ex vivo explants isolated from human term placentas were treated with PFOA, PFOS, and GenX (10-1000 ng/mL) for 24 hours and mRNA expression was quantified using this technique. Selected genes showing significant (p < 0.01) changes for one or more PFAS were confirmed using traditional qPCR in a 96 well plate format, and protein expression was analyzed by western blot. Ultimately, this panel can be utilized in future studies to provide a comprehensive analysis of placental toxicity for any environmental toxicant of concern.

Placental Redox Potential and Histiotrophic Nutrition in Organogenesis—Stage Mouse Conceptuses Treated with Valproic Acid

S. R. Lapeho, and C. Harris. University of Michigan, Ann Arbor, MI.

Neural Tube Defects (NTDs) comprise a group of morphological birth defects with unknown etiology. Exposure to anesthetics drugs including valproic acid (VPA) increases NTD incidence by mechanisms that implicate increased reactive oxygen species but not induction of the protective Nrf2 antioxidant response. This mouse whole embryo culture study (gestational days [GD] 8-9) explores redox mechanisms of VPA on neural tube closure. We hypoth- esized that pre-treatment of conceptuses with 1,2-dithiole-3-thione (D3T), a synthetic Nrf2 inducer, on GD8 would increase glutathione (GSH) and elicit a more negative, protective, GSH/GSSG redox potential (Eh) across the develop- mental time course. HPLC measurements of GSH and glutathione disul- fide (GSSG) indicated an increased Eh from -217.71mV to -173.6mV following a 14hr VPA exposure in embryos that was significantly different from both the control and the co-treated D3T+VPA group. At 20hr, Eh of control versus D3T+VPA increased in the embryo (-225.28mV to -152.49mV) and in visceral yolk sac (-204.89mV to -135.74mV). Total GSH (GSH+2GSSG) concentrations decreased significantly at 20hr from 4.8mM in the control embryos to 1.8mM in the D3T + VPA embryos. Altered GSH status and increased Eh produced indirectly through decreases in protein uptake and degradation (histiostrophic nutrition pathways, HNP) were also evaluated. Clearance of FITC-Ab from the culture medium at 1, 3, or 6hrs on GD8 was measured for all exposure con- ditions. HNP activities in the VPA and D3T+VPA groups were decreased between 32-55% at 1 and 3hr but were variable and not statistically significant. The HNP results do suggest that VPA may have acute early effects on HNP activity that is also not correlated with cellular redox activity. These results indicate that VPA exposure does not produce extensive, uniform, depletion of total GSH or increased Eh, in all conceptal tissues during organogenesis and that Nrf2 induction by D3T is sufficient alone or with VPA to protect against VPA-induced changes. Previous evidence implicating increased reactive oxygen species with higher incidence of neural tube defects following VPA exposure was not shown to be correlated with the conceptual GSH redox state but will require a more directed spatial and temporal analysis of oxidative post-trans- nential protein modifications.

Maternal Bococizumab (Anti-PCSK9 Monoclonal Antibody) Administration Does Not Affect Rat Pre- and Postnatal Development

S. N. Campion1, G. D. Cappon2, E. M. Lewis2, and C. J. Bowman1. 1Pfizer, Inc., Groton, CT; and 2Charles River Laboratories, Inc., Horsham, PA.

Bococizumab is a humanized monoclonal IgG2a antibody against propro- tein convertase subtilisin/kexin type 9 (PCSK9) for the treatment of hyper- lipidemia. In a previous study conducted in rats, there were no effects on embryo-fetal development in the presence of decreased maternal and fetal cholesterol. In a pre- and postnatal development study bococizumab was ad- ministered intravenously to pregnant Sprague-Dawley (SD) rats (n=22/group) at 0, 10, 30, and 100 mg/kg once every three days beginning on Gestation Day 6 and continuing through Lactation Day 20. The doses evaluated were previously demonstrated to decrease maternal and fetal cholesterol during gestation in a dose-dependent manner. Bococizumab was well tolerated and no area, warranting in F0 females or any natural delivery parameters. In addition, there were no clinical signs or effects on body weight, food consump- tion, sexual maturation, behavioral endpoints (motor activity, Morris water maze, and acoustic startle testing), or reproductive endpoints in the F1 rats. This study has demonstrated no adverse effects on pre- and postnatal development at doses of bococizumab that cause reductions in maternal and fetal cholesterol.

Role of Nrf2a in Modulating MEHP-Induced Hepatosteatosis following Embryonic Exposure in Danio rerio

H. Moreau1,2, K. Sant1,2, L. M. Williams1, and A. Timme-Laragy2. 1Bates College, Lewiston, ME; 2University of Massachusetts Amherst, Amherst, MA; and 3San Diego State University, San Diego, CA.

Di(2-ethylhexyl) phthalate is a plasticizer and ubiquitous human toxicant. Its bioactive metabolite, mono(2-ethylhexyl) phthalate (MEHP) has been linked to abnormal development, increased oxidative stress, and metabolic syn- drome—namely obesity. Nrf2 is a transcription factor that regulates gene expression through Antioxidant Response Elements (AREs) in the promotor- ers of genes and functions as an inducible regulator of oxidative stress. The objective of this study was to investigate the role of Nrf2a in juvenile adi- posity following embryonic exposure to MEHP. Zebrafish (Danio rerio) wild type (wt) and mutant (m) embryos from a Nrf2a mutant line were exposed to 0 or 200 μg/L MEHP through immersion beginning at 6 hours post fertilization (hpf) and concluding at 120 hpf. At 120 hpf fish were placed in clean system water and maintained to 15 days post fertilization (dpf). At 15 dpf fish were imaged for length and stained with Oil Red O to visualize lipid depots. Wild type control fish were significantly longer than mutant control fish. Developmental MEHP exposure significantly increased hepatosteatosis in both wild type and Nrf2a mutant fish, an effect that was exacerbated in mutant fish. Adipogenesis was moderately increased in fish exposed to MEHP, though this trend was not statistically significant. These data indicate develop- mental exposure to MEHP may increase risk for hepatosteatosis, and that impaired Nrf2a function may exacerbate this phenotype. This result is consis- tent with Nrf2a’s previously reported facilitation of hepatoprotection in adults. Our data suggest that toxicant-induced oxidative stress during embryonic development is a risk factor for hepatosteatosis later in life, and Nrf2 function is important for mitigating this stress and decreasing risk for hepatosteatosis.
Sensitivity of Micro-Computed Tomography (micro-CT) Imaging to Visualize Skeletal Variations and Malformations in Embryo-Fetal Development Toxicity Studies

Embryo-fetal developmental (EFD) toxicity studies are an essential means for determining the potential effects of a drug on the developing fetus. Traditionally, these studies utilize the Alizarin red staining method to identify variations and malformations in the fetal skeleton. Wise et al. (2013) determined that micro-CT using spatial resolution (~60 µm) was able to visualize small skeletal structures in a fetus when compared to Alizarin red staining. However, small elements of ossification identified in staining were unseen by micro-CT. In an unpublished, in-house study, it was demonstrated that micro-CT, using high resolution (35 µm pixel), could visualize small skeletal structures in a fetus, including small degrees of ossification. The purpose of this study was to utilize a developmental toxicant known to induce skeletal malformations and variations in early organogenesis and without overt systematic toxicity, and to compare the skeletal findings between the Alizarin red staining and micro-CT imaging methods. Therefore, Acetylalsaliclyc Acid (aspirin) was chosen as the test item. Forty-four time-mated, Sprague Dawley rats (22/group) were dosed with either vehicle control (0.2 % carboxymethyl-cellulose in water) or 500 mg/kg of aspirin on Gestation Day (GD) 9. Cerean sections were performed on GD 21 and the fetuses were euthanized. Micro-CT imaging was performed on the rat fetuses at 35 µm pixel size. Following micro-CT imaging, the same fetuses were eviscerated and manually processed using the Alizarin red staining method. Skeletal anomalies of the ribs, sternebrae, and thoracic vertebrae, including ossification defects that were observed from the Alizarin red stained fetuses were also observed in micro-CT imaging, utilizing both 2D and 3D images. In conclusion, micro-CT imaging was demonstrated to be sensitive enough to visualize rat fetus skeletal assessments. Thus, supporting the use of micro-CT imaging for replacement of Alizarin red staining in developmental studies. Replacing traditional staining with micro-CT imaging would allow for high throughput skeletal imaging with reduced processing time, reduced hazardous waste production, and reduced archival products associated with traditional staining.

Validation of a Novel Human Stem Cell-Based Gene Expression Assay for In Vitro DART Assessment

Testing for developmental and reproductive toxicology (DART) is a crucial part of the toxicological risk assessment. Today, DART mostly relies on animal testing. However, an alternative in vitro test, such as embryonic stem cell differentiation-based assays, are increasingly being used. However, these in vitro assays often do not provide mechanistic insight and the results are difficult to translate to human risk due to inter-species differences. To improve in vitro identification of developmental toxicants, we identified 43 potential biomarkers in human induced pluripotent stem cells (hiPSC), marking different developmental stages from stem cells to mature tissues. To test whether compounds affect development, first we optimised the differentiation protocols for hiPSC towards cardiomyocytes, hepatocytes and neural rosettes and confirmed the expression of selected biomarkers (OCt4, BMP4, MYH6, FOXA2, SOX17, AFP, ALB, SOX1, PAX6) by qPCR. During differentiation, expression of the developmental stage marker OCT4 decreased, while expression increased for matured tissue markers MYH6 in cardiomyocytes, ALB and AFP in hepatocytes and PAX6 and SOX1 during neuronal rosette differentiation. Next, we exposed differentiating cells to 15 different compounds (both known teratogenic compounds as well as non-teratogenic compounds). We observed a downregulation of the cardiomyocyte-specific biomarker MYH6, hepatocyte-specific markers ALB and AFP and neural specific biomarker PAX6 during teratogenic compound treatment. The cardiomyocyte-specific biomarker PAX6, the hepatocyte-specific markers ALB and AFP, and the neural specific biomarker PAX6 were significantly downregulated at 100 µM, while the other treatments did not show differences. Blastocyst formation was reduced to only 24% at 1000 µM MEHP, while hatching initiation was decreased by 1% and 100 µM MEHP. Fully hatched embryos were sharply reduced to just 1.33% with 1000 µM MEHP, while the other treatments did not show differences. The diameter and volume of the hatched ones were similar between groups. The ratio of inner cell mass to trophectoderm cells appeared to be more pronouncedly affected at the low concentration of 1 µM MEHP, and was increased, although statistical analysis was not yet done. In conclusion, MEHP has negative effects on preimplantation embryonic development at various stages, depending on the dose, and further studies need to be carried out.

Bisphenol A Exposure Differentially Affects Echinoderm Embryogenesis

I. Veras, A. Bonilla, B. Zhongli, H. Aguilar, T. Onorato, H. Zaki, G. Reyes, N. Oulhen, and G. Wessels. LaGuardia Community College, Long Island City, NY; and Brown University, Providence, RI.

For many the ocean is a wonderful peaceful oasis but for marine invertebrate larvae it can be a harsh and stressful journey to adulthood. Larvae are exposed to numerous environmental stresses resulting from both nature and anthropogenic effects; such stresses include temperature change, oxygen availability, and environmental toxicants. One such environmental toxicant is Bisphenol A (BPA), a plasticizer found in such products as plastic bottles, cans, electronics and medical devices, which acts as an endocrine disruptor thus causing fertility and developmental defects. Increased ocean pollution with items containing BPA poses a serious hazard to marine life. Therefore, we investigated the effect of BPA on embryogenesis of the sea star, Patiria miniata. Eggs and sperm were treated with BPA (0, 1, 5, 10 µM) 30 minutes before fertilization and analyses were performed on developing embryos 24 and 48h post-fertilization. We found that BPA exposure significantly increases nascent protein synthesis and mitochondrial activity of P. miniata embryos. Additionally, we performed the same BPA treatment on the sea urchins, Lytechinus variegatus and Strongylocentrotus purpuratus. BPA exposure significantly decreased mitochondrial activity and nascent protein synthesis of L. variegatus embryos but did not affect nascent protein synthesis of S. purpuratus embryos. Our findings suggest that BPA exposure differentially affects sea stars and sea urchins and that not all species of echinoderms respond the same to the environmental stress of BPA exposure.

Mono(2-ethylhexyl) Phthalate (MEHP) Adversely Affects Mice Embryonic Development In Vitro

R. Braz Arcanjo, and R. A. Nowak. University of Illinois at Urbana-Champaign, Urbana, IL.

MEHP is the first active metabolite from the breakdown of DEHP, which is used to provide flexibility to plastics and is commonly found in food packaging, personal care products and medical supplies. MEHP is an endocrine disrupting chemical, and its high concentration in the body has been linked with negative reproductive outcomes. The objective of this research is to investigate negative effects of MEHP on early embryonic development using an in vitro model. Embryos were collected from the oviduct of superovulated CD-1 female mice mated with C57BL/6 males. Six to ten embryos per group were cultured in 30 µl drops of either KSOm cell medium, vehicle (DMSO 0.005% or 0.05%) or 0, 1, 10, 100 and 1000 µM MEHP and were observed daily over six days. After, diameters of embryos were measured, and blastocysts were fixed for differential staining of inner cell mass (marked by Oct-4) and trophectoderm (marked by CDX-2) by immunofluorescence. Analyses of blastocysts and cell types were done with a confocal LSM 880 microscope and Imaris Software. Percentage data were analyzed by chi-square and Fisher’s exact test considering Bonferroni adjustment. Continuous variables were tested for normality and compared against control by one-way ANOVA and Tukey’s post-test or Kruskal-Wallis test and Dunn’s post-test. Statistical analyses were done in GraphPad Prism 7.0 and p < 0.05 was considered significant. The percent of embryos that developed to the 2-cell stage was significantly reduced by 1% and 100 µM MEHP. Percentage reaching 4-cell stage was reduced by 1, 10 and 100 µM MEHP. The 10 µM MEHP also had a detrimental effect at 8-cell and morula stages. Blastocyst formation was reduced to only 24% at 1000 µM MEHP, while hatching initiation was decreased by 1% and 100 µM MEHP. Fully hatched embryos were sharply reduced to just 1.33% with 1000 µM MEHP, while the other treatments did not show differences. The diameter and volume of the hatched ones were similar between groups. The ratio of inner cell mass to trophectoderm cells appeared to be more pronouncedly affected at the low concentration of 1 µM MEHP, and was increased, although statistical analysis was not yet done. In conclusion, MEHP has negative effects on preimplantation embryonic development at various stages, depending on the dose, and further studies need to be carried out.

2403 Modulation of Peroxisome Proliferator-ACTivated Receptors Gamma (PPARγ) Signaling Perturbs Embryonic Pancreas Development in the Zebrafish, Danio rerio

O. L. Venezia$^1$, K. E. Sant$^2$, and A. R. Timme-Laragy$^3$, $^1$University of Massachusetts Amherst, Amherst, MA; and $^2$San Diego State University, San Diego, CA.

Peroxisome proliferator-activated receptors (PPARs) are essential transcription factors for glucose and lipid homeostasis, as well as critical development processes such as adipocyte differentiation. Differentiation of preadipocytes into adipocytes is modulated by PPAR gamma (PPARγ) - demonstrating the formation of ectopic adipocytes and abnormal birth weight when altered. Toxicants such as phthalates, butylparaben, and PFOS are reported to have affinity for PPARγ, and have been previously shown to elicit adverse effects on the developing zebrafish (Danio rerio). This begs the question of how disruption of PPAR activity during development may alter fetal metabolic processes that are carried into adulthood, such as in the pancreas. Here we examine the effects of altered PPARγ activity on the developing exocrine and endocrine pancreas in zebrafish embryos. Transgenic fish lines that express GFP in beta cells of the endocrine pancreas (Tg(ins:GFP)) or in ptf1a expressing endocrine cells of the exocrine pancreas (Tg(ptf1a:GFP)) were used to assess the impact of PPARγ modulation on pancreas development in live zebrafish embryos. Beginning at 24 hours post fertilization, embryos were exposed daily to either Rosiglitazone (selective PPARγ agonist) or T0070907 (selective PPARγ antagonist) at concentrations of 0 (0.01% v/v DMSO), 0.1, 1, and 10 µM. At 96 hpf, embryos were imaged live with brightfield and fluorescent microscopy, and images were analyzed using morphometrics. Fish length and yolk sac utilization suggests that morphological delays were associated with 10 µM T0070907 and Rosiglitazone exposures. T0070907 exposure correlates with a decrease in islet area but demonstrates a u-shaped dose curve response in exocrine pancreas length, while Rosiglitazone appears to only alter endocrine pancreas area in a non-dose dependent manner. However, Rosiglitazone results in an increased occurrence of endocrine pancreatic deformities as 21% of 10 µM exposed embryos display a ‘wispy’ or ‘curved’ pancreas, when compared to 0% of controls. In addition, a 7% increase in fragmentation of endocrine pancreas islets was observed in both 1µM and 10µM Rosiglitazone exposed embryos, compared to controls. These findings suggest that pancreas development is sensitive to modulation of PPARγ, but it does not fully recapitulate the morphologies observed with preclinical studies. This work is being supported by grant funding from F32ES028085 and NIH RO1ES025748.

2404 Improving In Silico Predictions in Developmental and Reproductive Toxicology

C. Villano$^1$, B. Rickard$^2$, and A. Fowkes$^3$, $^1$Bristol-Myers Squibb, New Brunswick, NJ; $^2$University of the Sciences, Philadelphia, PA; and $^3$Lhasa Limited, Leeds, United Kingdom.

In silico predictions for toxicity are able to assist risk assessors with chemical safety assessments. The confidence in a specific method can dictate whether the approach is used to support compound prioritization or for regulatory decision-making. Developmental and reproductive toxicity (DART) continues to be a challenge for in silico predictions, partially due to a lack of data availability across a broad chemical space. While there is a large amount of publicly available data, a significant amount of information from DART studies, including those conducted by pharmaceutical companies, remains in confidential locations. In an attempt to broaden the chemical space for DART in silico evaluations, data from embryo-fetal development studies in rats and rabbits was curated by Bristol-Myers Squibb (BMS) and provided to Lhasa Limited for evaluation. The data consisted of 22 compounds with publicly available structures and known pharmacology and was shared with Lhasa Limited for evaluation using in silico tools. One goal of this initiative was to potentially uncover new structural alerts for incorporation into Derek Nexus’ knowledge base, as well as strengthening existing alerts. Evaluation of the dataset alongside publicly available data, was unable to generate new structural alerts predicting for reprootoxicity. However, molecular initiating events of interest for DART were identified for potential incorporation into an adverse outcome pathway (AOP) framework. For example, the development-toxicity associated with tyrosine kinase inhibitors, can be rationalized in terms of their potential to disrupt the receptors’ normal function during organogenesis. Subsequent literature review of relevant mechanistic studies of the prioritized targets enabled synthesis of new putative AOPs. AOPs such as these are able to document existing evidence to support a pathway leading from a molecular initiating event (MIE) to an adverse outcome such as embryo lethality, teratogenicity, or impaired fertility. Documenting the evidence in this way can ground relevant in silico models and provide scientific rationale of their output to risk assessors, thus supporting better decision-making. This data sharing initiative has highlighted some chemical space of concern for DART, which in silico approaches should cover, in order to increase user confidence in this setting.

2405 Toxicity Interaction of the Two Most Common Agricultural Herbicides in the United States: Glyphosate and Atrazine

L. Brulinski, J. Tai, and J. L. Freeman, Purdue University, West Lafayette, IN.

Glyphosate and atrazine are the two most commonly used agricultural herbicides in the United States. These herbicides are sprayed on crops to reduce weed populations, but move into drinking water sources following rain events. There is a lot of controversy surrounding the use of these two herbicides because of suspected hazardous health effects. The US EPA established the maximum contaminant level (MCL) of glyphosate in drinking water at 700 ppb (µg/L) and the IARC designated glyphosate as “probably carcinogenic to humans.” Though atrazine has been suspected of being a carcinogen, the main health concerns surround endocrine disruption with the MCL set at 3 ppb. Though there are countless studies concerning the individual toxicity of these herbicides, there is limited research on the potential toxic interaction making this a substantial gap in our knowledge. This study aims to test the hypothesis that a toxicity interaction occurs between atrazine and glyphosate at treatment concentrations below those observed for the single chemical exposure. This study in conjunction with previous research by our group, first identified developmental toxicity profiles of the individual herbicides using the zebrafish model system. This data was then used to inform on treatment concentrations to evaluate mixture interactions on behavioral and morphological outcomes. Zebrafish were bred and their embryos immediately collected and exposed to one of four treatments, which included the MCL for each herbicide alone or in mixture since single chemical analysis indicated changes in behavior and morphology at concentrations 10x the MCL for each herbicide. Currently, at 120 hours post fertilization the behavior results showed that all treatment groups were significantly different from the control (p<0.05; n=4 with 32 subsamples/biological replicate). The morphological data including tail length, head length, head width, and brain length were not significantly different in the mixture exposure (p>0.05; n=7 with 11-12 subsamples/biological replicate).

2406 Patterns of Hyaluronic Deposition in Normal and Diseased Pediatric Livers

M. Czerwinski$^1$, A. Katz$^2$, J. Surgier$^3$, S. E. Tague$^4$, and M. T. Pritchard$^5$, $^1$Sekisui XenoTech LLC, Kansas City, KS; $^2$Children’s Mercy Hospital, Kansas City, MO; and $^3$University of Kansas Medical Center, Kansas City, KS.

The incidence of obesity and non-alcoholic fatty liver disease (NAFLD) is growing in children. Hyaluronan (HA), an extracellular matrix (ECM) glycosaminoglycan, is increased in liver and blood from adults with advanced liver disease. HA accumulation is also associated with fibrosis and fibrosis in extrahepatic tissues. HA levels have not been examined in healthy or diseased livers from pediatric patients. Here, we sought to determine if hepatic HA deposition was associated with donor age and/or disease by using a pediatric liver tissue microarray (TMA). The TMA contained 25 tissues from donors aged 4 months to 18 years old and 5 adult controls (3 mm diameter cores, 4 µm-thick array). Donor demographics and health data were collected from interviews with next of kin and hospital records. Three consecutively cut arrays were stained with hematoxylin and eosin (H&E) and Gomori’s trichrome for evaluation of tissue histology, and collagen, respectively, or with HA binding protein (HABP) to localize HA. Images of the arrays were obtained with a Nikon HCA system and a Hamamatsu Orca Flash 4 camera (HABP) or a Nikon DS-F13 camera (H&E and Gomori’s trichrome). HA was detected in 24 pediatric and in 5 adult control tissues. Well-defined HA staining was observed in the ECM-rich portal tracts while thin but distinct rims of HA were observed surrounding central veins. These observations were independent of donor age. HA was also observed in livers from patients with histological evidence of fibrosis. Moreover, in overweight or obese patients with NAFLD and fibrosis, typical HA-positive regions were expanded, more diffuse, and also found surrounding steatotic hepatocytes outside of portal tracts. There was variability in this staining pattern as this assessment was complicated by micro- and macrovesicular steatosis ranging 50 - 80% in the NAFLD patients. In tissues deemed normal or near normal based on microscopic examination and medical history, the HA staining was less intense than in diseased tissues independent of donor age. The pediatric liver TMA allowed demonstration of normal and disease-associated HA localization and the identification of distinct staining patterns in different patient cohorts.
Advanced paternal age is associated with elevated risk for a constellation of somatic and neuropsychiatric diseases in offspring. We recently demonstrated that offspring of aged male mice exhibit accelerated aging across most organ systems, neuroinflammation, and reduced survival. Sperm from aged fathers and brain tissue from old father offspring displayed enhanced mammalian target of rapamycin (mTOR) activation suggesting that offspring of aged fathers age faster due to inherited mTOR hyperactivity, and that they could thus be more susceptible to exogenous stressors implicated in neurodegenerative processes. To test this hypothesis, we prepared primary cortical neuron cultures from embryos collected from young pregnant females that were mated to young (less than 24 weeks old) or old males (over 90 weeks old). In cortical neuron cultures from the two conditions, we compared baseline and rotenone-induced alterations in cytotoxicity, and in live-cell imaging experiments evaluated reactive oxygen species generation, and electrophysiological activity by means of calcium imaging. In line with our predictions, neurons from old father offspring showed enhanced susceptibility to rotenone-induced cytotoxicity, and showed a baseline and rotenone-induced enhancement of mitochondrial superoxide production. Calcium imaging revealed reductions in calcium burst activity in old father offspring neurons, without apparent cytotoxicity or impairments in depolarization in response to potassium chloride (KCl). Our results suggest that paternal age can influence offspring risk for brain aging and neurodegeneration, likely through baseline mTOR hyperactivation, as well as exaggerated responses to environmental stressors.

In Vivo Evaluation of Bisphenol Analogue Exposure on Mouse Adipose Gene and Protein Profiles

V. A. Chappell, D. K. Tucker, and S. E. Fenton. NIEHS, Durham, NC.

Bisphenol A (BPA), reported to be an endocrine disrupting compound (EDC), is a high production volume chemical used in the manufacturing of plastics and epoxy resins. BPA has been associated with aberrant reproductive and developmental effects in rodents and humans, including obesity and metabolic disease. A recent voluntary replacement of BPA with other bisphenolic chemicals, including the fluorinated and sulfonated derivatives, BP4F and BPS, leaves many research gaps regarding the effects of these bisphenol analogues on adipose tissue. These studies assessed the effects of BP4F and BPS prenatal exposure on adipose tissue gene and protein expression in mice; and adipogenesis, lipid accumulation and gene expression in murine 3T3-L1 preadipocytes in culture. Timed pregnant CD-1 mice were exposed to vehicle, BP4F (5mg/kg), or BPS (0.5mg/kg) via oral gavage between gestation days 10–17. White adipose tissues were collected and processed from resulting offspring at postnatal day (PND) 35 and 90 for RNA and protein evaluation. Quantitative real-time PCR (qPCR) data revealed increased mRNA levels of several genes in the prenatally BPS exposed females on PND35; including Pparγ, Gpr30, and Esr2. PND35 BPS males exhibited increased levels of Esr2, and decreased Gpr30 and Esr2 expression. PND35 BPS male mice exhibited increases in both Pparγ and Esr1. At PND90, we observed more changes in adipose gene expression in BPS females, including increased levels of Cebpa, Fasn, Acaca, Acacb, Esr1 and decreased Gpr30 and Esr2. PND90 BPS males exhibited increased Fasn, Lpl, Acaca, Gr, and Esr2. Prenatal BPS female exposed mice and males at PND90 showed little to no change in gene expression compared to vehicle control mice. Preliminary protein data showed elevated FAS and FABP4 levels in BPS exposed females at PND90. Also, 3T3-L1 preadipocyte cells were induced to differentiate and treated in parallel with BP4F, BPS, BPAF, and BPS (serial log dilutions of 1µM to 10µM) for 8 days. High-content imaging was used to analyze adipocyte number and lipid droplet accumulation. RNA was isolated on day 8 for qPCR analysis. High-content imaging of adipocyte cells treated with bisphenolic chemicals resulted in significant increases in both lipid accumulation and adipocyte number (BPS>BP4F>BPSA). qPCR analysis of adipsigenic genes on day 8 of exposure to these chemicals are on-going. These data appear to be consistent with the growing evidence that EDCs, like bisphenol analogues, have the potential to disrupt adipogenesis and human health.

2408 In Vitro and In Vivo Evaluation of Bisphenol Analogue Exposure on Mouse Adipose Gene and Protein Profiles

2411 In Utero and Lactational (IUL) TCDD Exposure Impedes Urethral Urinary Flow in Male Mice

In utero and lactational (IUL) 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) exposure exacerbates anastomotic dysfunction in mouse model that mimics urinary symptoms in men with benign prostatic hyperplasia. These symptoms include incomplete bladder emptying and increased urinary frequency linked to impaired urethral urethral passage. In male mice exposed to IUL or vehicle TCDD we used a urine void spot assay to assess urination frequency, contrast-enhanced ultrasound to determine velocity of urethral passage, and an α-adrenergic receptor antagonist to relax prostate smooth muscle and reduce urethral urinary flow. We hypothesized that IUL TCDD exposure would increase the frequency of small volume voids and the velocity of urethral passage (indicators of prostate-induced urethral obstruction). We also hypothesized an α-adrenergic receptor antagonist would reduce urinary flow. Prostate-specific C57Bl/6J dams were gavaged with TCDD (1 µg/kg maternal dose) or corn oil (5 mL/kg vehicle control) at embryonic day 13. Male pups were aged 6 weeks and given either subcutaneous slow release implants of testosterone (25 mg) and estradiol (2.5 mg) to induce urinary dysfunction or a sham operation (controls). Urinary function was assessed biweekly using the non-invasive void spot assay. At 8 weeks, mice were anesthetized, DEFINITELY contrast agent was injected into the bladder, and ultrasound was used to visualize urethral passage of contrast agent. This velocity was recorded at baseline and 1, 5, and 15 min after treatment with an α-adrenergic receptor antagonist (Tamsulosin, 100 µg/kg iv). Mice treated with hormones for 2 weeks showed more voids in smaller volume spots than sham operated controls, evidence of increased urinary frequency. IUL TCDD treatment combined with hormone implantation appeared to most dramatically increase urinary frequency compared to all groups, while IUL TCDD treatment without hormone implantation did not change urinary frequency compared to untreated controls. Velocity of contrast agent passage through the urethra was greater in IUL TCDD + hormone treated mice than in corn oil + hormone treated mice, indicating urethral obstruction. Tamsulosin decreased contrast agent velocity in all groups, suggesting it lessened obstruction, but the change was greatest in IUL TCDD treated animals. These results provide compelling evidence that IUL TCDD exposure + hormone treatment increases prostate smooth muscle tone to reduce urethral urine passage. 2412 Maternal Exposure to Polynbrominated Diphenyl Ether (PBDE47) Increased Asthma Susceptibility in Adult Offspring

Polynbrominated diphenyl ethers (PBDEs) found in flame-retardants can easily transfer to the fetus through the placenta and be transferable in breast milk. Studies have linked PBDEs to cognitive dysfunction and inflammatory responses. However, there has been no evidence that PBDEs can cause asthma in offspring. We hypothesized that PBDE47 (the most common congeners of PBDEs) was associated with tumor necrosis factor-alpha (TNFα) promoter methylation and protein expression in female cord blood. In this study, we hypothesize maternal PBDE47 exposure could modulate offspring’s inflammatory responses, perhaps through epigenetic regulation of gene transcription. Objective: We examined the effect of maternal exposure of PBDE47 on female offspring’s asthma risk using an experimental asthma model. Methods: We exposed female adult B6/S129 mice to 0.1mg/mg/kg bw of PBDE47 or vehicle control (corn oil) at pre-conception, embryonic days 7 and 9, and postnatal day 4 and 16 via oral gavage. Six-week-old offspring were challenged with 100µg of house allergen (house-dust-mites, HDH) s.c. v/v per day. Tmajuant C57Bl/6J dams were gavaged with HDH-induced AHR. We also assessed the airway inflammation by examining immune cells profile in bronchoalveolar lavage (BALF) and IgE/G production in blood plasma. Moreover, we performed reduced represented bisulfite sequencing (RRBS) to identify differential DNA methylation changes in mouse lung. Results: Female offspring from PBDE47-exposed mother showed a lower airway sensitivity compared to those from unexposed mother. Maternal exposure to PBDE47 did not modulate the induction of eosinophils and IgE/G production in response to HDH challenges. Strikingly, RRBS data revealed PBDE47-mediated differential DNA methylation patterns in offspring’s lung tissues. Gene candidates enriched in cytokine signaling, Wnt signaling and integrin signaling pathways that may contribute to cell proliferation, contraction and cytokine production in lungs. Future studies are required to validate the role of these signaling pathways on asthma pathogenesis. Herein, our data suggest maternal exposure to PBDE47 increased offspring’s asthma risk. This response, independent of airway inflammation, may be driven by epigenetic alterations in modulating DNA methylation of genes regulating structure and function in the lung.

2413 Peri-implantation Ozone Exposure Induces Sexually Dimorphic Placental-Fetal Brain Axis Abnormalities

Peri-implantation ozone exposure induces fetal growth restriction in the rat. However, the influence of placental health in mediating the impact of ozone on fetal size and neurodevelopment has not been studied. Therefore, we examined placental metabolic adaptations and alterations in neurodevelopment. To this end, we exposed pregnant female Sprague-Dawley rats to ozone (2.63 ± 0.05 ppm) 1 hour/day starting on gestation day (GD) 19 from Long-Evans rats, we investigated placental metabolic endpoints including oxygen consumption and respiration, mitochondrial biogenesis, and changes in macronutrient concentrations and markers of autophagy. Fetal energy homeostasis was determined using body composition, hepatic triglycerides, and hypothalamic RNAseq. Results show that male placentas from ozone-exposed dams had increased mitochondrial respiration, ATP production, increased mitochondrial content, and reduced concentrations of triglycerides, cholesterol, and glucose. While female placentas failed to show these changes, they had evidence of AMPK phosphorylation and autophagy. Taken together, we next hypothesized that male and female fetuses would have sex-specific differences in body adiposity related to the aforementioned placental adaptations. Accordingly, male fetuses from ozone-exposed dams had reduced adiposity and hepatic triglyceride levels, whereas the female fetuses did not. Lastly, RNAseq within the hypothalamus of male fetuses revealed a reduction in ribosomal protein mRNA, a phenomenon that may be related to reduced amino acid availability for protein diminished cellular growth. While the hypothalamus of female fetuses did not appear to be nutrient-starved, RNAseq analysis of the hypothalamus revealed significant reductions in serotoninergic and dopaminergic genes. Furthermore, female hypothalami had reduced autophagic-related gene expression and increased ribosomal protein mRNAs. Together, we demonstrate that following peri-implantation ozone exposure, the placenta adapts in a sexually dimorphic manner. This adaptation may impact the nutrient availability of the fetus and disrupt neurodevelopment, rendering offspring sensitive to neurological deficits later in life. Disclaimer: This abstract does not reflect US EPA policy.

2414 Gestational Exposure to Inhaled Nano-Sized Titanium Dioxide Impairs Fetal Nutrition

Exposure to engineered nanomaterials (ENM) during pregnancy has the potential to alter both the mother and fetus through a variety of host behavioral, physiological and metabolic mechanisms. The molecular mechanisms associated with impaired fetal growth remains unknown. To investigate nutritional impairments associated with ENM exposure, 6 pregnant Sprague-Dawley rats were exposed to nano-sized titanium dioxide (nano-TiO2) aerosols beginning at gestation day 4 (9.35 ± 0.15 µm, m, 11 days, 5 hours/day, mean particle size 162 ± 7.67 nm) (HPGA, IESTechno) and continued through GD 19. Comparisons were made to 6 GD 20 Naive (un-exposed) control rats. Litter characteristics, maternal, and fetal plasma were collected on GD 20. ENM exposed animals had smaller litter sizes (15.7 ± 0.6 control pups per litter vs. 11.0 ± 0.6 exposed), placental weights (0.54 ± 0.01 g control placenta vs. 0.216 ± 0.01 g exposed placenta) (410.5 ± 11.2 g control dams vs. 339.3 ± 14.5 g exposed dams), and maternal fetal plasma was assessed for ω-3 and ω-6 PUFA concentrations using liquid chromatography-mass spectrometry (LC-MS) techniques. In these, palmitic acid was lower (p=0.053) in the exposed (2.21 ± 0.11 µg/mL) fetal plasma compared to control (2.67 ± 0.10 µg/mL). Further, PUFAs placental transport mRNA expression of fatty acid uptake (lipoprotein lipase (0.35 ±0.12)), trafficking (FABPA (0.80 ±0.42)), and synthesis (Elovl (0.45 ±0.08)) genes were significantly reduced, as normalized to control, after a single 5-hour nano-TiO2 inhalation exposure. These results indicate that exposure to ENM aerosols during gestation may affect placental fatty acid transport, synthesis and utilization, leading to impaired fetal growth and IUGR phenotype. Future directions will explore maternal PUFFA supplementation to improve health outcomes and promote fetal development. Supported by NIH-R00-ES024728; P30-ES050522; T32-ES007148; R25-ES052072; ASPET-SURF.
2415 Alterations in Fetal Lung Development by Maternal Allergen and Methyl Enriched Diet Exposure

Early life exposure to allergens is a risk factor for the development of asthma in later life. Furthermore, the effects of maternal-fetal interaction on offspring asthma susceptibility remain understudied, even though pregnant women are recommended to increase folate intake during pregnancy. Here, we aim to determine the joint effect of maternal exposure to allergens and methyl enriched diet on offspring lung development. Methods: Female C57BL/6 mice were maintained on either regular chow or methyl enriched (ME) diet before conception and until harvest. They were sensitized to house dust mite (HDM), a ubiquitous indoor allergen, two weeks before mating. Dams were further challenged to HDM three times a week until harvest at embryonic day 14. Unexposed dams were administered saline as a control. We measured placental weight, pup sex, and sex ratios in both groups. To determine sex to exposure to HDM and ME diet on fetal growth outcomes. We also examined the expression of genes related to fetal lung growth in female pups. We showed that maternal exposure to ME diet, with and without HDM exposure, significantly increased pup weight (P<0.001) and length (P<0.001). ME diet alone did not change expression of dihydrofolate reductase (Dhfr), but in combination with maternal HDM exposure, female pups displayed reduced mRNA levels of Dhfr in fetal lungs when compared to those from unexposed dams (P<0.05), or HDM-exposed dams on regular chow (P<0.005). In addition, maternal ME diet was associated with a significant increase in corticotropin-releasing hormone (Crh) mRNA levels in fetal lungs compared to pups from dams fed regular chow (P<0.01). Also, pups of HDM-exposed dams fed ME diet displayed increased Crh expression when compared to pups from HDM-exposed dams fed on regular chow (P<0.05). Conclusion: ME diet is rich in methyl donors, suggesting a role in epigenetic regulation of gene transcription. In addition to key roles in folate metabolism, Dhfr can regenerate tetrahydrobiopterin (BH4) from dihydrobiopterin (BH2), thus coupling eNOS, which is known to be critical for lung development. Upregulation of Crh by maternal ME diet intake is intriguing, particularly given that fetal expression of Crh in lungs is crucial for the maturation of type II alveolar cells, Club cell maturation, and surfactant synthesis. Taken together, our data suggest a joint effect of maternal exposure to HDM and ME diet on fetal lung development, which may modulate asthma risk in later life.

2416 Rats Exposed to Nanoparticles during Gestation Do Not Develop Metabolic Disease in Early Adulthood
S. B. Fournier, and P. A. Stapleton, Rutgers, The State University of New Jersey, Piscataway, NJ.

Disruption of the maternal environment during gestation can impact fetal health leading to intrauterine growth restriction, low birth weight, and risk of cardiovascular/metabolic disease in adulthood. In our model of maternal in-halation of engineered nanomaterials (ENM) during pregnancy, we have identified hemodynamic perturbations in the maternal, fetal, and offspring vasculature after chronic exposure initiated on gestational day (GD) 4. However, neither the cardiovascular implications of late-stage gestational exposures, nor the cardiometabolic effects in the progeny past 12-weeks of age are known. Timed-pregnant Sprague-Dawley rats were exposed to nano-sized titanium dioxide aerosols (9.35 ± 0.15 mg/m³), 4 hours, primary particle size 21 nm, median particle size 162 ± 7.67 nm (SMPS, TSI)) 5 days per week via whole-body inhalation (HPGA, IESTechco) starting on GD 4 or 17, prior to delivery (GD 20). A subset of animals was exposed to filtered air during gestation as controls. Animals delivered in-house and offspring were weighed weekly. At 6 months, a cohort of male and female progeny were exposed to a chronic fat- and fat-free mass [computed tomography (CT)] along with fasted plasma concentrations of glucose, total cholesterol, LDL, HDL (Pointe Scientific), and insulin (Sigma-Aldrich). At 6 months, we identified progeny derived from exposure to ENM during pregnancy to assess the effects of maternal-fetal stress, and to determine the influence of maternal environments on sex-specific cardiometabolic disease in the progeny in early adulthood. Further analyses will be conducted to evaluate mechanisms of maternal-fetal stress, inflammation, oxidative stress, epigenetics, and lipoproteins to identify the molecular link between maternal exposure and offspring health. Supported by NIH-R00-ES024783; P30-ES005022; ASPET-SURF.

2417 The Sex-Specific Influence of Gestational Air Pollution Exposure on Placental Metabolic Gene Expression within the Rhode Island Child Health Study (RICHIS)
K. Kaur1, C. Lesseur2, M. Deyssenhoff3, J. Zelikoff4, M. Carmen2, and J. Chen5. 1New York University School of Medicine, New York, NY; 2Icahn School of Medicine at Mt. Sinai, New York, NY; and 3Emory University School of Medicine, Atlanta, GA.

Morbidity and mortality due to air pollution is a growing burden to society. Studies have demonstrated that exposure to ambient PM2.5 contributes to adverse metabolic health outcomes. Given the importance of the placenta in determining fetal growth and its potential to influence metabolic health outcomes in later life, we explored the influence of PM2.5 exposure on sex-specific placental metabolism within the Rhode Island Child Health Study (RICHIS) cohort population. Using Gene Ontology annotations, a list of placental metabolic genes (n=657) was constructed related to lipid and/or glucose metabolism. This list of genes was then curated to include genes expressed in the term placenta (n=657) via the Gene Ontology database and placental RNA-seq data (n=148) from RICHIS, which was used to assess expression of the selected genes. Linear regression analyses were employed to determine the association between placental metabolic gene expression and PM2.5 exposure in a sex-specific manner. Thirty-two genes were significantly associated with PM2.5 exposure, out of which 24 genes were associated in a sex-specific manner. We selected 5 genes for RT-PCR verification in additional placentals from RICHIS, which included 2 significant genes from each sex-specific analysis and one gene (CLTCL1) that was significantly associated in both sex-specific analyses. CLTCL1 was upregulated in male term placentas, but downregulated in female term placentas. Placental metabolic genes associated with PM2.5 identified in this subset are involved with lipid rather than glucose metabolism. Funding: NIH-NIEHS P30ES023515.

2418 Sex-Dependent Effects of Early-Life Cadmium Exposure and High-Fat Diet on the Liver, Heart, and Kidney
J. Young1, Y. Liang1,2, M. Merchant1, G. Arteel3, J. Freedman1, and L. Cai3. 1University of Louisville, Louisville, KY; First Affiliated Hospital of Wenzhou Medical University, Wenzhou, China; and 3University of Pittsburgh, Pittsburgh, PA.

More than 1/3 of adults in the United States are considered obese. Obesity is a primary risk factor for a spectrum of inflammatory disease, non-alcoholic fatty liver disease and cardiometabolic syndrome. Other genetic and/or environmental factors however contribute to their pathogenesis. Data suggest that exposure to the environmental metal toxicant cadmium (Cd) is a risk factor for these metabolic diseases. Additionally, gender may be a contributing factor. To explore the relationship among obesity, Cd exposure and gender C57BL/6J mice were exposed to 0, 0.5 or 5 ppm Cd-containing drinking water for >2 weeks before breeding. Pregnant dams and offspring were then continuously exposed to the same Cd concentration. At weaning, offspring were fed either low-fat (LFD) or high-fat (HFD) diets. Animals were sacrificed PWN 10 or 24 and liver, kidney and heart collected for histopathological and biochemical analyses. Female mice accumulated significantly more Cd in liver and kidney, but not heart, compared to males. In the heart, only female mice developed cardiac fibrosis with the combination of HFD and Cd exposure (Sirius Red staining, increased collagen protein and mRNA expression). In the liver, Cd exposure exacerbated HFD-induced liver injury in male, but not female mice (histology and total cholesterol levels). Although more Cd accumulated in female kidneys, Cd-exacerbated, HFD-induced changes in renal parenchyma were significantly greater in male mice. In addition, proteomic analysis identified a number of sex-dependent differences in canonical renal signaling pathways. These results indicate gender-specific responses to Cd exposure in these organs that cannot solely be attributed to difference in Cd accumulation. Future work will focus on elucidating molecular mechanisms responsible for the observed sexual dimorphic phenotypes.
Long-Lasting Effects of Developmental Exposure to 2,2',4,4'-Tetramethylphenyl Ether on Blood-Liver Balance of Lipids in Male Mice

A. Khalil1,2, S. E. Cevik1, S. Hung1, S. Kolla1, M. Roy1, and A. Suvorov1,2
1University of Massachusetts Amherst, Amherst, MA; and 2City of Scientific Research and Technological Applications, Alexandria, Egypt.

2,2',4,4'-Tetramethylphenyl ether (BDE-47) is one of the dominant congeners of polybrominated diphenyl ethers (PBDE) - a group of flame retardants that have been widely used in North America and Europe over the last 50 years until recent industrial ban. Around 20% of U.S. population was born during the maximum plateau of PBDE environmental concentration. PBDEs are strongly resistant to degradation and persist in environment. The study was designed to analyze long lasting metabolic effects of exposures to BDE-47. CD-1 mice were prenatally or neonatally exposed to 1 mg/kg body weight of BDE-47 or vehicle, and changes in liver histology, transcriptome, and liver-blood balance of triglycerides were monitored in 10 month old male offspring. In both exposure groups, long term reprogramming of lipid metabolism was clear, including increased liver triglycerides and decreased blood triglycerides, and altered expression of metabolic genes in the liver. Significant up-regulation of lipid influx transporter Cd36 in pre- and neonatal exposure groups was seen as a potential mechanism of blood/liver imbalance of triglycerides. Opposite directional changes in expression of many metabolic genes including Cd36 and levels of circulating triglycerides were observed in comparison with our previous studies of transcriptomic signature of PBDE, which used lower exposure dose (0.2 mg/kg body weight). In conclusion, this study shows that environmentally relevant developmental exposures to BDE-47 permanently alter blood-liver balance of lipids, with low and moderate doses having opposite effect on liver transcriptomics and triglyceride balance. These results suggest that PBDE exposure may be an important factor associated with heath conditions, such as risks of cardio-vascular diseases and non-alcoholic fatty liver via modulation of blood/liver balance of lipids. Further studies for these findings are needed to be relevant to human diseases.

Early-Life TCDD Exposure Shapes Gene Expression across the Life Course of Mice

J. P. Parker1, T. I. Konneker1, N. E. Allard1, B. Horman1, A. Safi2, L. Song2, H. B. Patiasil1, G. E. Crawford1, and D. L. Aylor3, North Carolina State University, Raleigh, NC; and 3Duke University, Durham, NC.

2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD) is a potent environmental toxin that is generated as a byproduct of industrial operations involving high temperature processing of organic material. It enters into environmental systems as a constituent of solid waste and flue gas. In vertebrate systems, TCDD activates the AhR-mediated xenobiotic response which modulates transcription of numerous genes responsible for metabolizing toxic compounds. The World Health Organization recognizes links between early-life exposure to TCDD and late-onset pathologies including neurological disability, reproductive impairment, and increased cancer risk. Our goal is to understand the consequences of early-life TCDD exposure on the molecular state of multiple tissues. Mice were exposed to TCDD from preconception through gestation and lactation. Tissue samples were taken three weeks, five weeks, twenty weeks, and forty weeks after birth. From our measurements of transcriptional profiles, we show that gestational TCDD exposure shapes gene expression both in the short-term and in the long-term. Furthermore, we performed analyses of open chromatin using ATAC-seq to contrast chromatin accessibility with associated gene expression. Early-life exposure to TCDD resulted in substantial changes in gene expression after accounting for tissue, age, and sex. A total of 2493 genes were differentially expressed in liver combined over both sexes and ages. Blood showed few differentially expressed genes at three weeks but substantially more in adult mice. The effects of TCDD differed dramatically between males and females. Furthermore, there is no overlap between the response in liver and in blood. Though there were clear gene expression signatures of TCDD exposure at both ages, the changes observed at three weeks did not persist into adulthood. We conclude that a complex cascade of gene regulatory events are set in motion by early-life TCDD exposure that result in long-term gene expression differences in adult mice.

Developmental Exposure to Brominated Flame Retardant 2,2',4,4'-Tetramethylphenyl Ether (BDE-47) Permanently Reprograms Liver Lipid Metabolism in Mice via mTOR-Dependent Pathway

J. P. McGaunn, V. R. Salemme, A. Polyanoff, and A. Suvorov, University of Massachusetts, Amherst, MA.

Abnormally high accumulation of triglycerides (TGs) in hepatocytes is called hepatic steatosis or non-alcoholic fatty liver disease (NAFLD). It is the most common chronic liver disease among adults and children, with 33% to 88% prevalence. NAFLD increases the risk of type 2 diabetes and many other morbidities. Increased blood triglyceride levels result in atherosclerosis, a major cause of heart attack. An emerging hypothesis connects the metabolic disease epidemic with chemical exposures during vulnerable windows of early development. Evidence suggests that developmental exposure to flame retardant BDE-47 permanently reprograms lipid metabolism, resulting in a NAFLD-like phenotype. These changes were associated with changes in activity of the mTOR pathway, an intracellular pathway that regulates aspects of the cell cycle and metabolism. Previously, we showed that BDE-47 activates mTOR signaling in mouse livers and permanently alters expression of fatty acid translocase Cd36, a membrane receptor responsible for uptake of fatty acids in hepatocytes. This discovery and network analysis identified several pathways that were differentially expressed. Key pathways impacted included oxidative stress, mitochondrial dysfunction, and fatty acid metabolism. These results show that Cd exposure during gestation specifically affects liver function and increased weight in female mice. Ongoing functional genomic studies will further explore the nature of the sexually dimorphic responses to Cd exposure and examine the ontogeny of the Cd-induced changes in hepatic transcriptome prior to postnatal day 42 in the mouse liver. Potential epigenetic mechanisms driving Cd-induced metabolic changes, including differential methylation of metal ion transporter promoter regions, are being explored.
changes in Cd36 expression and changes in triglycerides in blood. These results may provide relevant mechanistic information critical to understanding and addressing the environmental factors involved in current epidemic of NAFLD and atherosclerosis.

2423 Reprogramming of Peroxisome Proliferator-Activated Receptor Target Genes in Mice Perinatally Exposed to Phthalates

K. Neier, T. R. Jones, M. A. Sartor, and D. C. Dolinoy, University of Michigan, Ann Arbor, MI.

Phthalates have been demonstrated to activate peroxisome proliferator-activated receptors (PPARs), nuclear receptors that act as transcription factors for a plethora of target genes involved in metabolism. Developmental exposures to phthalates have been linked with adverse metabolic outcomes in animal and human studies, but underlying mechanisms remain unclear. We investigated reprogramming of PPAR target genes as a link between perinatal phthalate exposures and later-in-life metabolic outcomes in an established mouse model of human-relevant exposure. Dams were exposed to phthalates via phytoestrogen-free diet from 2 weeks prior to mating until weaning at postnatal day 21 (PND21). Dams were randomized to one of four experimental groups: 1) 7% corn oil control chow, 2) 25mg DEHP/kg chow, 3) 75mg DINP/kg chow, or 4) 25mg DEHP + 75mg DINP/kg chow. One male and female offspring per litter were weaned onto control chow and followed to 10 months of age. Histological analysis of tissues from sacrificed embryos and postnatal day 21 (PND21) sequencing was performed on RNA isolated from livers collected at PND21 and 10 months (n=6/sex/group/age). Differential expression analysis was carried out via DESeq2 comparing each group to controls, stratifying by age and sex. The group with the greatest number of differentially expressed genes in the liver (adjusted p<0.10) was females perinatally exposed to DINP only, with 64 genes at PND21 and 175 genes at 10 months of age. To identify targets in the liver that were reprogrammed by perinatal phthalate exposures, we examined pathway enrichment for genes that were differentially expressed at both PND21 and 10 months via LRPath. Females perinatally exposed to DINP-only had the largest number of significantly enriched KEGG pathways (23 pathways with FDR<0.05). Enriched pathways included biosynthesis of unsaturated fatty acids (FDR=0.010), PPAR signaling pathway (FDR=0.042), fat digestion and absorption (FDR=0.042), and type II diabetes (FDR=0.047). Genes driving these metabolic pathways included several PPAR target genes, indicating that they may be reprogrammed in the liver by perinatal exposure to DINP, particularly in females. Ongoing work to quantitatively validate expression and investigate DNA methylation at these candidate reprogrammed PPAR target genes is underway, as well as parallel analyses in adipose.

2423a Participation of Endothelial Small GTPase RhoA in Embryo Development and Retinal Angiogenesis

F. Zahra1, M. Sajib1, Y. Ichiyama2, P. Tullar1, Y. Kubota1, and C. Mikelis1.
1Texas Tech University, Amarillo, TX; and 2Keio University School of Medicine, Tokyo, Japan.

Angiogenesis, the formation of new blood vessels, is a highly orchestrated process requiring a well-regulated balance between pro-angiogenic and anti-angiogenic factors and corresponding signaling networks. Imbalanced angiogenesis is a characteristic of several diseases such as cancer, inflammation, rheumatoid arthritis, atherosclerosis and age-related macular degeneration. The Rho family of small GTPases plays a central role in angiogenesis, signal transduction, gene expression which are necessary for vascular development and angiogenesis. Among the small GTPases of the Rho family, RhoA, Rac1 and Cdc42 are the best characterized. Although the role of endothelial Rac1 and Cdc42 in embryonic vascular development and retinal angiogenesis has been studied recently, the role of endothelial RhoA is yet to be explored. In this study, we aim to identify the role of endothelial RhoA in vascular development in vivo by generating endothelial RhoA deficiency through the Tie2-Cre and Cdhs-CreERT2 promoters. In vivo deletion of RhoA in embryonic endothelial cells leads to decreased survival of endothelial RhoA deficient mice. On the other hand, inducible RhoA deficiency in the retinal vessels in different developmental days did not affect the radial growth, the number of filopodia per area and the area with deep vascular plexus. In vitro, RhoA seems to be involved in endothelial cell migration, invasion and sprouting triggered by important angiogenesis inducers, such as Vascular Endothelial Growth Factor (VEGF) and Sphinogistine-1 Phosphate (SIP). These ongoing experiments aim to provide a better understanding of the numerous functions regulated by the endothelial small GTPase RhoA in normal physiology and human diseases.

2424 Shipping Study to Evaluate the Performance of the Labcyte Epi-Model 24 Tissues for Use in the Skin Irritation Test (OECD Test Guideline 439) after Long-Haul Airfreight

G. Costin1, E. Willier1, H. Raabe1, A. Amici1, H. Mitake2, and M. Hatanaka2.
1IVS, Gaithersburg, MD; and 2Japan Tissue Engineering Co., Ltd., Aichi, Japan.

It is recommended that an evaluation of the impact of shipping Reconstructed human Epidermis (RHE) tissues be conducted especially after long-haul airfreight shipments. The OECD Test Guideline 439, in vitro Skin Irritation: Reconstructed Human Epidermis Test Method, recommends that users do so by verifying the barrier properties of the tissues after receipt. In this study, LabCyte EPI-MODEL 24 tissues were received in the USA after an overnight shipment from Japan and were tested to evaluate their performance after shipment using several endpoints. First, the viability of untreated tissues incubated overnight in culture medium was assessed using the vital dye MTT and expressed as Optical Density (OD) values. The calculated OD values were 1.2 (JTEC) and 0.99 (IVS) and within the range established by the manufacturer (0.8 – 2.5). The barrier function was further evaluated after the tissues were exposed to the assay negative control (Phosphate Buffered Saline - PBS) and to four concentrations of the positive control, Sodium Lauryl Sulfate (SLS) (1.0, 2.0, 3.0 and 4.0 mg/mL). The calculated IC50 values were 2.7 mg/mL (JTEC) and 3.4 mg/mL (IVS), respectively, and within the established historical range (1.4 - 4.0 mg/mL). The analysis of the results generated by the two labs (JTEC and IVS) demonstrated that the tissue lot met the acceptance criteria developed by the tissue manufacturer under conditions of shipping stress. Finally, the histological analysis of untreated fixed tissues identified all tissue layers and supported the conclusion that the tissue model was acceptable for use in subsequent studies after long-haul airfreight shipment. Such shipping studies are critical to gaining confidence in the tissues’ performance when used for research, industrial, and regulatory testing purposes.

2425 Increasing Confidence in the EASA Skin Sensitization Assay Using a Measurement Science Approach

J. Gordon1, R. Uhl1, B. Toman1, J. Elliott2, and E. Peterson2.
1US Consumer Product Safety Commission, Rockville, MD; and 2National Institute for Standards and Technology, Gaithersburg, MD.

NICEATM is currently coordinating a multi-laboratory validation study to characterize the usefulness and limitations of the Electrophilic Allergen Screening Assay (EASA) for risk and hazard assessment for skin sensitization classification. The EASA assay functions by assessing the ability of potential skin sensitizer compounds to elicit a chemical reaction by assessing depletion of one of two probe molecules using absorbance or fluorescence measurements. However, the use of this assay in a single cuvette format resulted in multiple measurement challenges such as low throughput, which hindered the ability to include additional control measurements, and a lack of access to laboratories still running single cuvette assays. To overcome these limitations, it was decided to redesign this assay protocol to work with a 96-well plate format. Cause-and-effect (C&E) analysis was performed to identify key sources of variability and potential biases which could impact the test results. Based on the C&E analysis, process control measurements were incorporated into a 96-well format to quantify key sources of variability each time the assay is performed. Additional control experiments to evaluate edge effects, cross-talk, well-to-well variability and statistical power of the assay system were also performed during system characterization. Ten compounds from Phase 1 of the inter-laboratory EASA study that were previously tested in the single cuvette assay, and 5 additional compounds were tested in the 96-well plate design. One key insight revealed by this process was the interference from five of the original ten Phase 1 test compounds (solubilized in acetonitrile) which would not have been previously detected using the single cuvette assay. Not taking the interference of these 5 compounds into account has been shown to lead to potential false negative and false positive identifications. Overall, the approach described here provides steps that can be taken to increase confidence in the EASA assay and serve as a platform for inter-laboratory comparisons, as well as reducing unseen bias which may have existed in previous assay development.

2019 SOT Annual Meeting 339
**2427** The Dermal Sensitization Threshold (DST)
Approach for Botanical Extracts Evaluated as Negative in *In Vitro* Test Methods; Botanical DST

Cosmetic ingredients often comprise naturally derived complex mixtures, such as botanical extracts, which may contain skin sensitizing constituents. For skin sensitization assessment methods of botanical extracts without animal testing, a strategy using non-target analytical screening techniques has been proposed. However, non-target qualitative and quantitative screening analyses of skin-sensitizing constituents in naturally derived complex mixtures are often difficult and resource-intensive. To address this problem, we developed a risk assessment strategy for undetermined constituents of botanical extracts by combining exposure assessment in addition to the hazard identification using the binary test battery with KeratinoSens® and h-CLAT. In our previous study for the sensitivity of the evaluations of skin sensitizing constituents in botanical extracts using the binary *in vitro* test battery with KeratinoSens® and h-CLAT, some sensitizers showed higher detection limits in *in vitro* test methods than in murine local lymph node assays (LLNA). Thus, to minimize the uncertainty associated with decreased sensitivity for these sensitizers, a risk assessment strategy was developed for botanical extracts with negative results from the binary test battery. Assuming that the no expected sensitization induction level of botanical extracts (botanical NESIL) can be derived for botanical extracts with negative *in vitro* test results, we assessed 146 sensitizers with *in vitro* and LLNA data according to the assumption of indeterminate constituents in botanical extracts. Next, we calculated 95th percentile probabilities of botanical NESILs and derived 6,010 μg/cm² as a dermal sensitization threshold for botanical extracts (botanical DST) with negative *in vitro* test results. Finally, we performed feasibility studies of this botanical DST value as an acceptable formulation ratio of botanical extract evaluated as negative in the binary test battery and performed the botanical DST approach for practical product examples. Feasibility studies indicated that acceptable formulation ratios of botanical extract evaluated as negative in the binary test battery were calculated as > 100% for rinse-off products and 0.3% - 12% for leave-on products. This approach would be a novel risk assessment strategy for incorporating the DST approach and information from *in vitro* test methods.

**2428** U-SENS: New Perspective for Chemicals Interfering with Fluorescence by Flow Cytometry

N. Ade1, S. Teluob, A. Viricel1, C. Piroiro, A. Del Bufalo2, and N. Alepee2. 1Epidkin, Lyon, France; and 2L’Oreal, Aulnay-sous-Bois, France. Sponsor: E. Dufour

The U937 Cell Line Activation Test U-SENS™ is one of the *in vitro* OECD endorsed test method (TG442E) along the skin sensitization AOP (Adverse Outcome Pathway). It could be used for hazard identification, potency and risk assessment. Experimental procedure: the human myeloid U937 cell line (CRL-1593.2) was treated for 45 h with a dose-range of substances. The CD86 (B70/ B7-2) costimulatory molecule expression was then measured by flow cytometry using the FITC mouse anti-human CD86 monoclonal antibody. Propidium iodide was used as the viability markers to exclude dead cells from the analysis. Some substances such as well-known hair dyes increase the auto-fluorescence of cells in the FITC channel by flow cytometry compromising the quantification of the CD86 induction. To avoid such interferences and biases, an alternative of the fluorophore FITC (excited at 488 nm), the APC (excited at 633 nm) has been evaluated. Based on the study of 4 interfering substances (1,4-phenylenediamine (pPD), 2-Methyl-p-phenylenediamine sulfate salt (pTD), 2,4,5,6-Tetraaminopyrimidine Sulfate (TAP), and 1,3-Phenylenediamine (mPD)), the non-specific fluorescence increase was drastically reduced with APC leading to clear dose response curves. The approach using an APC-coupled mouse anti-human CD86 monoclonal antibody was further validated on a set of 24 substances composed of an equal number of sensitizers and non-sensitizers. All acceptance criteria applied to the standard protocol were met (CV<0.7, EC150, CD86 baseline expression, ...). As a conclusion, the use of the alternative APC coupled antibody opens new perspectives to evaluate skin sensitizers interfering with the fluorescence at 488 nm in the U-SENS™ test method (OECD 442E).

**2429** The Kinetic Direct Peptide Reactivity Assay (k-DPRA): An *In Chemico* Method to Characterize the Skin Sensitization Potency of Chemicals

B. wareing, S. Kolle, B. Birk, and R. Landsiedel. BASF SE, Ludwigshafen am Rhein, Germany.

While the skin sensitization hazard of substances can meanwhile be identified using non-animal methods, the classification of potency UN GHS sub-categories 1A and 1B remains challenging. The kinetic DPRA (k-DPRA) is a modification of the DRPA (OECD TG 442C). In the k-DPRA the reaction kinetics of a test substance towards a synthetic cysteine-containing peptide is evaluated. For this purpose, several concentrations of the test substance are incubated with the synthetic peptide for several incubation times at 25°C. After the respective incubation time, the reaction is stopped by addition of the fluorescent dye monobromobimane. The highly reactive and non-fluorescent monobromobimane rapidly reacts with unbound cysteine moieties of the model peptide to form a fluorescent complex. The remaining non-depleated peptide concentration is determined thereafter by fluorescence measurement. By stopping the reaction with monobromobimane, the extent of peptide depletion can be determined at precisely defined time points. Kinetic rates of peptide cysteine-depletion are then used to distinguish between two levels of skin sensitization potency, i.e. to discriminate between CLP/UN GHS sub-categories 1A and 1B. In addition, kinetic rates generated with this method have a strong quantitative correlation to sensitizer potency and can therefore be used in defined approaches (DA) with a quantitative data integration procedure (DIP) for skin sensitization potency assessment. During an in house validation (Wareing et al., 2017) 35 of 38 substances with known sensitization potency were correctly assigned to the potency sub-categories (compared to LLNA data), and the predictivity for 14 human data was equally high. These results warrant the k-DPRA for further validation and that it be used as part of defined approach(es) to assess skin sensitization in order to fully replace *in vivo* testing for assessing skin sensitization including potency sub-classification. A multi-laboratory validation study is ongoing.
2430 A New Method for Skin Sensitization Potential for Poorly Soluble Compounds Using a 3D Keratinocyte / THP-1 Co-Culture

A. Thélu1, 2, M. Stricher1, A. Josseaume1, L. Beaudenguin1, L. De La Barreira1, H. Ficheux1, S. Catoire1, and S. Kerdine-Römer1.1, 2 THOR Personal Care, Compiègne, France; and 1UMR-S 996 Université Paris Sud / Paris Saclay, Chatenay-Malabry, France.

Allergic contact dermatitis is caused by skin contact with an allergen. The identification and assessment of the sensitising potential of new compounds is essential to prevent allergic response. The development of alternative methods is required for the cosmetics industry considering the questionable relevance of the use of animal testing to predict human hazard and the effective ban on the use of animals for safety testing. For now, a combination of different tests is required to predict the skin sensitising potential of chemical substances, each providing information on one or more key steps of the mechanism. Among these assays, six tests are already validated by European Centre for the Validation of Alternative Methods (ECVAM) and test guidelines are edited by OECD, namely Direct Peptide Reactivity Assay (DPRA), KeratinSensTM, LuSens, human Cell Line Activation Test (h-CLAT), U937 cell line activation test (U-SENS®) and the interleukine-8 reporter gene assay (IL-8 Luc assay). To circumvent the solubility limitation of the tested compound in the ECVAM validated methods and in particular in h-CLAT protocol, a new in vitro method is designed using a co-culture model. We developed a co-culture system consisting of VitroDerm, an in-house reconstructed human epidermis (RHe) and a monocyctic cell line (THP-1) and the optimisation of the h-CLAT protocol has been performed. A comparison between regular h-CLAT (THP-1 monoculture) and h-CLAT using the VitroDerm / THP-1 co-culture is carried out on 12 reference chemicals (sensitisers or non sensitisers). CD86 and CD54 were quantified by flow cytometry on THP-1 cells. The VitroDerm / THP-1 co-culture model allows a correct classification of 12 reference chemicals compared to THP-1 monoculture leading to an accuracy, specificity and sensitivity of 100%. The major advantages of this method is to take into account the bioavailability factor with skin metabolism aspects. This test can be used to assess skin sensitization potential of poorly soluble compounds. Finally, the VitroDerm / THP-1 co-culture opens new horizon on intercellular interplay via paracrine interaction.

2431 Skin Sensitization Potential: Addressing the 3 Key Events of AOP Using a 3D Keratinocyte / THP-1 Co-Culture

A. Thélu1, 2, L. De La Barreira1, H. Ficheux1, S. Catoire1, and S. Kerdine-Römer1.1, 2 THOR Personal Care, Compiègne, France; and 1UMR-S 996 Université Paris Sud / Paris Saclay, Chatenay-Malabry, France.

Allergic contact dermatitis is caused by skin contact with an allergen. The identification and assessment of the sensitising potential of new compounds is essential to prevent allergic response. The development of alternative methods is required for the cosmetics industry considering the questionable relevance of the use of animal testing to predict human hazard and the effective ban on the use of animals for safety testing. We developed a co-culture system consisting of VitroDerm, an in-house reconstructed human epidermis (RHe) and a monocyctic cell line (THP-1) to use this in the context of skin sensitisation analysis. Whilst the methods already validated by ECVAM address one key event, the VitroDerm / THP-1 co-culture enables the modelling of the first three key events of the skin sensitisation Adverse Outcome Pathway (AOP): the covalent binding of a chemical to cutaneous proteins (key event 1), the activation of keratinocytes (key event 2) and the dendritic cell activation (key event 3). First, the co-culture model was characterised (cell viability, histology and basal expression of CD54 and CD86 by flow cytometry) in order to select the best settings in terms of culture medium composition or treatment duration, for example. Then, the cellular interplay between the cell types of the co-culture is observed by analysis of the paracrine interaction using immunobassay. We used 7 reference chemicals to identify a gene signature from microarray analysis (whole human genome 60k). Finally, a differential extracellular release of cytokines (such as CCL3, CCL4, CCL5, CXCL1, CXCL8, CXCL10 and IL-18) is obtained and enables the distinction between sensitisers and non sensitisers. The VitroDerm / THP-1 co-culture is a promising model for skin sensitisation assessment and provides various advantages over ECVAM validated monoculture based methods. The presence of RHe within the co-culture allows closer replication of in vivo-like bioavailability, metabolism, keratinocyte inflammation as well as cross-talk between keratinocyte and dendritic cell surrogate, and thus contributes to modelling the natural process of sensitiser exposure to skin and activation of immune cells.

2432 Effects of Ammonia Vapor Exposure on Viability in a Full-Thickness Human Skin Tissue Model

J. Molignano1, M. Bachelor1, P. J. Hayden2, H. D. Garcia3, K. Toon3, and V. E. Ryder1.1 MattTek Corporation, Ashland, MA; 2KBRWyle, Houston, TX; and 3NASA Johnson Space Center, Houston, TX.

In this study, EpiDermFT, an in vitro 3D model of human skin, was used to evaluate the effects of ammonia vapor on skin to simulate in vivo exposure. The US Segment of the International Space Station (ISS) utilizes ammonia in the external loops of the active thermal control system. There is a low likelihood failure scenario that would allow ammonia to enter the habitable volume of the ISS via the interface heat exchangers. Protective masks have been developed to protect the eyes and respiratory tracts of crew in the event of a breach, but the dose/response for the effects of elevated ammonia vapor concentrations on intact human skin is largely unknown. Since EpiDermFT is cultured at the air-liquid interface and is amenable to topical exposures of test material, this 3D tissue model was an appropriate test system to simulate in vivo exposure to ammonia vapor. A custom exposure device was developed by Vitrocell and engineered to expose the apical surface of EpiDermFT tissues to either clean air (as a control) or ammonia gas at concentrations of 10, 100, 1000, 10,000, 30,000 or 50,000 ppm for 1, 5 or 20 minutes. Tissues were assessed immediately following exposure or 24 hours post-exposure for cell viability using the MTT assay and for morphological changes indicative of toxicity. Data indicate that concentrations between 10-1000 ppm ammonia for up to 20 min did not have an immediate or delayed (24 hr) effect on dermal tissue viability. Signs of toxicity, especially 24 hr post-exposure were noted at 10,000 ppm ammonia and increased in severity with both increasing exposure time and concentration. To our knowledge, this report represents the first evaluation of ammonia vapor on skin. Altogether, we demonstrate the utility of the EpiDermFT model as a relevant substitute of human skin for evaluation of cytotoxicity in response to environmental insults.

2433 Evaluation of the EpiSensA for Identifying Dermal Sensitization Potential of Complex Actives and Crop Protection Formulations

M. J. LeBaron1, H. Mizumachi1, B. Settivari1, M. Miyazawa2, M. S. Marty1, and H. Sakaguchi2.1 Dow Chemical Company, Midland, MI; 2Kao Corporation, Tochigi, Japan; and 3Corteva Agriscience, Newark, DE.

The EpiSensA, developed by Kao Corporation, is emerging as one of the most promising in vitro assays for predicting dermal sensitization potential of chemicals. The assay predicts the sensitization potential based on the marker gene expression of differentiated three-dimensional reconstructed human epidermal keratinocytes, which have better metabolic capability and broader applicability domain compared to existing assays adopted to OECD TG. Previously, the EpiSensA demonstrated >90% accuracy for identifying known dermal sensitizers from 131 chemical dataset including lipophilic chemicals and pre/pro-hapten. In the present study, the performance of the assay was evaluated by testing a set of 9 materials (5 methacrylates, 3 silicone materials, and 1 crop protection formulation) that had prior in vivo studies (via LLNA and/or Guinea pig studies). The in silico models correctly predicted 6 of 7 materials, including a structural alert (false positive) for lauryl methacrylate. The DPRA and KeratinSens assays identified 6/9 (3 false negatives and 5/9 materials 3 false negatives and 1 false positive) correctly, respectively. The EpiSensA correctly predicted 8/9 materials with one silicone material as false negative. The false negative result for this silicone material, classified as weak sensitizer via LLNA, was consistent across the DPRA and the KeratinSens assays. Overall, consistent with prior evaluations, the EpiSensA demonstrated an accuracy level of 88.9% relative to available in vivo data. In addition, potency classification based on the concentration showing positive marker gene expression of EpiSensA was performed. The EpiSensA correctly predicted the potency for four out of five sensitizers classified as weak potency via LLNA (EC3 ≥ 10%). In summary, EpiSensA could identify dermal sensitization potential and potency of complex actives and crop protection formulations, and continues to show promise as an in vitro alternative for dermal sensitization.
The 3T3 Neutral Red Uptake (NRU) Phototoxicity assay is an established in vitro assay used to evaluate the potential phototoxicity of a test article. Since recommended by EMA and ICH guidance, the 3T3 NRU-PT assay has been used quite extensively in the pharmaceutical industry. The assay methods and prediction model are described in OECD Test Guideline (TG) 432 and the INVITTOX Protocol No. 78. In these documents, the following acceptable criteria for positive control chlorpromazine (CPZ) were defined: the $IC_{50}$ (+Irr) should be within the range of 0.1-2.0 $µg/mL$, the $IC_{50}$ (-Irr) should be within the range of 7.0-90.0 $µg/mL$, the photo irritation factor (PIF) should be $>6$. We used EBSS as the solvent to dissolve the CPZ in our facility and the historical data indicated that the $IC_{50}$ (+Irr) fall in the high end of recommended common range (actual range: 0.6675 to 2.861). We had observed that different solvents showed a significant impact on $IC_{50}$ value. In this abstract, the cytotoxicity and phototoxicity potential of CPZ dissolved in common solvents of DMSO and EBSS were evaluated for the impact. Two lots of CPZ were dissolved in DMSO and EBSS respectively. The solutions in DMSO were then diluted with EBSS at 1% (v/v) before treating cell cultures and the solutions in EBSS were directly used for cell treatment, the concentrations for both treatments are 0.0316, 0.1, 0.316, 1.0, 3.16, 10, 31.6 and 100 $µg/mL$. The results for two lots indicated that the cytotoxicity was obviously impacted by solvents but the phototoxicity potential of CPZ was not influenced. For lot 1 dissolved in EBSS, $IC_{50}$ (+Irr), $IC_{50}$ (-Irr) and PIF were 1.563 $µg/mL$, 45.91 $µg/mL$ and 29.38 respectively; while dissolved in DMSO, $IC_{50}$ (+Irr), $IC_{50}$ (-Irr) and PIF were 0.465 $µg/mL$, 12.54 $µg/mL$ and 26.988 respectively. For lot 2 dissolved in EBSS, $IC_{50}$ (+Irr), $IC_{50}$ (-Irr) and PIF were 1.169 $µg/mL$, 41.59 $µg/mL$ and 24.508 respectively; While dissolved in DMSO, $IC_{50}$ (+Irr), $IC_{50}$ (-Irr) and PIF were 0.4245 $µg/mL$, 9.807 $µg/mL$ and 23.142 respectively. Our data showed different solvents resulted in variabilities for $IC_{50}$ determination, we therefore suggest to remove $IC_{50}$ acceptable criteria or laboratories need to generate the $IC_{50}$ range based on specific solvent for this assay.

**2435 How to Assess a Phototoxicity Risk Related to Topical Exposure by Using the In Vitro SkinEthic RHE Model**

C. Videau\(^1\), C. Grégoire\(^1\), N. Alépée\(^2\), S. Dreyfuss\(^1\), and N. Seyler\(^1\). \(^1\)Episkin SA, Lyon, France; and \(^2\)L’Oréal, Aulnay sous Bois, France. Sponsor: E. Dufour

The skin exposure to photoactive chemicals may produce abnormal skin reaction, an acute light-induced phototoxic response, which occurs when photoreactive chemicals are activated by solar lights and transformed into photoreactive molecules. This conversion of lasiocarpine is mainly catalyzed by CYP3A4, of which abundance and activity differs between individuals and ethnic groups. The aim of the present study was to predict the effect of inter-individual and inter-ethnic variation in liver toxicity of lasiocarpine predicted by integrating physiologically based kinetic (PBK) and Monte Carlo modeling.

**2436 A Study on the Correlation between In Vivo Tests and In Vitro Tests for Oral Mucosal Irritation Evaluation**

S. Aizawa\(^1\), S. Watanabe\(^1\), K. Yoshida\(^1\), and Y. Handa\(^2\). \(^1\)Lion Corporation, Odawara-shi, Japan; and \(^2\)Kurabo Industries, Ltd., Neyagawashi, Japan. Sponsor: S. Aizawa, Japanese Society of Toxicology

Oral mucosal irritation is one significant element in the safety evaluation of oral care products. For an oral mucosal irritation test, the in vivo test method defined by the Cosmetic, Toiletry, and Fragrance Association (CTFA), is well known. However, we have examined the formation of ‘in vitro’ test method using a three-dimensional human buccal mucosal model as an alternative. We compared cytotoxicity of the in vitro test of oral care products and their ingredients and oral mucosal stimulation intensity of the in vivo test in order to confirm the correlation. For the in vitro test, a three-dimensional human buccal mucosal model EpiOral™ (manufactured by MatTek Corporation) was used. Among each toothpaste product and their ingredient of strong irritation, moderate irritation, and no irritation by in vivo test, we were selected as test substances. The test substances were applied to the pre-cultured EpiOral™ and rinsed out with PBS after exposure for a prescribed period of time. The cell viability was evaluated by the MITT assay at test concentrations and time points. We also evaluated the correlation between the irritation classification of test substances based on the cell viability and the in vivo data from modified CTFA method. In vitro data of oral care products and their ingredients tended to be consistent with the results of classification based on the oral mucosal stimulation intensity in the in vivo test. This suggests that it is possible to assess the in vivo test results from the in vitro test results, and it has been determined that the in vitro test is useful for oral mucosal irritation evaluation of oral care products.

**2437 Evaluation of Epiprostestinal™-Model for Absorption Studies In Vitro in an Automated Flow-Through Device**

S. Wölkl\(^1\), E. Fabian\(^1\), H. Maxfled\(^1\), J. Markus\(^2\), H. Kandara\(^\text{a}^1\), B. van Ravenzwaai\(^\text{a}^1\), and R. Landsiedel\(^2\). \(^1\)BASF SE, Ludwigshafen am Rhein, Germany; \(^2\)MatTek in Vitro Life Science Laboratories, Bratislava, Slovakia; and \(^3\)MatTek in Vitro Life Science Laboratories, Bratislava, Slovakia.

The Epiprostestinal™ model was developed by MatTek Corporation and is constructed as a 3D model, which reflects the anatomy of the gastrointestinal (GI) wall in the in vivo situation. Advantages of the model are its commercial availability, technical reproducibility and ready to use delivery. In the current project, we evaluated the Epiprostestinal™ model for the prediction of GI absorption in an automated technical flow-through system for 8 test labeled absorption tests (Antipyrine, Caffeine, Carbamazepine, Cimetidine, Ketoprofene, Metformin, Ranitidine and Warfarin) in respect of viability, barrier function, mass balance and absorption kinetics. Model validity was guaranteed by in-tact histology (in comparison to untreated models) and transepithelial electrical resistance (TEER) as well as absence of cytotoxicity (MTT measurements). Recovery of mass balance yielded 80 - 120 % of applied dose for 7 out of 8 test substances. Data were comparable between experiments (high and low dose). Papp values ranged from 2.7 (Metformin) to 60.4 (Antipyrine) $10^{-6}$ cm/sec and were comparable to literature data for 6 out of 7 compounds. Deviation between Epiprostintestinal™ model and Caco-2 was less than factor 3. Results were also comparable to ex vivo Ussing chamber experiments for Cimetidine, Ranitidine, Metformin and Antipyrine described in the literature (deviation below factor 3). The experimentally measured Papp values correlated with OSIAR calculated Papp values (deviation below factor 3) for 7 test-substances. Based on the findings described, Epiprostintestinal™ model is a promising tool for the determination of gastrointestinal absorption of test-substances in a fast, cost effective and technically easy to handle set up.

**2438 Inter-individual and Inter-ethnic Variation in Liver Toxicity of Lasiocarpine Predicted by Integrating Physiologically Based Kinetic (PBK) and Monte Carlo Modeling**

J. Ning\(^1\), L. M.C.M. Rietjens\(^1\), and M. Strikwold\(^2\). \(^1\)Wageningen University, Wageningen, Netherlands; and \(^2\)Van Hall Larenstein University, Leeuwarden, Netherlands.

Lasiocarpine is a pyrrolizidine alkaloid (PA) and able to cause liver toxicity following metabolic conversion to an unstable and reactive dehydro-PA metabolite. This conversion of lasiocarpine is mainly catalyzed by CYP3A4, of which abundance and activity differs between individuals and ethnic groups. The aim of the present study was to predict the effect of inter-individual and
2439 Mitochondrial-Destroying ToxCast Chemicals Inhibiting the Electron Transport Chain

Mitochondria generate the majority of cellular ATP through aerobic respiration and are central to cell proliferation, metabolic regulation, and apoptosis. Impaired mitochondrial function is linked to disease states such as Parkinson’s disease and metabolic syndrome; therefore, identifying mitochondrial-disrupting chemicals is important. We screened ToxCast Phase I/II chemicals using a modified Agilent Seahorse mitochondrial stress assay protocol with hepatocellular carcinoma HepG2 cells to identify compounds that altered basal, maximal, or inhibited oxygen consumption rates (OCR). Of 1,051 blinded test samples, 805 were inactive in a single-concentration format while remaining 246 samples were re-evaluated in a multiplex concentration format. These data were used to classify active chemicals as electron transport chain inhibitors (ETCi), uncouplers, or ATP synthase inhibitors. The largest classification group was ETCi with more than 120 chemicals. A subset of putative ETCi were mechanistically characterized using an electron flow assay to elucidate the inhibited ETC complex. Cells were permeabilized using a reagent that leave mitochondrial membranes intact and permitted the direct exposure to twenty suspected ETCi, each at three concentrations (31μM, 64μM, and 100μM). Mitochondria were fully uncoupled with carbonyl cyanide–4(trifluoromethoxy)phenylhydrazone (FCCP) to maximize OCR and initially provided glutamate and malate as complex I substrates. OCR was measured then challenged with three sequential injections: 1) suspected ETCi, 2) rotenone (complex I inhibitor)/succinate (complex II substrate), and 3) antimycin A (complex III inhibitor)/ascorbate and TMPD (complex IV substrates). The ETCi mechanism of each test chemical was elucidated using OCR recovery data. We determined that six chemicals specifically blocked complex I, three were specific to complex II/III, and five inhibited multiple ETC complexes. The ETCi mechanism of each test chemical was elucidated using OCR recovery data. We determined that six chemicals specifically blocked complex I, three were specific to complex II/III, and five inhibited multiple ETC complexes. This effort is the first of its kind to identify mechanisms of putative ETCi identified using a screening-based approach and will be expanded to include all identified ETCi with the ToxCast Phase I/II chemicals. This abstract does not necessarily reflect US EPA policy.

2440 The Power of Resolution: Contextual Understanding of Chemical-Biological Interactions

S. S. Ferguson1, S. C. Ramaiyah2, S. S. Auerbach1, T. O. Saddler1, J. R. Rice1, P. E. Dunlap1, N. S. Sipes1, M. J. DeVito1, R. R. Shah2, P. R. Bushel3, B. Merrick4, and R. S. Paules1. 1NIH, Research Triangle Park, NC; and 2Scion, LLC, Research Triangle Park, NC.

Prediction of human response to chemical exposures is a major challenge in both pharmaceutical and environmental toxicology research. Transcriptomics has proven to be a powerful tool to explore chemical-biological interactions. However, limited throughput, high-costs and complexity of transcriptomic interpretations have yielded numerous studies lacking sufficient experimental context for predictive application. We utilized a novel high-throughput transcriptomics platform to explore a broad range of exposures to 24 reference compounds in both differentiated and undifferentiated human HepaRG cultures. Our goals were to 1) explore transcriptomic characteristics distinguishing liver injury compounds, 2) assess impacts of differentiation state on baseline and compound-induced responses (e.g., metabolically-activated), and 3) identify and resolve reference biological-response pathways and their quantitative translation to human exposures. Study data revealed the predictive utility of transcriptomic concentration-response modeling to quantitatively identify human liver injury compounds by their respective benchmark concentrations (BMCs), and model hepatic responses to classical reference compounds yielding plausibly-relevant estimations of human potency.

2441 Identification of Peroxisome Proliferators by Metabolomics in HepG2 Cells

H. Kamp1, S. Sperber1, B. Birk2, V. Haake2, T. Walk2, and B. van Ravenswaay1, 1BASF SE, Ludwigshafen am Rhein, Germany; and 2Metanomics GmbH, Berlin, Germany.

BASF and metanomics established the database MetaMap-Tox containing the plasma metabolome of more than 800 compounds derived 28-day studies in rats. Over the last few years, a highly stable and reproducible liver in vitro model was established, in which the intracellular metabolome of HepG2 cells can be specifically altered through treatment with different hepatotoxins. Within the EU-funded Horizon 2020 project EU-ToxRisk, we have analysed the intracellular metabolome of HepG2 cells treated with two classes of peroxisome proliferators (phenoxy carboxylic acid herbicides: MCPP, MCPP, 2,4-D, 2,4-DP; and the phthalate DEHP and the corresponding mono ester MEHP). The metabolome consisted of 236 unique metabolites, thereof 35 amino acids and derivatives, 11 carbohydrates and related compounds, 54 lipids, 14 energy metabolites, 6 nucleobases, 14 vitamins and cofactors as well as other miscellaneous or unknown metabolites. In a principle component analysis, three variables were separated with regard to the control treatments along the first principal component. The metabolite profile shows an overall representation of lipid changes, indicating changes in lipid metabolism as can be seen for peroxisome proliferators in vivo. DEHP was not distinguishable from the control along the first principal component. This is probably due to the fact that p-hydroxy acids derived from the PPARs and need metabolic ester cleavage to the mono esters. Interestingly, DEHP and MEHP were separated from the controls along the second principle component indicating another biological activity in HepG2 cells. The data for the herbicides are well in line with the in vivo data as published in van Ravenswaay et al., 2016 and show that these in vitro data might be used to substantiate a read across based on in vitro methodologies.

2442 A Novel In Vitro All-Human Tri-culture Model That Maintains Structural Organization and Key Functions of Primary Hepatocytes over Several Weeks

A. C. Murchison1, K. K. Wolf1, E. K. Breathwaite1, J. R. Weaver1, M. L. Treadwell1, V. Soldatow1, J. Chen1, E. L. LeCluyse1, and J. Lee1. 1LifeNet Health, Virginia Beach, VA; and 2LifeNet Health, Research Triangle Park, NC.

Predicting drug- and chemical-induced hepatotoxicity remains a great challenge. Animal-based testing during compound development too often fails to identify this risk, unable to mimic the role of non-parenchymal cells in response to compound perturbations and disease progression. Conventional in vitro model systems such as primary human hepatocytes lack or exhibit the loss of key functions as well as cellular architecture and integrity over time. We have developed an all-human tri-culture system, in both 24- and 96-well formats, comprised of primary human hepatocytes with endothelial and stromal cells derived from donated human tissues. Cell lines and densities and ratios were established based on the restoration and maintenance of key self-assembled cellular structures and functions over a 4 week period, measured by the localization of key cell-cell interaction and junctional polarity markers, albumin and urea synthesis, and CYP450 basal and induced activities. Experiments comparing mono- and tri-cultures of hepatocytes from multiple donors, healthy and diseased, demonstrated that basal albumin and urea synthesis rates and CYP450 basal and induced activities decreased markedly (>50% decrease of albumin and urea, undetectable levels of CYP450 basal expression due to cell loss) in monocultures. These cellular and biochemical parameters increased in the tri-cultures over the initial 4 to 7 days, reaching steady-state levels between 7 and 10 days on time and exceeding the healthy donor levels of albumin and urea expression maintained within a 20% range, and CYP450 fold change of >10. These promising results directly corresponded to hepatocellular remodelling facilitated by E-cad- and Cx32-mediated cell-cell interactions and cell junction and functional bile canalicular formation. Regardless of donor background, the presence of non-parenchymal cells sustained and enhanced hepatocyte integrity, polarity and performance over several weeks in culture.
Overall, this all-human tri-culture system represents an exciting and promising new analytical tool for studying the efficacy and liability of human compounds on hepatocellular function of both healthy and diseased human donors.

**2443 Studies on Physiological Equivalence of Human Hepatocytes and Liver Cells Harvested from Humanized-Liver Chimeric Mice**
H. Suemizu1, Y. Higuchi1, N. Yoneda1, H. Yamazaki2, and S. Uehara1.
1Central Institute for Experimental Animals, Kawasaki, Japan; and 2Showa Pharmaceutical University, Machida, Japan.

Human hepatocytes are an important tool for drug development and in vitro toxicity studies. However, due to the limited number of usable hepatocytes, it is difficult to perform reproducible studies using the same donor. To overcome this issue, we developed a TK-NOG mouse that makes it possible for human hepatocytes to proliferate within the host liver tissue. In this study, we isolated hepatocytes from TK-NOG chimeric mice with humanized liver (Hu-liver) and evaluated whether the hepatocytes could be used as alternative cells for primary human hepatocytes in in vitro toxicity studies. Purity and viability of the prepared hepatocytes (Hu-liver cells) were analyzed using flow cytometry. Up to 97% of the Hu-liver cells stained positive for human leukocyte antigen (HLA), with a mean viability exceeding 85% (n = 10). Monolayer cultured Hu-liver cells were bi-nucleated and displayed a cobblestone cell morphology. These are typical characteristics that are normally observed in human hepatocyte cultures. There was a good correlation between the mRNA expression levels of 16 P450 forms belonging to P450 subfamilies 1 to 4 in the Hu-liver cells and the expression levels in the human donor hepatocytes. The variations in individual P450 mRNA levels between the Hu-liver cells and donor human hepatocytes were within 5-fold for 13 P450 forms. Similar to the findings for the donor human hepatocytes, omeprazole/Rhodamined caused induction (>2.0-fold) of CYP1A2 and CYP3A4 mRNA in the Hu-liver cells. In contrast, there were only a few Hu-liver cell lots that showed induction (>2.0-fold) of CYP2B6, CYP2C8, CYP2C9, and CYP2C19 mRNA by the same inducers. Furthermore, we also performed a testosterone assay as a CYP3A probe to investigate the induction ability of the enzymatic activity in Hu-liver cells. After treatment with the CYP3A inducer, rifampicin, there was a significant increase in the production of 6β-hydroxytestosterone in the Hu-liver cells. These results demonstrated that Hu-liver cells have characteristics that are similar to those of human hepatocytes. These findings suggest that Hu-liver cells can potentially be used for in vitro toxicity studies.

**2444 Mode-of-Action Prediction of Liver Toxicants Using Metabolomics In Vitro**
S. Sperber1, V. Starck2, B. Birk1, V. Haake2, H. Kamp1, T. Walk2, and B. van Ravenzwaay3.

Analogous the in vivo metabolome database MetaMapTox (containing the profiles of >900 compounds), an in vitro liver metabolome platform using the liver carcinoma-derived HepG2 cell line has been established. This in vitro database contains the intracellular metabolite profiles of more than 80 toxicants with different modes of actions as well as negative substances. The modes of action for liver toxicity covered within the database range from peroxisome proliferation, liver enzyme induction, steatosis to general liver toxicity. To investigate the applicability of the platform for predicting the mode of action for liver toxicity of an unknown substance a double-blind study has been conducted with 4 treatments: Wy 14643, a peroxisome proliferator; Boscalid, an enzyme inducer; Carbon tetrachloride (CCL4), liver toxicity; Cidonion ethyl, a mixture of different modes of action and two structurally similar industrial chemicals without liver toxicity. All compounds were tested at two concentrations (minimal cytotoxicity and no cytotoxicity - spacing ca. 3 - 4-fold). Cells treated with the test substances for 48 h and the intracellular metabolome was determined using GC-MS and LC-MS/MS analysis. To evaluate the findings a profile comparison, which compares the metabolite profile of the respective treatment with the entire metabolite profiles of the reference compounds available in the database using Pearson correlation, was conducted. In addition, other statistical methods (calculation of euclidean and mahalanobis distances, hierarchical clustering and principle component analysis) were also used to determine the best prediction tool for this kind of data. The best overall prediction was obtained with the Pearson correlation analysis. Wy 14643 was correctly classified by all other tests as a peroxisome proliferator and Boscalid was correctly predicted by 3 out of 4 tests to be a liver enzyme inducer. CCL4 resulted in a mixed classification (Steatosis, Liver Enzyme Induction, general liver toxicity) as well as Cidonion-ethyl (Liver Enzyme Induction, Peroxisome Proliferation, general liver toxicity). The non-

**2445 Cytotoxicity and Oxidative Stress of Nivalenol and Sterigmatocstin on Human Hepatocarcinoma Cells**
M. Ruiz1, C. Fedeli2, V. Zingales1, A. Juan-Garcia1, and M. Fernandez-Franzon1.
1University of Valencia, Valencia, Spain; and 2Università degli Studi di Perugia, Perugia, Italy.

Sterigmatocystin (STE) is a carcinogenic mycotoxin, produced mainly by Aspergillus and Fusarium species, it is structurally similar to the aflatoxin B1. Nivalenol (NIV), produced by various Fusarium fungi, belongs to the trichothecenes group. Based on currently evidence, STE and NIV alone or combined can produce some toxic effects. The present study is conducted to investigate the cytotoxicity of STE and NIV as well as the possible mechanism under their toxicity on hepatocarcinoma HepG2 cells individually. Then the effects of STE and NIV were assessed in binary combination. The concentrations tested were from 0.156 to 25 µM for STE and from 0.156 to 5 µM for NIV. The highest cytotoxicity in HepG2 corresponded to NIV. The concentrations tested in combinations ranged from 0.78 to 12.5 µM (STE), and from 0.08 to 1.25 µM (NIV), with ratios of 10.1. The STE-NIV mixture exhibited additive effects. This study also explores oxidative cellular damage tested individually and combined by lipid peroxidation (LPO), reactive oxygen species (ROS) production and mitochondrial membrane permeability (MMP).

**2446 Development of a Multi-functional Fit-for-Purpose Rat Liver Co-Culture Assay for Haptotoxicity Testing**
ScitoVation, Durham, NC. Sponsor: P. McMullen.

Extensive in vivo experiments for toxicity testing are cost-prohibitive and not always predictive of human responses. In both the regulatory and the industrial arenas, the goal is to move away from in-life rodent studies and towards safety assessment strategies that rely on testing species-relevant cells in vitro. The liver has been a major focus of these efforts, yet there are currently no in vitro alternatives for hepatotoxicity testing accepted by regulators, and the assays that do exist typically utilize hepatocyte monolayer culture or focus on a single phenotypic endpoint. While hepatocytes have been the primary component of in vitro toxicity assay development, it has become increasingly clear that the non-parenchymal cells (NPCs) (i.e., hepatic stellate cells, Kupffer cells, and liver sinusoidal endothelial cells) play a critical role in the progression of liver pathologies. The goal of this study was to develop a multi-functional organotypic co-culture system, in which primary rat hepatocytes are cultured with the CYP3A inducer, rifampicin, there was a significant increase in the production of 6β-hydroxytestosterone in the Hu-liver cells. These results demonstrated that Hu-liver cells have characteristics that are similar to those of human hepatocytes. These findings suggest that Hu-liver cells can potentially be used for in vitro toxicity studies.
Cardiotoxicity is a major safety liability for drugs, both in development and post-marketing, but has been largely neglected for environmental chemicals. Epidemiologic data suggest that about 35% of ischaemic heart disease burden is attributable to environmental risk, yet no in vivo or in vitro cardiotoxicity tests are required for non-pharmaceutical compounds. Moreover, the human population exhibits a large degree of variability in baseline cardiovascular risk, and data are lacking on the degree to which susceptibility to chemically-induced cardiotoxicity also varies. Human induced pluripotent stem cell (iPSC)-derived cardiomyocytes are an emerging in vitro model for cardiotoxicity screening of drugs. We have shown that inter-individual variability both in baseline cardiophysiologic and phenotypic characteristics as well as in drug-induced changes in beating parameters can be reproducibly modeled using a population of cardiomyocytes derived from different human donors. We therefore hypothesize that such an in vitro population-based model could be used to assess cardiotoxicity hazard, dose-response, and toxicodynamic variability for understanding the cardiotoxic liability of environmental chemicals. To test this hypothesis, we conducted concentration-response screening of 138 chemicals (drugs, pesticides, industrial chemicals, and food constituents) in iPSC-derived cardiomyocytes from 42 human individuals, comprising both sexes and differing ethnic backgrounds. We quantified kinetic calcium flux and high-content imaging data following chemical exposure, examined a range of cardiophysiologic and cytotoxicity phenotypes, and calculated point-of-departure (POD) values for each chemical and donor. We observed chemical-to-chemical variation in both potency and the degree of population variability. Treatment with known positive and negative drugs for cardiotoxicity exhibited in vitro phenotypes consistent with reported in vivo effects (or lack thereof). Additionally, consistent with previous studies using a single donor line, numerous non-pharmaceuticals showed cardiotoxicity with varying levels of potency. We observed inter-individual variability in responses across compounds, with ranges consistent with that observed in other population-based studies in vitro and in vivo. These results demonstrate the potential to use a population-based in vitro model to characterize not only cardiotoxicity hazard, but also inter-individual variability in susceptibility to such hazards.

**2448 Matured Human Cardiac Microtissues Provide Increased Predictive Value for Cardiac Toxicity Testing**

B. Charreol,1 N. Huebsch,1,2 V. Charwat,1 B. A. Siemons,1 S. Boggess,1,3 N. Jeffreys,2 N. Deveshwar3, J. Serrano,2 M. Snuder,2 E. Miller,2 and K. E. Healy1

In the ongoing efforts to reduce, refine and replace animal studies (3R), in vitro test systems are gaining increasing relevance. While classical 2D cell culture models are simple and easy to use, they fail to recapitulate more complex human tissue functions. The integration of human induced pluripotent stem cell derived cells (hiPSC) into microphysiologic system (MPS) helps to overcome these limitations as it enables better spatio-temporal control of culture conditions while allowing real time monitoring of toxicology studies. However, the immature electrophysiologic and structural properties of hiPSC-derived cardiomyocytes (CM) limits their utility for cardiotoxicity screens in the drug development pipeline. We recapitulated post-natal switching of the heart’s primary ATP source from sugar to fatty acids to enhance electrophysiologic maturation of hiPSC-CM. We hypothesized that this metabolic maturation will increase the predictive value of in vitro cardiac MPS. To this end, we have established a system mimicking in vivo heart muscle structure and function. By integrating force-sensing micropillars and electrode biosensors in our MPS system, we were able to derive the force of contraction and electrophysiology metrics in a non-invasive, paced, semi-real time, and cost-effective way. We identified fatty-acid based media that minimized the action potential duration while maximizing tissue contractile motion. MPS cultured in this optimized maturation media exhibit APD similar to that of adult human left ventricle. Interestingly, the same media did not alter the APD of hiPSC-CM monolayers. Matured cardiac MPS was superior to both hiPSC-CM monolayers and standard MPS in terms of its ability to predict safety margins for drugs that exhibit false positive toxicity (Verapamil), or false negative toxicity (Alfuzosin). With the addition of electrode and contraction force sensors, our matured cardiac MPS platform becomes much closer to being suitable for pharmaceutical pre-clinical toxicology trials in drug development processes and disrupts the current time consuming and costly drug approval steps, which will bring treatments to be commercialized and available to patients in a much faster and reliable way.

**2449 Evaluation of Corneal Damage Recovery Using 3-Dimensional Model**

H. Kojima1, Y. Kato2, A. Sato2, and N. Yamamoto1

1National Institute of Health Sciences, Kawasaki, Japan; 2Nippon Menard Cosmetic Co, Ltd, Nagoya, Japan; and 3Fujita Health University, Aichi, Japan.

To advance the replacement of animal testing with alternative test methods, some OECD Test Guidelines (TGs) have been approved as alternative to in vivo Draize eye irritation test, where eye irritancy of substance is tested on animal’s eye. While it is not considered valid as a stand-alone replacement for the in vivo rabbit eye test, some test methods are recommended to identify chemical substances that do not require classification for eye irritation or serious eye damage as defined by the UN GHS (No Category) and may therefore be used as an initial step within the Bottom-Up testing strategy approach (OECD GD 263). However, a chemical substance that is not predicted as causing serious eye damage or as not classified for eye irritation-serious eye damage, that is, weak eye irritant such as UN GHS Category 2 with these test methods would require additional information to establish a definitive classification. In this kind of situation, we studied model and test method that can evaluate recoverability by using UN GHS category 2 substance. A 3-dimensional corneal reconstruction model was prepared with the immortalized corneal epithelial cell line (iHCE-NY1). The substances of differing eye irritation categories were applied to the model and recoverability by post culture was analyzed with cell viability and pathological finding using 30 substances. As results, all the substances by UN GHS category 1 were not recovered. On the other hand, frank tissue degeneration was observed by UN GHS category 2 substances almost 50%. The post culture of our corneal model may be the possibility to evaluate correctly the liquid substances by UN GHS category 1 and 2. Reference (OECD 2018). Guidelines for Testing of Chemicals. Organisation for Economic Cooperation and Development, Paris. Available at: http://www.oecd.org/chemistry/guidance-on-testing-chemicals.htm.

**2450 Molecular Footprints of Oxidative Stress in Corneal Injuries of Different Origin: Utilization of Human Organotypic 3D Corneal Tissue Model**

Y. Kaluzhny, M. Kinuthia, T. Truong, A. Lapointe, M. Klausner, and P. Hayden, MotTek Corporation, Ashland, MA.

Oxidative stress (OS) plays an important role in many corneal injuries (CI), including chemical burns, UVB irradiation, and exposure to vesicating agents. Current methods used to investigate mechanisms of OS utilize monolayer cell cultures or animals that result in poor data extrapolation and standardization, low throughput and high cost. Physiologically relevant, human-based in vitro models for ocular research are needed. This study evaluated the utility of an in vitro reconstructed 3D tissue model (Epicon) to study molecular mechanisms of OS corneal damage. The constructs are comprised of normal human corneal epithelial cells that are cultured at the air-liquid interface, develop a tight barrier (TEER 1000±250 Ω•cm²), express tight junctions, mucins, and key corneal detoxification enzymes similar to in vivo human cornea. OS was generated by exposure to 60/120 mJ of UVB, topical application of 20/50 mM of hydrogen peroxide (H2O2) for 2h or 1.5 mg/ml of nitrogen mustard (NM, warfare agent) for 10/30 min. Barrier function, tissue viability, reactive oxygen species (ROS), lipid oxidation, cytokine release, histology, and gene expression were evaluated after 2/24h post-exposure. HP reduced tissue barrier to 50% and viability (MTT assay) to 70% after 2h incubation compared to negative control (NC). NM reduced tissue barrier to 76%, however tissue viability was not affected after 2h. 20 mM HP- and 10 min NM-treated tissues recovered after 24h, while 50 mM HP- and 30 min NM-treated tissues degraded as confirmed by TEER, MTT assay, LDH release, and histological analysis. UVB irradiation didn’t have an effect on tissue barrier, viability, and LDH release, but intracellular ROS increased by 17x when compared to the NC. The highest lipid oxidation (20 X1 increase) and IL-8 release (18.6X increase) relative to NC were observed for 10min/NM-treated tissues at 24h post-treatment. Utilizing a PCR gene array we compared effects of different CI corneal injuries on the expression of 84 OS responsive genes, and found a specific molecular footprint for each mechanism of corneal injury. In summary, the in vitro reconstructed human corneal tissue model structurally and functionally reproduced key features of in vivo corneal tissue. Unique toxicity and molecular responses were
revealed for various types of ocular damage. This model is anticipated to be a useful tool to study molecular mechanisms of corneal damage and to evaluate new corneal drug formulations.

2451 The EYEIRR-IS Assay: Development of an In Vitro Method Using SkinEthic HCE Model for Liquid Chemical Eye Irritation Sub-categorization

F. Cottrez1, V. Leblanc1, H. Groux1, and N. Alepee2. Immunosearch, Grace, France; and 1Oreal, Aulnay Sous Bois, France. Sponsor: E. DuFour

Over the last 20 years, many efforts have been made to find reliable and relevant alternative methods to evaluate eye irritation hazard. Although several in vitro and ex vivo test methods have been regulatory accepted by the OECD for the identification of either UN GHS Category 1 (e.g. BCOP) or No Category chemicals (e.g. SkinEthicHCE EIT), none of them could distinguish chemicals that cause eye severe damage (Cat 1) from those causing eye irritation (Cat 2). Using a toxicogenomic approach on the human 3D corneal epithelial model SkinEthicHCE, we developed a new assay: EYEIRR-IS, to subcategorize liquid chemical irritants into Cat 1 or Cat 2 subclasses. An optimized protocol based on a 10 minute treatment followed by 6 h post-treatment incubation on 2 concentrations of liquid chemicals (100% and 30%) was assessed on a balanced set of 18 substances (4 Cat 1, 5 Cat 2, 9 No Cat referenced in the OECD reference chemicals list). A prediction model based on the analysis of 10 specific genes overexpression level to calculate a Liquid Irritation Index was used to sub categorize the liquid chemicals. The preliminary data showed promising results, with the correct identification of all Cat 1 and Cat 2 chemicals. The majority of the known in vivo non classified chemicals (7 out of 9) were well classified in vitro. These results suggest that the EYEIRR-IS test method may be a promising in vitro tool for the assessment on liquid chemicals of the irritation potential in all of the GHS classes. Further experiments are ongoing to further assess the predictivity of EYEIRR-IS on a larger set of chemicals.

2452 Identifying Eye Irritants (GHS Category 2) Using Validated, Nonanimal Tests

OECD Test Guideline 405 prescribes a weight-of-evidence (WoE) analysis and sequential testing strategy for the classification of acute eye hazards, including: “Perform validated and accepted in vitro or ex vivo ocular test(s).” Four tests qualify: three designed to identify severe eye irritation/corrosion (GHS Category 1) and one to identify non-irritants (GHS No Category). GHS Category 2 (eye irritant) classification is impossible using any single test. The EpiOcular Eye Irritation Test; EIT (OECD 492) classifies a substance to be No Category, or contrarily causes (uncategorizable) eye effects. Conversely, the Bovine Corneal Opacity and Permeability (BCOP) Test (OECD 437) is used for ruling in or ruling out Category 1 effects. By using a dual-assay/approach system - the combination of the EIT and BCOP test - we have determined, with a high degree of accuracy, GHS Acute Eye Hazard Category 2 chemicals that cause reversible eye irritation. When a BCOP test rules out GHS Category 1, and the EIT rules out GHS No Category, analysis of these results indicates the only other possible designation - Category 2. Per GHS, Category 2 classification defaults to Category 2A, because differentiation between Category 2A and 2B cannot be made. After testing 42 chemicals, we correctly identified 93% of the Category 2A/B chemicals as Category 2. The potential of the BCOPETI dual-assay system, coupled with WoE evaluation, to correctly classify substances into GHS Category 1, Category 2A, and No Category is encouraging. We predict using this testing strategy would greatly reduce reliance on Draize Rabbit Eye Tests.

2453 Prevalidation of the OptiSafe Ocular Irritation Assay for the Detection of Ocular Corrosives

S. J. Lebrun1, N. Choksi1, A. Daniel1, D. Allen1, and W. Casey1. Lebrun Labs, Anaheim, CA; 2TILS, Research Triangle Park, NC; and 3NI/NS/NICETAM, Research Triangle Park, NC.

OptiSafeTM is a novel, shelf stable, test tube-based assay that can discriminate ocular irritants/corrosives from nonirritants and does not use animal tissues or cells. It can determine whether an unknown substance is an ocular nonirritant by measuring and comparing chemical models for three variables: damage to the corneal stroma, damage to phospholipid bilayers, and the potential to induce pH extremes in a system. A substance can be evaluated in less than 2 hours, and results can be obtained in fewer than 24 hours. Previous studies indicated that predictions of EPA Category IV or GHS category NC (not classified) by the OptiSafe ocular irritation assay had high sensitivity, suggesting that it may represent a new tool for the in vitro assessment of the ocular toxicity potential of chemicals in a tiered-testing strategy. While a limited number of ocular corrosives have been tested, the initial analyses of retrospective and prospective OptiSafe data suggest that the test method is also sensitive for the detection of ocular corrosives. OptiSafe correctly predicted, with 100% specificity, the sensitivity was 87.5% and the specificity was 70%. The EPI Category I prediction yielded a sensitivity of 85.7% and a specificity of 67.6%. OptiSafe had a higher sensitivity for the detection of ocular corrosives and similar or lower specificity compared to other in vitro test methods: Bovine Cornea Opacity/Permeability Assay; EpiOcular; Short-Time Exposure. To confirm the results of these initial studies, additional ocular corrosives will be assessed to provide a more complete description of the sensitivity and accuracy for the detection of ocular corrosives. If the validation results are confirmed, then OptiSafe may represent a new approach that moves closer to the in vivo category test paradigm. NC/IV classification results can be accepted with a higher level of confidence, and noncorrosive results can be accepted with an above-average level of confidence. While positives may require confirmation by other methods, nonirritant and noncorrosive results may be acceptable. This approach may find applications in scenarios where there is a time-sensitive need to determine whether a substance is safe for eye area exposure. This project was funded in whole or in part with federal funds from the NIH under Contract No. HHSN27201500010C.

2454 Updated Survey of CAMVA and BCOP Assays Used to Predict Ocular Irritancy of Personal Care Products—7 Years Later

Kao USA Inc has used the combination of bovine corneal opacity and permeability (BCOP) and chorioallantoic membrane vascular assay (CAMVA) in vitro to assess ocular irritation since 1996. In 2011, Kao USA created a decision tree to outline when to conduct ocular testing of new cosmetic formulations. Here, data from 150 BCOP and CAMVA studies, conducted since 2011, were surveyed to 1) confirm the decision tree continues to accurately predict the irritant classifications of certain product categories and 2) determine if any decision tree updates are required. The new data predict hair shampoos, skin cleansers, and ethanol-based hair styling sprays are ocular irritants, confirming the original predictions. Conversely, the new data predict artificial sweeteners are non-irritants, also consistent with the original predictions. The accuracy rate of decision tree predictions for these product categories is 89.7% (78/87 products). The false negative rate is 8% (7/87), but is explained by deeper examination of individual BCOP scores and CAMVA IRCt values. For example, some tested products that have irritant BCOP scores near the non-irritant threshold and have non-irritant CAMVA scores are not considered irritants because the BCOP assay has a known limitation in discerning between mild irritants and non-irritants. Hair conditioners were not included in the original decision tree due to wide variability in the original test results surveyed. This work includes a review of 52 conditioners with new data that 1) new conditioners are predicted to be non-irritants and supports a potential update to the decision tree. Ocular testing decision tree predictions are one piece of information used in a conservative weight-of-evidence framework to classify cosmetic formulations. Ongoing re-reviews of the resulting predictions are planned to ensure continued accuracy of the decision tree predictions, to strengthen existing and future conclusions, and to ultimately support a robust safety assessment of cosmetic formulations.

2455 In Vitro Metabolome Analysis Can Predict Nephrotoxicity and Its Mode-of-Action

B. Birk1, S. Sperber1, S. Wallisch1, H. Huener1, A. Verlohrner1, T. Walk2, V. Haake1, M. Spitzer1, H. Kamp1, and B. van Ravenzwaay1. 1BASF SE, Ludwigshafen am Rhein, Germany; 2Metanomics GmbH, Berlin, Germany; and 3Metanomics, Berlin, Germany.

Nephrotoxicity and its mode of action (MoA) is a highly relevant toxicological endpoint for chemicals. Therefore, reliable and robust in vitro methods are the preferred methods for screening and thorough mechanistic understanding in the regulatory context. A tubular fibroblast rat cell line (NRK-52e) is cultivated on Lumox dishes (Sarstedt), treated for 48h and sensitively harvested. LC-MS/MS and GC-MS/MS technology was applied to quantify 353 endogenous metabolites. 9 different nephrotoxic compounds are the preferred methods for screening and thorough mechanistic understanding. A new nephrotoxic test system was developed to further assess the predictivity of EYEIRR-IS on a larger set of chemicals.
Evaluation of a Method for Assessing Respiratory Toxicity in vitro

Y. Wang, Q. Wu, L. Mushkelishvili, K. Davis, P. Tripathi, R. Xiong, D. Rua, E. Mayhall, J. Weeks, M. Bryant, and X. Cao. 1 US FDA/NCTR, Jefferson, AR; and 2 US FDA/NCTR, Silver Spring, MD.

Ortho-phenylaldehyde (OPA) is a liquid chemical stunt used for the high-level disinfection of heat-sensitive medical devices, such as endoscopes and microsurgical instruments. Although viewed as a safer alternative to glutaraldehyde, a known skin and respiratory sensitizer, an OPA exposure limit to control associated health risks from inhalation exposure has not been established. To simulate human OPA inhalation exposure, we treated a human airway epithelial cell line (A549) to an in vitro aerosol. A single exposure to OPA aerosols at the air interface with a single dose of OPA aerosols prepared from solutions containing 0 (control), 0.2, 0.5 and 1.0 mg/ml OPA; tissue responses were evaluated at 20 min, 24 h and up to 5 days later. Treatments with 0.2 and 0.5 mg/ml OPA were non-cytotoxic and significantly increased trans-epithelial electrical resistance (TEER). 1.0 mg/ml OPA, however, was cytotoxic based on the lactate dehydrogenase (LDH) release assay and TEER measurements. Except for apical LDH release, membrane leakage from the basolateral side and TEER returned to baseline following a 5-day recovery. Single OPA exposures decreased the levels of reduced (GSH) and oxidized glutathione (GSSG), lowered GSH/GSSG ratios and upregulated the expression of heme oxygenase-1, indicating induction of oxidative stress. Dose-dependent functional disruptions, such as inhibition of cilia beating frequency (CBF), decreases in MUC5AC secretion and aberrant cytokine secretions were observed 24 h following single exposures. Measurements made up to 5 days following the exposures indicated that alterations in CBF, MUC5AC secretion and cytokine secretion only partially recovered from the treatments, while MUC5AC secretion and induction of aldo-keto reductase 1B10 persisted over the same timeframe. No morphological changes were observed following a single exposure. Taken together, these findings suggest that OPA exposure induces respiratory epithelial irritation. Our findings will help support setting a limit to inhalation exposure for this chemical as a high-level disinfectant.
2460 Validation of an In Vitro Alternative Method for Acute Respiratory Toxicity Testing

M. Debatis, G. R. Jackson, A. Maimone, M. Klausner, and P. J. Hayden, MatTek Corporation, Ashland, MA.

Determination of acute respiratory toxicity potential is important for establishing safe use of chemicals and consumer products. Inhalation toxicity testing and classification procedures currently accepted by worldwide government regulatory agencies require the use of tests based on lethal effects in animals. The current work provides an update on the development and validation of an alternative non-animal method for determining acute respiratory toxicity using the EpiAirway™ in vitro human airway model. The in vitro test method exposed EpiAirway tissues to four concentrations of test chemicals for three hours via apical application using either aqueous or corn oil vehicles. After the initial three hour exposure, the test chemicals were rinsed off and the tissues were incubated for an additional 21 hours. An IC75 concentration (concentration required to reduce the endpoint value to 75% of vehicle exposed controls) was determined from the dose-response data using barrier function (determined by measuring transepithelial electrical resistance (TEER)) and tissue viability (MTT assay) as endpoints. Based on the determined IC75 value, EpiAirway tissues were exposed to six serial dilutions of the test chemicals, using the IC75 as the highest dose. Tissues were apically exposed for three hours, followed by rinsing, every Monday, Wednesday and Friday, with TEER measured prior to each dose application. Experiments were continued for at least 30 days to determine no-observed-adverse-effect level (NOAEL) doses. Experiments conducted with formaldehyde, ethanol and dimethylacetamide found NOAEL values of 0.0001, 0.5 and >0.5 mg/ml, respectively. Expansion of the data set to include chemicals of different classes, chemical structures and physical properties is ongoing. These results indicate that in vitro airway tissue models using TEER as a convenient non-destructive endpoint are a promising alternative to animal tests for assessment of chronic respiratory toxicity.

2462 Development of a Chronic Respiratory Toxicity Assay Using an In Vitro Human Airway Model

G. R. Jackson, M. Debatis, A. G. Maimone, M. Klausner, J. Oldach, and P. J. Hayden, MatTek Corporation, Ashland, MA.

Knowledge of chronic respiratory toxicity potential is important for establishing safe use of chemicals and consumer products. The current work describes efforts to develop an alternative, non-animal method for determining chronic respiratory toxicity using the EpiAirway™ in vitro human airway model. Initial acute toxicity experiments were conducted by exposing EpiAirway tissues to four concentrations of test chemicals via apical application using either aqueous or corn oil vehicles for three hours. After exposure, the test chemicals were rinsed off and the tissues were incubated for an additional 21 hours. An IC75 concentration (concentration required to reduce the endpoint value to 75% of vehicle exposed controls) was determined from the dose-response data using barrier function (determined by measuring transepithelial electrical resistance (TEER)) and tissue viability (MTT assay) as endpoints. Based on the determined IC75 value, EpiAirway tissues were exposed to six serial dilutions of the test chemicals, using the IC75 as the highest dose. Tissues were apically exposed for three hours, followed by rinsing, every Monday, Wednesday and Friday, with TEER measured prior to each dose application. Experiments were continued for at least 30 days to determine no-observed-adverse-effect level (NOAEL) doses. Experiments conducted with formaldehyde, ethanol and dimethylacetamide found NOAEL values of 0.0001, 0.5 and >0.5 mg/ml, respectively. Expansion of the data set to include chemicals of different classes, chemical structures and physical properties is ongoing. These results indicate that in vitro airway tissue models using TEER as a convenient non-destructive endpoint are a promising alternative to animal tests for assessment of chronic respiratory toxicity.
2464 Authentic Lung and Gingival Fibroblasts Cell Models for In Vitro Toxicity Testing

L. Romero, and C. Zou, ATCC Cell Systems, Gaithersburg, MD.

There is increasing demand for in vitro models for toxicity testing to replace animal models. Drivers for this change include decreased overall cost for cell-based models and the ability to do more high throughput screening. Development of cell based in vitro models for toxicity testing is a challenging task. Primary cells can best represent the in vivo situation, however, donor variability and replicative senescence restrict the potential usefulness of this cell model in the study of toxicity. Conversely, continuous cell lines may lose their relevant physiologies and thus their usefulness. Human telomerase reverse transcriptase (hTERT)-immortalized primary cells provide a better solution: cells can be continuously subcultured while retaining the physiological characteristics of the parental primary cell. In this study, we established two clonal hTERT immortalized cell lines by expressing hTERT in lung fibroblasts and gingival fibroblasts isolated from normal donors. Both lines have been cultured continuously for more than 35 population doublings without any signs of replicative senescence. Further, both hTERT-immortalized fibroblasts retained normal diploid karyotype over extended culture period, demonstrated no indication of malignant transformation, and maintained typical fibroblast characteristics (e.g., positive TE staining, a fibroblast marker; and negative K14 staining, an epithelial cell marker). Both cell lines responded to TGF-beta treatment with elevated smooth muscle actin expression as did the parental cells. Notably, both cell lines are sensitive to toxicological agent (Chlorhexidine) treatment, and showed similar patterns as their primary counterparts in a dose-dependent manner. The results show that the hTERT immortalized lung fibroblasts and gingival fibroblasts cell lines retain the important physiological characteristic of the primary cells from which they were derived and provide very useful in vitro cell models for toxicity screening.

2465 Development of a Fit-for-Purpose In Vitro Model of Lung Toxicity

A shift in toxicity testing from in vivo animal models to in vitro human cell-based models is a major focus of current research, due to the high cost, low throughput, ethical concerns, and questionable human relevance of in vivo testing. While many high throughput in vitro assays for biological perturbations do exist (as illustrated by the ToxCast effort), it is clear that more physiologically relevant cellular models are required to reproduce adverse outcomes. The lung epithelium is a frequent target of chemicals under regulation for toxic effects, yet efforts to develop in vitro lung models fit for the purpose of toxicity testing have been relatively few. To reproduce such adverse effects as proliferation and fibrosis, it will be necessary to utilize cellular models of the lung that incorporate multiple differentiated cell types growing at the air-liquid interface (ALI). Furthermore, to ensure interpretable dosimetry, exposure of cells to test compounds must be via the air. We are exploring testing approaches that meet these criteria. As a proof-of-principle experiment, we have treated primary human bronchial-tracheal epithelial cell lines (HBTECs), grown at ALI, with chloroform vapor using the Vitrocell inhalation exposure system. Chloroform is metabolized by CYP2E1 to form reactive intermediates, including phosgene, which react with glutathione GSH). Metabolically competent cells are expected to be indeplete GSH through conjugation as well as oxidation to GSSG; therefore, we chose to monitor oxidized and total GSH after exposure. To identify exposures likely to span the point-of-departure for this endpoint, we first performed a range-finding experiment with A549 human alveolar carcinoma cells treated with chloroform in solution for 24 hours. 1 μM had little effect on total and oxidized GSH levels compared to vehicle, whereas 25 μM greatly increased oxidation. Chloroform concentrations bracketing this POD (2.5, 10, and 40 μM) were selected and converted to equivalent 1 h vapor-based exposures, (69, 267, and 1069 ppm, respectively), by matching the nominal AUCs of the media and vapor-based exposure using a blood/aire partition coefficient. HBTECs grown at ALI were then treated with increasing concentrations of chloroform vapor for 1 or 3 hours. At both timepoints, GSH levels were significantly reduced, and GSSG/GSH ratios were increased, at 1000 ppm chloroform compared to clean air treatment. This result demonstrates the promise of this system for in vitro inhalation safety testing.

2466 Interference of Barcoded DNA Measurements When Determining High-Throughput CYP-Mediated Cytotoxicity

E. A. Woolard, G. Carswell, S. Simmons, and B. Chorley. IORISE, Durham, NC, and US EPA/ORD, Research Triangle Park, NC.

Many cell lines used in current high-throughput chemical testing lack chemically metabolized, and therefore may misclassify the hazard potential of metabolites relevant to human exposures. To help address this challenge, we engineered HEK293T cells to overexpress cytochrome P450 monoxygenase (CYP) recombinant transgenes commonly involved in chemical metabolism within the human liver (CYP1A1, CYP1A2, CYP2E1, and CYP3A4). Each clone was treated with unique untranscribed DNA barcode, which can distinguish each clone in a mixed clonal culture by PCR and serve as a quantitative measure of cell number. This method allows adaptation for high-throughput assessments of chemical induced cytotoxicity thereby specific CYP-mediated bioactivation. As a proof of concept, we analyzed clonal toxicity to a potent hepatotoxicant, aflatoxin B1 (AFB1). Traditional cytotoxicity assays confirmed AFB1 bioactivation and greater toxicity in CYP3A4- and 1A1-expressing clones (62% and 31% cell loss compared to controls at 80 μM AFB1, respectively). Surprisingly, when clone-associated DNA barcodes were measured by droplet digital PCR (ddPCR), we observed significant increases in CYP3A4 and 1A1 barcode counts after AFB1 exposure (by 4.5-fold and 2.5-fold compared to controls, respectively) incorrectly suggesting detoxification rather than bioactivation. We speculate the intact, normal DNA from fresh cell lysate restricts probe access more than the fragmented DNA present in apoptotic cells leading to higher barcode readings. To address this issue, optimized homogenization of sample and direct ddPCR measurement in the cell lysate reduced variance; however, increased barcode counts in clones sensitive to AFB1 were still observed. Moreover, exposure to a known apoptosis-inducer in these cells, staurosporine, resulted in the same phenomenon. Mechanism of cell death is currently being assessed as the primary factor in the observed aberrant barcode measurements. This abstract does not necessarily reflect US EPA policy.

2467 Exploring the Feasibility of A549 Cells for Use in a Vapor Exposure Test System for Acute Toxicity Evaluation

The 3M Strategic Toxicology Laboratory (STL) is an internal corporate resource providing support to 3M businesses that emphasizes the use of in vitro methodology. The purpose of the current study is to validate an in vitro acute vapor inhalation model using the VitrocellTM vapor exposure system and A549 adenocarcinomic human alveolar basal epithelial cells. Multiple variables were examined including seeding density, airflow rate, growth duration in submersed culture, and subsequent time at the air-liquid interface (ALI) prior to exposure. Cell viability was assessed using the MTT assay. Results indicated that a seeding density of 500,000 cells/well grown for 7 days with the apical surface submerged provided the optimal optical density (OD) readings between 2.0-2.5, which provided sufficient sensitivity to evaluate viability. To evaluate the incubation time at the ALI, A549 inserts that were freshly brought to the ALI or were cultured at the ALI for 14 days prior to use, were exposed to increasing concentrations (0-12,000 ppm) of trans-dichloroethylene (t-DCE) for 3 hours. t-DCE vapor was chosen because of its intrinsic low toxicity in vivo, and concentrations were measured with a micro-GC sampling system continuously throughout the exposure. A549 cells moved to the ALI immediately before t-DCE exposure demonstrated 30-40% viability after 4,000, 8,000, and 12,000 ppm exposures, compared to incubator controls. Further, visual observations revealed that the center of each insert, directly under the air inlet in the Vitrocell, appeared to be non-viable, including the clean air controls. In contrast, cells that adhered to the ALI and allowed to continue growth in the incubator for 3 or 7 days then exposed to clean air at a flow rate of 1.2, 3 or 5 ml/min, or 14 days before t-DCE exposure were 80-90% viable compared to incubator controls, and non-viable centers were not observed. In summary, a seeding density of 500,000 A549 cells/well was optimal for this model. Conditioning the ALI by lifting them to the ALI for an additional 7-14 days prior to use made them more tolerant to the exposure conditions within the Vitrocell. While these data provide a starting point for the use of A549 cells to evaluate acute toxicity screening within the Vitrocell vapor exposure system, further studies are needed using a variety of known in vivo toxicants to better characterize the utility of this in vitro test system in screening for vapor toxicants.
Beauvericin and enniatin B are two emergent mycotoxins from Fusarium fungi which are frequently detected concomitantly in cereals and cereal-based products. They have been studied individually in vitro and in vivo, showing contradictory toxicological results. While in vitro they have shown ionophoric activity and subsequent mitochondrial toxic properties among others, in vivo only slight adverse effects, as loss of weight, have been found. At transcriptome level in Jurkat lymphoblastoid T-cell line, it revealed a similar down-regulation pattern affecting most of the genes involved in the electron transport chain pathway. In order to delve into the adverse outcome pathway that leads to homeostasis triggered by these mycotoxins, it was proposed to investigate the changes in mitochondrial protein expression in Jurkat cells. The chosen combination of beauvericin and enniatin B was 1:1 at three different doses: 0.01 - 0.1 - 1.5 µM. Control cells were exposed to 0.5% DMSO. Cells were treated during 24 h and then mitochondria were extracted. Three biological replicates and technical duplicates from each treatment were injected in a Nano-LC Q-TOF UHPLCMS and raw data were processed using Swissprote database limited to human entries. After comparing the control and the three doses results, from the 1821 proteins identified and quantified, 340 proteins were selected using the parameters: max fold change ≥ 1.5 and Anova p-value ≤ 0.05. These selected proteins were analyzed by different bioinformatics tools for proteomics data interpretation. The most overrepresented pathways in Jurkat lymphoblastoid T-cell line was the citric acid cycle and respiratory electron transport, mitochondrial protein import and respiratory electron transport, ATP synthesis by chemiosmotic coupling, and heat production by uncoupling proteins. PANTHER version 13.1 indicated ATP synthesis as the most overrepresented pathway and mitochondrial ATP synthesis coupled proton transport as the gene ontology biological process. These results suggest that mitochondria are the main target for beauvericin and enniatin B mixture toxicity. Acknowledgements: This work was supported by the Spanish Ministry of Science, Innovation and Universities (AGL 2016-77610R).

Pyrogens are substances that can produce fever when present as contaminants in a drug or medical device; most pyrogens are biological substances derived from bacteria, fungi, and viruses. Material-mediated pyrogens (MMPs), while less common, may also be present. It’s important that medical device products for implantation or other systemic exposure meet pyrogen limit specifications before they are marketed, and animal-based pyrogen tests (i.e., LAL and rabbit pyrogen tests) are often conducted to investigate the presence of pyrogens. Non-animal pyrogen activation tests (MAT) are widely available but infrequently used. To review the MAT and discuss ongoing challenges to its widespread implementation, NICEATM and the PETA International Science Consortium (PISC) co-organized a September 2018 workshop. Workshop participants explored how the US FDA’s Medical Device Development Tools (MDDT) Program could be used to qualify the use of MAT as a standalone pyrogen test for specific medical device contexts of use. Attendees discussed practical aspects of pyrogen testing and the evidence needed to support qualification of MAT as a replacement for animal-based pyrogen tests. Scientists from the US FDA Center for Devices and Radiological Health (CDER), the US EPA, and consultants for use of the MAT in assessment of medical device biocompatibility and sterility and the role of the MDDT Program for qualification of MAT. There was general agreement that the MAT likely could be qualified as acceptable for batch-release testing for microbial-based pyrogens. However, additional studies were recommended to demonstrate its ability to detect known MMPs. This testing would determine whether the MAT can be used for both biocompatibility and sterility or if other information on MMPs would be needed to address biocompatibility. Participants also discussed information gaps on MMPs, potential test controls, and other challenges and opportunities for implementing the use of MAT as a comprehensive pyrogen test. Funded in whole or in part with federal funds from the NIEHS, NIH under Contract No. HHSN27220150010C.

Flavorings in e-cigarette liquids are a primary driver of e-cigarette use among teens. While recent studies have investigated pulmonary toxicities associated with exposure to flavorings in e-cigarettes, little research has been conducted on the impact of flavorings on the pharmacokinetics of nicotine, the primary addictive compound of e-cigarettes. Utilizing recombinant CYP2A6, the major enzyme responsible for the metabolism of nicotine, we screened 3 e-liquids, Strawberry Poptart (SP), Apple Watermelon (AW), and Flamethrower (FT) at concentrations ranging from 0.0025% to 0.25% (v/v), for CYP2A6 activity inhibition. CYP2A6 activity was determined by measuring the formation of the fluorescent metabolite of 3-cyano-7-hydroxycoumarin, a substrate of CYP2A6. Incubation with FT and SP strongly inhibited CYP2A6 as low as at 0.0025%, while AW exhibited no CYP2A6 inhibition. GC-MS analysis was conducted on FT and SP to identify compounds responsible for CYP2A6 inhibition. Trans-cinnamaldehyde, a potential inhibitor of CYP2A6, was identified in FT, while benzaldehyde was identified in SP. We subsequently screened both aldehydes using recombinant CYP2A6 at concentrations ranging from 0.25μM to 250μM. Trans-cinnamaldehyde and benzaldehyde exhibited near maximal inhibition of CYP2A6 at 2.5μM and 25μM, respectively. To confirm our findings in a cell-based system, we developed a novel in vitro cell culture apparatus capable of screening volatile compounds when heated in an incubator-something not feasible in traditional cell culture systems. In the novel culture system, BEAC-2B cells transduced to overexpress CYP2A6 were cultured and subsequently exposed to e-liquids and flavoring compounds in the presence of nicotine. We quantified nicotine levels using LC-MS. Exposure to SP, FT, and both flavoring aldehydes significantly reduced the metabolism of nicotine by CYP2A6 at concentrations consistent with what was observed using recombinant CYP2A6. In summary, these data indicate that some flavoring compounds in e-cigarettes have the capacity to inhibit CYP2A6 activity, the enzyme responsible for catalyzing nicotine. This may increase serum concentrations of nicotine and have implications for the risks associated with e-cigarette use. This abstract may not reflect official US EPA policy.

Unhealthy diet and lack of exercise are major contributors to weight gain and obesity; however, recent studies have suggested that environmental exposures, so-called “obesogens”, may also play a role. It has been proposed that exposure to certain agents early in adipose tissue development may increase the susceptibility to metabolic syndrome later in life by disrupting hormone homeostasis and changes in adipocyte differentiation, thereby increasing the fat storage capacity and/or the number of fat cells. In vitro systems to identify potential obesogenic chemicals are a cost-effective strategy to identify potential hazards. Here, we tested a recently developed white adipose tissue (WAT)-on-a-chip system with a footprint of less than 1 mm² consisting of a separate media channel and WAT chamber connected via a small microporous membrane. WAT MPS technology was transferred from the University of California at Berkeley to Texas A&M University and then utilized as MPS platform to study the effects of chemicals on adipogenesis. Two cell lines, 3T3-L1 mouse fibroblast and human subcutaneous preadipocytes were studied in both traditional 2D culture and in 3D WAT MPS. Dexamethasone, triamcinolone, mifepristone, diethyl sulfate, and GW9662 were tested in concentration-response fashion based on their purported effects on glucocorticoid receptor (GR) and PPAR-regulated pathways. Maturation of adipocytes was quantified using markers including lipid accumulation, adiponectin secretion, expression of key genes, free fatty acid release, and glucose uptake. We demonstrated successful technology transfer of a complex MPS between laboratories and established a functional and viable adipose tissue in the WAT platform for over two weeks in culture. We found that dexamethasone and triamcinolone had effects on adipogenesis in both traditional 2D culture and 3D MPS platform. This research was funded by grants U24 TR001950 and UH3 TR000487.
2472 New Screening Approach of Chemicals—Investigation of Retinoic Acid Receptor Alpha (RAR Alpha) Interaction by Combining Two Different Techniques

Reproductive toxicity is one of the most sensitive endpoints within regulatory toxicology of chemicals. Identification of reproductive toxicity and the mode of action is important. Changes of the retinoic acid receptor alpha (RARα) hemostasis can lead to adverse effects including teratogenity. The RARα is a nuclear receptor present in the cellular nucleus and bound to the retinoic acid responsive elements in front of target genes. A key step in the ligand induced transcription of those controlled genes is the recruitment of cofactors by RARα. A cell-based system in transfected HEK293 cells, expressing RARα (BPS Bioscience) and a micro array system called MARCoNi (PamStation®) were compared and the strength and limitations to identify RARα-interaction were determined. Six known agonists (e.g. A2M801), four antagonists (e.g. BMS195614) and four non-responders (e.g. Ketaconazole) were tested with both methods. The dose response of peptides/cofactors, known as relevant for the RARα interaction, corresponded nicely to the response of the HEK293 cell line. Exemplarily: after ATRA treatment 16 selected cofactors/45 peptide motifs revealed ECO50 values between 6.6⋅10⁻⁸ M and 1.0⋅10⁻⁸ M and was comparable to ECO50 value of 1.9⋅10⁻⁷ M for ATRA in HEK293 cells. While the HEK293 cell line is suitable to determine the agonistic and antagonistic property of a chemical in an easy and economical way, the experiments in the MARCoNi-system revealed the molecular initiating event by influencing corepressor or coactivator expression. Since the agonistic effects are identified properly with both methods, the MARCoNi-system allows a better understanding of mechanistical processes for diverse antagonists. The combination of both methods increases the value of each individual method by compensation of the limitations of each other. Based on this a testing strategy was implemented at BASF to investigate the RARα interaction including mechanistical understanding of chemicals in the screening phase of new chemicals.

2473 Alginate Immobilization of Metabolic Enzymes (AIME) Coupled to an Estragon Receptor Transactivation Assay Detects Bioactivated and Bioinactivated Estragon Receptor Agonists

D. E. DeGroot1, T. J. Zurlinden1, R. S. Thomas1, M. Lee2, P. L. Carmichael2, and C. Deisenroth1. 1 US EPA, Research Triangle Park, NC; and 2Unilever, Bedford, United Kingdom.

The Alginate Immobilization of Metabolic Enzymes (AIME) is a high-throughput-screening (HTS)-compatible platform that retrofits existing in vitro assays with metabolic competence by attaching alginic-hepatic S9 microspheres to solid supports extending from custom microplate lids. We have previously demonstrated that the AIME platform can be coupled with the VM7Luc4E2 estrogen receptor (ER) transactivation assay using methoxychlor as a reference chemical for bioactivation to a more potent ER agonist. In this study, we selected 34 compounds reported to have more ER activity after bioactivation. The changes were already seen only at 12h of exposure and were more expressed for the majority of the hits was below the compound-dependent cytotoxicity cutoff, indicating relevant bioactivity. These data demonstrate the metabolism-coupled AIME-VM7Luc4E2 HTS platform can effectively detect bioactivated and bioinactivated ER compounds and provides new positive and negative reference compounds for metabolism-dependent ER assays. This abstract does not necessarily reflect the policy of the US EPA.

2474 Development and Characterization of an In Vitro Human iPSC-Derived Neuropheroid Model

J. L. Mohn, M. Klausner, and P. J. Hayden. MatTek Corporation, Ashland, MA.

Multiple approaches have recently been described to generate in vitro neural organoid models from human induced pluripotent stem cells (iPSC). While these models are effective at recapitulating many features of human fetal brain development, the processes used to generate them are not amenable to large-scale production and high-throughput applications. The goal of this exploratory research is to develop a scalable and reproducible in vitro, 3-dimensional neuropheroid model that may be used for high-throughput applications assessing neurodevelopmental toxicity (DNT) and drug development. Methods: Neuropheroids were generated by seeding iPSC-derived neural progenitor cells (NPCs) in ultra-low adhesion multi-well plates. Neuronal differentiation was induced with medium containing BDNF and GDNF. Neuropheroids were maintained in culture for up to 8 weeks. Immunofluorescent analysis of neuropheroids was performed on frozen sections and gene expression was assessed using real-time quantitative PCR (qPCR). This approach yielded neuropheroids of consistent size over time, both within and across batches. Immunofluorescent analysis of frozen neuropheroid sections revealed widespread expression of neuronal markers MAP2 and βIII-tubulin, as well as VGLUT1, indicating presence of presynaptic glutamatergic specializations. qPCR analyses showed increased in expression of neuronal genes including MAP2 and synaptophysin over time, while expression of progenitor markers (SOX2, nestin) decreased. Neuropheroids of consistent size containing mature neurons were successfully generated using this approach. The model is easily scalable and can be adapted to either 96- or 384-well plate formats, allowing use in high-throughput applications. Further efforts will use this platform to establish assays measuring cellular toxicity and processes modeling DNT. Neuropheroid complexity will also be improved by the incorporation of additional cell types such as astrocytes and microglia.

2475 3D-Bioprinting Microtissues with Human 1T1 Urothelial Cells Exposed to Diuron and Its Metabolites

Three-dimensional (3D) cell culturing has been used as an alternative method to toxicological assays that use laboratory animals, including for pesticides hazard evaluation. Exposure to the herbicide Diuron has been associated with rat urothelial proliferative lesions and tumors. This study aimed to standardize the 3D bioprinting technique to culture 1T1 urothelial cells, donated by Samuel M. Cohen, UNMC, Omaha-NE, as microtissues, applying both methods. The bioprinting protocol for and 14 compounds reported to be unaffected by metabolism was designed for a training set evaluating the AIME approach (Pinto et al. DOI: 10.1021/acs.chemrestox.6b00079). All 48 compounds, plus assay-specific controls selected from OECD test guidelines, were screened using the AIME-VM7Luc4E2 coupled assay. AIME lids were prepared with either phenobarbital/5,6-benzo[alpha]pyrene-induced rat hepatic S9 (metabolism positive) or algalate-only (metabolism negative) microspheres and immediately added to 96-well plates containing test compounds in 50-point concentration-response in cell culture medium supplemented with an NADPH regeneration system. Following a 2-hour incubation period, the conditioned medium was transferred to estragon-stripped VM7Luc4E2 cells and incubated for 24 hours to evaluate ER transactivation and cell viability. The resulting scores for the AIME-coupled assay were 0.71 and 0.91 for metabolism positive and metabolism negative treatments, respectively. To capture efficacy and potency shifts resulting from metabolic activity, the difference in the fitted area under the curve for corresponding treatment groups (+/− metabolism) was calculated. Bioactivation was identified for 21 compounds while bioinactivation was observed for 18 compounds. Half-maximal active concentrations (AC₅₀) for the majority of the hits was below the compound-dependent cytotoxicity cutoff, indicating relevant bioactivity. These data demonstrate the metabolism-coupled AIME-VM7Luc4E2 HTS platform can effectively detect bioactivated and bioinactivated ER compounds and provides new positive and negative reference compounds for metabolism-dependent ER assays. This abstract does not necessarily reflect the policy of the US EPA.

2019 SOT Annual Meeting
Using ViaLight Plus Cell Proliferation and Cytotoxicity BioAssay to Analyze Cell Viability in a 3D Breast Model

Due to increasing regulations surrounding in vivo studies, complex in vitro models are necessary for pre-screening compounds for toxicity and efficacy prior to preclinical studies. 3D cell culture models provide a more physiologically relevant system for evaluating drug compounds, but the dense, tissue-like matrix of the model can make evaluation of various endpoints difficult. One such endpoint that can be challenging to measure in 3D is cell number and viability. Which is critical in understanding the efficacy of cytotoxic or cytoprotective compounds. This work describes how to measure cell viability, and compare cell numbers, in a 3D hydrogel cell culture with the ViaLight™ Plus Cell Proliferation and Cytotoxicity BioAssay. The ViaLight™ assay is based on the biosensor luminescent detection of cellular ATP as a measure of cell viability thus determining cell numbers. We constructed a breast model using the RAFT™ 3D Cell Culture System. Our model is a co-culture of human mammary fibroblasts (HMF) embedded in the RAFT™ Collagen matrix, and human mammary epithelial cells (HMEC) overlaying on top of the matrix, to model the interaction of breast and stromal cells in vivo. Cell morphology was determined using microscopy and results demonstrate that HMEC are 90% confluent and HMF are fully stretched in the matrix after 3 days in culture. Cell proliferation was quantified with the ViaLight™ assay, which correlates cell number with increasing biosensor luminescence of cellular ATP. Data from this assay demonstrates an increase in cell number from both RAFT™ mono-culture and co-culture models from Day 3. On day 3, we added PIK-75 (Selleckchem S1205) to induce cell cycle arrest, which resulted in decreased biosensor luminescence from Day 4 to Day 8 and demonstrated the capability of the system to detect changes in cell numbers, and, in this case, cell loss. We demonstrate the feasibility of co-culturing HMF and HMEC, the RAFT™ system, as a 3D mammary acini model. Furthermore, the ViaLight™ assay can be used to measure changes in cell number in the 3D model after treatment with an anti-cancer drug. This assay, and its ability to evaluate cell number in a 3D model, can be used to bridge the gap between 2D HTS and preclinical studies by providing more physiologically-relevant data to better predict the in vivo efficacy, toxicity, and dosage of the drug candidates identified in HTS, thereby reducing the burden of subsequent studies in drug discovery.

Identification of Risk Factors for Breast Cancer Using Engineered In Vitro Techniques

Identification of Risk Factors for Breast Cancer by Activation of Fibroblasts and Thus Secretion of Collagen I

Our preliminary studies show that under acute ROS exposure, epithelial cells show loss of polarity and altered nuclear morphology that controls chromatin arrangement and differentiation. Our central hypothesis is that microenvironmental stress in synergy with altered matrix stiffness leads to increased breast cancer risk. To test our hypothesis we use a 3D cell culture model that consists of a co-culture of human mammary epithelial HMT-3522 S1 and human mammary fibroblasts HMs322 HTERT cells. Acute OS was induced by exposure to 250 μM H2O2 for four hours and chronic OS by treating the cells with 25 μM H2O2 for 10 days. Immunostaining with DAPI for nucleus and phalloidin for actin cytoskeleton, changes in phenotype of cells under ROS and altered stiffness were assessed. To test the effect of matrix stiffness on nuclear morphology S1 cells were cultured on collagen I coated with laminin 111 to induce differentiation, and fibroblasts were embedded in collagen I matrix of normal and at-risk stiffness in vivo. Increased stiffness leads to significantly less circular nuclei in both S1 cells and fibroblasts. Fibroblasts show a loss of spindly phenotype under acute ROS. Chronic ROS leads to less circular and bigger nuclei in S1 cells similar to as observed when stiffness of the matrix was increased suggesting that both ROS and matrix stiffness impact epithelial cells and fibroblasts independently. To understand whether these two micro-environmental features synergistically exacerbate the risk of cancer under in vivo conditions, a tissue chip will be developed where S1 cells will be cultured on top of collagen in collagen I matrix and co-cultured with HMs in hemichannels on paper to mimic ductal geometry with holes (to enable the epithelium to sense the stiffness underneath) and placed on top of collagen I embedded fibroblasts.

A Multiple Organ Integrated In Vitro Model for Studying Repetitive Dose Toxicity

Repetitive dose animal toxicology studies are still required within many regulatory frameworks for human risk assessments, but they are costly, time-consuming, and questionable validity, and ultimately limited in the information they can provide. Replacement of these in vivo studies with an adequate in vitro approach is a major technological challenge. Here, we present the first ever optimized, multiple organ, integrated in vitro system with simulated blood flow capable of addressing human systemic toxicity risk. Two well studied compounds, acetaminophen (APAP) and cyclohexamide (CYHex) were tested as a proof of concept. The compounds were evaluated in an integrated in vitro platform (HuDMOP™) that links human 3D intestine (EpiIntestinal™, MatTek), breast cancer by activation of fibroblasts and thus secretion of collagen I. ROS could also influence mammographic density, another risk factor for breast cancer, known to play a role in breast cancer risk and when not cleared by antioxidants mechanisms in the breast tissue-chip will be developed where S1 cells will be cultured on top of collagen I matrix and co-cultured with HMs in hemichannels on paper to mimic ductal geometry with holes (to enable the epithelium to sense the stiffness underneath) and placed on top of collagen I embedded fibroblasts.
The majority of pharmaceutical drug candidates that enter clinical trials ultimately fail safety and efficacy testing because of drug induced vascular injury (DIVI). The mechanisms of injury are often difficult to decipher as the drug metabolism, the toxic dose, and the affected vascular bed are species dependent. Several in vitro tools have been developed to evaluate DIVI, but the mechanisms and biomarkers for DIVI remain unclear. DIVI has been assessed in an engineered microfluidic model of a rat small artery. Our device consists of a monolayer of endothelial cells (ECs) and multiple layers of smooth muscle cells (SMCs), separated by a novel semi-permeable membrane. Media is circulated through each device-bioreactor system by a micro peristaltic pump. The engineered endothelial cell layer is matured and compounds are recirculated under shear stress. Vascular injury is characterized by leakage of FITC-Dextran (FD70) and by histological changes in the vascular wall. ECM bilayers in these microfluidic devices and static transwells were challenged with drugs known to induce DIVI in rats (fenoldopam, midodrine and nicorandil) as well as a negative control (yohimbine). Each drug was tested at Cmax, 10X Cmax, and 100X Cmax at the following rates: 0, 67, 91% fenoldopam; 0, 50, 100% midodrine and nicorandil. Drug exposure with FD70 leakage also showed histopathological changes. However, no FD70 leakage and histopathological changes were observed in static transwells tested with the same drugs. In conclusion, these results demonstrate a dose-dependent correlation between DIVI observed in our in vitro microfluidic device and that observed during in vivo rat testing. Furthermore, the pressure and shear parameters can be modified within our model, allowing our engineered vascular device to effectively assess both the impacts of drug toxicity and hemodynamic factors on DIVI.

Assessment of corneal drug penetration is crucial for development of effective ophthalmic medicines. Current studies utilize excised animal corneas that are not suitable for rapid drug screening, have poor species extrapolation and standardization. Physiologically relevant, human-based in vitro models for development of new ophthalmics are needed. This study evaluated the utility of an in vitro reconstructed tissue model (EpiCorneal) to study ophthalmic drug delivery. The model contains normal human corneal epithelial cells that grow at the air-liquid interface and develop a tight barrier (TEER 1000 ±250 Ω*cm). The performance of the reconstructed corneal tissues was demonstrated using formulations of known antiglaucoma drugs. The effect on drug absorption, tissue viability (MTT assay) and integrity (TEER, LY leakage) was investigated after 0.5h and 2h treatments and compared to the tissues treated with the Krebs-Ringer buffer (KRB). Steady-state flux reached by latanoprost (LAT) in commercial formulation and LAT in KRB was 3.47 and 2.04 nmol/(cm²h), respectively. Flux for bimatoprost (BIM) in commercial formulation (Lumigan) and BIM in KRB was 18.33 and 3.43 nmol/(cm²h), and Papp was 5.48x10⁻⁵ and 1.47x10⁻⁵ cm/sec, respectively. Flux for bimatoprost (BIM) in commercial formulation (Lumigan) and BIM in KRB was 18.33 and 3.43 nmol/(cm²h), and Papp was 5.48x10⁻⁵ and 1.47x10⁻⁵ cm/sec, respectively. Flux reached after application of free acid metabolites of LAT/BIM in KRB was 0.18.50.53 ml/m² (cm²/h), and Papp was 1.22x10⁻⁵ 1.85x10⁻⁵ cm/sec, respectively. Incubation with commercial LAT/Lumigan for 0.5h resulted in a 1.8/3.2-fold increase in tissue leakage and a decline in TEER to 42.2/ 44.1%; additionally, tissue viability declined to 71.0/74.2% after 2h. All other eye drop formulations did not have an impact after 0.5h. However, 2h exposure reduced TEER to 65.7%/77.8% for LAT/BIM. Both commercial formulations contained 0.02% Benzalkonium Chloride (BAC) as a preservative. By itself BAC at concentrations 0.005% and 0.01% in KRB did not have an effect on 3D tissues; however, at 0.02% it reduced TEER to 51.6% and 0.04% - reduced TEER to 18.3%, increased LY leakage (3.5%), and reduced viability to 43.8%. In summary, the EpiCorneal model demonstrated high predictive capabilities for drug bioavailability/biocompatibility of various known ophthalmic formulations/exciipients. The tissue model may be useful for evaluation of corneal drug permeability and safety during the development of new ophthalmics.
The HuDMOP™ system is an integrated meso-scale multiple organ culture plate that may be used to predict human pharmacokinetics (PK) and pharmacodynamics (PD). Here we assessed 2-phenoxyethanol (PE) PK and PD in this system. PE is commonly used in cosmetics, personal care products, and pharmaceuticals. PE is well characterized and is metabolized to 2-phenoxyacetic acid (PAA) in the body. The first HuDMOP™ setup utilized conditions of Tumult in testis (Epilintestine™), MatTek and primary human hepatocytes in sandwich culture (HHSC) linked via simulated blood system. In the second setup, intestine was linked to HHSC and kidney cells (primary human proximal tubule epithelial cells (HRPTEC)) via a simulated blood system. PE solutions (100 µL of 0.5, 1, 5, and 50 mM) were applied to the apical side of the intestinal model. Samples were collected from the basolateral intestine media, liver media, kidney media, and the simulated blood (perfusion) at 0, 1, 2, 4, 6 and 24 hr. PE and PAA were measured in each sample by LC-MS/MS. Maximum concentration of PE in the intestinal basolateral media and perfusate was reached at 1-4 hr and was dose dependent. PE in the liver media was quantifiable at 2.4 hr, occurring more rapidly with higher doses. PE was also observed in the kidney media by 4 hr while PAA was detected at 24 hr in liver media and in the perfusate. The time to maximum PE and PAA concentration, and movement of PE and PAA through both setups, was dose and time dependent. Tissue health was determined by measuring Ki-67, an indicator of proliferation. No substantial toxicity was measured over the 24 hr period. Finally, expression of interleukin-8 (IL-8), tumor necrosis factor alpha (TNFa), cytochrome P450s 1A1 (CYP1A1) and 3A4 (CYP3A44) were assessed by qPCR in all tissue types. No changes in expression were observed in the liver, and kidney, however a slight induction of CYP3A4 (2-fold) and IL-8 (2.7-fold) and 2.7-fold, respectively were observed in the intestinal tissue. These results suggest no substantial irritation response to PE or PAA which fits the known toxicological profile of PE at the concentrations assessed. Additionally, the PE Tmax observed here (1-4 hr) matches known in vivo results (1 hr). The observed PE Cmax, while dose dependent, appeared to correlate with the concentration in vivo results as well. These data indicate that the HuDMOP™ model may be an effective platform to properly model PE and predict PK and PD in humans.
Automated approaches to perform high throughput toxicity screening often employ microscopy to capture photomicrographs from multi-well cell culture plates (e.g., 96- and 384-well) generating thousands of images that require time-consuming manual analysis. Moreover, human interpretation of cell culture morphologies remains an interpretative activity, analogous to the practice of clinical pathology, and remains a significant barrier in regulatory adoption of these methods. To automate this subjective and time-consuming manual process, we have developed a method that uses deep learning to automatically classify digital assay images. In the preliminary phase of our efforts, we have trained a convolutional neural network (CNN) to classify assay images into healthy (comparable to vehicle controls) and altered (not comparable to vehicle controls). The dataset comprised 282 high-resolution (1392x1036 pixels) assay images from differentiated cultures of HepaRG cells, annotated for altered and healthy classes by two expert annotators. Inter-annotator agreement was 0.61 (Cohen’s kappa measure); we considered only those images which were agreed upon by both annotators. Traditional feature-engineering methods coupled with shallow classifiers (e.g. random forest, SVM) resulted in accuracies ranging from 50-80%. To improve these results, we developed three deep-learning based approaches: 1) pretrained CNN as fixed-feature extractor; 2) fine-tuning of pre-trained models; 3) training a CNN from scratch. Each image was divided into an n x n square grid where n=16. Each patch was annotated as the entire image leading to an n²-fold increase in the size of the dataset. Splitting the assay image into patches also has the advantage of detecting focal damage that often radiated out over time. The predicted label to use for each image was decided by adopting two different methods of aggregation across patches: 1) majority vote, and 2) mean predicted probability. All three deep-learning methods scored ~95% five-fold cross-validation accuracy when classifying assay patches into healthy and altered classes, with approach Number 3 performing the best (97.3%). The CNN trained from scratch had 96.7% accuracy on a ‘hold-out’ test set of 30 images. These results clearly demonstrate that deep-learning based image classification of cell toxicity can yield highly accurate results in small culture wells that is highly automated and reproducible for high throughput screening in toxicology.
Classifying Polycyclic Aromatic Hydrocarbons by Carcinogenic Potential Using Human Systems Biology Data in a Pathway-Based Interactive Model

Y. Chang, L. K. Siddens, S. L. Simonich, and S. C. Tilton, Oregon State University, Corvallis, OR.

Current US EPA framework for human carcinogenic risk assessment of polycyclic aromatic hydrocarbons (PAHs) uses the relative potency factor (RPF) approach, a component-based approach that estimates RFPs for single PAHs using mouse in vivo tumor data. Key assumptions of this approach are that PAH-induced toxicity in mouse in vivo is representative of human PAH toxicity, and that mechanisms of toxicity are similar to benzo[a]pyrene (BAP), the reference carcinogen. To explore the validity of these assumptions, we evaluated differences in global gene expression of PAH-treated human bronchial epithelial cell (HBEC) model, and tested predictive model performance in PAH/PAH mixture classification by feeding the model with mouse in vivo or human in vitro data. HBEC were treated for 48 hrs with the following: benzo[a]pyrene (BAP), dibenzof[cd]chrysene (DBC), pyrene (PYR), coal tar extract (CTE), phenanthrene, benzo[a]anthracene, and simulated air mixture of PAHs representative of components in extracts from Beijing. Previously, a predictive model integrated 4 pathways linking 12 hr in vivo mouse dermal exposures to in vivo mouse tumor outcome. Bayesian integration of these pathways (apoptosis, interferon gamma signaling, response to DNA damage, and cell response to chemical stimulus) using k-nearest neighbors algorithm with LOOCV successfully classified treatments into low, moderate, and high tumorigenic potential. Model performance was tested by seeding with HBEC data for a subset of PAH treatments previously used in the mouse to develop the model, and successfully classified BAP, DBC, PYR, and CTE with a classification accuracy of 0.92. However, the model performed poorly (<0.30) when additional treatments with potency ranges that were not tested in mice were seeded into the model. While the model supported concordance between mouse and human in tested chemicals, it required pathway modification to better reflect a broader range of PAH potencies compared to BAP. This preliminary model is a valuable first step towards using systems biology data to assess carcinogenic potential, and supports using mechanistic data to inform whole mixture carcinogenic risk assessments of complex PAH mixtures.

An Integrated Approach for Animal-Free Genotoxicity Testing: In Vitro and In Silico Evaluation and Mode-of-Action Classification

New alternative approaches (NAMs) for the rapid and cost-effective screening of genotoxicity are promising potential replacements for traditional tests. ILS has developed a workflow to evaluate chemicals for possible genotoxicity potential as determined by in silico predictive modeling and human-relevant in vitro testing. High-throughput mammalian cell-based genotoxicity screening assays in human relevant TK6 cells were performed using a validated MultiFlow® DNA damage - p53, yH2AX, Phospho-Histone H3 kit which informs on genotoxicity and potential mode-of-action. Chemicals were also evaluated using 14 CASE Ultra-Software (MultiCase, Inc.) for quantitative structure-activity relationship (QSAR) genotoxicity predictions, including assessment of an overall genotoxicity prediction as well as consensus predictions from 4 models for carcinogenicity and 10 models for mutagenicity. For this proof-of-concept study, food-use chemicals were evaluated, including direct food additives and flavoring compounds. Results highlight that the MultiCase predictive modeling dataset rarely contained similar chemistries as seen in many of the food-use chemicals, namely flavorings. Since the predictive modeling approach relies on QSAR, which is based on chemical structure analog similarity, this is a serious limitation. Conversely, the in vitro approach are more amenable to screening compounds with a variety of structure types. Overall, food-use compounds were correctly identified as negative for genotoxicity based on in silico and in vitro data. While this reflects high accuracy, it also limits the capacity to evaluate performance metrics due to a heavy bias toward the resulting dataset’s abundance of true negative findings with very few positive chemicals. This study demonstrates effective NAM use for evaluating genotoxicity, emphasizes the need for study design considerations when considering predictive modeling software, and exemplifies the impact of domain of applicability limitations when considering alternative approaches. Ultimately, this integrated approach, leveraging both in vitro assays and in silico predictions, can be applied to any class of chemicals to effectively screen for genotoxicity potential.

In Silico Acute Toxicity Protocols and Models

G. J. Myatt1, D. A. Bower1, K. P. Cross1, C. Johnson1, D. P. Quigley1, and C. Zwickl1,2.1Leadscope, Inc., Columbus, OH; and 2Transendix LLC, Indianapolis, IN.

In silico toxicology is an important alternative approach to animal testing that can provide many benefits. Whole computational approaches can quickly calculate a prediction, the process of selecting and acquiring models, performing an expert review, integrating experimental data and model results, and documenting conclusions and uncertainties can be time-consuming and difficult to repeat. It is also challenging to defend the results, primarily due to a lack of published procedures for performing an in silico assessment. To support the development of such protocols, a SS-member international cross-industry consortium has been assembled that includes representatives from international regulatory agencies and government research laboratories in the United States, Canada, Japan and Europe, as well as large companies from various industrial sectors (e.g., pharmaceutical, food, cosmetics, environmental chemicals), academic groups and other stakeholders. The protocols will ensure any in silico assessments are performed in a consistent, repeatable, well-documented and defendable manner to support their broader acceptance. To support the implementation of the acute toxicity protocol, this work presents the development of a series of in silico models to predict acute toxicity based on GHS categories from rat oral studies. A battery of structural fragment-based models were used to predict these categories. Each model predicts a range of contiguous values such as the probability that a chemical is in GHS category 1 or 2. The cross-validated performance of these models ranged from 70.3% - 78.6% sensitivity and from 67.9% - 97.2% specificity.

The Delaney Clause, from 1958 to 2019: Making the Model Relevant

M. Krishan, Danone North America, Louisville, CO.

The Delaney Clause of the Federal Food, Drug, and Cosmetic Act, named after Congressman Jim Delaney, was enacted in 1958 because he was worried that potentially harmful chemicals from food were responsible for causing cancer. It states that “no additive shall be deemed to be safe if it is found, after tests which are appropriate for the evaluation of the safety of food additives, to induce cancer in man or animal.” The US FDA and US EPA are the two federal agencies charged with implementing this clause. It has been 60 years and significant advances in cancer research have elucidated the causes and mechanisms by which chemicals induce cancer. Advancements in analytical methodologies are allowing for accurate and progressively lower detection limits, resulting in detection of trace amounts of chemicals. Based on the current scientific knowledge, there is a need to look at the Delaney Clause from a different lens and make it more relevant. As a scientific community, we are committed to improving public health by promoting the development and utilization of appropriate and relevant science in risk assessment and regulatory decision-making. The objective of this roundtable session is to provide a balanced discussion and propose a path forward. The presenters in the session will provide (1) a historical overview of the scientific advances in cancer research since the 1950s, (2) the role of the Delaney Clause from a different lens and make it more relevant based on 21st-century science.
process has been undergoing “fixes” in real time as attempts are made to navigate the statutory requirements for new chemicals without undue delays hindering innovation. More recently, discussions about data transparency for information used by US EPA in its regulatory decisions have become a prominent part of the narrative. In addition, there are extensive efforts around how nonanimal approaches can be used to fill data and information needs. There are both challenges and opportunities that must be addressed. Each of the three presentations will provide the perspective of the groups they represent on how these challenges and opportunities can be addressed to achieve progress toward an improved chemicals management process in the US.

2499 Differing Effects of Perfluorooctanesulfonic Acid-Induced Hepatic Steatosis: Influence of Diet Type and Timing for Hepatic Steatosis Outcomes

A. Slitt. University of Rhode Island, Kingston, RI.

It is estimated that 20-30% of the population present with non-alcoholic fatty liver disease (NAFLD) in the United States alone. The contribution of environmental factors as risk factors for fatty liver disease is not well known. Per- and polyfluoroalkyl substances (PFASs) are a group of man-made chemicals that can be found in food packaging, stain repellent fabrics, and non-stick products. PFOS, PFOA, PFNA, and PFHxS are known to have multiple adverse liver effects in rodents and have been detected in human liver biopsy samples. The aim of our studies have been to evaluate the interaction between diet and PFOS exposure to determine whether they are an additive risk factor for hepatic steatosis and could augment hepatic lipid content and biomarkers associated with NAFLD. This presentation will summarize the findings of several new studies we have conducted with various diet combinations, such as a high fat diet (HFD) versus a 45% moderate fat diet (MFD), and diets containing high fructose, as well as shifts in timing of diet relative to PFOS exposure (0.0003% in diet). Endpoints related to hepatic steatosis, gene expression, as well as relative changes in protein abundance in liver using MS-SWATH will be presented. For example, hepatic steatosis was augmented in adult male mice that had an obesity and diabetes phenotype established after 8 weeks of HFD feeding. This was associated with increased expression of Cyp4a14 and other genes involved in lipid deposition/metabolism (C3D6, Fabp4, Slc271a). In contrast, simultaneously starting a MFD and PFOS exposure in early adulthood appeared to be protective in mice. Both studies demonstrated induction of genes related to the antioxidant response and the Nuclear Factor E2 Related Factor 2 (Nrf2) and Constitutive Androstane Receptor (Car) pathways. Use of novel antioxidant response element transgenic reporter mice will be also presented to determine whether PFOS exposure influences Nrf2 activation in liver, as well as other tissues. Overall, Cyp4a14 and C3D6 were consistently upregulated in liver after low dose PFOS treatment in the various models. Timing of HFD introduction may be an important consideration for the influence of various PFASs on the development of hepatic steatosis, and mechanisms that explore the impact of a HFD on hepatic PFOS levels and signaling must be considered.

2500 The Progression of Steatosis to Steatohepatitis with Fibrosis following Aryl Hydrocarbon Receptor (AhR) Activation

T. Zacharewski. Michigan State University, East Lansing, MI.

Aryl hydrocarbon receptor (AhR) activation by persistent environmental contaminants elicits a broad spectrum of adaptive and adverse responses. This includes a non-alcoholic fatty liver disease (NAFLD)-like syndrome, involving the dose-dependent progression of benign and reversible steatosis to steatohepatitis with fibrosis. NAFLD is a risk factor for more complex diseases such as metabolic syndrome, diabetes, cardiovascular disease, hepatocellular carcinoma and is also emerging as a leading cause of liver transplants. The integration of complementary RNA-Seq, ChIP-Seq and metabolomics data with histopathology suggests the dose-dependent activation of AhR by TCDD programs multiple metabolic pathways, consistent with the multiple-hit hypothesis describing NAFLD development and progression. For example, TCDD increased fatty acid transport, repressed \( \beta \)-oxidation and inhibited lipid efflux resulting in hepatic steatosis. In addition, the hepatic accumulation of free fatty acids and the induction of cytochrome P450s, increased ROS levels and lipid peroxidation leading to extracellular matrix remodeling and the deposition of collagen along portal tracts. In response, hepatocytes mount a Warburg-like response involving the reprogramming of central carbon metabolism to support ROS defenses. More specifically, TCDD induced pyruvate kinase muscle isoform 2 (Pkm2) which has reduced catalytic activity compared to Pkm1. Pkm2 induction facilitates the accumulation of upstream intermediates that are redirected to the pentose phosphate pathway and the serine/glycine biosynthetic pathway to produce NADPH and intermediates in support of glutathione biosynthesis and recycling. AhR activation by TCDD also induced a de-differentiated hepatocyte phenotype, as suggested by the repression of amino acid metabolism and loss of typical liver-specific and sexually dimorphic gene expression patterns that further compromise liver function. This presentation will present new data demonstrating the development of environmental factors in NAFLD progression and a more comprehensive understanding of key factors involved in the progression of NAFLD. Taken together, information from this session has implications for risk assessment in affected populations and for defining mechanisms and potential biomarkers of liver damage.
2501 Toxicant-Associated Steatohepatitis: Clinical and Translational Studies
M. Cave. University of Louisville, Louisville, KY.

Since the initial description of toxicant associated steatohepatitis (TASH) in 2010, epidemiologic studies have demonstrated associations between pollutant exposures and fatty liver disease. This session reviews the progress and challenges facing liver disease cohort studies. TASH was initially described in vinyl chloride workers who had a high prevalence of biopsy-proven steatohepatitis. While affected workers had normal liver enzymes, the hepatocellular necrosis biomarker, cytokeratin 18 M65, was elevated. Altered cytokines and insulin resistance were identified as possible mechanisms. A subsequent serum metabolomics study demonstrated a unique metabolite signature in vinyl chloride workers. Altered AMPK signaling and mitochondrial dysfunction were predicted. These mechanisms have subsequently been confirmed in animal exposure models. We then performed the first exposome-wide analysis investigating pollutants and fatty liver disease using NHANES. PCBs were dose-dependently associated with increased odds for suspected fatty liver disease. These results have been confirmed by other groups. It is challenging to perform liver biopsies in environmental cohort studies, and liver enzymes may be normal in TASH. We are currently addressing this challenge with biomarker panels (e.g., cytokotyosis markers, adipokineyons, and microRNAs). The Anniston Community Health Survey (ACHS) is a residential cohort with high rates of obesity and PCB exposures. In ACHS, there was a high prevalence of liver disease associated with hepatocellular necrosis, insulin resistance, cytokine elevation, and PCB exposures consistent with TASH. Liquid liver biopsy was performed in a subset of participants using a targeted serum microRNA panel. Pathway analysis confirmed steatohepatitis in participants previously categorized as having TASH. In the subset of subjects with liver disease participating in the ACHS-II re-contact study, dioxins and dioxin-like chemical exposures (including non-ortho PCBs) were associated with altered serologic biomarkers of hepatic intermediary metabolism, inflammation, fibrosis, and function. These mechanisms have been confirmed in animal models of PCB or vinyl chloride exposure. The clinical and translational studies demonstrate that pollutant exposures may cause steatosis or drive the progression of diet-induced steatosis to more advanced liver disease.

2502 Integrated ‘Omic Approaches to Toxicity Assessments
J. Rager. University of North Carolina at Chapel Hill, Chapel Hill, TX.

Recent advances surrounding assay and sequencing-based technologies have increased the feasibility of multi-omics research, wherein two or more ‘omic profiles (e.g., genomics, transcriptomics, epigenomics, metabolomics, and proteomics) are integrated and evaluated to further understand molecular mediators of biological function and cellular health. Multi-omic analysis strategies rely upon the joint analysis of multiple data types, yielding toxicity responses that may not have been identified given the analysis of only one ‘omic endpoint. Integrated analyses provide insights into how the features of the ‘omics interact through biological networks, resulting in an integrated systems level understanding of toxicity. The utilization of multi-omic strategies presents the opportunity to elucidate hierarchical processes in complex systems that can further substantiate mechanisms of action linking chemical exposures to disease, which ultimately aids in the accurate assessment of chemical risk and overall protection of public health. Integrated ‘omics strategies are also employed to understand mechanisms of action linking pharmaceuticals to health outcomes. However, methods and associated databases that can be leveraged to integrate multi-omic response signatures that result in findings useful for drug development and chemical assessments are still under development, with current limitations that require further research. This session will address this growing research area by discussing multi-omic data integration tools, data reduction methods, dose-response modeling, toxicity predictions based on machine learning algorithms, and systems level analyses to elucidate molecular pathways involved in disease etiology. Case studies also will be discussed to provide examples of how multi-omic response signatures can inform toxicity assessments relevant to environmental regulation and the chemical/pharmaceutical industries.

2503 Computational Tools for Multi-‘Omic Integration
K. Uppal. Emory University, Atlanta, GA. Sponsor: J. Rager

Current approaches for multi-omics data integration can be classified into: data-driven, pathway-driven, and literature-driven. The presentation will first give a comparative overview of the three approaches with examples of available bioinformatics tools for each category. The last half of the talk will focus on xMwas, a multi-omic data integration tool, which is available both as a web-based application and R package. The software allows network-based integrative analysis of up to four datasets generated from the same subjects. It features additional capabilities such as detection of modules (clusters) in integrative networks and differential centrality analysis.

2504 An Integrated ‘Omic Dose-Response Assessment from Short-Term In Vivo Studies of Two Aromatics Phosphate Flame Retardants
S. S. Auerbach. NIEHS/NTP, Research Triangle Park, NC.

Aromatic phosphate (AP) flame retardants are inhibitors of several esterases with a diverse collection of substrates. We have performed dose-response transcriptomics and serum metabolomics following a repeated dose study in male rats exposed to two different APs. Dose-sensitive integration of the transcriptomics, metabolomics, clinical chemistry and organ weights from the first study of triphenyl phosphate (TPHP) identified a novel relationship between changes in liver weight, cholesterol, triglycerides, sphingolipids and gene expression associated with lipid and xenobiotic metabolism. Hub gene analysis indicated PXR/CAR signaling interacts with cholesterol metabolism (specifically esterase activity) signaling which is plausibly associated with changes in serum cholesterol and increases in liver weight. Replication of the integrated analysis findings was observed in the second AP study that employed isopropylated phenol phosphate (IPP), suggesting that these effects are likely consistent across the AP class.

2505 On-the-Fly Machine Learning to Predict Adverse Drug Reactions by ‘Omic Integration of Drug Properties
A. Ma’ayan. Icahn School of Medicine at Mount Sinai, New York, NY. Sponsor: J. Rager

By collecting and organizing knowledge about the properties of drugs and small molecules, including chemical structure, metabolomics, imaging, transcriptomics, known and predicted targets, and clinical indications and use, we can predict adverse events and side effects of clinically used drugs and experimental compounds with machine learning. A system will be presented where users can select the adverse event that they wish to predict, the data sets the wish to use for training, and the machine learning methods they wish to employ. After making those selections, the user will be presented with a complete report that lists the probability of the predicted adverse events and an evaluation of the quality of such predictions.

2506 Scientific and Regulatory Update in the Application of the 3Rs Principle in Chemical and Drug Development
A. Hayes. University of South Florida, Tampa, FL.

The 3Rs principle (3Rs), developed as a framework for humane research, has become embedded in animal use legislation. There remains ample opportunity to improve efficient usage of animals and to facilitate the 3Rs, with the availability of new in vitro/in silico technologies. Most toxicology studies are conducted to determine safe doses and a reasonable margin of safety. This facet is considered during pharmaceutical development. In case of nonproprietary pharmaceuticals wherein the toxicity of the active is known and the excipients are not novel or adhere to regulatory guidelines, the need to conduct in vivo studies is minimal. However, country regulatory requirements vary and repeat of studies may be necessary. At the global level, although there are ongoing discussions on the 3Rs, follow-up and implementation have not been rapid and many countries have a lot of catching up to do, especially in revamping their country regulation. This symposium session will address the following objectives: (1) to understand the need to conduct animal studies to address safety/efficacy and meet regulatory requirements for nonproprietary
pharmaceuticals; (2) to adopt in vitro, in chemico, and in silico approaches for skin sensitization; and (3) to comprehend human-relevant, non-animal methodologies to predict toxicity and provide a scientific underpinning for the use of read-across techniques.

Despite efforts to implement the 3Rs, large number of animals are still used for nonclinical research and testing. Nonclinical research is required for regulatory approval of pharmaceuticals, and most of these tests include animals. The US FDA has an abbreviated approval process for nonproprietary pharmaceutical products where no safety or efficacy data is required if the generic is comparable to the innovator product. In terms of active ingredient, strength, dosage form, route of administration, quality and performance characteristics, the European Union has implemented regulations that mandate use of alternative approaches whereas both China and Russia are working through the process of developing appropriate approaches to the implementation of the 3Rs in their countries. There are various options to effectively implement the 3Rs using in vitro alternative approaches, consideration of mutual acceptance of data, use of efficient study design, and harmonization of country regulations to name a few. Applying advances in the scientific thought process and state of the art technology to the development of sound alternative strategies can improve animal welfare and further reduce and replace animal use. In this symposium different strategies that have worked for effective implementation of the 3Rs in nonclinical development of nonproprietary pharmaceuticals will be illuminated. To better understand the need to conduct animal studies in generic drug development, several scenarios with relevant examples to address safety and regulatory requirement will be presented.

In a March 2016 open letter to stakeholders, former US EPA’s OPP Office Director, Jack HOUSENG, detailed OPP’s efforts to modernize the acute toxicity “six-pack” studies (acute oral, dermal, and inhalation, eye irritation, dermal irritation, and skin sensitization) and reduce animal testing. This letter committed OPP to explore opportunities to reduce barriers to alternative methods to animal testing and facilitate the use of OECD in vitro methods and computational approaches. In collaboration with NTP’s Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM) and the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM), industry and non-governmental organizations, the US EPA is making significant progress towards the adoption of integrated approaches to testing and assessment (IATA) and the reduction of the use of animals in acute toxicity testing. This presentation will provide an overview and update on progress to date and on-going collaborative projects, including a 2018 interim policy to adopt in vitro, in chemico, and in silico approaches for skin sensitization.

In Europe the principles of the 3Rs (refine, reduce, replace) are recognized at the level of policy and legislation. The Directive 2010/63/EU, which is a binding legal requirement for all member states of the European Union (EU), asks for considering the 3Rs systematically when considering animal experimentation. Advancing the “3Rs” through implementation of alternative approaches is not only benefitting animals but equally aimed at developing better and more predictive scientific tools to protect human and animal health and the environment. Most notable, amongst the legislations impacting the use of the 3Rs is the cosmetics regulation, which prohibits the testing of finished cosmetic products and cosmetic ingredients on animals. Also the European Chemicals Agency (ECHA) urges the use of non-animal methodologies for the purpose of chemical registration. Research in this field is sponsored by the European Commission through the flagship project EU-ToxRisk. This research initiative, comprising 36 partner labs, focuses on human-relevant, non-animal methodologies to predict toxicity. One major focus is to provide scientific foundation and guidance for the use of read-across (RAX) techniques. RAX makes toxicity predictions on unknown chemicals by linking them to known compounds. Structural and physicochemical similarity data will be linked in defined, quantifiable ways to adverse outcomes by incorporating mechanistic and toxicokinetic knowledge gained from new methods rooted in the 3Rs. Incorporation of similarities on the key event activation level (termed ‘biological RAX’) will advance the RAX concept to a robust process of assessing toxicological properties of chemicals that will be of practical regulatory use.

The determination of adversity, and a No-Observed-Adverse-Effect-Level (NOAEL), is often a fundamental component of the analysis of toxicological data. A NOAEL is often the basis for the determination of the First-In-Human (FIH) dose, although alternative methodologies like Highest Non-Severely Toxic Dose (HNSTD) and Minimum Anticipated Biological Effect Level (MABEL) have emerged to address specific situations. While the definition of adversity has often been a judgment call based on experience, a number of organizations have undertaken efforts to streamline and standardize the definitions and guidance on how to determine adversity. Study directors, pathologists, safety pharmacologists, preclinical drug development leads, and regulatory reviewers are among the key players involved in safety assessment who may have different perspectives and sometimes disagreements about determining adversity. The purpose of the session is to discuss the current thinking process behind the determination of adversity in nonclinical toxicology studies from multiple points of view. Moreover, all the speakers will also discuss their perspectives about dealing with unique situations in a toxicology study such as nonlinear vs. linear kinetics, sex differences in toxicokinetics and observed toxicity, misuse of historical control data, No-to-Partial Recovery of toxic effects, and on-target vs. off-target effects. Presenters will discuss these scenarios with the help of case studies wherever possible.
A study pathologist plays a critical role in categorizing adversity of gross histopathological lesions and clinical pathological changes. Sometimes, these findings may not be obvious to determine the adversity of the drug in the test species. In that scenario, how to handle the pathological findings and communicate those in the contributing scientists report in a way that helps Study Director to determine a NOAEL for the overall study? This presentation intends to give the attendees a pathologist’s perspective on determining adversity of anatomical and clinical pathological findings in toxicity studies. The presentation will discuss various factors such as severity, complete recovery versus partial recovery, functional significance, and sex differences in lesions; linear versus non-linear kinetics, and use and limitations of historical control data that are considered while evaluating adversity of histopathological findings. These factors will be discussed in the context of small and large molecule therapeutics. The challenges faced in communicating adversities in pathology reports will be addressed. This presentation will further discuss the handling of changes in the non-traditional clinical pathology biomarkers (Clinical Pathologist’s perspective) evaluated in GLP toxicology studies during adversity determination. The points in the presentation will be illustrated with the case studies.

A NOAEL is commonly used as a benchmark for FIH studies for many pharmaceuticals. The NOAEL is determined using the toxicology study data, as well as expert professional opinion of those data, in the toxicology package. Although the aggregate findings may be used between studies to inform the clinical team, the NOAEL should be determined for each study. Furthermore, the findings that inform the NOAEL may impact other aspects of the clinical trial (such as dose escalation or monitoring). Disagreements in the NOAEL (between regulatory and industry partners) are uncommon but may involve disagreement between the expert professional opinions/interpretations regarding adverse findings. Lastly, it is normally understood that for some immunomodulatory compounds, there may be challenges that may confound the use of a NOAEL for translation to human trials. Sponsors often rely on alternative methodologies (such as the MABEL) to set the first in human dose. This talk will discuss challenges to NOAEL selection and interpretation of the NOAEL into risk assessment during drug development with examples of some case studies.

The bisphenol class of chemicals includes over 20 analogues that have different structural, chemical, and biological activities. The primary analogue of interest in this class is Bisphenol A (BPA), a chemical widely utilized in plastics, epoxy resins, and other products. Most of the other analogues are not routinely used or used at high production levels, but exposure to some has led to evaluations to determine if there is any toxicological evidence for concern. The complications associated with toxicological evaluation of BPA may be attributed to the ubiquitous nature of this chemical. Carefully assessing the effects of this compound in animal studies is extremely difficult due to the requirement to control and monitor BPA from all external sources. It has therefore become essential to characterize dosing solutions, housing materials, and internal dose measurements to ensure that the animals are exposed to the levels of the chemical that the protocol dictates. While the analogues may not generate such a high level of attention, the primary question regarding their potential risks to humans is exposure levels. BPA is currently found at levels far exceeding any other analogue and its unique nature ensures that it is not easily replaced in a majority of products; however, there is evidence that the analogues are in use and information on their potential effects and endocrine activity will be essential if their use increases. An additional concern associated with assessing classes of compounds is determining effective methods to quickly and efficiently evaluate multiple analogues. High-throughput screening data and in vitro assays are not reliably "predicting" in vivo outcomes. This may be due to the use of assays not applicable for this class, focusing assessments to just the estrogen and androgen receptors, limitations with in vitro metabolism, or not recognizing that there needs to be a compromise when evaluating chemicals that are potential endocrine activators. Therefore, how to best generate reproducible and reliable data and understand the biology and/or chemistry of conflicts as they arise, as well as collecting routine internal measurements of the compound(s), may need to be a primary focus for those assessing chemicals in this group. The session will begin with an overview of the bisphenol class of chemicals and highlight its uses and products and then discuss testing of select analogues by different types of the in vitro assessments for this class of chemicals. In summary, the session will provide an overview of the bisphenol class of chemicals and the data that we have to date on the analogues, and discuss best methods for evaluating these compounds and the next steps in the assessment process. Disclaimer: This overview does not necessarily reflect any Agency opinions.

Bisphenol A is synthetic industrial chemical which has come under scrutiny in recent years. The chemical’s important industrial footprint and utility in various applications has led to a search for chemical substitutes. These substitutes are often structurally similar analogues to BPA and belong to a class of chemicals called bisphenols. To date, there are well over a dozen known analogues which range significantly in industrial utility and end uses. With a focus on the most common analogues, BPF (4,4′-methylene diphenol), BPS (4-hydroxyphenyl sulfone), and BPAP (4,4′-hexafluorodiphenyl ether), this session will provide a review of this class of chemistries along with the major uses. From epoxy lining to polycarbonate to even more obscure uses the attendee will learn why this class of chemistries is so useful, economically important, and hard to replace.
2517 Estrogenicity and Antiandrogenicity of Bisphenols: Uncertainties in Extrapolating from In Vitro Molecular Initiating Events (MIE) and In Vivo Key Events (KE) to Adverse Reproductive Outcomes

L. E. Gray, US EPA/ORD, Research Triangle Park, NC.

The Frank R. Launten Chemical Safety For The 21st Century Act requires that the US EPA minimize the use of vertebrate animals in testing chemicals by incorporating alternative test methods and employing a tiered screening and testing process that uses the results of screening-level tests or to inform the decision as to whether additional tests are necessary. These methods must "...provide information of equivalent or better scientific quality and relevance for assessing risks of injury to health or the environment of chemical substances or mixtures". This presentation will use the bisphenols as an example of the strengths and limitations of using the in vitro MIEs and in vivo KEs from the androgen (AR) and estrogen (ER) AOP to predict the adverse effects of chemicals on reproductive development and function. For the bisphenols, the in vitro ER activities are useful to identify potential estrogenicity since the analogues that are active in vitro typically are active in vivo. However, in vitro potency is not predictive of the potency in vivo. For example, BPS is weaker than is BPA in vitro while the reverse is true in vivo and BPA and BPF are equipotent in vitro, whereas BPAF is more potent in vivo, especially in mul-
tigenic species. A comparison of the in vitro AR antagonism with the in vivo effects of ~60 chemicals reveals that in vitro assays of AR antagonism have relatively high negative prediction rates, but low positive prediction rates. A significant percent of chemicals are AR antagonists in vitro but fail to induce effects that are pathognomonic for AR antagonism activity in the Hershberger assay or in multigenic tests. Based upon the above ob-
servations, the following tiered testing strategy is proposed for discussion. Chemicals should be grouped by class to determine if it is valid to utilize the in vitro data to prioritize in vivo studies. For the bisphenols, a positive in vitro ER signal could be used to prioritize analogues for short term in vitro ER screening assays. With evidence of AR antagonism discovered, bis-
phenols should not automatically trigger in vivo tests. In chemical classes like the bisphenols, where some of the in vitro data are of uncertain value, other non-animal methods and short term in vivo assays should be used to prioritize the need for more extensive testing in vivo.

2518 In Vitro Static and Dynamic Skin Metabolism Methods and Strategies to Address the Safety Assessment of Topically Applied Chemicals

A. Schepky, Beiersdorf AG, Hamburg, Germany.

Understanding a chemical's bioavailability, either locally or systemically, is important for predicting adverse effects and conducting a safety assessment. Metabolism was originally thought to be an inactivation or detoxification pathway for xenobiotics; however, today it is generally accepted that metabolism-mediated toxicity is important in regulatory toxicity. Therefore, all in vitro toxicity methods proposed for regulatory risk assessment should include careful consideration of metabolism-mediated toxicity. In addition to a detailed knowledge on metabolism, the biokinetics of the test chemicals and in the in vitro method setup will be vital for designing the most valuable and predictive integrated test strategies. The main exposure route of cosmetic ingredients is via the skin. However, once the parent compound or metabolites formed in the skin enter the systemic circulation, they can be further metabolized systemically (e.g., by the liver). In vivo skin models can help to predict the amount of parent and metabolite(s) formed locally in the skin and escaping first-pass skin metabolism. The session will present examples of metabolism of relevant chemicals in ex vivo human skin explants compared to 59 fractions from EpiSkin. Incubations with human liver 59 were also included to allow a comparison of liver metabolism to local skin metabolism. In addition, it was shown how the frequency and route of application of a chemical and its interaction with different organs can affect the kinetics and ratio of different metabolites formed systemically. For example, first pass skin effects have been reported for aromatic hair dyes as well as for several topically applied glucocorticoids. The route of exposure (topical vs. systemic application) may differentially de-
termines a chemical's effect on the liver. Qualitative as well as quantitative dif-
fences may be important aspects for risk assessment in cosmetic risk assess-
ment. The session will present how a 3D skin liver dynamic model can help us understand the interaction between skin and liver metabolism over extended and repeated exposure and test chemical-organ (e.g., sys-
temic) and how it affects systemic concentrations of both parent chemical and its metabolites. The threshold of toxicological concern (TTC) is a safety assessment tool that involves establishing a low-level exposure value, from known chemicals with curated toxicity data, below which there is a low probability of adverse effects. The concept of TTC as currently understood has evolved over the last 50 years and a logical next step in the con-
tinued evolution of TTC is to develop this concept further by converting the external NOAEL values to internal concentrations. This is especially relevant for chemicals with a low absorption, either via the oral or dermal routes, and thus relevant to the cosmetics, pharmaceutical, and chemistry industries. The development of iTTC thresholds would provide conservative hazard-based values that could be utilized in exposure-based safety assessments in the con-
text of (1) refinement of de minimis exposure levels for dermal exposures, (2) metabolite-based structure-activity relationship (SAR) assessments, (3) low-
level aggregate exposures from different dose routes, or (4) in vitro biological assays. The session will provide an update on the development of iTTCs and present case study examples for possible uses. In the absence of the use of animal studies in the cosmetics industry for safety assessment, in vitro alter-
natives and strategies to waive additional tests (e.g., the iTTC) are essential.

2519 Studying In Vitro Metabolism of Cosmetics Ingredients in Skin Explants or by Using Liver- or Skin-Derived S9 Sub-Cellular Fractions

C. Jacques Jamin, Pierre Fabre Dermotherapeutique, Toulouse, France.

Sponsor: A. Schepky

We evaluated 2 in vitro skin models for their suitability to investigate skin met-
abolism since this is important for assessing local toxicity and/or penetration of chemicals. In the ex vivo viable human skin explant model, chemicals are applied topically and distribution of the parent and its metabolites is mea-
sured in the skin and receptor fluid up to 48 h. Pig skin can be used as an alter-
native to human skin supplier limited. To identify specific metabolites, we compared the metabolism of 10 chemicals e.g. cosmetics (parabens, caffeine, resorcinol) and reference chemicals for toxicity assays (2-AAF, 2-chloroaniline in genotoxicity assays) using pig and human skin. The extent of metabolism was the same in pig and human skin. While some species differences in me-
tabolite formation were expected due to a lack of aryl SULT in pigs, there were other quantitative species differences in the relative amounts of com-
mon metabolites. Our data suggests that pig skin is metabolically competent and could be a useful tool to evaluate first-pass metabolism prior to testing in human-derived tissues. EpiSkin™ S9 fractions are short-term assays (up to 4 h) for higher throughput initial metabolism screening. We first confirmed whether this model provided similar information to the ex vivo skin explants. Incubations also included human liver 59 to compare dermal and hepatic me-
tabolism. Both in vitro skin models had functional Phase 1 and 2 enzymes, in-
ccluding CYPs. There was a good concordance between the models regarding the metabolite metabolism and formation. Not expected due to a lack of aryl SULT in pigs, there were differences in the metabolism of 2 chemicals were attributed to a lack of the appropriate cofactor (S9) and extensive protein binding in ex vivo skin. S9 incubations al-
lowed a ranking of chemicals into low, medium and high clearance chemicals and a comparison of rates of metabolism across chemicals with similar struc-
tures. S9 incubations enabled organ-specific metabolism to be studied under the same conditions. In conclusion, both skin models provide valuable information on the dermal metabolism of topically applied chemicals. The ex vivo skin model allows longer-term incubations and combines metabolism with skin penetration; whereas, EpiSkin S9 is a high throughput screening assay, providing an indication of the metabolic stability of a chemical in the skin.

2520 Understanding Chemical Metabolism in Skin and Liver Models over Extended and Repeated Exposure in a Multi-Organ Chip Device

J. Kuehnl, Beiersdorf AG, Hamburg, Germany. Sponsor: A. Schepky

Read-across approaches for different exposure scenarios require information on their respective bioavailability, since this may influence a chemical's sys-
temic effects. Cosmetic ingredients are mainly exposed to the skin; however, the parent compound or metabolites formed in the skin may be further me-
tabolized by the liver after entering the systemic circulation. Information on the first-pass effect of drugs is also important to assess - either in the skin for local skin therapeutics or in the liver for orally-administered drugs. To ad-
dress this, dynamic multi-organ-chip (MOC) based models aim to emulate the physiology of single organs and their interactions. These models may also help to interpret organ-specific toxicity e.g. toxicity in a target organ due to a metabolite formed in a different organ. Cosmetics Europe is evaluating the TissUse skin-liver MOC for its ability to add information on metabolism following single or repeat application via the topical and systemic routes. Initial proof-of-concept (POC) studies were performed on known xenobiotic metabolising enzyme (XMEs) inducers, permethrin and heparinoid. Data show that the route of exposure and the dosing frequency affect systemic concentra-
tions of parent chemicals and their metabolites; and chemical exposure al-
ters the XME profile of liver organoids over time, depending on the route and 2019 SOT Annual Meeting 361
frequency of exposure. To ensure changes in metabolite profiles are not due to toxicity, in-life measurements of organoid functionality and histology of the skin models are performed in parallel. The methodology was transferred to a second lab in which both POC chemicals were tested. Results for in-life measurements and metabolite profiles revealed excellent intra- and inter-laboratory reproducibility. Moreover, the changes in the kinetics profiles of the parent chemicals and metabolites were similar in both labs. In conclusion, our data support the use of the skin-liver MOC model to discriminate differences in the metabolite profile and kinetics of chemicals applied systemically and topically, after single or repeated application. These POC studies will help to support a biological concept that may help in read-across approaches for several repeated dose toxicity endpoints (with a focus on metabolism), especially in light of the Cosmetics Directive ban on in vivo studies.

2521 Internal Thresholds of Toxicological Concern as Tools for Assessment of Exposures via Oral and Dermal Routes

C. Ellison, Procter & Gamble Company, Cincinnati, OH. Sponsor: A. Scheppy.

The Threshold of Toxicological Concern (TTC) is an important risk assessment tool, which has evolved over the last 50 years, and establishes acceptable low-level exposure values to be applied to chemicals with limited toxicological data. This concept is based on external oral toxicity data, namely, the No-Observed-Adverse-Effect-Level (NOAEL), and as such, the corresponding threshold limits represent external exposures. With continued global interest in animal alternative methods for human safety risk assessment, one of the logical next steps in the continued evolution of TTC is to develop this concept further so that it is representative of internal exposures (i.e. a TTC based on plasma concentration). Therefore, as part of the Cosmetics Europe (CoSEu) Long Range Science Strategy (LRSS) research program, CoSEu has initiated a project that is working towards the development of internal TTCs (iTTC) that can be used for the human safety assessment. iTTC would provide threshold values that could be utilized in exposure-based safety assessments in the context of; (1) refinement of de minimis exposure levels for dermal exposures; (2) metabolism-based structure-activity relationship (SAR) assessments; (3) low level aggregate exposures from different dose routes; or (4) in vitro biological assays. We will provide an update on the development of iTTCs and present case study examples for possible uses.

2522 Innovation in Biomarker Qualification

S. Ramaiah, Pfizer, Inc., Cambridge, MA.

Biomarkers have become highly utilized tools in the drug development process. However, the unknown regulatory acceptance of biomarker data has made the routine incorporation of these tools and interpretation of their data unclear for some companies. Qualification of biomarkers removes this uncertainty for drug developers. This session will provide attendees with an overview of the US FDA Center for Drug Evaluation and Research (CDER) Biomarker Qualification Program (BQP) under the 21st Century Cures Act. US FDA BQP works with external stakeholders to develop biomarkers as drug development tools (DDT) to provide regulatory certainty regarding the acceptance of these tools. Presenters will discuss how the Critical Path Institute (C-Path), through their Predictive Safety Testing Consortium (PSTC), is working to advance qualification of novel safety biomarkers. Further, the newly formed TransBioLine (Translational Biomarker Pipeline) consortium of EFPiA pharmaceutical companies and leading European academic institutions and bioanalytical companies, which has been established to build on previous consortia work to advance regulatory qualification of new and emerging safety biomarkers, will be presented.

2523 21st-Century Cures Biomarker Qualification Program

C. Leptak, US FDA, White Oak, MD. Sponsor: J. Sauer

Qualified biomarkers can be powerful tools in advancing public health and medical outcomes by promoting efficiencies and innovation in drug development. As set forth in section 507 of the 21st Century Cures Act, the US Food & Drug Administration's Center for Drug Evaluation and Research (CDER) has enhanced its Biomarker Qualification Program (BQP) by working with external stakeholders to develop biomarkers as drug development tools (DDT). This presentation will review the BQP’s goals transparency provisions and resources, as well as the three submission phases needed for biomarker qualification, 1) the Letter of Intent, 2) the Qualification Plan, and 3) the Full Qualification Package. Finally, advancements made in the development of evidentiary criteria for the qualification of biomarkers over the past few years will be discussed.

2524 Critical Path Institute’s Predictive Safety Testing Consortium: Identifying Innovative Biomarkers to Accelerate Drug Development

J. Sauer, Critical Path Institute, Tucson, AZ.

Safety paradigms for testing new chemical entities have not changed in decades. Although companies have developed newer safety testing methods, these are not generally accepted by regulatory agencies as proof of safety. This is because methods are often different from company to company and in many cases have not been independently validated. The Critical Path Institute’s Predictive Safety Testing Consortium (PSTC) was formed in 2006 to serve as a catalyst in the identification of new drug development tools (DDT) by bringing together pharmaceutical companies in the pre-competitive space to share and validate innovative safety testing biomarkers. Validated biomarkers are then submitted for formal regulatory qualification. This presentation will address PSTC’s four-fold objectives in qualifying novel biomarkers: 1) to qualify and make DDTs publicly available to be used for a specific context of use in drug development, 2) to streamline drug development and review of regulatory applications, 3) to facilitate integration of qualified DDTs in regulatory review, and 4) to provide a framework for scientific collaboration to facilitate DDT development. Attendees will learn how PSTC leverages the expertise of multiple stakeholders including academic scientists, pharmaceutical and biomedical industry scientists, and regulatory authorities, to advance qualification of novel biomarkers. By working together as a consortium, industry leaders collaborate on safety biomarker projects by first identifying the drug development need; defining the content of use (COU) for the novel biomarker, identifying potential benefits and risks, and determining the evidence needed to support the COU based on the benefits and risks. Integrated within this presentation will be examples of novel safety biomarkers that have received regulatory approval for a specific COU based on the collaborative efforts of the consortium. In addition, current efforts will be shared to further advance innovation in qualification of novel biomarkers for hepatotoxicity, nephrotoxicity, testicular toxicity, and pancreatic, skeletal muscle and vascular injury will be highlighted. Attendees will also learn about PSTC’s biomarker data repository program as a new tool for advancing such qualifications.

2525 An Overview of the Innovative Medicines Initiative (IMI) TransBioLine Project

S. Ramaiah, Pfizer, Inc., Cambridge, MA.

Circulating safety biomarkers can improve the benefit to risk for patients and decrease attrition of drug candidates in industry via early detection and intervention. However, adverse event data related to a given adverse event for a specific organ specific biomarker discovery, development and qualification are of strong interest to drug developers, regulators and the broader scientific and patient communities. Additionally, the dual function of many safety biomarkers as diagnostic and efficacy biomarkers further augments their utility. Biomarker qualification requires innovative scientific approaches including bioanalytical platforms, and access to large sets of well annotated human samples and large international scientific partnerships that include industry, academic research, clinical investigators, bioanalytical companies and regulatory authorities. Recent success in biomarker qualification efforts achieved by the Critical Path Institute’s Predictive Safety Testing Consortium (PSTC) and the Foundations for the National Institutes of Health (FNIH) exemplifies innovative approaches and partnerships for formal qualification of emerging biomarkers. Also, the previous Innovative Medicines Institute (IMI) project SAFE-T consortium and the PSTC have generated several safety biomarker candidates that are under review by EMA, US FDA and PMDA. Despite these advances, significant safety biomarker gaps requiring regulatory acceptance exist regarding translation to humans across multiple organ systems. To address this challenge, TransBioLine (Translational Biomarker Pipeline), a consortium of EFPiA pharmaceutical companies and leading European academic institutions and bioanalytical companies, has been established to build on previous consortia work to advance clinical evaluation and regulatory qualification of new and emerging safety biomarkers addressing gaps in several major target organs: kidney, liver, pancreas, vascular system, and central nervous system. To supplement this work, unique circulating miRNA and protein signatures will be investigated. Regulatory qualification will be accomplished in collaboration with non-European consortia such as PSTC, the FNIH biomarker consortium and US DILIN. An overview of the TransBioLine project, including details on the context of use, purpose of each of the biomarker work packages and deliverables for regulatory qualification will be presented.
The host and its associated microbiome evolved as a cooperative unit that influences multi-organ host physiological and pathological outcomes. Disruption of host-microbial mutualism is associated with numerous effects upon metabolism, immune function, and organogenesis. For example, senescent periods of brain development and formation of neural circuitry are influenced by both intrinsic and extrinsic signals, including maturation of the gastrointestinal microbiome. While a connection between gut microbiota and the brain may seem unlikely, emerging data support the concept of the microbiota-gut-brain axis. Alterations in gut microbiota are associated with decreased social behavior, increased stress response, hyperactivity, reduced anxiety, and deficits in learning and memory. These findings implicate the microbiota as an omnipresent environmental factor that influences brain development, directly impacting functions of memory, behavior, personality, and higher cognition. The session contains presentations by both academic and government scientists to introduce concepts on the role of physiologic perturbations or toxic insults to the gut microbiome and its implications in neurodevelopment using both human and animal models. The first speaker illustrates how human microbial colonization at birth and life-stage transitions of the microbiome have implications in later cognitive function. A proposed mechanism for communication between gut microbes and the developing brain is presented next. Using conventional and germ-free mice, microbial signaling molecules capable of influencing host brain development and behavior have been identified. The final presentation utilizes a zebrafish model to investigate host-associated microbiota capacity to modify developmental neurotoxicity of environmental chemicals. Overall, these presentations will provide a better understanding of the function of the microbiota-gut-brain axis in neurodevelopment and the potential consequences of chemical exposures.

Complex bidirectional interactions between intestinal microbes and the nervous system may be vulnerable to perturbations via exposure to environmental chemicals, particularly during sensitive early life stages. We developed an experimental system comprised of colonized and microbe-free axenic zebrafish to test the hypothesis that microbiota modifies the developmental neurotoxicity of environmental chemicals. A light/dark locomotor activity assay was used as a functional readout of neurodevelopment. To test the effect of chemical exposures on locomotor activity and microbiota community structure, we exposed conventionally colonized zebrafish to triclosan, triclocarban, bisphenol A (BPA), BPF, or estradiol (E2) on 1, 6, 7, 8, and 9 dpf. At 10 dpf, E2 treatment had no effect on microbiota while exposure to all other test compounds perturbed community structure. We next exposed axenic, colonized and axenic zebrafish to triclosan, triclocarban, bisphenol A (BPA), BPF, or BPS and revealed that colonization status failed to modify chemical effects on locomotor activity. In comparison, E2 exposure caused hypoactivity in the light period in colonized zebrafish but had no effect on axenic zebrafish. To characterize neurobehavioral requirements for microbial colonization, we isolated strains of Actinobacter, Comamonas, and Comamonadaceae from 10 dpf colonized zebrafish. Monocolonization of axenic zebrafish with Actinobacter or Comamonas caused control-like behavior whereas monoclonization with Comamonas failed to block hyperactivity. However, conserved behavior was achieved in axenic zebrafish co-colonized with all three commensal strains. Taken together, these results suggest that recapitulation of a defined microbiota that contains sufficient diversity to reflect the full repertoire of toxicodynamic and toxicokinetic interactions between xenobiotics and microbiota may be difficult. These data also show that, while environmental chemicals often disrupt the composition of the intestinal microbiome, microbial colonization status does not generally modify the neurobehavioral effects of multiple antimicrobial and industrial chemicals. This abstract does not necessarily reflect the views of the US EPA.

The mammalian gastrointestinal (GI) tract harbors a dynamic and complex community of microorganisms, including many host physiological processes including dietary energy extraction, the production of vitamins, and protection against pathogens. Recent scientific discoveries showing an unprecedented role for the gut microbiota in host development and physiology beyond the GI tract, including the regulation of brain development and behavior has triggered a paradigm shift in our conceptualization of the origin of human brain disorders. Deciphering the molecular mechanisms underpinning the influence exerted by the gut microbiota on the developing brain has therefore become a key research priority. Recently, we demonstrated that bacterial peptidoglycans (PGN) derived from the commensal gut microbiota can be translocated into the brain and sensed by specific pattern-recognition receptors (PRRs) of the innate immune system. Using expression-profiling techniques, we demonstrated that two families of PRRs that specifically detect PGN (that is, PGN-recognition proteins and NOD-like receptors), and the PGN transporter PepT1 are highly expressed in the developing and neonatally sensitive periods of brain development and formation of neural circuitry. Therefore, these findings may have important implications in neurodevelopment using both human and animal models. The first speaker illustrates how human microbial colonization at birth and life-stage transitions of the microbiome have implications in later cognitive function. A proposed mechanism for communication between gut microbes and the developing brain is presented next. Using conventional and germ-free mice, microbial signaling molecules capable of influencing host brain development and behavior have been identified. The final presentation utilizes a zebrafish model to investigate host-associated microbiota capacity to modify developmental neurotoxicity of environmental chemicals. Overall, these presentations will provide a better understanding of the function of the microbiota-gut-brain axis in neurodevelopment and the potential consequences of chemical exposures.

The Critical Path Institute’s Predictive Safety Testing Consortium (PSTC) has been working on regulatory endorsement of translational safety biomarkers for a number of target organ toxicities. Working groups within PSTC have been established focusing on liver, kidney, skeletal muscle, vascular, pancreas, and testes, identifying and evaluating novel safety biomarkers that outperform conventional biomarkers of toxicity for these tissues. This symposium will focus on working group updates for kidney, pancreas, and vascular injury biomarkers. Each presentation will provide an overview of the progress within each working group and clinical translation efforts for the kidney injury working group, the early transition to the clinic for the vascular injury working group, and the early identification of novel pancreatic injury biomarkers in preclinical species to inform future translational work. The presentations will provide an overview of the biomarkers under evaluation, proof of concept data (both preclinical and clinical), and the status of regulatory
A significant number of drug candidates entering development present with histopathological lesions in the kidneys of animals; some at doses without projected clinical exposure margins, only in one species, or in subchronic studies after initiation of first in human (FiH) trials; and often at doses without concurrent increases in serum creatinine or blood urea nitrogen (BUN). A collection of urine biomarkers including Kim-1, clusterin, albumin, and osteopontin, among others, was qualified in 2008 for use in IND enabling rat studies to demonstrate the ability to safely monitor for drug-induced renal tubular injury, and to support their use on a case-by-case basis in clinical trials to scientifically resolve human translational relevance. To broaden this clinical qualification, a collaborative project was launched in 2011 under the FNIH consisting of pharmaceutical companies, academic investigators, CRO’s, the Critical Path Institute’s Predictive Safety Testing Consortium (PSTC) and US FDA, utilizing a learn and confirm strategy. Learning phase results will be presented for 8 biomarkers: Kim-1, clusterin, albumin, osteopontin, NGAL, cystatin-C, NAG and total protein; these urinary biomarkers were prioritized among a large set of candidates. Sufficient analytical assay performance was established for these biomarkers along with statistical thresholds of normal variability and medically meaningful thresholds. Proof-of-concept performance value was also demonstrated using existing samples from cisplatin-treated mesothelioma subjects. In addition, an algorithm was established for a composite measure of 6 biomarkers to encourage their use under a limited context of use, prior to full qualification. Confirmatory phase results will be presented which demonstrate alignment with US FDA and EMA on context of use and a statistical analysis plan. The urine biomarkers measured in this phase used samples collected from prospective trials conducted over the past 6 years in over 200 subjects from 6 sites being treated with cisplatin, tobramycin, or from non-nephrotoxic controls and the blinded data entered into a database. Both a blinded adjudication and a pre-set step-down rules-based statistical analysis were conducted in preparation for submitting data to the US FDA and EMA for a qualification decision.

Nonclinical drug-induced exocrine pancreatic injury can have a significant negative impact on the development potential of a test article. The lack of reliable, noninvasive translational biomarkers for clinical detection, monitoring or prediction of the toxicity can preclude advancing the product to clinical testing. This presentation will outline the issue from the non-clinical and clinical perspective and discuss current efforts within the pharmaceutical industry and the Critical Path Institute’s Predictive Safety Testing Consortium (PSTC) Pancreatic Injury Working Group to identify and ultimately qualify novel translational biomarkers of acinar pancreatic toxicity. The presentation will include study results of exploratory biomarkers tested in a broad range of rodent models with a variety of testing methodologies. These exploratory biomarkers include tissue-specific microRNAs, proteins and enzyme activities measured in readily accessible matrices. Tissue localization results and histologic correlations to understand the robustness of the markers’ specificity and sensitivity will also be covered. The presentation will end with an overview of the Innovative Medicines Initiative (IMI) TransBioLine pancreatic injury work package, focused on clinical evaluation of candidate microRNAs, and the synergies between the two consortia.

Developing biomarkers for vascular injury is uniquely challenging and requires creative approaches. The goals of vascular injury (VI) biomarker clinical qualification are 1) to identify a panel of safety biomarkers that can be used in conjunction with preclinical and clinical information in healthy volunteers to monitor vascular integrity in early clinical trials and 2) to indirectly demonstrate dual utility of these biomarkers as diagnostic, prognostic and efficacy biomarkers in patient populations used as surrogates for detection of drug-induced vascular injury (DIVI). The qualification approach is a panel utilizing endothelial (angiopietin 2, p-selectin, VCAM1, and thrombomodulin), smooth muscle (caldesmon, calponin-1, Smoothelin B) and inflammatory (NFκB, MMP3, IL6, IL8, IP10, GroA, TIMP1, PTX3) biomarkers to confer both sensitivity and specificity for the vascular bed. The list of biomarkers has been prioritized based on biomarker biology and nonclinical and clinical safety and pharmacodynamic data. We will advance the clinical qualification in patients with systemic vascular conditions and in patients with targeted non-infectious vascular diseases. This presentation will emphasize the need to evaluate vascular beds by ophthalmoscopy and imaging techniques such as optical coherence tomography (OCT), including angiography (OCT-A) and fluorescein angiography (FA). We will also explore bioimaging approaches for systemic vasculitides such as tracer-based methods with endothelium-depleted biomarkers, and novel MRI techniques for renal vasculitides such as dynamic susceptibility contrast (DSC), arterial spin labelling (ASL) and Intra-voxel Incoherent Motion (IVIM). To inform and supplement human patient data, biomarker performance will be assessed in animal models of retinal and systemic vascular injury. Key to this work is the development and validation of cross-species translational assays as well as the development of biostatistical approaches to enable individual and combinatorial evaluations of the biomarker panel. This presentation will provide preliminary data supporting this approach to identifying biomarkers of vascular injury.

Perfluoralkyl substances (PFAS) are a diverse group of chemicals that have been used in the production of industrial and consumer products world-wide since the 1950s. Structurally, PFAS have a characteristic hydrophobic alkylated chain that is saturated with fluorine atoms attached to a hydrophilic head. Their hydrophobic and hydrophilic properties make PFAS suitable for manufacturing of a variety of products, including nonstick cookware, liquid repellants, fire-fighting foams, protective coatings, additives, textiles, and leather and carpet goods. The two most extensively studied PFAS are perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). Although no longer manufactured in the United States, PFOA and PFOS are still used in the manufacturing of consumer products in other countries that can be imported into the country. Consequently, most people have been exposed to PFOA and PFOS unknowingly, as they tend to end up in the environment (air, water, soil, etc.). In addition, PFOA and PFOS are known to be persistent, bioaccumulative, and toxic (PBT) in animals and humans. Studies have shown that they can cause immunological, reproductive, and developmental toxicity in experimental animals, as well as liver and kidney damage. Exposure to both chemicals has also been linked to the formation of cancerous tumors in animals. There is evidence that humans exposed to PFOA and PFOS can develop increased cholesterol levels, thyroid hormone disruption, and cancer.

The goal of this session is to bring together graduate students and postdoctoral scientists from different sectors to address the emerging scientific, environmental health, and regulatory issues raised by PFOA and PFOS. The first speaker will present on the use of various zebrafish assays to assess development and neurotoxicity of PFOA and PFOS. The second speaker will discuss the potential mechanisms by which PFOA and PFOS cause fetal growth restriction in mice. Finally, the last speaker will talk about the modulatory effects of PFOA and PFOS on Gabaa receptor function and neuronal network activity in primary rat cortical neurons.

Perfluoralkyl substances (PFAS) are structurally diverse class of industrial chemicals with widespread environmental occurrence. Exposure to long-chain PFAS like perfluorooctane sulfonic acid (PFOS) or perfluorooctanoic acid (PFOA) are associated with developmental toxicity and neurotoxicity. Long-chain PFAS have therefore been replaced with short-chain and polyfluorooether compounds. For hazard identification of replacement PFAS, developmental toxicity (DevTox) and developmental neurotoxicity (DNT) using locomotor activity as functional readout were assessed in 6 day post-fertilization (6 dpf) zebrafish exposed to 0.044-80.0 μM ammonium 4,8-di-oxa-3H-perfluoronoanoate (ADONA), GenX (HFPO-DA), Nafion byproduct 1 (Nafion BP1), perfluorohexanoic acid (PFHxa), PFOA, PFOS, potassium perfluorohexane-1-sulfonate (PFHxs), or 0.4% DMSO with daily renewal on 0-5 dpf.
Exposure to 3.1-27.2 μM PFOS or 80 μM PFHxS resulted in failed swim bladder inflation and abnormal ventroflexion of the tail. ADONA, GenX, PFHxA, PFOA, or Nafion BP1 exposures were negative for DevTox. The DNT assay consisted of two consecutive 10 min light periods (L1 and L2) and two consecutive 10 min dark periods (D1 and D2). Exposure to 0.1-3.1 μM PFOS or 4.4-44.8 μM PFHxS triggered locomotor hyperactivity in the L1, L2, and D1 periods while exposure to 14.0-25.1 μM PFHxA produced hyperactivity in the D1 and D2 phases. All other test chemicals were negative. Because exposure to structurally similar sulfonic acid-containing PFAS (i.e. PFOS and PFHxS) caused identical morphological and behavioral phenotypes, we hypothesized that this group of PFAS has a shared toxicity mechanism. To address this, perfluorooctanesulfonic acid (PFOS, four-carbon), perfluorodecanesulfonic acid (PFHxS, seven-carbon), and PFOA (eight-carbon) were assessed for DevTox and DNT. Chemical potency for DevTox and hyperactivity in the DNT assay was correlated with carbon chain length (PFOS>PFHxS>PFOA; PFBS was negative). Together, exposure to PFOS, PFHxS, or PFHxA caused DevTox while exposure to non-teratogenic concentrations of PFOS, PFHxS, or PFHxA provoked hyperactivity. Taken together, this work identified relationships between chemical structures and in vivo phenotypes that may arise from putative shared mechanisms of PFAS toxicity. This abstract does not necessarily reflect US EPA policy.

2536 An In Vitro Screen of a Panel of Perfluoroalkyl Substances and an In Vivo Assessment of Effects on Placental and Fetal Growth

B. Blake. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Perfluoroalkyl substances (PFASs) are ubiquitous environmental contaminants and are associated with fetal growth restriction (FGR). Perfluorooctanoic acid (PFOA) is one of the most well-studied PFASs and it is estimated that a 1 ng/mL increase in serum PFOA is associated with an 18.9g decrease in human birth weight. The mechanism through which PFOA affects fetal growth is not known and we hypothesize that the feto-placental unit is a target. PFOA is one of thousands of PFASs, and determining modes of action against the developing fetus as well as a method for PFAS prioritization are necessary. A high-throughput, multiplexed screen was developed using human placental Jeg-3 cells for PFAS prioritization. The 24h screen included assays to determine the effects of PFAS ranging from 50-500μM on proliferation, cell viability, and mitochondrial function. Doses were selected based off assay optimization due to toxicological implications. In-vivo-relevant doses for chemicals for which human exposures have yet to be defined. Of 33 PFAS screened, 56% showed effects on proliferation, 36% on mitochondrial function, and 39% on cell viability. To determine a potential mechanism of FGR for PFOA and evaluate whether its replacement, GenX, has similar effects on placental and fetal growth, pregnant CD-1 mice were exposed to PFOA (1 and 5 mg/kg/day) or GenX (2 and 10 mg/kg/day) from embryonic day 1.5 until E11.5 or E17.5 (n=5-8 per group). Doses were selected based on previous studies in our lab. Maternal weight gain was elevated at E11.5 in a dose-response manner with effects most prominent in mice exposed to GenX at 10 mg/kg/day (21% increased weight) followed by PFOA at 5 mg/kg/day (10% increased weight). At E17.5, mice exposed to 5 mg/kg/day PFOA or 10 mg/kg/day GenX had increased placental weights (18% and 22% respectively), decreased fetal weights (21% and 5% respectively), decreased fetal length (6% and 0.6% respectively) and decreased fetus/placenta ratios (32% and 21% respectively). These data suggest both PFOA and GenX can affect the placenta and embryo, possibly via diverging mechanisms where PFOA appears to affect both the fetus and placenta, whereas GenX appears to primarily impact the placenta. These findings implicate GenX as a potential public health threat rather than a safe alternative.

2537 Perfluorooctane Sulfonate (PFOS) and Perfluorooctanoate (PFOA) Differentially Modulate GABAA Receptor Function and Spontaneous Neuronal Network Activity

A. M. Tukker, Utrecht University, Utrecht, Netherlands.

There is increasing concern about the possible (developmental) neurotoxic effects of environmental pollutants, including the highly persistent compounds perfluorooctanoic acid (PFOA) and perfluorooctanoic acid (PFOA). Earlier studies indicated that the inhibitory GABAA receptor is an important regulator in neuronal development and function, but also a sensitive target for persistent organic pollutants. Therefore, this study aims to explore the effect of two perfluorinated compounds (PFCs) on GABAA receptor function and neuronal network activity. Using two-electrode voltage-clamp, we demonstrate that PFOS (0.001-100 μM) and PFOA (0.001-100 μM) induced concentration-dependent antagonistic effects on human α1β2γ2L GABAA receptors, expressed in Xenopus laevis oocytes. Notably, the inhibitory effects of PFOS and PFOA were already evident at human-relevant submicromolar concentrations (0.1 μM). While the inhibition by PFOA was independent of the GABA concentration (LOEC 1 μM in co-application with 1 mM GABA), the degree of inhibition evoked by PFOS increased at higher GABA concentrations (LOEC 0.1 μM in co-application with 1 mM GABA). As PFC-induced inhibition of GABAA receptors is hypothesized to increase neuronal activity, we assessed the effects of PFOS and PFOA on spontaneous neuronal network activity in primary rat cortical cultures grown on multi-well micro-electrode arrays (mwMEA). Surprisingly, only the highest concentration tested (100μM) induced a transient (PFOA) or persistent (PFOS) inhibition of neuronal activity, whereas lower concentrations were without effect. These data therefore indicate that the variability in PFCs’ structurally similar sulfonic-acid containing PFAS (i.e. PFOS and PFHxS) caused identiﬁcation of modes of action against the developing fetus as well as a method for PFAS prioritization are necessary. A high-throughput, multiplexed screen was developed using human placental Jeg-3 cells for PFAS prioritization. The 24h screen included assays to determine the effects of PFAS ranging from 50-500μM on proliferation, cell viability, and mitochondrial function. Doses were selected based off assay optimization due to toxicological implications. In-vivo-relevant doses for chemicals for which human exposures have yet to be defined. Of 33 PFAS screened, 56% showed effects on proliferation, 36% on mitochondrial function, and 39% on cell viability. To determine a potential mechanism of FGR for PFOA and evaluate whether its replacement, GenX, has similar effects on placental and fetal growth, pregnant CD-1 mice were exposed to PFOA (1 and 5 mg/kg/day) or GenX (2 and 10 mg/kg/day) from embryonic day 1.5 until E11.5 or E17.5 (n=5-8 per group). Doses were selected based on previous studies in our lab. Maternal weight gain was elevated at E11.5 in a dose-response manner with effects most prominent in mice exposed to GenX at 10 mg/kg/day (21% increased weight) followed by PFOA at 5 mg/kg/day (10% increased weight). At E17.5, mice exposed to 5 mg/kg/day PFOA or 10 mg/kg/day GenX had increased placental weights (18% and 22% respectively), decreased fetal weights (21% and 5% respectively), decreased fetal length (6% and 0.6% respectively) and decreased fetus/placenta ratios (32% and 21% respectively). These data suggest both PFOA and GenX can affect the placenta and embryo, possibly via diverging mechanisms where PFOA appears to affect both the fetus and placenta, whereas GenX appears to primarily impact the placenta. These findings implicate GenX as a potential public health threat rather than a safe alternative.

2538 Species Relevance: Approaches to Determine the Most Relevant Species for Safety Assessment of Pharmaceutical Products

M. Delatte. US FDA, Silver Spring, MD.

Most development programs for pharmaceutical products employ a rodent and nonrodent species for assessment of potential hazards. In a risk assessment, findings from the most relevant species are typically used to determine safe clinical exposure levels. Many scientists typically conclude that the most sensitive species is the most relevant species. However, there are instances in which the most relevant species may be selected based on anatomy, physiology, target site for efficacy, pharmacokinetic profile, or other relevant factors. Identifying the most relevant species is a critical step in hazard/risk assessment given the need to determine that the hazards identified are clinically relevant and representative of effects likely to occur in humans, based on qualitative and quantitative aspects of the hazard(s) identified. This session will introduce the attendees to multiple factors that may impact species relevance when conducting a hazard assessment. The second talk will discuss risk assessment of small molecules and approaches used to determine the most relevant species in pharmacology and general toxicology studies. The third talk will discuss approaches used to determine the most relevant rodent species for carcinogenicity assessment of small molecules. The fourth presentation will discuss hazard assessment of biologic products and approaches used to determine the most relevant species for reproductive toxicology studies and carcinogenicity assessment. Together, the information presented in these talks will highlight the importance of and provide a framework for selecting the most relevant species when conducting a safety assessment.

2539 Comparative Anatomy and Physiology in Animal Species Commonly Used for Drug Safety Testing

J. Turk, Amgen, St. Louis, MO. Sponsor: M. Delatte.

Toxicology studies involve the use of a wide range of laboratory animals that present unique anatomical and physiological characteristics relevant to species selection for toxicology assessments. This introductory session will provide an overview of salient species differences, but also similarities from rodents to non-rodents, and will ultimately address translational considerations as the comparison is extended to humans. The homology across species differs with organ systems which has interpretation implications when evaluating drug-induced adverse effects. Organ system differences mandate a scientific review of anatomical and physiological features during species selection. Even when present, anatomical differences may not significantly impact tissue response to drug exposure and consequently may have minimal implications relative to species relevance in the context of toxicology studies. As the session introduces comparative anatomy and physiology across species, it will set the stage for an in-depth discussion on factors involved in the species selection process for drug safety testing.
Non-clinical toxicology and pharmacology studies involve risk identification but also risk characterization. While the value of different animal species may be equivalent for risk identification, differences may emerge during risk characterization and establishment of safety margins. In addition, the value of the various animal species used for risk identification and characterization varies based on the liability and types of drug induced adverse effects that are evaluated. As such, this session will explore divergences and similarities observed in animal species with implications for interpretation in toxicology and pharmacology. It will discuss well known species characteristics but also unique cases involving vehicle reactions, species specific metabolism, or clinically irrelevant animal features, all in the context of a science-driven approach.

Lastly, translational considerations will be discussed related to strategic decisions when contemplating selection of the most sensitive species compared to the most relevant species.

Species Selection in Toxicology and Pharmacology Studies: Challenges, Opportunities, and Lessons Learned

S. Authier. Citoxlab North America, Laval, QC, Canada. Sponsor: M. Delatte

An overview of current models, including details regarding the engraftment of specific immune cell subsets, and their potential application. The limitations of each of these models also will be discussed. Examples of current applications will be discussed, including assessment of their value in evaluating cytokine release, graft-versus-host disease, and comparative assessments of biosimilar products. Recent advances in humanized mouse models will be presented including novel, rapid, and sensitive in vivo models to assess individual responses to immune therapy agents and in combination therapies.

Species Considerations for Nonclinical Carcinogenicity Evaluations

O. McMaster. US FDA, Silver Spring, MD.

Carcinogenicity studies are conducted for drug products if the expected clinical use is for = six months and/or if there is cause for concern, such as preneoplastic lesions. The conventional approach typically includes one long-term rodent carcinogenicity study, plus one other study (such as a short- or medium-term in vivo rodent test system such as TgRasH2 mouse or a long-term rodent carcinogenicity study in a second rodent species). The choice of species for a long-term carcinogenicity study should be based on consideration of the drug pharmacology, toxicology, toxicokinetics and route of administration. The conventional approach may not be appropriate for biopharmaceuticals due to the unique and diverse structural and biological properties including species specificity. Selecting relevant animal species for testing should be done very meticulously as studies in non-relevant species could be misleading and are discouraged. Even when the results of a carcinogenicity study are unequivocally positive, the data may be irrelevant for assessing risk to humans based on the species in which the finding was detected. This talk will discuss the various factors which must be considered in selecting the species/animal models that best predict the risk of human carcinogenicity.

Biologic Product Species Selection: When Data Conflict

J. Dubinion. US FDA, Silver Spring, MD. Sponsor: M. Delatte

ICH Guidance S6 (R1) provides assay recommendations (sequence homology, target binding affinity, receptor/ligand occupancy, and functional activity) for determining species relevancy for biologic drug products. While the guidance suggests that tissue cross reactivity studies are of limited value for species selection, it also describes specific cases where comparison of tissue binding profiles between human and animal tissues can guide selection of toxicology species. This flexibility can sometimes be misinterpreted by sponsors especially when the data from the recommended assays conflict with findings from tissue cross reactivity studies. This talk will discuss hazard assessment of biologic drug products in relation to species selection. It will highlight the importance of selecting relevant species based on the best scientific data early in drug development, and methods to prevent costly changes in animal species for completion of reproductive developmental toxicity/carcinogenicity later in product development.

The Current Application, Limitations, and Recent Advances in Humanized Mouse Models for Evaluations of Immune Function and Preclinical Immunotoxicology Studies

M. Collinge. Pfizer, Inc., Groton, CT.

Significant advances have been made in recent years in the development of humanized mice for use in preclinical pharmacology and toxicology studies to support the development of pharmaceutical biotherapeutics. Multiple models currently exist, and the selection of the appropriate model is critical to provide meaningful and clinically translatable data. This session will provide

Species Selection in Toxicology and Pharmacology Studies: Challenges, Opportunities, and Lessons Learned

S. Authier. Citoxlab North America, Laval, QC, Canada. Sponsor: M. Delatte

NSG Mice Deficient in Murine MHC Class I and Class II Expression Support Engraftment of Functional Human T Cells in the Absence of Acute Xenogeneic GVHD following Injection of PBMC

M. Brehm. University of Massachusetts Medical School, Worcester, MA. Sponsor: M. Collinge

Recent Advances in Humanized Mouse Models for Toxicology Assessment of Novel Therapeutics

J. Keck. Jackson Laboratory, Sacramento, CA. Sponsor: M. Collinge

Immunotherapy is becoming a powerful therapeutic method in cancer and autoimmunology diseases. Monoclonal antibodies (mAbs) have been successfully used for immunotherapy for many years. Many of these mAbs are targeted against proteins on the surface of immune cells, especially T-cells and B-cells. However, mAbs can have a variety of adverse effects at the time of infusion, such as cytokine release syndrome (CRS), which can be lethal. There are generally two existing methods for immunotoxicity testing prior to clinical trials of a drug: namely, in vivo testing in animal models and in vitro human peripheral blood mononuclear cell (PBMC) assays. Unfortunately, these two methods
developed a tiered approach to assess the safety of botanicals which includes an assessment of botanical-drug interaction (BDI). The scientific literature is replete with reports of various botanical extracts and/or constituents as potent inhibitors of drug metabolizing enzymes and transporters. Unfortunately, most of these studies use simplistic in vitro screening-based systems without follow-up in more physiologically-relevant models. Additionally, the potential for botanical extracts to induce metabolism enzymes and/or transporters is rarely studied; particularly in in vitro systems. Thus, in the rare instances when clinical studies are conducted to confirm botanical-drug interaction (BDI) potential, there is usually a poor correlation between in vitro studies and clinically-relevant changes in the pharmacokinetics of drugs under study. Recently, our laboratory has proposed a new paradigm to assess BDIs using sandwich-cultured human hepatocytes (SCHH) and an in vitro clearance approach that treats the complex botanical mixture as a single entity, regardless of the constituent profile. Our experimental design captures major clinically-relevant hepatic pathways and data output that makes direct predictions of clinical BDI and the impact on a victim drug (e.g. liver clearance). In studying the complex mixture in this way, we can capture the overall net effect of any synergism or additive effects that might be occurring.

**S 2547 When “Natural” Is Not Synonymous with “Safe”: Toxicity of Natural Products Alone and in Combination with Pharmaceutical Agents**

D. Mendrick, US FDA, Silver Spring, MD.

Retail sales of vitamins and nutritional supplements have increased from $23.8 billion in 2007 to $36.1 billion in 2017, with more than 70% of Americans currently taking some dietary supplement daily. While many equate these “natural” products with “safe,” it is well recognized by scientists that active ingredients in natural products can result in toxicity. Additionally, when these products are used in concert with pharmaceutical agents, they can alter drug metabolism and drug delivery, thereby enhancing or reducing the therapeutic effect of the drug(s). However, there is no current requirement for dietary supplements to be registered with the US FDA, and only post-marketing adverse events have to be reported. With the widespread use of nutritional supplements, these dietary supplement-drug interactions can be underappreciated and cause the failure of promising drugs. This symposium will explore the toxicity of natural products alone and in combination with conventional drugs. Systematic approaches for assessing natural product-drug interactions, including in vitro, PBPK modeling, and human clinical studies, will be presented. Methodology to handle the complex mixtures represented by natural products in various test systems also will be discussed. Finally, a case study involving a natural product (cannabidiol) and potential for drug interaction will be highlighted.

**S 2548 Causative Ingredients and Mechanisms Underlying Interactions between Prescription and Nonprescription Medications and Natural Products**

M. F. Paine. Washington State University, Spokane, WA. Sponsor: D. Mendrick

Common mechanisms underlying pharmacokinetic interactions between natural products (NPs) and conventional drugs include induction and inhibition of drug metabolizing enzymes and transporters, leading to altered systemic or tissue drug concentrations and potentially, suboptimal therapeutic effects. Rigorous guidelines for assessing the risk of NP-drug interactions are non-existent, due in part to NPs being inherently complex mixtures that vary substantially in bioactive ingredient composition. The National Center for Complementary and Integrative Health established the Center of Excellence for Natural Product-Drug Interaction (NaPDI) Research in September, 2015. A key deliverable of the NaPDI Center is a set of recommended approaches to guide researchers in the proper conduct of NP-drug interaction studies. These approaches will be based on results generated from a series of ongoing interaction projects focused on four systematically selected NPs as precipitants of NP-drug interaction effects. The data generated from these projects are being entered into a data repository that will be disseminated to researchers via a public access portal. The efforts of the NaPDI Center should lead to improved design of future NP-drug interaction research and eventually, improved decisions about the optimal management of these complex interactions.

**S 2549 Botanical-Drug Interaction Assessment: A Critical Component of a Systematic Approach to Botanical Safety**

A. Roe. Procter & Gamble Company, Cincinnati, OH.

Exposure to botanicals in dietary supplements is increasing across many geographic areas; with increased expectations from consumers, regulators, and industry stewards centered on quality and safety of these products. We have observed variability in artisanal CBD products and the limitations in extrapolating the known information on pharmacology of purified CBD to artisanal products will be discussed.

**S 2550 Cannabidiol Pharmacology and Drug-Drug Interactions with Anti-Epileptic Drugs (AEDs)**

There has been increasing interest in the use of cannabinoids in the treatment of epilepsy. While there is indication that some cannabinoids, particularly cannabidiol (CBD), are effective in treating epilepsy, there is an assumption frequently observed in the community that CBD is completely safe and without side effects or drug-drug interactions since it is plant-based. A highly purified CBD solution has recently been US FDA approved. This presentation will introduce the pharmacology of cannabidiol, including proposed mechanisms of action, pharmacokinetics, metabolism, and excretion. Further, CBD’s drug-drug interactions with other anti-epileptic drugs (AEDs) will be discussed, as documented, clinically significant interactions with clobazam and valproate have been identified and are likely due to CBD’s effects on certain CYP450 enzymes. Other potential pharmacokinetic interactions have been seen with topiramate, zonisamide, rufinamide, and eslicarbazepine. However, more data are needed to confirm many of these potential drug-drug interactions. In closing, variability in artisanal CBD products and the limitations in extrapolating the known information on pharmacology of purified CBD to artisanal products will be discussed.

**W 2551 New Approaches Using Mode-of-Action to Predict Acute and Systemic Toxicity**

C. Willett. Humane Society of the United States, Washington, DC.

There is a transformation occurring in toxicology: a shift toward characterizing chemical safety based on an understanding of the biomolecular activity of the chemical coupled with a deeper understanding of how that activity can lead to adverse effects at the organ, individual, or population level. New approach methodologies (NAMs) can be used to identify a chemical’s mode of action (MoA), including the molecular initiating events (MIEs) and downstream key events possibly leading to adverse outcomes (AOs). Application of this NaPDI paradigm is furthest advanced for biology where the MIEs are better established, such as skin sensitization, genetic toxicity, and endocrine models. However, for systemic acute or repeat-dose toxicity, where several possible MIEs may be involved, the ability to identify specific MIEs and use in vitro data to predict complex toxicological outcomes is much less mature and urgently needed. This session provides three innovative approaches to predicting chemical safety by identification of MoA based on NAM data: one for acute mammalian systemic toxicity, and two different approaches for repeat-dose target organ toxicity. The presentations will provide a synopsis of the state-of-the-science regarding availability of databases for these endpoints, as well as application of integrating computational and in vitro models in a predictive fashion. The session will emphasize successes and limitations in current NAMs for these endpoints and highlight the priority needs for future dedicated research to improve modeling. Discussion will focus on what is needed to bring these approaches into broad regulatory use.
We have developed in silico mechanistic profilers that identify putative molecular initiating events. We built these either using defined SMARTS codes or by using machine learning and artificial intelligence with structural scaffolding and fingerprinting of in vitro data, which is integrated in some cases with a consensus model using protein docking binding energies. Uniquely, our models can provide both positive and negative predictivity when there are enough specific negative in vitro data. We are aligning the predicted in silico targets with appropriate in vitro models in an integrated manner to predict in vivo toxicity. As proof of concept, we will show application of this integrated approach to acute mammalian toxicity wherein we have profilers that account for most GHS 1-3 MIEs. We also show both the merits and limitations of down-stream in vitro models for basal cytotoxicity. For instance, we demonstrate using in silico approaches to identify in vitro models that lack comprehensive predictivity due to poor metabolic capability, inability to delineate cytotoxicity from known cytotoxic reactive chemistries, or by questionable in vivo data curation results. These studies will highlight potential research gaps and future projects.

Toxic effects following repeated dose exposure are one of the key drivers for assigning regulation classifications to chemicals. Determining whether a substance has a specific mode of action, which may drive toxicity in one or more organs, or is non-specific in its action is an essential part of determining toxic potency, and hence will influence regulatory classifications. Data from New Approach Methodologies (NAMs) can assist in identifying modes of action associated with regulatory classifications, although no overarching strategy is yet available. To resolve this, a study was initiated to investigate repeated dose toxicity data-associated specific target organ toxicity - repeat exposure (STOT-RE) classifications for substances for which in silico profiling was undertaken and ToxCast data were available. Data from NAMs supported grouping of known specific mechanisms (e.g. for hepatotoxicity) which could be associated with classifications. It was more difficult to develop definitive associations between NAMs and non-specific mechanisms of action, although a combination of the absence of in silico alerts and ToxCast hits was indicative of substances with low toxicity. The funding of CEFIC LRI Project AIMT B is gratefully acknowledged.

Although predicting adverse effects has traditionally concentrated on observations at the organ and organismal level, we know that these adverse events are the culmination of a chain of events that begins with an interaction between the exogenous chemical and an endogenous target at the molecular level. Accordingly, we have concentrated on trying to understand the modes of action of toxicants at a molecular level, both by analyzing chemical features and by identifying the initial biological responses to toxicants. We have curated large in vivo data sets of rodent and rabbit developmental and reproductive toxicity (DART) data as well as human data, to catalog the kinds of chemical structures that are associated with DART. Using these data, we are deriving mode of action ontologies that link molecular targets to in vivo effects. We are supporting our assumptions about mode of action by using global gene expression analysis in a series of cell types that provide biological diversity. This talk will demonstrate progress on the mode of action ontology, and provide examples of how the ontology and data from toxicogenomics provide support for prediction of toxicity by read across. In the process, we will gain greater understanding of the universe of modes of action for DART, which should ultimately be robust enough to support predictions even for chemicals that have no analogs that have in vivo data.

Echocardiography provides a non-invasive means to assess cardiac structure and function and is widely used clinically to assess left ventricular function, hypertrophy, valvular disease, and myocardial infarction. Increasingly, echocardiography has become a sought-after tool in nonclinical research to make informed decisions on intended pharmacology and/or off-target actions of test articles under development. This session will aim to provide an overview of the utility of echocardiography in nonclinical research, including the latest technologies, species and study design considerations, and a regulatory viewpoint on the utility of nonclinical echocardiography data in the assessment of Investigational New Drug (IND) submissions and subsequent clinical trials. The session will start with an outline of the use of small (rodents) and large (dogs, monkeys) animal echocardiography, including a description of common endpoints assessed. In addition, the first presenter will address the utility of echocardiography in healthy animals and animal models of cardiac disease as part of nonclinical safety assessment. The second presentation will address a range of anatomic, behavioral, and hemodynamic factors that affect quantitative analyses, including common design elements used to maximize data quality and effect size detection thresholds, and potential pitfalls to avoid. The third talk will discuss how nonclinical ultrasound data generated in animals are utilized and interpreted as part of an IND submission and how these data may impact early clinical trials. The target audience is toxicologists who may have limited exposure to the utility of echocardiography in nonclinical animal studies and are looking to expand their knowledge in the area. By the end of the session, attendees should better understand the technical considerations and strategies for employing echocardiography in nonclinical animal studies and how animal-based echocardiography data generated as part of a drug safety assessment program may impact IND submission and subsequent clinical trials. Based on the fact that cardiovascular liabilities continue to be a leading cause of drug attrition in late-stage clinical trials and post-market approval, it is expected that additional measures to assess cardiac function will be of great interest to the toxicology and drug development communities.

Echocardiography provides a non-invasive means to assess cardiac structure and function. High-frequency ultrasound with resolution to 30 µm and frame rates of over 30 Hz can capture the minute detail of rapidly moving rodent hearts. Clinical ultrasound platforms are perfectly suited to imaging larger animals. Therefore, both systems are ideal for nonclinical imaging and drug screening in a wide range of animal species. The utility of echocardiography including measures of wall thickness, chamber dimensions, valve structure, and various wall thickness in 2, 3, and even 4-dimensions will be presented. Echocardiography can also assess cardiac performance including measures of systolic and diastolic function and tissue movement via strain. Doppler measures of blood velocities moving through valves and other blood vessels will add additional insight. This presentation will cover the range of measurements used in cardiac ultrasound in healthy animals and animal models of cardiac disease that may be employed as part of nonclinical safety assessment studies.

Echocardiography is increasingly used as an assessment of the cardiac effects of test articles. The modality permits non-invasive, repetitive, rapid assessments of cardiac size, including markers for myocardial mass, indices of hemodynamics, and quantitative indices for systolic and diastolic function. Anatomic, behavioral, and hemodynamic factors that affect quantitative analysis will be described including common design elements used to maximize data quality and effect size detection thresholds, and potential pitfalls to avoid will be discussed. Interpretation schemes will be discussed, including principles such as asymmetric cause/effect analysis. Hypothetical examples of optimum versus non-optimum use of echocardiography in test article development will be presented.
The US FDA supports efforts to improve the informative and translational value of nonclinical studies. These efforts are in alignment with the trends of increasing, reducing, and replacing animal studies while also increasing the safety of clinical trials for participants. Recent advances in echocardiography give this imaging modality the potential to have a significant impact on nonclinical safety assessment. Echocardiography is a non-invasive or minimally invasive technique that offers in-life visualization of several components of cardiac function and blood flow and quantitative assessment of physiologic or toxicologic changes. This real-time evaluation of cardiac function offers several possible roles in nonclinical safety assessment, with the potential for translation to the clinic. Its successful implementation in nonclinical studies and submission to regulatory agencies is dependent on several key factors, including the observer, analysis, and reporting. This presentation will discuss the potential use of echocardiography in nonclinical studies and the types of beneficial information to include when submitting to regulatory agencies.

Tips for Improving Scientific Communication with a General Audience

J. Shannahah, Purdue University, West Lafayette, IN.

For research to broadly and positively impact public health, it must be efficiently communicated to, and understood by, the general public. The majority of university-level scientific training focuses on performing cutting-edge research and sharing those findings with other scientists within one’s own field. In a time when information is readily accessible, ensuring effective and accurate scientific messaging through community outreach is necessary for maximizing societal impact and understanding. This is true during one-on-one conversations with nonscientists, and through interactions utilizing social and mass media. Deficiencies in the capacity to share science-related topics with media and the general public result in misinterpretation of conclusions and decreased community engagement in science. This session is designed to bring in scientific outreach experts to share tips and strategies for researchers to successfully communicate science with the general public. Speakers will focus on (1) individual interactions, (2) controlling your message, (3) the use of innovative social media platforms, and (4) effective utilization of mass media. These interactive presentations will include real-world examples of successful scientific communication as well as illustrations of common errors scientists are prone to committing. These discussions will be highly applicable to all attendees, including graduate students, postdoctoral trainees, and senior toxicologists. This session will allow both trainees and seasoned toxicologists to learn and implement this increasingly useful and necessary skill set.

Establishing Effective Alternatives for Acute Oral and Inhalation Systemic Toxicity Testing

A. Karmaus, ILS, Morrisville, NC.

Acute systemic toxicity testing is required by regulatory agencies worldwide, providing the basis for hazard labeling and risk management of industrial chemicals, agrochemical formulations, and pharmaceuticals, and represents the highest cumulative animal use across chemical sectors. The development of test methods that reduce or replace animal use for acute systemic toxicity tests is one of the highest priority activities of the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM), which is comprised of representatives from 16 US federal regulatory and research agencies that use or generate toxicological testing information. Despite the multitude of in vitro and in silico methods, a lack of regulatory acceptance of defined approaches prevents the widespread adoption of these approaches by industry. This session will demonstrate how engaging regulators and stakeholders up-front facilitates effective integration of alternatives, ensuring a path to success in reducing the use of animals in acute testing. Efforts in the United States to identify, develop, validate, and implement alternatives to the traditional acute systemic toxicity tests associated with oral and inhalation exposures will be highlighted. Overall, this session will review the current status of developing alternative approaches to acute systemic toxicity testing to meet agency needs, challenges in integrating new methods, and approaches to facilitate the adoption of these alternative methods in the near term and achieve the goal of significantly reducing animal use in acute toxicity testing by 2020.

Derivation of a Dataset for Modeling Acute Oral Toxicity and Variability Assessment of In Vivo LD50 Data

N. Kleinsteuere, NIEHS/NICETAM, Research Triangle Park, NC.

Alternative models developed for estimating acute systemic toxicity are generally evaluated using in vivo LD50 values. However, in vivo acute systemic toxicity studies can produce variable results, even when conducted according to accepted test guidelines. This variability can make assessment of alternative models extremely challenging. To characterize the variability of in vivo acute systemic toxicity data, we examined a large compilation of LD50 values reported in rat oral acute toxicity studies. Data were obtained from multiple curated databases including the NLM’s Hazardous Substances Data Bank and ChemiDplus, the OECD’s eChemPortal, and the JRC’s AcutoxBase. The resulting dataset comprised a total of 21,210 rat oral LD50 values representing 15,698 unique chemicals. A subset of >1000 chemicals that had been evaluated in at least three independent rat oral acute toxicity studies were used to assess variability. Chemicals with the highest variability were manually curated to ensure data reliability. Of this subset, many chemicals were identified that had LD50 values ranging across at least two, and sometimes three, orders of magnitude. This degree of variability can confound hazard categorization, particularly when LD50 values fell into multiple different Global Harmonization Scheme (GHS) oral acute toxicity labeling categories or US EPA hazard categories. These findings underscore the importance of considering an appropriate margin of uncertainty when using in vivo oral acute toxicity data to assess the performance of alternative methods and provide a reference dataset to ensure that appropriately representative LD50 data are routinely used for the development and validation of alternative models.
ultimately produce publicly accessible CaT莫斯 predictions via the US EPA’s CompTox Dashboard interface and the consensus models will be available for further chemical screening via the OPERA predictive tool.

2564 In Silico and In Vitro Approaches to Assess Inhalation Toxicity Testing
A. Clippinger, PETA International Science Consortium Ltd., Norfolk, VA.

Scientific and ethical drivers have led to interest in developing human-relevant, mechanistically based approaches for inhalation toxicity testing that can be used instead of animals. As a result, multi-stakeholder collaborations have formed between industry, government, non-profit organizations, method developers, and academia to advance these approaches. This presentation will highlight progress and ongoing work of an international multi-stakeholder collaborative that has focused on determining federal agency needs, curating existing data, and identifying gaps in in silico or in vitro methods available to assess toxicity following inhalation exposures. Partnerships have been established to better understand inhalation dosimetry of various agents and mechanisms of toxicity to support the development of adverse outcome pathways (AOPs). AOPs can be used to direct the design of integrated approaches to testing and assessment that evaluate all existing data, and incorporate dosimetry considerations, physicochemical property information, and in vitro and computational approaches in an integrative fashion. Proof-of-concept testing is being conducted to show the utility of non-animal approaches to predict the toxicity of inhaled substances. The ideal testing approach will vary depending on the test substance and purpose of the study, and results from proof-of-concept testing will be used to further the development and optimization of testing approaches that will be fit for regulatory decision-making.

2565 Integrating Nonanimal Alternative Approaches to Assess the Risk to Human Health from Inhaled Materials
J. Hotchkiss, Dow Chemical Company, Midland, MI.

There is need to identify nonanimal alternatives to assess the acute toxicity of inhaled materials for hazard identification. In vitro exposure of 3D human organotypic epithelial cultures grown at the air liquid interface (ALI) may provide an immediate path to assess airway epithelial responses to deposited and adsorbed aerosols, vapors and gases that are relevant for human risk assessment. Commercially available organotypic airway cultures reproduce many features of in vivo human respiratory epithelium, including 3D epithelial structure, functional cilia, mucus secretion, barrier properties and metabolic activity. This study examined cytotoxicity, inflammatory, metaplastic and oxidant injury exposure response profiles of large (Epithelix Mucilair HF™; MAF) and small (Epithelix Smallair HF; SAF) airway epithelial cultures. Test materials (SDS; direct cytotoxicity, TNF-α; induction of acute inflammation response, IL-13; induction of mucous cell metaplasia, H2O2; oxidant injury) with well-defined airway epithelial responses in vivo and in vitro were applied directly to the apical epithelial surface via pipetting or as a liquid aerosol using a VitroCell Cloud in vitro exposure system. The results of this study underscore the need to measure multiple endpoints to evaluate the acute exposure response profiles and the ability of the large and small airway epithelial cultures to recover/adapt to injury. These data also confirm the need to use deposited/absorbed dose and not exposure atmosphere concentration when assessing the acute toxicity of inhaled test materials using alternative in vitro test systems. This in vitro model is a key component to develop an integrated approach for acute inhalation toxicity assessment that will integrate cheminformatics evaluation of the potential mode of action based on the molecular initiating event (MIE) and key events identified by the appropriate adverse outcome pathway (AOP).

2566 Progress toward Charting the Course for Improving Carcinogenicity Assessments of Human Pharmaceuticals and Pesticides
J. Van der Laan, Medicines Evaluation Board, Utrecht, Netherlands.

Health authorities responsible for regulating pharmaceuticals and pesticides request studies to determine carcinogenic potential. These studies conform to Guidelines of the International Council on Harmonization (ICH S1) for drugs and OECD guidelines for pesticides. For drugs these studies are requested to be conducted when human treatment is necessary for longer than six months; for crop protection chemicals they are required for most exposure scenarios. The value of the rodent bioassays continues to be questioned because of their lack of relevance to humans. Retrospective analyses of various datasets (PhRMA, US FDA, JPMa, and EU) concluded that the outcome of these rodent studies could be predicted as follows: negative predictions can be made when carcinogenic signals such as the absence of hyperplasia in a six-months study and when certain pharmacological properties are absent, whereas positive predictions are possible when such signals are present. In-between compounds remain for which the outcome is equivocal and where experimental studies may add value to identify real hazards. These hypotheses stimulated ICH to evaluate compounds in a prospective way in an ongoing exercise. US EPA and the pesticide industry are similarly stimulated to consider harmonization on such alternative approaches. This symposium is intended to provide transparency into the progress being made to establish internationally harmonized approaches to enable more flexible carcinogenicity assessment strategies focused on mechanisms while reducing reliance on the two-year rodent bioassay. Case examples for pharmaceutical and pesticide development will be provided that demonstrate how successful implementation might look. The opportunities that emerging new technologies and rich scientific information sources can play to impact the future evolution of this flexible framework will be described.

2567 ICH S1 Project Status Update: The Need for Carcinogenicity assessment
J. W. van der Laan, Medicines Evaluation Board, Utrecht, Netherlands.

Sponsors are encouraged to submit Carcinogenicity Assessment Documents (CADs) to Drug Regulatory Authorities (DRA’s) for all investigational pharmaceuticals with ongoing or planned 2-yr rat carcinogenicity studies. The CAD addresses a weight of evidence approach of the carcinogenic risk of an investigational drug. This approach is based on available pharmacology and toxicology data and a rationale for why the conduct of long-term studies would not add value to that assessment. Drug Regulatory Authorities independently review the submitted documents and evaluate the degree of concordance with Sponsors. During this prospective evaluation period waiver requests will not be granted, as the data are collected solely for real world experience. Submitted CADs will finely be compared to the real outcome of the 2-yr carcinogenicity studies. Main objective will be the assessment of accuracy of the predictions. This presentation will inform about the present details of this prospective analyses. Thus far 48 CADs have been collected, with more than 20 agreed virtual waivers. The presentation will discuss the strengths and weaknesses of the CADs, and the reasons why the DRA’s decided to deviate from the initial categorization by the sponsor.

2568 Lessons Learned from Completed Submissions: Case Studies
T. Bourcier, US FDA, Silver Spring, MD.

The prospective weight-of-evidence (WOE) assessment of carcinogenic risk and whether a 2yr rat study would add value to the WOE is documented in the carcinogenicity assessment document (CAD) substantially prior to the end of the rat study. Once submitted, the results of the 2yr rat Final Study Report (FSR) are compared to the assessment and predictions made in the associated CAD. An interim analysis of 14 CAD/FSR cases conducted in a joint session of the S1 expert working group determined that the WOE supporting a Category 3 designation was in fact reasonably consistent with the actual 2yr rat study outcome in this initial cohort of completed cases. Case studies will illustrate scenarios where Drug Regulatory Agencies and Sponsors both agreed and disagreed with the predicted value of the 2yr rat study for the assessment of carcinogenicity. Insights that emerge from these and other case studies will shape the scope and regulatory perspective of any alternative WOE approach the S1 Expert Working Group implements in the S1 guidelines.

2569 Leveraging New Capabilities to Optimize the Framework of Carcinogenicity Evaluation
F. D. Sistare, Merck & Co., Kenilworth, NJ.

Experience gained over decades of pharmaceutical rodent carcinogenicity testing has triggered a more flexible testing strategy proposal that if adopted will reduce animal testing burdens for drug candidates recognizable devoid of human carcinogenic risk. New challenges surface under such a flexible potential future framework that could reduce 2 yr rat carcinogenicity testing well beyond the anticipated 40% target. Use of the Tox2Flash2 model, and specific case applications of other genetically engineered rodents is anticipated to rise, as the need for 2 yr mouse study data also wanes. One underutilized pragmatic approach expected to gain momentum is more routine and early application of mechanism-based tissue carcinogenomic biomarkers.
to reliably discriminate human irrelevant from human relevant tumorigenic mechanisms, both of which oppose early histologic risk factors of neoplasia. Such a flexible framework for carcinogenicity testing will encourage deeper mechanistic insights from early shorter term conventional animal testing, will leverage new knowledge of cancer genetics and molecular pathway interactions to support target risk evaluations, and encourage earlier adoption and implementation of other emerging capabilities and endpoints to inform off-target toxicity potential. Examples will be presented describing practical applications of: (1) a routine early carcinogenic screening strategy in pharmaceutical development to alert and de-risk dose human relevant sustained off-target AhR activation while differentially informing rodent specific PPARα, CAR, PXR driven tumor mechanisms; (2) a genetically engineered rodent model applied early to address and avoid a theoretical target based carcinogenic risk concern, and (3) a strategic decision informed by a cancer genetic database.

2570 Application of Next-Generation Sequencing Approaches to Enhance Carcinogenicity Assessment of Pharmaceuticals In Vivo

M. Fielden, Amgen, Thousand Oaks, CA.

In addition to considering pharmacology, genetic toxicology, and chronic toxicology studies in the assessment of carcinogenic risk, ICH S1 also encourages the use of new biomarkers and technologies to aid in the overall assessment. Additional endpoints may be needed to de-risk target-based concerns or to assess in vivo translation of in vitro hazards. Due to the genetic basis of cancer we have focused on advancing DNA sequencing-based methods to inform carcinogenic mechanisms, including effects on genomic instability, in vivo mutagenesis and subclonal selection as early measures of preneoplasia. We have demonstrated the ability of Duplex Sequencing to identify chemical-induced mutagenesis in vivo, which permits evaluation of somatic mutagenesis in routine toxicity studies. In addition, we evaluated urethane-treated Tg.rasH2 mice for somatic mutations across a number of endogenous genes including the human HRAS transgene. Mutations in human codon 61 of HRAS, a well-known cancer driver, were detected as small subclones in the most cancer predisposed tissue (lung). These findings indicate the ability of Duplex Sequencing to identify rare variants that reflect the earliest stages of neoplastic evolution prior to overt lung tumor formation in a human-relevant cancer gene merely weeks after exposure. Whole-exome sequencing has also been used to evaluate translocations, copy number variants and insertions/deletions, which are well-established hallmarks of cancer not otherwise informed by standard assays. These alternative weight of evidence approaches are expected to reduce the uncertainty around potential cancer risk factors to help support risk categorizations that realize the benefits of the proposed ICH S1 modifications.

2571 The Chronic Cancer Bioassay Is Frequently Conducted for Pesticides When It Is Not Always Needed to Protect Human Health

D. C. Wolff, Syngenta, Research Triangle Park, NC.

A systematic approach that evaluates and integrates mechanism-based knowledge with exposure consideration allows for hazard characterization that are scientifically defensible and appropriate for regulatory decision-making of crop protection products. Using a problem formulation based and exposure driven evaluation strategy enables public health protective decisions to be made without unnecessary use of animals in large scale and redundant studies. Using the knowledge accumulated from the intended use, pesticide indication, and class of chemistry of the proposed pesticide will focus the questions that need to be answered to protect human populations from cancer risk. Investigation of the metabolic profile and subclonal selection as early measures of preneoplasia. We have demonstrated the ability of Duplex Sequencing to identify chemical-induced mutagenesis in vivo, which permits evaluation of somatic mutagenesis in routine toxicity studies. In addition, we evaluated urethane-treated Tg.rasH2 mice for somatic mutations across a number of endogenous genes including the human HRAS transgene. Mutations in human codon 61 of HRAS, a well-known cancer driver, were detected as small subclones in the most cancer predisposed tissue (lung). These findings indicate the ability of Duplex Sequencing to identify rare variants that reflect the earliest stages of neoplastic evolution prior to overt lung tumor formation in a human-relevant cancer gene merely weeks after exposure. Whole-exome sequencing has also been used to evaluate translocations, copy number variants and insertions/deletions, which are well-established hallmarks of cancer not otherwise informed by standard assays. These alternative weight of evidence approaches are expected to reduce the uncertainty around potential cancer risk factors to help support risk categorizations that realize the benefits of the proposed ICH S1 modifications.

2572 The Role of Dynamic RNA Modifications in Environmental Response and Disease

F. Tyson, NIEHS, Research Triangle Park, NC.

This symposium will discuss how dynamic RNA modifications can interpret environmental stimuli/challenges and respond by altering gene regulation, biological pathways, and disease outcomes. Chemical modifications of proteins, DNA, and RNA nucleoside moieties appear to have critical roles in regulating gene expression. These chemical modifications are central to the field of functional RNA modifications and emerging evidence suggests these modifications have critical roles in basic biological processes. These include: embryonic stem cell differentiation, excitotoxic cell death, development, intergenerational inheritance of acquired traits, regulation of RNA stability, temperature adaptation, meiotic progression, and regulation of RNA-RNA and RNA-protein binding interactions. A small number of covalent RNA modifications have been studied extensively, and recent evidence suggests that other newly discovered RNA modifications have interesting biological and disease functions in mammals. Moreover, recent studies have identified N6-methyladenosine (m6A) sites in thousands of human mRNAs, suggesting that this modification may play a role in regulation of alternative splicing and gene expression. The impact of the environment on chemical modifications of RNA molecules (the epitranscriptome) in the development of adverse human health outcomes is relatively unexplored. Technology advances in recent years have accelerated the detection of RNA modifications, and the RNA Modification Database currently lists approximately 100 RNA modifications identified in eukaryotic cells. This database also reveals transfer and ribosomal RNA are heavily modified, and many of these same modifications occur in messenger RNA and non-coding RNAs (including long non-coding and microRNAs). The function of most of the modifications found in messenger and non-coding RNAs remains a mystery, despite their potential to influence RNA properties and functions, including RNA stability, trafficking, localization, activity (enzymatic, sensing, or regulatory), and interactions with other molecules. This session will bring together toxicologists with investigators in the emerging area of functional RNA modifications to discuss the state-of-the-science as well as to identify research opportunities to interrogate how environmental exposures impact this layer of cellular regulation. Questions this session will address include: Have technologies for assessing RNA modifications matured enough to apply them to investigate how environment agents and exposures impact the role of functional RNA modifications and contribute to adverse health outcomes? Does the latest research suggest diverse environmental exposures can modify functional RNA modifications and/or the readers, writers, and erasers of these modifications? Was evidence presented that suggested or confirmed that stressors can have impacts on phenotypes through RNA modification mediated mechanisms? How can toxicologists leverage knowledge about epitranscriptomics to develop new biomarkers for toxicity or targets for therapeutic intervention?

2573 RNA Methylation in Gene Expression Regulation

C. He. University of Chicago, Chicago, IL. Sponsor: J. Goodrich

Over 100 types of post-transcriptional RNA modifications have been identified in all kingdoms of life. We have discovered the first two RNA demethylases, FTO and ALKBH5, which catalyze oxidative demethylation of the most prevalent modifications of mammalian messenger RNA (mRNA) and other nuclear RNA, N6-methyladenosine (m6A). These findings indicate that dynamic RNA modifications could impact biological regulation analogous to the well-known DNA and histone chemical modifications. We have also characterized proteins that selectively recognize m6A-modified mRNA and affect the translation status and lifetime of the target mRNA, as well as molecular machines that deposit the m6A methylation on mRNA. Functional studies reveal m6A methylation as a fundamental mechanism to synchronize groups of functional RNA modifications and emerging evidence suggests these modifications have critical roles in basic biological processes. These include: embryonic stem cell differentiation, excitotoxic cell death, development, intergenerational inheritance of acquired traits, regulation of RNA stability, temperature adaptation, meiotic progression, and regulation of RNA-RNA and RNA-protein binding interactions. A small number of covalent RNA modifications have been studied extensively, and recent evidence suggests that other newly discovered RNA modifications have interesting biological and disease functions in mammals. Moreover, recent studies have identified N6-methyladenosine (m6A) sites in thousands of human mRNAs, suggesting that this modification may play a role in regulation of alternative splicing and gene expression. The impact of the environment on chemical modifications of RNA molecules (the epitranscriptome) in the development of adverse human health outcomes is relatively unexplored. Technology advances in recent years have accelerated the detection of RNA modifications, and the RNA Modification Database currently lists approximately 100 RNA modifications identified in eukaryotic cells. This database also reveals transfer and ribosomal RNA are heavily modified, and many of these same modifications occur in messenger RNA and non-coding RNAs (including long non-coding and microRNAs). The function of most of the modifications found in messenger and non-coding RNAs remains a mystery, despite their potential to influence RNA properties and functions, including RNA stability, trafficking, localization, activity (enzymatic, sensing, or regulatory), and interactions with other molecules. This session will bring together toxicologists with investigators in the emerging area of functional RNA modifications to discuss the state-of-the-science as well as to identify research opportunities to interrogate how environmental exposures impact this layer of cellular regulation. Questions this session will address include: Have technologies for assessing RNA modifications matured enough to apply them to investigate how environment agents and exposures impact the role of functional RNA modifications and contribute to adverse health outcomes? Does the latest research suggest diverse environmental exposures can modify functional RNA modifications and/or the readers, writers, and erasers of these modifications? Was evidence presented that suggested or confirmed that stressors can have impacts on phenotypes through RNA modification mediated mechanisms? How can toxicologists leverage knowledge about epitranscriptomics to develop new biomarkers for toxicity or targets for therapeutic intervention?
N6-methyladenosine (m6A) is an abundant, reversible chemical modification that regulates function and stability of many types of RNAs. We use biochemical and structural methods to elucidate how m6A marks are generated by RNA methyltransferases. We show that Metl3 and Metl14 cooperate to recognize and catalyze modification of target RNAs. Metl3 is the catalytically active enzyme, while Metl14 has a structural role to support the necessary conformation and to bind the substrate RNA. We also show that Metl16, another m6A writer, uses a distinct mechanism to recognize and bind the RNA substrates. We determine the molecular basis for how the RNA methyltransferases manifest distinct substrate specificities. Moreover, we show that a polypeptide in the catalytic domain of METTL16 can undergo a conformational change, and that it can act as an autoregulatory switch for the methyltransferase activity. Furthermore, we reveal how disease mutations of m6A writers lead to aberrant methyltransferase activity. Together, our study shows that each m6A writer enzyme has evolved to modify a specific set of RNAs, with controlled efficiency for the specific RNA/enzyme combination. Exposure to certain harmful chemicals such as arsenic has been shown to have an impact on the methylation levels of DNA and proteins, as well as changing intracellular SAM levels. Since our model of METTL16 activity directly links intracelular SAM levels to RNA methylation, our mechanistic studies may also provide insight into how certain environmental factors might have a widespread impact on the epitranscriptome.

Once deemed heretical, the idea of "inheritance of acquired characteristics" is now supported by increasing evidence from multiple species, including mammals. We showed that paternally acquired traits (e.g. metabolic disorders induced by high-fat diet, HFD) can be "memorized" in the sperm, encoded in the form of RNAs and RNA modifications, and transmit paternally acquired phenotypes to the offspring via shaping early embryo development. We previously discovered that sperm RNAs, particularly 30-40nt RNA fractions that enriched with tRNA-derived small RNAs (tsRNAs), can act as epigenetic factors in mediating intergenerational inheritance of acquired traits, e.g., paternal metabolic disorders and trauma induced stress phenotypes. Our latest research further showed that deletion of a mouse tRNA methyltransferase, Dnm2, abolished sperm tsRNA-mediated transmission of HFD-induced metabolic disorders to offspring. Dnm2 deletion prevented the elevation of RNA modifications (mSc, m2G) in sperm 30-40nt RNA fractions that are induced by HFD. Also, Dnm2 deletion altered the sperm small RNA expression profile, including levels of tsRNAs and tRNA-derived small RNAs (tsRNAs), which may resemble the presence in composing a sperm RNA-binding signature that is needed for paternal epigenetic memory. Finally, we showed that Dnm2-mediated mSc contributes to the secondary structure and biological properties of tsncRNAs, implicating sperm RNA modifications as an additional layer of paternal hereditary information.

A major adaptive cellular response to environmental stress is the formation of stress granules. Stress granules are RNA-protein assemblies that function, in part, by sequestering specific cellular mRNAs. However, the specific mRNAs that are targeted to stress granules are not fully understood. Here we show that diverse types of environment stress, including UV, heat shock, arsenite, and endoplasmic reticulum stress elicited by thapsigargin all induce the formation of stress granules that are enriched in m6A RNAs with the modified nucleotide N6-methyladenosine (m6A). Using a transcriptomic analysis of stress granules, we find that mRNA that lack m6A are largely excluded from stress granules, while the enrichment of mRNAs in stress granules is directly proportional to the number of m6A in an mRNA. The enrichment of m6A mRNA is seen in stress granules irrespective of the type of stress used to elicit stress granule formation. The stress granule-targeting effect of m6A is mediated by its binding to the YTHDF family of m6A-binding proteins. We find that YTHDF partition into stress granules elicted by UV, heat shock, arsenite, and endoplasmic reticulum stress. Furthermore, we find that the sequestration of m6A mRNAs results in their preferential translational suppression during stress. Moreover, the significance of m6A mRNAs and YTHDF mRNAs in stress granules is demonstrated by experiments in which we depleted either m6A or YTHDF proteins from cells. In these cells, stress granule formation was markedly impaired. Overall, these data reveal that a fundamental role of stress granules elicited by diverse toxic insults is to sequester m6A mRNAs and control their translation during and after stress. Our data support the idea that selective control of m6A mRNAs is critical for the proper control of the translational program during and after stress.

Epitranscriptomic signals regulate gene expression by altering RNA structure and stability, with some tRNA modifications directly linked to translational regulation. We used systems based approaches to demonstrate that prokaryotic and eukaryotic cells respond to stress and toxicants by enzymatically reprogramming the levels of modified nucleosides (5'-oxacytidyluridine (cm5OSU), 5'-methyl-5'-O-methyl-2'-G-methyluridine (cm5Gm)), and more) in tRNA, to generate unique epitranscriptomic signatures representing responses to specific toxicants. Further we demonstrated that stress induced changes in the levels of specific modified uridines and cytidines in the anticondon of tRNA translationally regulate codon-biased transcripts. Example systems from Saccharomyces cerevisiae, human cells and mice demonstrate that the absence of specific RNA modifications and the enzymes that catalyze their incorporation into tRNA corrupts the responses to DNA damage and reactive oxygen species (ROS). Notably, we developed a transgenic mouse that is deficient in the tRNA methyltransferase Alkbh8 which is required for the formation of S-methylthiocarbamoyluridine (mcm5SU) and mcm5Um on tRNA for selenocysteine. These modifications are utilized during the process of stop codon recoding to allow for the incorporation of selenocysteine into selenoproteins (i.e. glutathione peroxidases and thioredoxin reductases) that play critical roles in the detoxification of ROS. We have shown that Alkbh8/-/- cells have decreased levels of selenoproteins, are sensitized to damage by external agents (H2O2, rotenone and naphthalene) that promote an increase in ROS and that Alkbh8/-/- lung tissue has exposure induced pathologies. Further, to compensate for the epitranscriptomic deficiency, Alkbh8/-/- cells and lung tissue upregulate complimentary stress response and damage mitigation systems. Results from our Alkbh8/-/- mouse model highlight how tRNA epitranscriptomic systems are up-regulated in response to environmental stressors to protect cells and lung tissue. The broad impact of epitranscriptomic systems in toxicology is only beginning to be realized as they regulate gene expression and control the synthesis of stress response proteins. Further epitranscriptomic responses have the potential to be used as biomarkers of response or exploited for pharmaceutical applications.

Unexpected ocular findings in general toxicology studies represent a unique challenge in pharmaceutical drug development. Eye lesions are uniquely monitorable in this setting, often using the same techniques that are applied in clinical studies. This allows for detailed assessment of the dose response and onset of lesions as well as their functional impact. However, understanding the specialized grading scales and imaging modalities is key to interpreting these data. Additionally, many tissues of the eye, particularly the retina, are terminally differentiated and unable to regenerate following toxic insult. This makes the detection, characterization, and mechanistic understanding of ocular lesions caused by novel therapeutics of vital importance for an assessment of human risk prior to clinical trials. The objective of this session will be to focus on adverse ocular findings on general toxicology studies for non-ophthalmology products. The first presentation will focus on the common ocular assessments used on these studies and frequently observed ocular lesions. This will be followed by three case studies in which unexpected ocular findings were observed on general toxicology studies, with a focus on the sponsor’s investigative and regulatory strategy to address these findings. Finally, a speaker from the US FDA will provide a perspective on regulatory expectations for therapies with adverse ocular effects.

A major adaptive cellular response to environmental stress is the formation of stress granules. Stress granules are RNA-protein assemblies that function, in part, by sequestering specific cellular mRNAs. However, the specific mRNAs that are targeted to stress granules are not fully understood. Here we show that diverse types of environment stress, including UV, heat shock, arsenite, and endoplasmic reticulum stress elicited by thapsigargin all induce the formation of stress granules that are enriched in m6A RNAs with the modified nucleotide N6-methyladenosine (m6A). The broad impact of epitranscriptomic systems in toxicology is only beginning to be realized as they regulate gene expression and control the synthesis of stress response proteins. Further epitranscriptomic responses have the potential to be used as biomarkers of response or exploited for pharmaceutical applications.
While the eye represents arguably the most elegantly complex and specialized structure in the biologic system, its unique morphologic and physiologic features also puts it at risk. From front to back, the eye comprises a variety of metabolically-active tissues supported by a robust blood supply, with the retina maintaining one of the highest metabolic demands of any mammalian tissue. Despite autoregulatory mechanisms and immunologic specializations that aim to protect the eye from endogenous harm, it remains highly susceptible to exogenous toxicity caused by, among other agents, systemically-administered drugs. These toxicities may be just as variable in their presentations as the tissues comprising the eye, ranging from minor and irreversible irritations involving the ocular surface, to severe and vision-threatening effects involving the retina. Given these risks, thorough assessment of the eyes in preclinical animal models is essential and must be rigorous in order to ensure the safety and well-being of animals and human patients, alike. This lecture will introduce and discuss the requisite components of the ophthalmic examination in general toxicology studies, including the necessary instrumentation, techniques, and procedures that ensure a complete ocular assessment. The importance of precise and consistent semi-quantitative scoring (grading) of ocular findings will also be discussed. Finally, a survey of the most frequent and clinically relevant background findings in common laboratory species will be presented, with a focus on their impact on interpretation of toxicology findings.

Antibody drug conjugates (ADCs) are a promising class of cancer therapeutics that takes advantage of the antibody (Ab) specificity to target tumor cells and the strong potency of small molecule cytotoxic drugs. Despite early clinical success and marketing approvals of Adcetris® and Kadcyla®, the clinical development of this class of cancer therapeutics continues to be hindered by safety issues. The majority of the clinical safety data available is with microtubule inhibitor (MTI) containing ADCs, which include the auristatins monomethyl auristatin E (MMAE) and monomethyl auristatin F (MMAF), and the maytansine derivatives, DM1 and DM4. Myelosuppression and peripheral neuropathy are the most common clinical toxicities with MTIs as a consequence of targeting the rapidly dividing cells of the bone marrow and inhibiting axonal transport critical for the long projecting peripheral nerves, respectively. However, ocular toxicity is another challenging clinical safety issue with MTI containing ADCs and in some cases the dose limiting toxicity. The ocular toxicity in patients manifests as keratitis, blurry vision and dry eye, and is not consistently seen in nonclinical toxicity studies. The assessment of ocular toxicity with MTI ADCs and specific case examples of the nonclinical to clinical translatable ability will be discussed in this talk.

Ocular Toxicity with Microtubule Inhibitor Containing Antibody Drug Conjugates: Nonclinical to Clinical Translatability Case Examples

Lessons Learned in How to Manage Ocular Findings: A Case Study

Can We Panelize Seizure?
by inexperienced operators. Thus, confirmation of drug-induced seizure or seizure-like activity requires a follow-up electroencephalogram (EEG) study. Some progress has been made in in-life detection of seizure using automated video systems that record and analyze animal movements, looking for abnormalities. Nonetheless, it would be far preferable to have an earlier prediction of seizurogenic risk that could be used to eliminate liabilities early in discovery while there are still options in chemistry. Two approaches offer exciting opportunities. Microelectrode array is now able to detect seizurogenic signals in iPSC-derived cortical neural stem cells differentiated to electrically active cortical neurons. This offers great potential to screen for seizurogenic liability in an in vitro system. A second approach could be based on an understanding of the neuronal ion channels implicated in the seizurogenic response. There is clear evidence for the involvement of ion channels in seizure. Genetic studies have pointed to a role for voltage-gated sodium and potassium channels and the ligand-gated ion channels, GABA-A and nicotinic acetylcholine receptors. Pharmacologically, a number of ion channel modulators are known to be seizurogenic, such as Chlorpromazine. Recently, great progress has been made in developing these in vitro seizure models and in characterizing the ion channels both at the expression level and at the functional level. These data may provide the opportunity to panelize seizure by creating a panel of ion channel assays that predict seizure, linked to an in vitro assay, with the ultimate aim of eliminating compounds predicted to be associated with the pro-seizurogenic state. The regulatory community has great expertise and experience of how to shape such work for decision-making from lessons learned from implementation of similar approaches in derisking cardiovascular liability. This session will address the issue, the basic science, and the regulatory context. It is relevant to academia, industry, CROs, and regulators who wish to learn more about these exciting, new, and high-impact developments in drug discovery and development.

**2585 Seizure Liability in Drug Discovery and Development: Current State of Play**

J. Valentin, UCB, Braine-l’Alleud, Belgium.

Drug-induced convulsions or seizures are a serious, potentially life-threatening adverse drug reaction that can result in failure of drugs to be licensed for use, withdrawn from the market or labelled as such. Compounds associated with this liability span a wide variety of pharmacological classes and therapy areas, including many not targeted at the central nervous system. Assessing the risk of seizurogenic and non-seizurogenic liabilities in the drug discovery process using low-throughput, resource intensive in vivo behavioral models. For example, one known CNS active compound was associated in preclinical species with convulsions confirmed as being seizures. The overall risk assessment did allow to progress into Phase I clinical trials with appropriate safety monitoring (incl. EEG) but several adverse events (syncpe, clinically observable seizure, asymptomatic EEG spikes) were noted at exposures below where seizure was seen preclinically, halting the clinical trial. In a second example from a neuroscience project, candidate compounds induced convulsions in rodent and non-rodent species, at low exposure levels. All compounds inducing convulsions in vivo showed a strong inhibitory activity on GABA-A channels, whereas compounds with mild or no inhibitory effect did not induce seizures supporting the hypothesis of an off-target mechanism. In EEG experiments, convulsions were always preceded by premonitory clinical signs and abnormal EEG, confirming their CNS origin. The lead compounds in this project were discontinued. These examples illustrate how current approaches do not allow sufficient time to mitigate risk by influencing chemical design. Early identification using cheaper, higher throughput and predictive assays with lower animals and compound requirements would be preferable. Over the last decade, several assays that are compatible with the design-make-test-analyze cycle have become available. In silico, in vitro and in vivo assays may be combined in a rational step-wise cascade to allow more effective i) hazard detection and elimination in hit identification and lead optimization, ii) risk assessment on drug candidates taking into account the safety margin, therapeutic indication and patient population and iii) risk mitigation and management in clinical development with appropriate monitoring and rescue therapies.

**2586 Identification and Confirmation of Seizure Liability In Vivo: The Importance of Behavioral Monitoring and EEG Recording**

S. Authier, Citoxlab North America, Laval, QC, Canada.

Although it would be advantageous to identify seizure risk in the early phases of drug discovery, ideally using in vitro methodologies, currently this risk is generally first detected in in vivo studies later in the drug discovery process. The first indication of a potential seizure liability is often CNS clinical signs such as tremor or abnormal movements which may not result from seizure activity, in addition tonic-clonic convulsions can be incorrectly diagnosed by non-expert observers. To confirm the presence of drug-induced seizure, an electroencephalogram (EEG) study is required. In addition, due to the low frequency of such clinical observations in traditional toxicology studies, these events can often be missed in short term studies and are not detected until chronic studies much later in drug development. For these reasons, it is helpful to obtain a full description of behavioural findings when assessing seizure risk. One way this can be achieved is by using continuous video monitoring, ideally combined with EEG recordings so both sets of data can be fully integrated. Overall, the in vivo toxicity testing paradigm aims i) establish the exposure to effects relationship; ii) characterize the convulsions, iii) detect premonitory signs that could be monitored in clinical setting, and iv) assess the development of potential tolerance or sensitization after repeat dosing and underlying seizure liability mechanisms.

**2587 Development of Seizure Prediction Methods Using MEA System in Human iPSC-Derived Neurons**

I. Suzuki. Tohoku Institute of Technology, Tohoku, Japan. Sponsor: J. Pierson

Functional evaluation assays using multi-electrode array (MEAs) in cultured hiPSC-derived neurons are being developed to predict the convulsive potential of new drugs. Dose-dependent firing data of more than 20 convulsive drugs and non-convulsant drugs were obtained. A principal component analysis approach coupled with artificial intelligence (AI), convulsive and non-convulsive drugs were separated and classified using effective parameter sets. AI extracted 4096 feature quantities from the training set of image data of firing patterns; AI analysis of the MEA data from the test set provided accurate answers on drug name and concentration. Furthermore, a comparison of in vitro results with in vivo human ECoG convulsive responses, showed that the characteristic in vivo convulsive firing enhancement of the high gamma wave and beta wave was observed in in vitro hiPSC-derived neurons. Some caution should be used in the interpretation of hiPSC-derived data for predicting seizure in the clinical setting: are the test cells expressing the correct ion channels and signaling molecules to allow a phenotypic response? Also, how representative are these cells of adult neurons? Since data are usually derived from one or maybe two or three human donors with their individual genetic fingerprint, how general are the results for the broader population? Coupled with this, AI is an emerging technique with its own challenges; how well do we understand the underlying data processing and thus the interpretation? Despite these ongoing discussions, in summary our data show that MEA measurement of hiPSC-derived neurons coupled with our analysis methods appear to be effective for the prediction of convulsion toxicity and their mechanisms of action, as well as the comparison of convulsions induced in vivo.

**2588 Using Ion Channels to Panelize Seizure: Where Are We Up To?**

M. Morton. ApconIX, Alderley Edge, United Kingdom. Sponsor: J. Pierson

There is clear evidence for the involvement of ion channels in seizure. Genetic studies have pointed to a role for voltage-gated sodium and potassium channels and the ligand-gated ion channels, GABA-A and nicotinic acetylcholine receptors. Pharmacologically, a number of ion channel modulators are known to be seizurogenic such as Chlorpromazine. Should we therefore be looking to screen compounds in early discovery against a panel of ion channels, and what would this panel look like? Ion channel screening against a panel of ion channels has been successfully employed for decades to reduce cardiovascular safety liability. Routine screening against the cardiac potassium, sodium and calcium channels, and optimization of medicinal chemistry away from these liabilities, has reduced the number of drug withdrawals due to hERG/QT prolongation. Coupled with an informatics approach, screening for cardiovascular liability in entering a new paradigm with the advent of the comprehensive in vitro proarhythmic assessment (CiPA). Can the same approach be applied to reducing seizure liability? The challenges include the complexity of CNS pharmacology along with the more practical challenges of identifying drugs and non-convulsant drugs were obtained using MEAs. Using a principal component analysis approach coupled with artificial intelligence (AI), convulsive and non-convulsive drugs were separated and classified using effective parameter sets. AI extracted 4096 feature quantities from the training set of image data of firing patterns; AI analysis of the MEA data from the test set provided accurate answers on drug name and concentration. Furthermore, a comparison of in vitro results with in vivo human ECoG convulsive responses, showed that the characteristic in vivo convulsive firing enhancement of the high gamma wave and beta wave was observed in in vitro hiPSC-derived neurons. Some caution should be used in the interpretation of hiPSC-derived data for predicting seizure in the clinical setting: are the test cells expressing the correct ion channels and signaling molecules to allow a phenotypic response? Also, how representative are these cells of adult neurons? Since data are usually derived from one or maybe two or three human donors with their individual genetic fingerprint, how general are the results for the broader population? Coupled with this, AI is an emerging technique with its own challenges; how well do we understand the underlying data processing and thus the interpretation? Despite these ongoing discussions, in summary our data show that MEA measurement of hiPSC-derived neurons coupled with our analysis methods appear to be effective for the prediction of convulsion toxicity and their mechanisms of action, as well as the comparison of convulsions induced in vivo.
D. Mellon. US FDA, Silver Spring, MD. Sponsor: J. Pierson

Convulsions pose a major challenge in drug development and their observance in in vivo studies is often a limiting factor in preclinical results in humans. Kindled seizures occurring in repeat dose toxicology studies late in development present even greater challenges which can derail a development program. Current approaches are limited to careful monitoring and use of EEG studies to understand risk; however, given potential for low frequency events, additional alternative assessments continue to assist in evaluation. Panelizing seizure risk early in development could identify compounds with greater risk early and avoid wasting resources. These assays could also have utility at later stages in development to help a weight-of-evidence approach in assessing the implications for human risk assessment of convulsions observed in toxicology studies and how to compare relative risk across different therapeutic options. However, we argue that the best way to avoid being able to use these approaches for regulatory decision making. The major challenges are in validating the predictivity of the available assessment tools which will require identification of appropriate endpoints and thresholds of concern derived from these data, standardizing methodologies, and building the database of in vitro and in vivo data to demonstrate reliability in their predictive capacity to inform the overall risk-benefit profile. Specifically, there needs to be scientific consensus on the channels involved in seizure and on how to measure the effect of potential new drugs on the function of these ion channels. Based on experience with panelizing cardiac arrhythmia via the GIPA, correlation of ion channel function with associated phenotype in vitro coupled with methods of data capture and processing will provide confidence in moving these methods forward into the regulatory framework.

A. Vale. University of Birmingham, United Kingdom.

Nerve agents are chemically related to organophosphorus insecticides and have a similar mechanism of toxicity, but their human acute toxicity is considerably greater, particularly via the dermal route. They act by inhibiting the enzyme acetylcholinesterase (AChE) which is responsible for the deactivation of acetylcholine (ACh) at neuromuscular junctions and at synapses in the central and peripheral nervous systems. In addition, the process of "aging" results in a monoalkyl product which does not reactivate spontaneously and cannot be reactivated by pyridinium oximes, such as pralidoxime and obidoxime. Nerve agents were employed most recently in an attack on Khan Sheikhoun, Syria, in April 2017. VX was used as a weapon of assassination on February 13, 2017, when Kim Jong-nam, was killed at Kuala Lumpur International Airport. In Salisbury, England, on March 4, 2018, Sergei Skripal, his daughter Yulia, and a policeman investigating the incident were severely poisoned following exposure to a Novichok agent. Subsequently, on June 30, 2018, two more individuals were severely poisoned with the same Novichok agent, one of whom died. All these releases indicate that countries and their clinicians must be prepared adequately to treat casualties optimally from nerve agent exposure. This requires an understanding of the mechanisms of toxicity of these agents, the factors that influence their clinical impact, and knowledge of potential treatments. Although the signs and symptoms manifested by exposed individuals will aid diagnosis, reliable point-of-care diagnostic systems will expedite triage and the application of appropriate medical countermeasures. Most of these systems are based on measurement of acetyl- or butyrylcholinesterase activity, but more recently an easy-to-use lateral flow assay has been developed that can be used for both rapid point-of-care diagnosis, as well as for detection of submicrogram amounts of nerve agents in/on various matrices. However, a useful verification of an exposure requires a variety of specialized techniques, and the utility of these methods will be exemplified by the analysis of various samples from the Syrian Arab Republic conflict in April 2013. Much research is underway to improve the current treatment regimens, which include an anticholinergic drug (e.g., atropine) to antagonize the effects of excess ACh at muscarinic effector sites, the use of an oxime (e.g., pralidoxime, obidoxime, and HI-6) to reactivate nerve agent-inhibited AChE, and a benzodiazepine to prevent or stop nerve agent-induced seizures. Four innovative treatment approaches will be described during the session. First, the development of catalytic scavengers: multiple candidate enzymes on differential expression levels have been expressed in a cell line coupled with a single enzyme capable of catalyzing the hydrolysis of a broad spectrum of organophosphorus (OP) compounds into nontoxic products. The most promising candidate enzyme platform is the bacterially produced recombinant variant of organophosphorus hydrolase from B. diminuta. In vivo studies, two different organo-phosphorus hydrolase variants were capable of providing protection against at least 2 x LD50s of all of the OPs tested. Second, a series of novel substituted phenoxylkyl pyridinium oximes have been produced, which reduce brain AChE inhibition in rats treated with high-dose challenges of OP compounds. These novel oximes also have shortened the time to cessation of OP-induced seizure-like behavior on the day of OP challenge and have reduced neurodegeneration observed four days after the challenge by such neural markers as NeuN. These oximes when delivered intramuscularly show a high ability to provide 24-hour survival from lethal OP dosages and they have a half-life of 2.5 hours or greater in the blood stream of the rat, and therefore have promising pharmacokinetics. Third, the use of the bispyridinium non-oxime compound MB327 increased the survival of rats poisoned with soman, without reactivation of AChE. Moreover, it has been shown in human and rodent muscle tissue that paralysis of the respiratory muscles could be restored partially by MB327. In addition, MB327 and several structurally analogous compounds were able to restore function of nicotinic receptors (Torpedo californica muscle-type and human α7 subtype) after desensitization (demonstrated with electrophysiological techniques using patch clamp and SSM-based electrophysiology). Moreover, molecular modeling allowed identification of a new allosteric binding site close to the transmembrane domain of the nicotinic receptor. From these data, it may be concluded that by using MB327 and its analogues as a template, new structures with improved binding properties may be able to antagonize paralysis of blocked muscle function, without reactivation of inhibited AChE. Fourth, improvement of nerve agent elimination by small molecule scavengers might further contribute a beneficial effect. Indeed, modified cycloexetrins are able to bind the highly toxic (-)-isomere of GF and calixarenes are able to enhance degradation of VX by a factor of 3500.
Poisoning by organophosphate (OP) anticholinesterases can result in a variety of signs of toxicity including seizures which, if prolonged, can lead to permanent brain damage. An important therapeutic need to combat OP poisoning has long been a brain-penetrating reactivator of inhibited acetylcholinesterase (AChE) that could assist in preventing or attenuating the seizure-induced damage. Because the typical pyridinium oxime reactivators, such as 2-PAM and HI-6, bear a permanent positive charge, they are not effective at reversing brain AChE inhibition and promoting neuroprotection because of their very limited ability to cross the blood-brain barrier. Several laboratories have pursued strategies to allow reactivators to enter the brain through either non-oxime structures or modified oxime structures, and some of these strategies have met with success. Our laboratories have developed a platform of novel substituted phenoxyalkyl pyridinium oximes that have catalytic activity. Formulation of the enzymes to promote circulatory stability and brain penetration of the enzymes to provide protection against all G- and V-type OP nerve agents. The most promising candidate enzyme platform is the bacterially produced recombinant variant of organophosphorus hydrolase (OPH) from B. diminuta. In vivo protective efficacy of candidate OPH scavengers as prophylactics was tested in guinea pigs by administering the enzyme via a carotid catheter (iv), followed 20 minutes later by subcutaneous injection of increasing doses of the OP nerve agents GA, GB, GD, GF, VX, VR, or VM. A stage-wise, adaptive dosing experimental design was used to determine the median lethal dose (LD50) of each OP in the context of enzyme prophylaxis. We report that a combination of two different OPH variants, administered at 5 mg/kg of each enzyme, is capable of providing protection against at least 2 LD50 of the OP compound tested. The results indicate that broad spectrum prophylactic protection against OP intoxication can be provided with a cocktail of two different catalytic scavengers with appropriate catalytic activity. Formulation of the enzymes to promote circulatory stability will also be discussed. This work was supported by the NIH CounterACT Center of Excellence grant USA5 NS058183 (to D.M.C.) and by the Defense Threat Reduction Agency-Joint Science and Technology Office, Medical S&T Division.

Electronic cigarettes (e-cigs) are vehicles for inhaled delivery of nicotine and are considered by some to be smoking cessation aid devices, although they are not approved by US FDA for cessation treatment, nor even considered as nicotine replacement therapy (NRT). The benefits of e-cigs as nicotine replacement vehicles are countered by an expanding body of knowledge regarding potential health hazards and social consequences. E-cig aerosols have a unique physical and chemical composition that is different from that of cigarette smoke, although both aerosols contain nicotine and other similar toxicants. At present, there are very limited regulatory or legal processes overseeing the production and sales of e-cig devices. Thus, the general safety of e-cigs regarding human health is still a matter of controversy. According to the CDC, e-cig use among high school students increased by more than 300% between 2013 and 2014, and its use has continued to increase. The 2016 Surgeon General’s report labeled e-cig use among adolescents and young adults a major public and societal health concern. The public perception of e-cigs as a healthier alternative to conventional cigarettes has led to the recent rise of e-cig use among youth and young adults, including women of childbearing age. Although research is emerging around e-cigs in general, there continues to be a lack of scientific evidence regarding the safety and risks of e-cig use on maternal and fetal health; however, adverse health effects of nicotine on maternal and fetal outcomes are well documented. In the US, more than 10% of women smoke during pregnancy, and recent national surveys show that this proportion is similar for the use of e-cig devices. Controversy, however, over e-cig use during pregnancy is being hotly debated between US and UK regulators. Currently, there are no guidelines for use of e-cigs during pregnancy. This highlights the urgent need to bridge the clinical and scientific knowledge gap related to e-cig use during pregnancy. Whether e-cig use during pregnancy is safer and represents a better risk-to-benefit ratio for the developing fetus than conventional cigarettes is unclear due to lack of studies. This session provides a unique focus on the knowns and unknowns of e-cig use during pregnancy, including ethical and societal implications. A panel discussion incorporating both US and UK basic research and policy frameworks will represent a strong base for discussing whether e-cig use could be a reasonable alternative for pregnant smokers who are otherwise unable to quit.
Electronic cigarettes or Electronic Nicotine Delivery Systems (ENDS) are widely available in almost unlimited variety, including different flavors, nicotine concentrations, propylene glycol and glycerin ratios, and battery options. With finalization of the ‘deeming’ rule on August 8, 2016, US FDA Center for Tobacco Products (CTP) regulates products that meet the regulatory definition of a tobacco product, including ENDS. Tobacco product regulation uses a public health standard – not the traditional ‘safety and efficacy’ standard used for other US FDA approved products. This public health standard requires US FDA to consider the impact of any tobacco product regulatory decision on the entire population – including current tobacco users, former users, users who may be trying to quit, nonusers, and youth and other vulnerable populations. Although current evidence suggests that ENDS may be less harmful than cigarettes for smokers who completely switch, the health effects are not well characterized and long-term data are not available. The health risks associated with ENDS are likely dependent on the specific device or e-liquid being used and on user behavior. There are limited data on the chemical constituents in the aerosols and the effects of acute/short-term exposure. Additionally, the effects of repeated inhalation of aerosolized chemicals, including propylene glycol, glycerin, and flavorings is unknown. Nicotine is known to have cardiovascular effects (increasing heart rate and blood pressure) and adverse impacts on maternal and fetal health during pregnancy including an adverse impact on the developing fetal brain. There is no amount of nicotine exposure that is considered safe during pregnancy. US FDA is interested in understanding the short and long-term health effects of ENDS use in both users and non-users of tobacco. Additional information will better inform the development of policy options and assist in evaluation of the impact of US FDA’s regulatory efforts.

Electronic Nicotine Delivery Systems in Context: The US FDA Perspective

Application of In Vitro Approaches for the Assessment of Next-Generation Tobacco and Nicotine Products: A Tobacco Company Perspective

There has been a significant increase in the use of next generation tobacco and nicotine products (NGPs), including e-cigarettes. Developing toxicological screens for consumer safety across the wide range of e-cigarette devices and liquids has become particularly important. The use of in vitro assays, modelling key tobacco-disease related endpoints may be suitable for NGP assessment. We will present the challenges and opportunities offered using in vitro approaches. Cellular exposure and test article generation principles will be outlined, in particular exploring the generation, dilution and delivery of aerosols to in vitro cellular systems, and exposure considerations. A number of assays will be explored including classical in vitro toxicological assessing mutagenicity and cytotoxicity, showing greatly reduced responses from NGPs relative to cigarettes. Human cellular-based in vitro assays incorporating continuous cell lines to more complex organotypic reconstituted tissue systems, integrating adverse outcome pathways and next generation technology will be presented. Data from in vitro can support the risk assessment of e-cigarettes as part of a larger weight-of-evidence and reinforce the potential of e-cigarettes to play an important role in tobacco harm reduction. This is particularly needed in the context of pregnancy where women are unable to quit smoking.

E-cigarettes in Pregnancy: Current Evidence and Recommendations for Practice in the United Kingdom
F. Bates. The Lullaby Trust, London, United Kingdom. Sponsor: A. Noel

In the United Kingdom (UK) about 2.9 million people use electronic cigarettes (e-cigs, vapes, and electronic nicotine delivery systems [ENDS]) for recreational purposes or as a smoking cessation aid. However, the public health community remains divided concerning the appropriateness of endorsing devices whose safety and efficacy for smoking cessation remain unclear; thus, ethical dilemmas arise concerning product safety, efficacy for smoking cessation and reduction, use among adult non-smokers, use among youth, use in public places and marketing. Perhaps one of the most challenging current ethical quandaries is the use of e-cigs during pregnancy. While pregnancy provides motivation for women to quit smoking, in 2016 in England, for example, there was only a 0.1% decrease in the prevalence of women who smoked during their pregnancy. The health effects related to maternal tobacco smoking have been widely studied and reported, whereas the evidence of short- and long-term effects of inhaled e-cig aerosols on pregnancy outcomes and on the health of offspring is largely unknown. In recent years e-cigs have become the most popular aid for smoking cessation in the UK and a significant proportion (16%) of pregnant women report using them during pregnancy. Due to these patterns of use and remaining challenges relating to reducing smoking in pregnancy, a multi-agency group comprises of some of the main health professional and research organizations, along with health charities and mother and baby organizations in England (the Smoking in Pregnancy Challenge Group) have developed practical guidance on vaping during pregnancy. This proposes a positive policy framework related to e-cig use during pregnancy for women who cannot quit smoking. Here, we will discuss the current evidence and recommendations for practice in the UK.

Lessons Learned about Prenatal E-cigarette Exposure from In Utero Exposures in Animal Models
J. Zelikoff. New York University School of Medicine, Tuxedo Park, NY.

Recent epidemiological data indicate that the popularity of electronic cigarettes (e-cigarettes), and consequently nicotine use, is rising in both adolescent and adult populations. As nicotine is a known developmental neurotoxin, these products present a potential threat for those exposed during early life stages. Despite this, few studies have evaluated the toxicity of e-cigarettes on the developing central nervous system (CNS) or on reproductive outcomes of the impacted offspring. This presentation will focus on the effects of early life exposure to e-cig aerosols with and without nicotine on neurdopment and later life behavior, as well as alterations on male offspring reproductive function. In addition, we will discuss the effects of maternal e-cig exposure with and without nicotine on adverse obstetric outcomes including birth weight and pregnancy duration. This presentation will lay toxicological groundwork demonstrating the potential public health threat of e-cigarettes for the developing fetus and offspring.
Extensive efforts in research and development have led to extraordinary advances in nanoscience, nanotechnology, and the utility of nanomaterials. Uses of nanomaterials range from structural improvements, to building materials, to improvement in medical devices and drug delivery. As a result, there has been an increase in the potential for human exposure to nanomaterials not only inadvertently in occupational settings, but also in consumers and patients that utilize nanomaterials. Multiwalled carbon nanotubes (MWCNT) are a class of nanomaterials used for a variety of applications including structural enhancement of building materials and sports equipment, and for improvement of electrical and thermal conductivity for electronics. Animal studies have largely focused on the health effects following pulmonary exposure in rodent models. Many of these studies have demonstrated the occurrence of pulmonary inflammation associated with fibrotic changes in the airways. However, the majority of these studies investigated pulmonary exposure at dose levels that are significantly higher than occupational exposure levels.

Recent studies have also demonstrated that pulmonary exposure to carbon nanotubes can result in systemic effects (cardiovascular changes and immunotoxicity), including increased expression of inflammatory cytokines genes in splenic lymphocytes in rats. These findings suggest that carbon nanotubes could target the immune system and raise the concern that low-level exposure may impact host resistance to infections or development of neoplastic diseases or increase susceptibility to allergy or autoimmune diseases. To address this issue, a consortium of academic and federal scientists initiated an integrated approach to investigate the toxicity of low-level occupationally relevant exposures to a representative high-purity “long and thin” aggregated MWCNT. Characterization of this MWCNT shows that it aggregates into micron-sized “cotton ball” structures that morphologically appear similar to MWCNTs sampled in the workplace. Key features of the approach were the well-characterized, GLP-compliant inhalation exposure system used for treatment of the rats and the partnership between the federal and academic laboratories assessing different models of impacts of the exposure on the immune system. Importantly, all of the immunotoxicity studies that will be discussed in this session were obtained from the same exposure cohorts, thereby enhancing the ability to integrate results across all studies and participating laboratories. The session will identify the occupational exposures to MWCNT, put the experimental work into a human-relevant context, and then highlight the complementary approaches undertaken by the different groups to characterize the effects of MWCNT on innate and adaptive immune responses following low-dose pulmonary inhalation exposures.

Inhalation exposure to MWCNT has been shown to exacerbate lung inflammation in rodent models of pre-existing allergic lung disease. However, to date no studies have addressed the effect of allergen post-exposure following inhalation of occupationally relevant doses of MWCNT. Male B6C3F1/N mice were exposed by whole body inhalation for 6 hours a day, 5 days a week, for 4 weeks to 0.06, 0.2 and 0.6 mg/m³ of MWCNTs. Mice then received 25 μg of HDM by intranasal aspiration 6 times over 3 weeks. Mice were necropsied at 3 and 30 days after the final HDM dose to evaluate changes in cell differential counts and cytokines in bronchoalveolar lavage fluid (BALF), IgE in serum and lung pathology. MWCNT exposure reduced TH2 immune responses 3 days after HDM post-exposure as evidenced by reduced eosinophils and IL-5 in BALF, reduced airway mucus cell metaplasia and reduced serum IgE. However, inflammatory lesions around small airway and vessels were only observed 3 days after HDM allergen in mice exposed to MWCNTs. Moreover, pro-fibrotic cytokines (IL-1β and TGF-ß1) and airway fibrosis were increased at 30 days by MWCNT exposure in a dose-dependent manner with or without HDM allergen post-exposure. In conclusion, inhaled MWCNTs reduced TH2 pulmonary immune responses to allergen in mice but caused pro-fibrotic events regardless of allergen post-exposure.
BHV-0223 is a novel 40 mg rapidly sublingually disintegrating (Zydex™) formulation of riluzole, bioequivalent to conventional riluzole 50 mg oral tablets, that offers a lower-dose treatment option for ALS and potentially less risk of liver toxicity. In patients on oral riluzole, approximately 50% experience alanine transaminase (ALT) levels above upper limit of normal (ULN), 8% above 3x ULN, and 2% above 5x ULN. To quantitatively and mechanistically compare the liver toxicity potential of oral riluzole versus BHV-0223, combining clinical and mechanistic in vitro data, using DILIsym®. DILIsym® (DILIsym Services, Research Triangle Park, NC) is a validated multi-scale computational model that supports evaluation of liver toxicity risks. BHV-0223 (40 mg BID) and oral riluzole (50 mg BID) were simulated by combining physiologically based pharmacokinetic modeling with mechanistic liver toxicity parameters derived from in vitro assays. Frequencies of ALT elevations were predicted in the simulated populations (SimPops). In the SimPops analysis, ALT >3x ULN was observed in 3.9% (1/285) versus 1.4% (4/285) of individuals with oral riluzole and sublingual BHV-0223, respectively. The validity of the DILIsym® representation of riluzole and assumptions is supported by its ability to predict rates of ALT elevations for oral riluzole comparable to that observed in clinical data. Combining a mechanistic, quantitative representation of hepatotoxicity with inter-individual variability in both susceptibility and liver exposure suggests that sublingual BHV-0223 confers diminished rates of liver toxicity compared to oral tablets of riluzole, consistent with having a lower overall dose of riluzole and bypassing first-pass liver metabolism.

With the surge of technology and continuing improvement of assays for better testing, scientists are increasingly in a position to ask whether or not to adopt new technologies. The lure of increased sensitivity and specificity, often accompanied by large price tags, put into conflict the scientists’ responsibility to contain costs and their obligation to make use of the best tools available. In this work, we present a visualization tool to help scientists swiftly evaluate the worth of new assays and means to improve the speed and quality of their decisions on whether or not to adopt them. Since each parameter (x) relevant to use of a toxicity test (prevalence, sensitivity and specificity) has a value between 0 and 1, the intervals [0, x] and [x, 1] define a partition on [0, 1]. The proper arrangement of these partitions can be used to define areas in [0, 1] x [0, 1] cross-space that partitions the cross-space into a set of areas. Our analogy is a square plot of land subdivided into smaller lots. We call the resultant graphic a real estate diagram. As an example, the experience in predicting human clinical Thorough QT (TQT) studies was recently described (Park et al., 2013). The data for a total of 204 compounds could be divided into chronological sets: we illustrate 2 blocks of two years 2005–2006 and 2011–2012. In the first block 13 of 29 submitted compounds had positive TQT studies; in the second block the prevalence was 4 of 42. In another study (Park et al., 2018) the hERG channel patch-clamp assay used in predicting TQT outcome had a sensitivity of 0.64 and specificity of 0.72. The test was considered positive if the inhibitory concentration for 50% block (IC50) was within 100x the clinical test concentration. Real estate diagrams were constructed to yield insight into the PPV and NPV of the TQT prediction. The structure of the real estate diagrams clearly illustrates that as prevalence has fallen increasing assay sensitivity will have a trivial effect on PPV and NPV. In the NPV case, because of the very low prevalence, it would be better to base decisions on NPV and cease expending resources on improving the assay’s sensitivity or specificity. As the scientists managing toxicity testing, toxicologists will be called upon to question whether their safety assessments regarding specific toxicities should be based on their assay’s positive or negative predictive value, the real estate diagram is a useful tool in making that assessment. References: Park, E., et al., (2013). International Journal of Cardiology, 168(5), 4975–4976. Park, E., et al. (2018). British Journal of Pharmacology, 175(4), 606–617.

The 2015 US FDA’s guidance for industry provides permissible daily intake (PDE) limits for elemental impurities through oral, parenteral and inhalation routes of exposure in human drug products but not for dermal or other dosing routes. The risk evaluation for elemental impurities via the transdermal delivery routes have not been explored. This evaluation focused on systematic bioavailability of 9 metal (As, Cd, Pb, Hg, Co, Ni, V, Pt and Pt) impurities. In each case, a transdermal PDE was extrapolated from the oral PDEs derived in 2015 US FDA’s Q3D Elemental Impurities Guidance for Industry (https://www.fda.gov/downloads/drugs/guidances/ucm371025.pdf). The transdermal bioavailability values derived are based upon a systematic review and evaluation of primary and secondary sources of literature. In considering transdermal PDE determination, we assumed similar systemic toxicity as from the oral route. We focused on the bioavailability of the metals as the potential toxicity to systemic targets. Estimates of metal bioavailability on skin ranged from 0.1 to 5% with a useful default assumption of 0.1% dermal absorption, if presented as dry particulate (dust) or 1% for liquid medium. However, some of the reviewed metals have exhibited toxicity on the skin or dermal hypersensitivity reactions which have merited consideration in setting dermal PDEs. This approach is compatible with Q3D guidance Option 3: Finished Product Analysis, in which the finished product (rather than individual components) can be evaluated against a PDE, which considers the bioavailability of the impurity within the product. The results of this risk evaluation yielded the transdermal PDEs involving pharmacokinetic adjustment of the oral PDE provided by US FDA 2015. The ratio of the oral to dermal bioavailability was calculated and multiplied by the oral PDE to derive the dermal for each element. Our analysis calculated the transdermal PDEs (ug/day) for each elemental impurity were: As (15), Cd (50), Pb (500), Hg (300), Co (50), Ni (200), V (1000), Pt (100) and Pt (100). PDE adjustment is also considered with respect to whether the elemental impurity is known to produce direct toxicity or hypersensitivity to the skin, in which case that becomes a key consideration in developing a dermal PDE for that impurity. Disclaimer: Authors declare that views expressed are of their own and have no conflict of interest of any nature or kind.

Off-target Activities of Troglitazone and Rosiglitazone in Tox21/ToxCast In Vitro Tests and Comparison of the Results with Systematically Reviewed In Vivo Animal Data and Human Adverse Events from Pharmacovigilance Databases Using Evidence-Based Approaches

K. Tsaioun1, S. Bandhakavi2, G. E. Vist1, R. Wright1, J. Mehta1, A. Abdelazziz1, R. Ram1, B. Harduy7, T. Hartung4, and H. Dirven1, 1Johns Hopkins University, Baltimore, MD; 2Northeastern University, Boston, MA; 3Norwegian Institute of Public Health, Oslo, Norway; 4KEVA Health, Cambridge, MA; 5Amazon, Munich, Germany; 6Safer Medicines Trust, London, United Kingdom; 7DiagnosticsConnect, Basel, Switzerland; and 8Center for Alternatives to Animal Testing (CAAT) at Johns Hopkins University, Baltimore, MD.

In order to study the ability of in vitro data to predict the hazards of chemicals, we analyzed the in vitro data from US EPA ToxCast™ (ToxCast) program of Troglitazone and Rosiglitazone, and compared it with the profile obtained from a systematic literature review on the results of standard toxicity tests in experimental animals and findings in adverse events (pharmacovigilance) database. Both Troglitazone and Rosiglitazone are considered as drugs: Troglitazone was withdrawn from the market because of drug-induced liver injury (DILI), while Rosiglitazone was linked to less DILI concern. Biological off-target activity analysis using ToxCast in vitro tests, normalized to the human C50 values, showed that Troglitazone had biological off-target activity in 50% more assays compared to Rosiglitazone. A protocol-driven systematic literature review of liver-associated effects of the 2 drugs in dogs, mice, rats, non-human primates and randomized human clinical trials was performed to serve as a comparator. In total after reviewing 6,805 studies, 105 abstracts for Troglitazone and 175 studies for Rosiglitazone were included for full-text review, following which the data was extracted from the included papers using a standardized form. A profile of adverse liver effects of the 2 drugs in humans and animal models will be presented. To incorporate the real-world data on frequencies of adverse effects in patients, the WHO Vigibase pharmacovigilance dataset was analyzed for DILIs events upon treatment with
the 2 drugs and a profile of reported MedDRA terms will be presented. More liver-specific adverse effects were recorded for Trogilitazone compared to Rosiglitazone. Results of these 3 data streams will be presented. Challenges with using evidence-based methods in this project and some solutions that the EBTC workgroup has found will be described.

2612 Supportive Care for Animals on Toxicology Studies: An Institutional Benchmark Survey

Abbvie, North Chicago, IL; Janssen, Spring House, PA; Bristol-Myers Squibb Co, New Brunswick, NJ; Covance, Madison, WI; Charles River Laboratories, Wilmington, MA; Boehringer-Ingelheim, Ridgefield, CT; and Amgen Research, South San Francisco, CA.

Contract Research Organizations (CROs) conducting toxicity studies on behalf of pharmaceutical sponsors routinely provide supportive care for animals on study. There is currently limited industry guidance on the definition and strategies for administering supportive care in toxicity studies. The 3Rs Leadership Group of the International Consortium for Innovation and Quality in Pharmaceutical Development (IQ Consortium) created a CRO Outreach Working Group (WG) at the beginning of 2015. One of the 2018 goals of this WG was to conduct a survey to better understand the scope of the information that is shared between pharmaceutical sponsors and CRO partners with regards to the decision process about the provision of supportive care. The survey also aimed to define supportive care strategies, identify alternative options and understand regulatory requirements for supportive care. The survey was distributed to the 3Rs Leadership Group of the IQ Consortium, and to several CRO partners, representing 35 organizations as potential respondents. Feedback on the survey questions was collected and analyzed to benchmark current practices and a potential path forward. The results of the survey form 13 respondents indicated the need to provide adequate information at the drafting stage of study design and several potential methods for future communication improvement between the pharmaceutical sponsors and CROs. Areas of enhancements were identified including greater consistency in the inclusion of sponsor veterinarians on project teams for externalized studies, the timing of initiation of supportive care, and a lack of sharing of regulatory feedback outcomes. Suggested best practices include having CRO veterinary staff involved in initial study planning meetings, creating a plan of action for veterinary care prior to study start, enhancing information sharing regarding expected toxicities from previous study findings, and sharing CRO guidelines on humane endpoints and animal welfare standards. Improved communication regarding supportive care will pave the way for enhanced 3Rs initiatives, refining the existing animal care paradigm and helping to ensure the most ethical toxicity study designs.

2613 New Opportunities for a Psychoactive Psychilysin in Neuropsychopharmacological Clinical Disorders

P. A. Duffy, S. Stansfield, G. Healing, R. Knight, and R. A. Roberts.

1ApconiX, Alderley Edge, United Kingdom; 2COMPASS Pathways, London, United Kingdom; and 3University of Birmingham, Birmingham, United Kingdom.

Abnormalities of neuropsychopharmacological function of the Central Nervous System (CNS) can result in morbidity and disease that have a huge impact on society as well as the wellbeing of the individual. As the CNS plays a central role not just in the field of psychiatry but also in the physiological control of many bodily functions, such disorders have the capacity to be manifest widely across different fields of medicine. Basic and clinical research into neuropsychopharmacological disease is ongoing within academia and the pharmaceutical industry but there is still an unmet medical need in many areas. What is becoming increasingly clear is that some previously researched pharmacology and drugs may present opportunities yet to be realised. The psychoactive drug psilocybin is currently under clinical development for potential benefit in treatment resistant depression. The compound, originally derived from a range of mushrooms including Psilocybe species, has been used recreationally and spiritually for hundreds of years. Additionally, there have been limited clinical studies in the psychiatric field in the 1960s. Although humans have been exposed to psilocybin over many decades, either illicitly or as an active agent in many clinical trials, no formal good laboratory practice (GLP) safety studies have ever been conducted under its safety. To supplement existing published information on the effects of psilocybin in animals and humans, we performed to GLP a hERG assay, a battery of genetic toxicity studies and an extended single dose study in rats at maximum tolerated dose (MTD). Unlike the development of a new chemical entity, the purpose was not to produce a dose response curve and then delineate a “safe” clinical dose. Rather, it was to confirm, under GLP, that we understood the toxicology in relation to previously published non-GLP data from experiments and clinical trials and to establish that there were no unreported toxicities that needed to be taken into consideration. Psilocybin was shown to have low potency interaction with the hERG channel (minimal effect at 1000µM and no effect at 100µM at a membrane potential of -60mV). It was also shown to produce a range of effects in rats that were entirely consistent with previously reported effects in animals and humans. This toxicology package filled significant gaps in the existing information in the literature and supported progression to clinical trials in treatment resistant depression.

2614 Functional, Histologic and Ultrastructural Assessment of Novel Optical Coherence Tomography Findings in the Cynomolgus Monkey

1Genentech, Inc., South San Francisco, CA; 2Ocular Services On Demand, Madison, WI; and 3University of Wisconsin-Madison, Madison, WI.

During development of four novel intravitreal therapeutics in the Cynomolgus monkey, optical coherence tomography (OCT) in the 24hr post-dose period identified two novel OCT findings not previously observed or reported in association with intravitreal (IVT) dosing. The first finding was a sub-foveal hyper-reflective band (HRB) in the space between the EZ line and RPE. The second was a hyper-reflective line at the junction of the photoreceptor outer segments (POS) and the retinal pigment epithelium (RPE), either isolated or peripheral to areas of retinal detachment, and not limited to the fovea. To further characterize these OCT findings and better understand the potential for translation and human risk, a study was undertaken in the non-human primate. Eight Cynomolgus monkeys were dosed bilaterally via ITV injection with a 100µl high osmolality vehicle previously identified as producing these OCT findings; or pegaptanib sodium, a clinically well-tolerated, large volume IVT injection. Following dosing, OCT was conducted to establish the presence and character of any changes in OCT from baseline, followed immediately by multi-focal electrophysiology (mERG), to help understand the functional consequence of these OCT findings. The animals were then euthanized, perfusion fixed and the eyes were processed for ultrastructural examination. OCT findings of HRB and HFL lines were observed in 5/8 eyes treated with high osmolality vehicle and 1/8 eyes treated with pegaptanib sodium. HFL were observed in 6/8 eyes treated with high osmolality vehicle, but were not identified in animals administered pegaptanib sodium. Functional consequences, manifest as changes in mERG, were not observed. Ultrastructurally, the HFL line was correlated with expansion of the photoreceptor layer, with increased space between the photoreceptor outer segments (consistent with edema). The HRB observed was consistent with regions of disk separation and distorion at the junction of the inner and outer photoreceptor segments. Ultrastructural correlates of both HRBs and HFLs were considered consistent with a transient, reversible lesion, in line with the rapid resolution of these findings on OCT. Because of the histopathological and ultrastructural nature of these lesions, and the lack of functional correlates, these novel OCT findings are considered to be non-adverse.

2615 Intestinal Toxicity in Rats Following Administration of CDK4/6 Inhibitors is Independent of Pharmacology

1Pfizer, San Diego, CA; 2Pfizer, Groton, CT; and 3Pfizer, Pearl River, NY.

Recently three different cyclin-dependent kinase 4 and 6 (CDK4/6) dual inhibitors were approved for the treatment of breast cancer (palbociclib, ribociclib and abemaciclib), all of which offer comparable therapeutic benefits. Their safety profiles however are different. For example, neutropenia is observed at 4 times higher dose for palbociclib compared to the other drugs, novel in that it is the most common adverse event for palbociclib and ribociclib, whereas diarrhea is the most common adverse event observed in patients treated with abemaciclib. In order to understand the mechanism of diarrhea associated with this class of drugs and to establish that there were no unreported toxicities that needed to be taken into consideration, Psilocybin was shown to have low potency interaction with the hERG channel (minimal effect at 1000µM and no effect at 100µM at a membrane potential of -60mV). It was also shown to produce a range of effects in rats that were entirely consistent with previously reported effects in animals and humans. This toxicology package filled significant gaps in the existing information in the literature and supported progression to clinical trials in treatment resistant depression.
2616 Assessing Immunogenicity of Host Cell Proteins in BLT-Immune Humanized Mice
S. B. Hosain, Y. Yan, C. L. San Emeterio, A. D. Knapton, and K. E. Howard.
US FDA, Silver Spring, MD. Sponsor: J. Weaver.

In recent years, development and clinical use of biologics has increased significantly due to their ability to effectively treat immune-mediated diseases and cancer. However, immunogenicity to biologics remains a major concern as repetitive administration of biologics can trigger immune responses in the form of anti-drug antibodies (ADAs). One potential cause of immunogenicity is host cell proteins (HCP). HCP represent cellular proteins from non-human cell lines that occur through the manufacturing process. Despite extensive purification and filtration processes, residual levels of HCP are present in marketed products. It is unclear if these proteins can serve as adjuvants to the immune system and help induce formation of ADA. Therefore, we tested various unique HCP fractions produced at US FDA in a bioassay using standard antibody production cell lines in bone marrow-liver-thymus (BLT) immune humanized mice to determine their ability to induce measurable immune responses in the absence of active pharmaceutical product. Groups of four–eight BLT-immune humanized mice were treated subcutaneously either 10 ng or 100 ng of one of five preparations of HCP or saline three days per week for eight weeks. As a positive control, one group was treated with hepatitis A vaccine. We assessed immune activation via flow cytometry in serial blood samples through changes in T cell activation markers. Cytokines and antibody production were evaluated through periodic serum sampling. Results showed that measurable increases in activation markers on T cells were evident in HCP-treated mice. We observed increased levels of plasma cells in bone marrow with specific preparations of HCP, and administering greater amounts of HCP did not necessarily cause more immunogenicity. Significant increases in T cell populations were observed with HCP treated mice but not saline controls. We also assessed immunoglobulin class switching and found that some HCP-treated groups developed IgG2 or IgG4 antibodies, suggesting maturation of antibody responses and cross talk between B and T cells in HCP-treated mice. Our results show that unique responses can occur to preparations of HCP and that repeated exposure to HCP alone can induce an immunogenic response in human immune cells.

2617 Safety Testing of Challenge Agents
J. Bussiere1, J. Solomon2, and C. Dean Jr.1.1 Amgen Inc., Thousand Oaks, CA; and 2Charles River Laboratories, Reno, NV.

Challenge agents (molecules that induce a response that can be inhibited by the therapeutic) may be used in clinical trials to support the pharmacodynamic (PD) activity of the therapeutic being tested. In general, these agents have been in limited human subjects but the nonclinical safety regulatory requirements for use in clinical trials are unclear. A target-specific peptide, maxadilan, a vasodilator, was utilized to demonstrate biological activity of a PAC1 (pituitary adenylate cyclase receptor-type 1) antagonist mAb measured by a dermal blood flow assay (DBF) using laser Doppler. Maxadilan administered intradermally was shown to increase DBF in the rat and cynomolgus monkey; this response was blocked by an anti-PAC1 antagonist mAb demonstrating utility as a challenge agent. To support the PD clinical trial, a 2-week intradermal (ID) and intravenous (IV) toxicology study was conducted in the rat. Rats were administered 0.3 to 30 μg maxadilan ID on Days 1, 7, and 14 or 0.005 μg/kg IV on Day 14. Clinical observations included red skin (pinnae) at >0.3 μg ID, or >0.005 μg/kg IV and salivation (both ID and IV high dose groups). Clinical pathology changes were consistent with mild indications of inflammation (increased WBCs and fibrinogen). Histologic myocardial degeneration was observed at >0.3 μg ID, and coronary artery necrosis (n=1 of 5) was present at 30 μg ID. These cardiovascular light microscopic changes were consistent with anticipated pharmacology of maxadilan. A second ID challenge agent, PACAP, was also planned to be used in a PD clinical trial. To support the PACAP challenge agent, an extended single dose rat IV study, and a rat safety pharmacology study were completed. Similar clinical findings to maxadilan were observed in the rat following doses of 0.005, 0.05 or 0.5 mg/kg in addition to increased fibrinogen and myocardial fibrosis. In the safety pharmacology study, a transient increase, then decrease in heart rate was observed in addition to a transient decrease in mean arterial pressure followed by an increase in pulse pressure were observed at all doses. A decrease in body temperature was seen at the mid and high dose. In summary, these nonclinical studies supported Phase 1 clinical trials using maxadilan and PACAP as challenge agents.

2618 The Protective Effect of Rosiglitazone against Electronic Cigarette/Tobacco Smoke-Induced Cerebrovascular Toxicity
F. Sivandzade, and L. Cucullo. Texas Tech University Health Sciences Center, Amarillo, TX.

The content of tobacco smoking (TS) and also e-cigarettes (EC) are associated with vascular endothelial dysfunction in a causative and dose-dependent manner primarily related to the content of reactive oxygen species (ROS), nicotine, oxidative stress, and smoking-induced inflammation. It is well established that both TS and EC promote glucose intolerance and increases the risk of developing type-2 diabetes mellitus (2DM) with which it shares other pathogenic traits including the high risk of neurological and cerebrovascular disorders via ROS generation, blood-brain barrier (BBB) impairment and inflammation. Herein, we investigated the protective effect of rosiglitazone (RSG) against oxidative stress damage at the BBB by chronic TS/EC exposure. For this purpose, we assessed intracerebral ROS generation and BBB integrity using immunofluorescence, western blotting, Intracellular ROS generation, and TEER measurement, as well as BBB permeability analyses using labeled dextran in mouse brain. Experiments were conducted on TS/EC-exposed mouse brain microvascular endothelial cells (mBMVEC-P3) treated with RSG (20 μM) based on cell viability evaluated by MTT cytotoxicity. Results were compared to corresponding untreated TC/EC exposed cultures. The results revealed that RSG as a peroxisome proliferator-activated receptor gamma (PPARY), at pharmacologically relevant levels, inhibited the NOD2 and PPARy pathway which reduced ROS generation and TS/EC toxicity at the cerebrovascular level. The results also confirm the RSG’s role in the reduction of inflammation and oxidative stress and also suppression of tight junction (TJ) protein downregulation and loss of BBB integrity induced by TS/EC. In contrast, nimesulide was kept for additional 3 months without further MH treatment. In MD mice, the typical TN symptoms were induced as expected, reflected by increased protein urine, renal lipid accumulation and lipotoxic effects inducing oxidative stress, and inflammatory reactions, and final fibrosis. However, these typical TN changes were significantly prevented by MH treatment at time points of 3 months after 3-month MH treatment, suggesting MH-induced renal protection from T2D has memory effect. Mechanistically MH renal proximal tubules from TN may be related to its lipid metabolic improvement by the activation of AMPK/PGC-1a/CPT1-mediated fatty acid oxidation. In addition, MH regulates glucose metabolism through the mTOR-AKT pathway. These results indicate that treatment of T2D with MH effectively prevents DN probably via AMPK-dependent improvement of glucose and lipid metabolisms. However how MH-activated AMPK pathways can persist long time even 3 months after completing 3-months of MH treatment remains further study.

2619 4-O-Methylhonokiol Ameliorates Type 2 Diabetes-Induced Nephropathy in Mice by Inhibiting Inflammation and Oxidative Stress
T. Ma1, Z. Zheng1, L. Bi1, and L. Cai1. 1University of Louisville, Louisville, KY; 2China-Japan Union Hospital of the Jilin University, Changchun, China; and 2The First Hospital of Jilin University, Changchun, China.

Diabetic nephropathy (DN), characterized by proteinuria and accumulation of extracellular matrix (ECM) proteins, is one of the most serious long-term complications of type 2 diabetes (T2D). 4-O-methylhonokiol (MH) is considered one of the major bioactive constituents of Magnolia stem bark. In our previous studies, we observed that MH partially attenuated heart damage in a HFD-induced obese mouse model. In this study, we aim to elucidate whether treatment with MH can ameliorate or slow-down progression of DN in a T2D murine model and, if so, whether the protective response of MH is associated with AMPK-associated anti-oxidant and anti-inflammatory effects. Mice were fed normal diet or high fat diet for 3 months to induce insulin resistance and then intraperitoneal injection of STZ to induce hyperglycemia as T2D model. Both T2D and control mice received gavage containing vehicle or MH once diabetes onsets for three months. Five mice from each group were sacrificed once completing 3-month MH treatment. The remaining anesthetized mice were kept for additional 3 months without further MH treatment. In T2D mice, the typical DN symptoms were induced as expected, reflected by increased proteinuria, renal lipid accumulation and lipotoxic effects inducing oxidative stress, and inflammatory reactions, and final fibrosis. However, these typical TN changes were significantly prevented by MH treatment at time points of 3 months after 3-month MH treatment, suggesting MH-induced renal protection from T2D has memory effect. Mechanistically, MH renal protection from DN may be related to its lipid metabolic improvement by the activation of AMPK/PGC-1α/CPT1-mediated fatty acid oxidation. In addition, MH regulates glucose metabolism through the mTOR-AKT pathway. These results indicate that treatment of T2D with MH effectively prevents DN probably via AMPK-dependent improvement of glucose and lipid metabolisms. However how MH-activated AMPK pathways can persist long time even 3 months after completing 3-months of MH treatment remains further study.
2620 Reactive Oxygen Species Produced by the Corrosion of Fe-Based Materials Induce Endothelial Dysfunction.

E. Scarcello, I. Lobysheva, C. Bouzin, C. Dessy, P. J. Jacques, and D. Lison, Catholic University of Louvain, Bruxelles, Belgium.

Fe-based materials are currently considered for manufacturing biodegradable coronary stents. Here, for the first time, we document the generation of reactive oxygen species (ROS) during Fe-based materials corrosion and their deleterious impacts on endothelial function. ROS generation was documented by the acellular terephthalic acid (TA) hydroxylation assay. Thoracic rat aortic rings were isolated from Wistar rats and endothelium was directly exposed (6 h) by inserting an iron wire into the lumen in the presence/absence of catalase, an antioxidant enzyme. Indirect exposure was included as a control to assess the potential role of solubilized iron ions by incising aortic rings with an iron wire outside the lumen. Nitric oxide (NO) production by aortic rings was measured by EPR spin-trapping, and endothelium-dependent relaxation in response to muscarinic stimulation was assessed with the organ-bath method (doi: 10.1371/journal.pone.0152579). Induction of oxidative stress in aortic rings was assessed via the mRNA expression of the oxidative stress response gene heme oxygenase-1 (HO-1). The permanent material currently used for coronary stents, the austenitic stainless steels 316L, was used as negative control in all tests. Iron exhibited a strong potential to generate ROS in the TA assay. ROS generation, but not corrosion, was inhibited by catalase. Direct contact with iron significantly impaired endothelium-dependent relaxation of aortic rings. Direct contact with the material in the presence of catalase, or indirect contact did not affect endothelium function. NO production by treated rat thoracic aortic rings was inhibited by ROS generated by the corrosion of iron, as indicated by the protective role of catalase. Expression of HO-1 was increased after direct exposure to iron, and not increased to indirect exposure or in the presence of catalase. The demonstration of ROS production during corrosion, induction of oxidative stress, inhibition of NO production and consequent endothelium dysfunction raise concern about the biocompatibility of biodegradable Fe-based alloys for vascular implants.

2621 Polyethylene Glycol (PEG) Coated Liposomes Increase Oxidative Stress in Endothelial Cells

V. C. Minarchick, A. Billups, D. Simberg, and J. Brown, University of Colorado Anschutz Medical Campus, Center for Nanomedicine and Nanosafety, Dept. of Pharmaceutical Sciences, Aurora, CO.

Polyethylene glycol (PEG) is a coating often used to improve biodistribution and safety of small molecules and liposomes for drug delivery. We have previously shown that PEG-coated liposomes attenuate endothelium-dependent arterial dilation, but the mechanism(s) of action is unknown. Preliminary data indicates that changes in reactive oxygen species (ROS) generation may play a role in the observed microvascular impairments; therefore, we hypothesize that PEG-coated liposomes will increase oxidative stress and inflammation in endothelial cells thereby contributing to microvascular dysfunction. Rat aortic endothelial cells were treated with PEG or non-PEG coated liposomes (3, 25, and 100 µg/ml). Flow cytometry was used to determine changes in ROS. Vascular activation [intercellular adhesion molecule-1 (ICAM)] and vascular cell adhesion molecule-1 (VCAM)), inflammation [interleukin (IL)-6], and anti-oxidant (Heme oxygnase-1, HemOx) gene expression changes were assessed via PCR. Additionally, oxidative stress potential was assessed by analyzing the ratio of glutathione disulfide (GSSG) to glutathione (GSH) via high performance liquid chromatography (HPLC). There was a significant increase in ROS following exposure to PEG-coated liposomes compared to the non-PEG liposomes and vehicle control (2.58 ± 0.56 vs. 1.39 ± 0.13 and 1 ± 0.15-fold change, respectively). There was also an increase in oxidative stress potential in the endothelial cells exposed to the highest dose of PEG and non-PEG coated liposomes (16 ±4 and -10.5 ± 4, respectively) as determined by an increase in the GSSG/GSH ratio. Finally, there was a 1.5-fold increase in VCAM and 3.5 and 7-fold increase in HemOx gene expression compared to control following treatment with 25 and 100 µg/ml of PEG-coated liposomes, indicating potential vascular activation and anti-oxidant alterations. Taken together, these results indicate liposomes may alter oxidative stress and vascular activation in endothelial cells, which may contribute to the previously observed microvascular impairments. It is critical to understand liposome formulations, including coatings, on both endothelial and vascular response for their safe implementation in medicine.

2622 3D Hepatocyte Spheroid Models in High-Throughput Transcriptomics and Benchmark Concentration Analysis for Predictive Liver Toxicology Screening

Improved tissue-like functionality with three-dimensional (3D) spheroid models offer better in vitro safety assessment of chemicals. Combining these models with novel low-cost, high-throughput transcriptomics methods would enable systematic characterization of chemical induced effects on biological systems. We have developed 3D hepatocyte spheroid models of human hepatic progenitor cell line, HepaRG and primary rat hepatocytes (Sprague-Dawley) in 384 well formats. HepaRG spheroids exhibit several hallmarks of polarized hepatocytes and tissue-like functionality. Xenobiotic metabolism assessment with clinical substrates of CYP1A2, CYP2B6 and CYP3A4 showed 2 to 20-fold higher than median activities compared to two-dimensional (2D) cultures of primary human hepatocytes (PHH). Similarly, primary rat hepatocytes also formed polarized spheroid-like structures and displayed a stable phenotype for more than 30 days compared to 2D sandwich cultures which are healthy for 3-5 days in culture. Specific activities of CYP1A1 and CYP3A enzymes were markedly higher than sandwich cultured rat hepatocytes. HepaRG spheroids were treated with ten concentrations of a reference set chemicals for 96-hours in repeated exposure regimens and assays using high-throughput gene expression analysis with the S1500+ gene set were performed. Baseline gene expression and biological pathway responses showed a significantly higher enrichment score in spheroids compared to 2D HepaRG cells. Exposure to aflatoxin B1 and benzo(a)pyrene showed activation of genes and pathways related to cell cycle, DNA damage and cancer at low non-cytotoxic concentrations. BMDExpress 2.2 was used to calculate point of departure for individual genes and pathways associated with concentration-related molecular perturbations. Activation of nuclear receptor pathways (CAR/RXR and PXR/RXR) was evident with lower exposure levels of phenobarbital and rifampicin preceding onset of stress-related pathways at higher cytotoxic concentrations. Similarly, biologically relevant pathways associated with exposure of 4-(methyltrinitroamino)-1-(3-pyridyl)-1-butane (NINK), cyclophosphamide, chlorpromazine and valproic acid were activated at sub-lethal concentrations in HepaRG spheroids. Incorporation of these physiologically relevant in vitro models and data-rich assay approaches are promising new tools in identifying sensitive molecular perturbations that lead to adverse effects of chemicals.
A Human In Vitro Skin Explant Assay to Assess the Immunotoxicity of Biopharmaceuticals and Aggregated Monoclonal Antibodies

To aid preclinical prediction of adverse immune reactions to biopharmaceutical drugs, we have developed a human in vitro skin explant assay. This assay uses autologous human blood and skin to assess histopathological damage caused by adverse immune reactions. This assay is a valuable preclinical tool for safety assessment of biologics. We tested 17 commercial biologics in the skin explant assay (n=10) and correlated the results with clinical occurrence of adverse hypersensitivity reactions. Results showed a statistically significant positive correlation between adverse clinical outcome and response in the skin explant assay (r=0.815, p<0.0001). Drugs known to cause adverse reactions e.g. Campath® and OKT3® gave a positive skin histopathology Grade II or above in the (34-90)% of individuals, respectively. An analogue of the TGN drug, TGN1412, gave a Grade III response in 90% of donors tested. Drugs which have been defined as clinically negative for adverse immune reactions, such as Enbrel® and Cimzia®, showed a negative response, with 10% and 30% of individuals reacting with the drug, respectively. We also assessed adverse reactions to biosimilars (Remsima® and Inflectra®) against the reference product (Remicade®). Overall, a negative response was observed for all three biologics in the skin explant assay. Interestingly, drug responses varied among donors, indicating that the assay may be able to predict the best personalised therapy for an individual patient. The assay was also used to assess if aggregated monoclonal antibodies gave rise to adverse immune reactions. Monoclonal antibodies were aggregated by heat (40°C) protocol and characterised by adverse hypersensitivity reactions. Transmission electron microscopy, revealing aggregation levels ranging from 2.5-6.0% of total protein content. Results showed that aggregated Herceptin® gave a Grade II positive response in 80% of donors and aggregated Rituximab® gave a Grade III positive response in 60% of donors tested. Sections also stained positive for Heat Shock Protein 70 (HSP70) as a marker of aptosis. Our novel human in vitro assay showed that it was highly sensitive for determining adverse immune reactions to biologics and aggregated mAbs and is a promising tool for the prediction of immunotoxicity.

Metallothionein Improves Angiogenic Function of Endothelial Progenitor Cells via HIF-1α/SDF-1/Akt Pathway in Diabetic Ischemia

K. Wang, X. Dai, J. Hei1, C. Yang, J. Chen1, J. Xu1, Z. Deng1, E. Carlson1, K. Wintergers1, P. Epstein1, L. Cal1, and Y. Tan1. University of Louisville, Louisville, KY; and University of North Dakota, Grand Forks, ND.

Diabetes mellitus associated dysfunction of endothelial progenitor cells (EPCs) may contribute to dysregulation of endothelial regeneration. Metallothionein (MT) acts as an antioxidant in various pathophysiological processes. Whether MT in EPCs has positive angiogenic effects and the mechanisms involved remain unclear. Endothelial MT overexpression (JTMT) mice were made diabetic by high fat diet followed by STZ administration (HFD/STZ). Diabetic and control hind limb ischemia model was established by femoral artery ligation. Bone marrow derived mononuclear leucocytes (MNCs) collected from JTMT mice were transplanted into db/db mice with hind limb ischemia. Blood reperfusion was monitored by a microcirculation imaging system and angiogenesis of ischemic muscle was assessed by CD31 staining. Oxidative stress was measured by DHE staining and western blot of 3-NT and 4-HNE. High glucose and hypoxia conditions in culture were adopted to mimic diabetic ischemia for mechanistic studies in EPCs. The critical role of HIF-1α in MT protection of EPC function was explored by siRNA knockdown of HIF-1α. MT improved blood perfusion of ischemic hind limb and promoted angiogenesis of ischemic muscle. MT overexpression of JTMT mice was significantly higher than control mice, which was highly correlated with mitochondrial respiration. Bone marrow derived mononuclear leucocytes (MNCs) collected from JTMT mice were transplanted into db/db mice with hind limb ischemia. Blood reperfusion was monitored by a microcirculation imaging system and angiogenesis of ischemic muscle was assessed by CD31 staining. Oxidative stress was measured by DHE staining and western blot of 3-NT and 4-HNE. High glucose and hypoxia conditions in culture were adopted to mimic diabetic ischemia for mechanistic studies in EPCs. The critical role of HIF-1α in MT protection of EPC function was explored by siRNA knockdown of HIF-1α. MT improved blood perfusion of ischemic hind limb and promoted angiogenesis of ischemic muscle. MT overexpression of JTMT mice was significantly higher than control mice, which was highly correlated with mitochondrial respiration. The expression of HIF-1α, SDF-1, VEGF and Akt signaling were all increased in JTMT mice, along with elevation of plasma SDF-1α and VEGF. Compared with WT mice, the expression of HIF-1α, SDF-1, VEGF and Akt signaling were all increased in JTMT mice, along with elevation of plasma SDF-1α and VEGF. Compared with WT mice, the expression of HIF-1α, SDF-1, VEGF and Akt signaling were all increased in JTMT mice, along with elevation of plasma SDF-1α and VEGF. Compared with WT mice, the expression of HIF-1α, SDF-1, VEGF and Akt signaling were all increased in JTMT mice, along with elevation of plasma SDF-1α and VEGF. Compared with WT mice, the expression of HIF-1α, SDF-1, VEGF and Akt signaling were all increased in JTMT mice, along with elevation of plasma SDF-1α and VEGF. Compared with WT mice, the expression of HIF-1α, SDF-1, VEGF and Akt signaling were all increased in JTMT mice, along with elevation of plasma SDF-1α and VEGF. Compa...

Crosstalk between GATA4 and Mitochondria during Cardiomyocyte Differentiation upon Exposure to Tyrosine Kinase Inhibitors

Q. Liu1,2, H. Wu1, C. Jiang1, M. Zhao1, B. Zhao1, K. Van Bortle1, E. Wei1, J. Wu1, and M. Snyder1. 1Department of Genetics, Stanford University School of Medicine, Palo Alto, CA; and 2Stanford Cardiovascular Institute, Stanford University School of Medicine, Palo Alto, CA.

Maternal drug exposure during pregnancy increases the risks of congenital heart defects (CHDs). For instance, tyrosine kinase inhibitors (TKIs) are known to induce cardiotoxicity and mitochondrial dysfunction; they also can cross the placenta, posing high risks for CHDs. However, there are still large knowledge gaps in the underlying mechanisms underlying early-onset heart defects due to maternal drug exposure. Recent advances have improved our ability to generate cardiomyocytes (CMs) from human stem cells, which provide a great opportunity for advancing mechanistic and predictive developmental toxicology. In this study, we used human embryonic stem cells (h-iPSCs) to study interactions between CM differentiation and CM mitochondrial dysfunction. The transplantation of CMs from the iPHRECs treated with several TKIs drugs (maximun, sunitinib, and vandetanib) at sublethal levels (lower than their clinical levels) during CM differentiation. We found that developmental exposure to TKIs induced impairment of mitochondrial respiration, disarrangement of sarcomere structure, increased calcineurin levels, and significant alterations in contractility and Ca2+-handling properties of differentiating CMs. Computational biological analyses of both transcriptomic and chromatin accessibility landscape revealed that TKI-exposure altered GATA4-mediated regulatory network, which was highly correlated with mitochondrial respiration. Using a gain-of-function approach with CRISPR-activation, we observed that increases in GATA4 overexpression restored CM functions and mitochondrial respiration despite of TKI exposure. Altogether, we applied a stem-cell-based system to identify a novel crosstalk between GATA4 activity and mitochondrial respiration during CM differentiation. This study provides new insights into the relationship between gene-regulation and mitochondrial functions, and significantly enriches our understanding of sublethal TKI-induced cardiotoxicity during cardiac development.

Identification of Novel Cardioprotective Mechanisms in Doxorubicin-Induced Cardiac Injury

M. S. Da Rocha, A. A. Morales, Y. Qi, J. P. Stahl, A. Wanschel, and C. O. Rodrigues. University of Miami, Miller School of Medicine, Miami, FL.

Anthracycline cardiotoxicity is an established severe complication from chemotherapy. Since their discovery over 50 decades ago, the cardiotoxic effect of anthracyclines remain a significant medical problem. This study aimed to identify early cardiac changes after doxorubicin treatment and investigate the modulation of c-Myc transcriptional activity as a potential cardioprotecti...
2628 Functional Characterization of a Novel Long Non-Coding RNA Linc00844 in Drug Metabolism and Hepatotoxicity

D. Li1, D. Yu2, S. Chen1, L. Wu1, B. Knox1, L. Gao1, W. Tong1, and B. Ning1.
1US FDA/NCTR, Jefferson, AR; and 2Qindao University, Qingdao, China.

Long noncoding RNAs (IncRNAs) are involved in various biological and pathological processes, such as development and carcinogenesis, by regulating gene expression; however, little is known about their functions in xenobiotic metabolism. Using acetalaminophen (APAP) metabolism in hepatocytes as a model, we identified IncRNAs that were potentially associated with drug metabolism and toxicity. We examined the expression profiles of IncRNAs, key drug metabolizing enzymes (DMEs) and nuclear receptors (NRs) in APAP-treated HepaRG cells using high-throughput RNA sequencing and in silico analyses. Our results showed that Linc00844 was significantly correlated with CYP3A4, CYP2E1, SULT2A1, NR112, and HNF4A on the expression level. We found that Linc00844 was specifically expressed in the brain, liver, and kidney using the GTEx RNA-seq dataset. We also validated the expression and localization of Linc00844 via RT-qPCR and characterized its sub-cellular localization via RNA fluorescence in situ hybridization. Moreover, we performed gain- and loss-of-function assays to evaluate the role of Linc00844 on gene expression of CYP3A4, CYP2E1, SULT2A1, NR112, and HNF4A in human liver cells. Using a series of depletion experiments of Linc00844, we demonstrated that the nucleotide sequence 115-554 was essential to the function of Linc00844. Our results suggest that Linc00844 may play an important role in drug metabolism by regulating DME and NR expression.

2629 Consequences of Neonatal Activation of PXR on Drug Metabolism in Adult Mice

P. Wang1,2, G. Liu1, X. Zhong1, and L. Zhang1. 1Zhengzhou University, Zhengzhou, China; and 2University of Connecticut, Storrs, CT.

Pregnane X receptor (PXR), which can be activated by xenobiotic chemicals including paediatric drugs, plays a key role in the regulation of drug metabolism enzymes (DMEs). The induction of DMEs due to the activation of PXR may reduce therapeutic efficacy or cause toxicity. The goal of this work was to demonstrate the impacts of neonatal PXR agonist exposure on DMES expression and drug sensitivity in adulthood. PCN (pregnenolone-16α-carbonitrile) was used as a PXR agonist for drug exposure at early age, C57BL/6 mice as animal model, and mice primary hepatocytes for drug sensitivity study. Both PCN dose (0, 50, 100, 150, 200 mg·kg\(^{-1}\)) and female mice. However, gender different impacts of neonatal PCN exposure was observed on the expression of CYP3A11 in a dose dependent manner in mice primary hepatocytes. Notably, attenuated PCN-induced CYP3A11 expression was observed in the primary hepatocytes derived from neonatal PCN exposure mice. Altogether, our study suggested that the persistent alterations of hepatic drug metabolism following neonatal PXR activation are dependent on the drug dose and treatment exposure time at early age. 2630 CYP1A2 Enzyme Localization in Normal and Diseased Pediatric Livers

B. W. Ogilvie1, M. Czerwinski1, A. Kats1, M. T. Pritchard1, and S. E. Tague1.
1Sekisui XenoTech LLC, Kansas City, KS; 2Children’s Mercy Hospital, Kansas City, MO; and 3University of Kansas Medical Center, Kansas City, KS.

CYP1A2 is a Phase 1 drug metabolizing enzyme whose expression begins between birth and 4 weeks of age, and gradually increases to about half of the adult level by age 10. The enzyme is expressed primarily in liver, where it constitutes 4 - 16% of the total hepatic CYP pool, and is a major determinant of the biotransformation of ~9% of clinically used drugs. Interestingly, CYP1A2 activity is decreased in adults with non-alcoholic fatty liver disease (NAFLD). Considering the increase in the number of medications given to children, as well as the rise in childhood obesity and NAFLD, this study utilized a pediatric liver tissue microarray (TMA) to determine if CYP1A2 abundance and localization was influenced by donor age and disease. The pediatric TMA contained 25 tissues from donors aged 4 months to 18 years old and 5 adult controls. The donor demographics and health data were collected from interviews with next of kin and from hospital records. Three consecutively cut arrays were stained with hematoxylin and eosin (H&E) and Go骂ori’s trichrome for tissue histology, and TRITC collagen, respectively, or with an immunofluorescent anti-CYP1A2 Ab. Images of stained arrays were obtained with a Nikon HCA system and a Hamamatsu Orca Flash 4 camera (CYP1A2) or a Nikon DS-Fi3 camera (H&E and Go吗ori’s trichrome). Disease status was determined from a pathologist’s review of the H&E and Go吗ori’s stains and patient medical records. CYP1A2 protein was detected in all tissues, except in one 4 months old, and increased with age, being greatest in the adult, normal control livers. In pediatric or adult tissues judged to be normal or having minimal pathological findings, CYP1A2 protein was located in zone 3 and 2 hepatocytes. A diffuse pattern of enzyme localization, associated with reduced CYP1A2 level, was seen in tissues affected by necrosis and ischemia. Pediatric NAFLD was also associated with diminished CYP1A2 staining (3 donors, 10 - 14 years old, steatosis 50 - 80%, BMI 32.2 - 32.5). In conclusion, the pediatric liver TMA was a useful tool to elucidate CYP1A2 protein localization in healthy and diseased livers. Moreover, CYP1A2 was reduced in diseased pediatric livers, paralleling what is seen in adults.

2631 Exploration of Hepatocyte Functionality with Tox21 Cell Lines

W. Qu. NIEHS, Research Triangle Park, NC.

The Tox21 Program has investigated thousands of chemicals using cell-based assay systems. These models have been widely utilized for their suspected lack of differentiated tissue functionality (e.g., xenobiotic metabolism). To explore these perceived limitations, Tox21 cell culture models were established and characterized for major human drug metabolizing enzymes (P450, UGT, and SULT). Tox21 cell lines (HeP2, BGI-Luc 4E2, HEK293, Hela, H11CT, ME180, CHO-K1, GH3-TRE-Luc, C3H10T1/2 and MCF-7aroERE) vs. primary human hepatocyte (PHH) suspensions from a 50-donor pool were evaluated drug substrate concentrations to observe detectable metabolite concentrations. These new cell lines were evaluated for glucuronidation and sulfation activity using hydroxocoumarin, biphenol A (BPA) and bisphenol S (BPS). For BPAF and BPS, both glucuronidated and sulfated metabolites were identified in PHHs, with proportionally lower levels of sulfated metabolites for both compounds in HeP2 & HEK293. No metabolites were observed in incubations with MCF-7 cells. Glucuronidated metabolites were not observed in any of the Tox21 cell lines. Tox21 cell models largely failed to support classical hepatic receptor signaling functionality (i.e., AhR, CAR, PXR) compared with sandwich cultures of PHHs growing more than 60% as much as PHHs. Together, these data provides an extensive characterization of the inadequacies of established Tox21 cell lines to model human hepatic xenobiotic metabolism and functional signal transduction pathways. Moreover, the disproportionate metabolite profile for BPS and BPAF towards sulfate conjugates highlights the risks with applying these models with extensively metabolized chemicals towards toxicological prediction.

2632 Glutathione S-Transferase Protection against the Acute Toxicity of Electrophiles is Not Limited to Their Enzymatic Function: Evidence for a Ligandin Contribution

Environmental and endogenous electrophiles cause tissue damage through their high reactivity with endogenous nucleophiles such as DNA, proteins, and lipids. Not surprisingly, organisms have developed numerous protective pathways against these electrophiles, including spontaneous and enzymatic conjugation with glutathione. Enzymatic conjugation is largely mediated by the extensive family of glutathione S-transferase (GST) enzymes, which are present in virtually all living cells and constitute up to 10% of cellular protein content. GSTs perform the first step in the transformation of an electrophile
to its mercapturic acid derivative, a highly soluble metabolite that is rapidly excreted in urine. However, the high expression level of GSTs, their high Kₜ values, and their substrate promiscuity, even between members of the same family, suggest that the protective activity of GSTs may extend beyond their enzymatic function. To address this question we generated a panel of mice lacking various GST gene families. We then compared the impact of these genetic lesions on the ability of the mice to form the mercapturic acid metabo-
lolite of acrylamide and also determined whether these GSTs protect against the tissue damage and metabolic changes that occur secondary to acrylamide exposure. We used ¹H NMR spectroscopy to measure the levels of mercapturic acid metabolites in the urine of mice after an acute acrylamide exposure. With this method, we were able to define the primary GSTs responsible for acry-
amide conjugation; however, the acute toxicity of acrylamide was only ob-
served in mice lacking all three gene families. This finding supports a model in which the cellular protection that is provided by GSTs is not restricted to their ability to conjugate a particular electrophile with glutathione; rather, the often overlooked ligandin function of GSTs can play an essential role in the protection of an organism against toxic electrophiles.

2634 Hepatocyte Hopping of Sorafenib-Glucuronide Is Decreased in Nonalcoholic Steatohepatitis

E. L. Toth¹, H. Li¹, K. L. Frost¹, S. R. Miller¹, D. You², D. Kozlowsky², L. M. Aleksunes², and N. J. Cherrington¹. ¹University of Arizona, Tucson, AZ, and ²Rutgers University, New Brunswick, NJ.

Hepatocyte hopping is a hepatocyte-to-blood-to-hepatocyte shuttling route that increases the efficiency of hepatic elimination by allowing for multiple chances at excretion. This process is mainly mediated through sinusoidal efflux of hepatic metabolites by Mrp3 and uptake by Oatp transporters in sequential hepatocytes until eventual biliary efflux by Mrp2. Sorafenib-glucuronide (SFB-G), a metabolite of sorafenib (SFB), is a known substrate of the transporters involved and undergoes hepatocyte hopping to produce relatively efficient biliary elimination. Nonalcoholic steatohepatitis (NASH), the advanced form of fatty liver disease, alters the function of multiple processes that impact metabolism and disposition, including the transporters involved in hepatocyte hopping. Therefore, the purpose of this study was to determine whether NASH significantly affects drug disposition through alterations in hepatocyte hopping. Male FVB and C57BL6 wild-type (WT), Gpat1α/1β cluster knockout (KO), and Mrp2 knockout (mKO) mice were fed a methionine and choline deficient (MCD) diet for 6 weeks to induce NASH. Mice were admin-
istered 10 mg/kg SFB by oral gavage and blood samples were collected via submental bleed at 20 minutes, 1, 2, 4, and 8 hours. Concentrations of SFB and SFB-G in plasma were determined through liquid-chromatography tandem mass spectrometry. Plasma concentrations of SFB-G increased by 108-fold in the oKO-C group when compared to the WT due to the loss of Oatp uptake. In the WT-MCD group, the increased expression of Mrp3 and decreased func-
tion of Mrp2 due to cellular stressors in NASH results in a 165-fold increase in SFB-G concentrations. The additional loss of Oatp transporter uptake along with the alterations to Mrp3 and Mrp2 by NASH in the oKO-MCD group resulted in a 3.2-fold increase in SFB-G plasma concentrations when compared to oKO-C. These results indicate that decreased canalicular efflux by Mrp2 during NASH increases the amount of SFB-G available for hepatocyte hopping. The concurrent increase in Mrp3 efflux and overall decrease in Oatp uptake limits the contribution of downstream hepatocytes to the total elimination of SFB-G. These changes in transporter function significantly reduce biliary elimination and alter drug disposition in NASH by limiting the process of hepatocyte hopping.

2635 Placental BCRP/ABCG2 Transporter Prevents Fetal Exposure to the Estrogenic Mycotoxin Zearalenone

J. T. Szilagyi¹,², L. Gorczyca¹, A. M. Brinker¹, B. Buckley¹, J. D. Laskin¹, and L. M. Aleksunes¹. ¹Rutgers, The State University of New Jersey, Piscataway, NJ; and ²University of North Carolina at Chapel Hill, Chapel Hill, NC.

In the placenta, the BCRP/ABCG2 efflux transporter limits the maternal-to-fetal transfer of drugs and chemicals. Previous research has pointed to the estrogenic mycotoxin zearalenone as a potential substrate for BCRP. Here, we examined the role of the BCRP transporter in the transplacental disposition of zearalenone during pregnancy. In vivo transwell transport assays employing human placenta and BCRP and Mrp7 transfected MDCK cells and human BeWo trophoblasts with reduced BCRP expression were used to characterize the impact of BCRP/BCrp on the disposition of zearalenone. In both in vitro models, the presence of BCRP/BCrp protein increased the basolateral-to-apical transport and reduced the apical-to-basolateral transport of zearalenone over a 2 h period. In vivo pharmacokinetic analyses were then performed on pregnant wild-type and Bcrp⁻/⁻ mice on gestational day 14 after a single tail vein injection of zearalenone. Zearalenone and its metabolite α-zearalenol were detectable in serum, placentas, and fetuses from all animals, and β-zeara-
lenol was detected in serum and fetuses, but not placentas. There were no notable differences in the maternal serum concentration or any of the metabolites between the two genotypes. In Bcrp⁻/⁻ mice, the free fetal concentrations of zearalenone, α-zearalenol, and β-zearalenol were increased by 115%, 84%, and 150%, respectively, when compared to wild-type mice. Concentrations of free zearalenone and α-zearalenol were elevated 145% and 78% in Bcrp⁻/⁻ pla-
centas, respectively, when compared to wild-type placentas. Taken together, these data indicate that the placental BCRP/BCrp transporter functions to re-
duce the fetal accumulation of zearalenone, which may impact susceptibility to developmental toxicities associated with in utero mycoestrogen exposure. This work was supported by the National Institutes of Environmental Health Sciences (Grants ES029275, ES020522, ES050022, ES007148, ES029794), a compo-
dent of the National Institutes of Health.

2636 Developmental Thyrotoxicosis via Dietary Iodine: Identifying Genetic Vulnerabilities Using the Zebrafish Model

B. A. Sumper, and J. L. Freeman, Purdue University, West Lafayette, IN.

Iodine is an essential precursor to thyroid hormone and is required during development to ensure proper growth. With this in mind, many industrialized countries introduced iodine into the diet through methods such as iodized salt. Because of the high variability in salt intake across the socioeconomic spectrum in children, a modern reevaluation of the consequences of various degrees of iodine overdose, also known as thyrotoxicosis, is being completed. Thyrotoxicosis shares multiple signs and symptoms with attention deficit hyperactivity disorder (ADHD) in children. In addition, variant manifestations of both diseases similarly occur, such as “ADD” and “apathetic thyrotoxicosis.” Exploring definitive differences between these two diseases would provide information in which the cellular protection that is provided by GSTs is not restricted to their ability to conjugate a particular electrophile with glutathione; rather, the often overlooked ligandin function of GSTs can play an essential role in the protection of an organism against toxic electrophiles.

Zearalenone during pregnancy. The examined role of the BCRP transporter in the transplacental disposition of zearalenone during pregnancy. In vivo transwell transport assays employing human placenta and BCRP and Mrp7 transfected MDCK cells and human BeWo trophoblasts with reduced BCRP expression were used to characterize the impact of BCRP/BCrp on the disposition of zearalenone. In both in vitro models, the presence of BCRP/BCrp protein increased the basolateral-to-apical transport and reduced the apical-to-basolateral transport of zearalenone over a 2 h period. In vivo pharmacokinetic analyses were then performed on pregnant wild-type and Bcrp⁻/⁻ mice on gestational day 14 after a single tail vein injection of zearalenone. Zearalenone and its metabolite α-zearalenol were detectable in serum, placentas, and fetuses from all animals, and β-zeara-
lenol was detected in serum and fetuses, but not placentas. There were no notable differences in the maternal serum concentration or any of the metabolites between the two genotypes. In Bcrp⁻/⁻ mice, the free fetal concentrations of zearalenone, α-zearalenol, and β-zearalenol were increased by 115%, 84%, and 150%, respectively, when compared to wild-type mice. Concentrations of free zearalenone and α-zearalenol were elevated 145% and 78% in Bcrp⁻/⁻ pla-
centas, respectively, when compared to wild-type placentas. Taken together, these data indicate that the placental BCRP/BCrp transporter functions to re-
duce the fetal accumulation of zearalenone, which may impact susceptibility to developmental toxicities associated with in utero mycoestrogen exposure. Identification of Potential Emerging Chemical Risks in Food from REACH Registered Chemicals

A. Bitsch1, M. Bohlen1, S. Escher1, G. Kass1, O. Licht1, M. MacLeod1, C. Merten1, H. Noteborn2, O. Licht1, and V. Silano3

The European Food Safety Authority (EFSA) is responsible for risk assessment of all aspects of food safety, including the establishment of procedures aimed at the identification of emerging risks to food safety. Data available for REACH registered substances were evaluated by taking the following endpoints into account: (a) environmental release (derived from tonnage and ERC), (b) bio-degradation (BIOWin predictions assessed in a battery approach), (c) bioaccumulation in food (modelled by ACC HUMANeady) and (d) toxicity assessed by classification for mutagenicity, carcinogenicity, reprotoxity and repeated dose toxicity. Two different approaches, weighting scenarios and Pivot table selections, were used to prioritise the potential of toxic chemicals to emerge in the food chain, therefore, to represent a possible risk to food safety. Of the 2336 substances with relevant data available, 212 were identified as priority substances for further evaluation. To confirm the accuracy of this prioritisation, 10 chemicals were selected for in-depth evaluation of information on occurrence, analytical methods and toxicology. The selection focused on chemicals that have not already been assessed in detail by other regulatory bodies and are not included in relevant lists (e.g. the Candidate List of the EU REACH Regulation). For four substances, data on the occurrence in the environment or in food/feed could be found. Enhanced monitoring in food/feed is recommended to better assess their relevance as emerging risks in the food chain. For the remaining six substances, no data on occurrence are available or existing data were considered uncertain. In these cases, monitoring in relevant environmental compartments is recommended to gain more insight into their relevance as environmental contaminants. This study also identified 517 substances for which non-prioritisation solely depended on the fact that they are not classified for the relevant toxicological hazards. If such hazards are identified in the future, these substances would qualify as priority substances within the framework as established in this study.

Occurrence and Co-occurrence of Aflatoxin and Fumonisin in Maize and Maize Products in Nigeria

N. Saha Tura1, L. Liverpool-Tasie1, O. Ademola2, A. Obadina2, and F. Wu4

Aflatoxins and fumonisins are mycotoxins (fungal toxins) that frequently contaminate maize, a key staple food in sub-Saharan Africa. Aflatoxin causes liver cancer and has been associated with acute liver toxicity and immunotoxicity, while fumonisin has been associated with neural tube defects. Both of these mycotoxins have been associated with child growth impairment. Previous animal studies have shown that co-exposure to these mycotoxins may increase hepatocarcinogenicity and other toxicological impacts. This study examines the occurrence and co-occurrence of aflatoxin and fumonisin along the maize value chain in southwest Nigeria. Mycotoxin analyses of maize samples collected from farmers and traders showed that aflatoxin levels increased with increasing time of storage, but fumonisin levels did not increase over time in storage. 90% of the animal feed samples collected from feed mills contained aflatoxin levels exceeding the maximum allowable level set by the US Food and Drug Administration (20 µg/kg). In Nigeria, maize feed vs. non-branded maize snacks, the geometric means of both total aflatoxin and total fumonisin levels tend to be higher in non-branded snacks than in branded snacks. Our study results also indicate that lactic acid fermentation, used to make the traditional maize porridge ogi, significantly reduces levels of aflatoxins and fumonisins. Despite regulatory limits in Nigeria for aflatoxins in maize products, 39.13% of the samples had aflatoxin levels above those limits. Though no regulatory limits currently exist for fumonisins, 9.64% of the samples contained total fumonisin levels higher than the United States regulatory limit. We found that aflatoxins and fumonisins contaminations in maize products extend beyond maize production to stored maize and final food products. Thus, adequately addressing the mycotoxin challenge requires consideration of the entire maize value chain.
**2642 Activated Charcoal as a Broad-Acting Sorbent for Endocrine-Disrupting Chemicals**

S. E. Hearon, M. Wang, and T. D. Phillips. Texas A&M University, College Station, TX.

Exposure to hazardous chemicals is of concern during natural and manmade disasters such as floods, droughts, and chemical spills. Chemicals can be distributed throughout the environment following these disasters, contaminate food and water sources, and thus increase the risk of human exposures. These chemicals include a variety of PAHs, industrial solvents, pesticides, heavy metals, and mycotoxins, some of which are considered endocrine disrupting chemicals (EDCs). EDCs are of concern due to their ability to interfere with endocrine systems and contribute to adverse health effects. To minimize exposures to EDCs during disaster events, activated charcoal (AC) can be used as a broad-acting sorbent. Our laboratory tested six medical-grade ACs from various sources (e.g., coconut shell, hardwood, bamboo, and coal) to evaluate sorption potential for EDCs. A model was developed using zearealenone, a food contaminant and known EDC, to evaluate the abilities of various ACs to adsorb onto active surfaces and protect against exposures. Representative chemicals of each class were evaluated, including DDT and glyphosate (pesticides), toluene (solvents), benzo[a]pyrene (PAHs), as well as arsenic and lead (heavy metals). Isothermal analyses using the Langmuir model (q = Qmax * (Kc/C) / (1 + Kc/C)) showed high binding capacities (Qmax) of ACs for these chemicals, with Qmax values ranging from 0.16 to 0.72 mol/kg. A living organism (Hydra vulgaris) was used as an in vivo toxicity indicator and showed that ACs provide approximately 90% protection of hydra from lead toxicity at 0.05% inclusion, and approximately 60% protection from arsenic toxicity at 0.5% inclusion. Further studies evaluated the thermodynamics of sorption reactions and derived therapeutic doses of ACs for use in disaster scenarios. These results suggest that AC can be used as a broad-acting sorbent to facilitate the protection of humans from contaminated food and water during natural and manmade disasters. Supported by NIHES SRP P42 ES0277704.

**2643 Total Arsenic and Speciation Analysis in Seaweeds from South Korea**

M. Kim, S. Choi, and K. Lee. Korea University, Seoul, Korea, Republic of; Sponsor: J. Lee.

Seaweed, which is rich in dietary fiber and minerals is a popular seafood in South Korea. The annual consumption of seaweed in South Korea is close to 5 kg, and more than 50 kinds of seaweeds are used for food. Toxicity and bioavailability of arsenic containing compounds are closely related to their chemical speciation. Due to the different toxicity between chemical forms, speciation analysis is important for evaluating arsenic uptake. In this study, total arsenic (TAs) and six arsenic species (arsenate (As III), arsenite (As IV), monomethylarsonic acid (MMA), dimethylarsinic acid (DMA), arsenobetaine (AsB), and arsenocholine (AsCh)) were analyzed in kelp (n = 33), seaweed (n = 25) seaweed fulvescens (n = 17) and gulfweed (n = 12) samples. South Korea’s Ministry of Food and Drug Safety provided a tAs analysis method and a structural analogue method was used for the pretreatment of the samples. We validated accuracy and resolution using the Langmuir model (q = Qmax * (Kc/C) / (1 + Kc/C)) showed high binding capacities (Qmax) of ACs for these chemicals, with Qmax values ranging from 0.16 to 0.72 mol/kg. A living organism (Hydra vulgaris) was used as an in vivo toxicity indicator and showed that ACs provide approximately 90% protection of hydra from lead toxicity at 0.05% inclusion, and approximately 60% protection from arsenic toxicity at 0.5% inclusion. Further studies evaluated the thermodynamics of sorption reactions and derived therapeutic doses of ACs for use in disaster scenarios. These results suggest that AC can be used as a broad-acting sorbent to facilitate the protection of humans from contaminated food and water during natural and manmade disasters. Supported by NIHES SRP P42 ES0277704.

**2644 How Can Developmental/Reproductive and Endocrine Activity Alerts Be Used in Risk Assessment of Food Contact Chemicals?**

S. Manganelli1, B. Schilter1, I. Perrini1, E. Benfenati2, and E. Lo Piparo1.

1 Nestlé Research, Lausanne, Switzerland; and 2 Istituto di Ricerche Farmacologiche, Milan, Italy.

The uncertainty relating the safety of food contact materials (FCM) triggers increasing public, scientific and regulatory attention. In silico models are an appealing solution for rapid and cost-efficient screening of these chemicals, since for most of them toxicological data is not available. Aside from prediction of chronic toxicity, for their complete hazard assessment, information on their potential developmental and reproductive toxicity (DART) is needed. Existing publicly available predictive in silico tools give a qualitative information related to the presence or absence of DART and/or endocrine effects. This approach is suitable for hazard identification (identification of intrinsic properties of a chemical to cause harm) but it does not give any information about hazard characterization (dose needed to trigger a toxic effect) and even less on its potential health risk. In this context, the present study was aimed at drawing up a fast in silico strategy to predict potential DART and endocrine activity of food contact chemicals in the absence of experimental data. In detail, a stepwise approach, incorporating in parallel structural alerts (SA) and docking on nuclear receptors followed by read-across to quantify the alert, was defined and applied on a diverse data set of 195 food contact chemicals [1] and structural analogues, including 72 chemicals toxicologically characterized for different DART endpoints and/or endocrine activity. The combination of SA and docking gave a full coverage of experimentally positive FCM, with only one misclassification for a FCM structural analogue. Out of 123 characterized chemicals, 12 were prioritized for positive DART and/or endocrine effects. Positive chemicals were promoted for read-across providing a quantitative estimation of the effects. These results showed that in contrast to the use of single models, often addressing specific endpoints and based on very specific and limited applicability domains, our strategy can be applied to different chemical classes and covers a broad range of effects. Most important, it gives a quantitative information to be compared with exposure for the calculation of a margin of exposure in a risk assessment approach. [1] Manganelli, S., et al. (2018). Integrated strategy for mutagenicity prediction applied to food contact chemicals. ALTEX 35, 169–178.

**2645 Monitoring of 8 Polycyclic Aromatic Hydrocarbons in 11 Different Regions of Tap Water in South Korea**

W. Kim1, G. Jeon1, J. Lee2, B. Moon2, and K. Lee1. Korea University, Seoul, Korea, Republic of; and 2 Chung-ang University, Ansan, Korea, Republic of; Sponsor: J. Lee.

Polycyclic aromatic hydrocarbons (PAHs) are organic compounds which are known to relate to damaging the DNA in human tissue and cause cancers or other adverse effects. They are formed as a result of incomplete combustion of organic materials. Once formed, those could contaminate many parts of the environment such as atmosphere, plants, and water. Direct food intake is one of the major routes of exposure to PAHs. During the cooking process, water is the essential ingredient in various recipes. Therefore, it is necessary to monitor PAHs in water. In this investigation, we measured 8 compounds of PAHs (benzo[a]pyrene, chrysene, benzo[b]fluoranthene, benz[a]anthracene, benzo[k]fluoranthene, benzo[a]pyrene, dibenz[a,h]anthracene and indeno[1,2,3-cd]pyrene) in 11 different regional tap water with gas chromatography with mass spectrometry, GC-MS. Benzo[a]pyrene-d12 and chrysene-d12 were used as internal standards. The ultrasonic extraction method was used for the pretreatment of the samples. We validated accuracies and precisions using an intra-inter day test and limit of detection (LOD). As a result, the standards accuracies ranged from 80 to 120 with precision values of 20%. The LOD of all PAHs were ranged between 0.016 to 0.313 ng/L. We could not detect all of 8 PAHs in the tap water in South Korea.

**2646 FDA Assessment of Coronary Heart Disease Risk of Industrially-Produced Trans Fatty Acids in Partially Hydrogenated Oils**

Partially hydrogenated oils (PHOs) are the main dietary source of industrially-produced trans fatty acids (IP-TFA). In 2015, the US FDA determined that there is no longer a consensus among qualified experts that PHOs are generally recognized as safe substances for any use in human foods. In 2018, US
2647 Vomitoxin-Adulterated Adlay Counteracts Toxin-Induced Injuries: New Safety Levels?

1 National Institute of Horticultural and Herbal Science, Eumsung, Korea, Republic of; and 2 Pusan National University, Yangsan, Korea, Republic of.

Adlay (Job’s tears, Coix lacerma-job) is a cereal crop that has long been used as traditional herbal medicine and as a highly nourishing food. However, vomitoxin (VT, deoxynivalenol), the most prevalent trichothecene mycotoxin worldwide, frequently spoils grains, including adlay, via fungal infection. Based on the assumption that the actions of VT in the gut could be modified by acetylation and glycoside (modified mycotoxin) of trichothecenes in commodities. We developed a simultaneous analytical method using a multifunctional column for the detection of 7 trichothecenes including four modified forms of 4,15-DAS (4,15-Diacetoxyscirpenol, 7-triacetoxy-3,7-dihydroxy-12,13-epoxytrichothec-9-ene and 4,15-diacetylenalinol), purified from cultures of F. equiseti and T-2 and HT-2 toxins in cereals. The performance of the current method was evaluated, and a total of 248 samples of five different commodities were analyzed for over two years by this method. 4,15-DAS was detected in Job’s tears products, corn flour and azuki beans; however, it was not found in wheat flour or rye flour. The four modified forms of 4,15-DAS were detected in samples of Job’s tears products, contaminated by 4,15-DAS. This is the first report on the quantification of the modified forms of 4,15-DAS in cereals.

2648 A Polyphasic Method for the Identification of Aflatoxigenic Aspergillus from Cashew Nuts

M. Adetunj,1,2 L. Ngoma,1 O. Atanda2, and M. Mwanza1.
1 North West University Mafikeng Campus, Mafikeng, South Africa; and 2 McPherson University, Seriki Sotayo, Nigeria.

The invasion of food by toxigenic fungi has become a treat to public health. This study aimed at enumerating the microbial profile, detection of aflatoxin producing genes and quantification of the levels of aflatoxin contamination of cashew nuts meant for human consumption. A polyphasic method of analysis using suitable culture media newly formulated β-Cyclodextrin Neutral Red Desiccated coconut agar (β-CDNRCDA) and Yeast Extract Sucrose agar (YES). Thin Layer Chromatography (TLC), Polymerase Chain Reaction (PCR) and High Performance Liquid Chromatographic (HPLC) method was adopted in determining the aflatoxigenic potential of the isolates, the presence of aflatoxin biosynthetic gene (aflM,aflD, aflR, aflJ and omt-A), and estimation of the total aflatoxin content of the nuts. The fungal counts ranged between 100-1300cfu/g and sixty-three isolates belonging to 18 fungal genera and 34 species were isolated. The Aspergillus spp. were the most frequently isolated (50.79%) while the Trichoderma spp. (15.99%) were the least frequent organisms. Fluorescence production was enhanced on β-CDNRCDA for characterization of aflatoxinogenic fungi. The GFP gene was amplified in all the isolates while aflM, aflR and aflJ gene were each amplified in 77.7% of the isolates and omt-A gene in 70.37%. The aflatoxin content of the nuts were below the 4µg/kg, EU recommended limit for total aflatoxins and ranged from 0.03-0.77 µg/kg. The present work reveals that a single method may not be sufficient for screening for the presence of aflatoxins in foods or isolates, but a combination of different methods will preferably yield a more confirmatory result.

2649 Development of an Analytical Method for the Simultaneous Detection of Modified 4,15-Diacetoxyscirpenol and Its Presence in Japanese Retail Food

Y. Sugita-Konishi1, N. Takeda1, M. Watanabe2, N. Kobayashi3, and T. Yashinari1.
1 Azabu University, Sagamihara, Japan; and 2 National Institute of Health Sciences, Kawasaki, Kanagawa, Japan.

Trichothecene mycotoxins are a group of more than 80 compounds that are mainly produced by the Fusarium species. They are classified into four types (A-D) based on their structure. 4,15-Diacetoxyscirpenol (4,15-DAS) is an A type trichothecene, in which T-2 and HT-2 belong. Regarding the contamination status and analytical methods, there have been many studies on T-2 and HT-2; in contrast, there have been few studies on 4,15-DAS. In 2016 the JECFA evaluated 4,15-DAS and established the total provisional maximum tolerable daily intake (PMDTI) with T-2 and HT-2. However, the contamination of 4,15-DAS in food consumed in Japan has not been surveyed. Recently, the contamination of chemically modified forms of 4,15-DAS with acetylation and glycoside (modified mycotoxin) of trichothecenes in commodities. We developed a simultaneous analytical method using a multifunctional column for the detection of 7 trichothecenes including four modified forms of 4,15-DAS (4,15-Diacetoxyscirpenol, 7-triacetoxy-3,7-dihydroxy-12,13-epoxytrichothec-9-ene and 4,15-diacetylenalinol) purified from cultures of F. equiseti and T-2 and HT-2 toxins in cereals. The performance of the current method was evaluated, and a total of 248 samples of five different commodities were analyzed for over two years by this method. 4,15-DAS was detected in Job’s tears products, corn flour and azuki beans; however, it was not found in wheat flour or rye flour. The four modified forms of 4,15-DAS were detected in samples of Job’s tears products, contaminated by 4,15-DAS. This is the first report on the quantification of the modified forms of 4,15-DAS in cereals.

2650 Toxin Enterosorbs for Inclusion in Food and Water during Emergencies and Natural Disasters

Texas A&M University, College Station, TX.

Following disasters, the mobilization and redistribution of contaminants can increase the risk of exposures to mixtures of hazardous substances and impact the safety of water and food being consumed. In this study, montmorillonite clays have been amended with natural products (i.e., L-carnitine, choline, and chlorophyllin) at 100% cation exchange capacity, or processed to simulate broad-acting carbons. The major goal of this study is to use these sorbents in the diet to reduce human and animal exposures to contaminants at the site of disasters. Based on equilibrium isothermal analysis, thermodynamic studies and mechanistic studies, we have demonstrated significantly increased binding capacities (Qmax, affinities (Kd) and enthalpies (ΔH) of sorption for paragat, glyphosate and benzo(a)pyrene. From dosimetry analyses, we have extrapolated the daily dose of sorbent needed to meet the regulatory levels for individual hazardous chemicals. This information will also facilitate the determination of dosage requirements for enterosorbent therapy. The hydra bioassay was used as a sensitive in vivo indicator of toxicity to confirm the safety and efficacy of sorbents for individual chemicals. Other Superfund chemicals were also shown to be adsorbed with high capacity and affinity, including pentachlorophenol, trichlorophenol, phenol, pyrene, lindane, diazinon, aldicarb and linuron. The hydra method was used to indicate the toxicity of “Designed” mixtures and “Real” mixtures from contaminated water and sediment from Superfund sites, and the ability of sorbents (at low inclusion levels) to protect against these chemical mixtures. We anticipate that a mixture of optimal sorbents developed from this study can be delivered in food,
snacks, condiments, flavored water, sachets or capsules during disasters to reduce human and animal exposure to chemicals and microbes. Supported by NIEHS SRP P42 ES0277704.

**2651 Safety Evaluation of L-Theanine Administered via Hard Chew to Dogs**
R. G. Henderson1, C. Doepker2, and J. G. Lopez3.1ToxStrategies, Inc., Wilmington, NC;2ToxStrategies, Inc., Newport, KY; and3Virbac Corporation, Fort Worth, TX.

L-theanine has been evaluated in several clinical trials, demonstrating beneficial effects in dogs and cats in recent years. However, specific safety trials of L-theanine in these target species in the public domain are lacking. The present study was designed to evaluate the safety of L-theanine at the recommended dose, and to demonstrate an adequate margin of safety in dogs. Beagle dogs (4 per sex/group; 9.54-14.53 kg) received one or five hard chews orally per day for 28 days; four control dogs were not given any chews. Each 25-g hard chew contained 0.184% L-theanine. Blood was collected on Days 14, 15, and 28. Body weights and clinical examinations were recorded weekly, and animals were returned to stock at study completion. All animals ate the chews spontaneously within one hour, demonstrating good palatability; there was no effect on food consumption. No abnormalities were noted during the clinical observations throughout the study. Mild or moderate symptoms were recorded in some animals, including development of otitis in one animal. Gastroenteritis, constipation, diarrhea, or vomiting were not among the noted abnormal findings. The absence of gastrointestinal symptoms in all groups determined not to be treatment-related and to be within normal physiological range. No treatment-related changes in body weight were observed. While diarrhea was recorded in a majority of the animals, including once in the controls, these effects were also present during the acclimation period, in general, for one dog in each housed pair and were determined not to be dose-related. Some individual hematological values fell outside the physiological ranges. For example, a few individual white-blood-cell counts were low in control-group animals on Day 14 or elevated in high-dose-group dogs before treatment. However, all mean hematological values were within the respective normal physiological ranges. Starting at Day 14, some animals in all groups had globulin values just below the reference range (mean 22 g/L, compared to 25-45 g/L); on Day 28, only the lower dose group remained lower (24 g/L). Similarly, mean chloride values were just over the reference range of 109-122 mmol/L for all groups, and only remained elevated in the 5x dose group on Day 28 (123 mmol/L). Thus, while some minor differences in pre- and post-treatment serum chemistry results were observed, they were determined not to be clinically significant. In conclusion, the L-theanine product was found to not cause adverse effects when administered to dogs orally for 28 days, including up to the targeted margin of safety of 5x the recommended dose.

**2652 Impact of Thermally Abused Oil on Gut Inflammation, Colon Tumorigenesis, and Hepatic Gene Expression in Mice Fed a Standard Diet or the Total Western Diet**
S. Phatak1, K. Campbell1, K. Hintze1,2, W. Helferich1, and A. Benninghoff1,2.
1Utah State University, Logan, UT;2Utah Science and Technology Research Initiative, Logan, UT; and3University of Illinois, Urbana, IL.

Deep frying foods damages macromolecule components and contributes to the formation of several toxic compounds known to negatively influence health outcomes, including increased colorectal cancer (CRC) risk. Evidence from in vitro experiments or in vivo animal studies suggest that exposure to oxidized dietary lipids can damage proteins, alter hepatic gene expression, disrupt inflammatory/immunity signaling, or alter glucose metabolism. The objective of this study was to determine the impact of thermally abused oil (TAO) in a healthy rodent diet (AIN93G) or the total Western diet (TWD) for rodents on health endpoints associated with chronic inflammation and CRC. We hypothesized that consumption of TAO would promote gut inflammation and colon tumorigenesis, as compared to diets prepared with fresh oil. The azoxymethane and dextran sodium sulfate model of inflammation-associated CRC was employed with a 2x2 experimental design, where C57BL/6J mice were fed standard AIN93G or TWD, each prepared with either fresh oil or TAO. AIN93G+TAO did not significantly impact any of the measured parameters as compared to AIN93G+fresh oil. Also, dietary exposure to TAO did not enhance colitis symptoms or colon tumorigenesis in mice fed either basal diet. Energy intake in mice provided TWD+TAO was significantly greater than observed in mice fed TAO+fresh oil, nevertheless, this change did not translate to increased body weight or fat mass gain. The observation that TAO appeared to disrupt glucose regulation in the context of a Western-style diet prompted further investigation of hepatic function via gene expression analysis on the Fluidigm Biomark platform. RNA was isolated from hepatocytes using TRI reagent and 48 primers were designed for genes of interest with key regulatory roles. This supplementary analysis will include gene targets associated with insulin homeostasis, lipid metabolism, immune regulation, xenobiotic metabolism, and conjugation, using novel reference genes for normalization.

**2653 Effects of Infant Formula Feeding on Neonatal Mammary Gland Development**
H. Lin1,2, M. Chaudhury1, N. Sharma3, S. Bhattacharyya1,2, L. Yeruva1,2, M. T. Ronis1, and K. E. Mercer1,3.1Arkansas Children’s Nutrition Center, Little Rock, AR;2University of Arkansas for Medical Sciences, Little Rock, AR; and3Louisiana State University Health Sciences Center, New Orleans, LA.

Soy formulas contain isoflavones, which are structurally similar to estradiol (E2). Given the mammary gland is sensitive to estrogens, there are concerns that soy formula feeding may promote premature mammary development. In this study, we used a neonatal piglet model to identify changes in early mammary gland development in response to different postnatal diets. Groups of female piglets (n=6/group) were fed cow’s milk formula (Milk), soy formula (Soy), or breastfed with the sow (Sow) postnatal day 2-21. To assess directly the effects of estrogen or isoflavone on mammary development, additional groups were fed Milk supplemented with estradiol (Milk+E2) or with genistein (Milk+G). In the Milk+E2 group, serum E2 concentration was significantly higher (10- to 20-fold) relative to other diet groups. Terminal end bud numbers were significantly increased in the Milk, Soy and Milk+G groups relative to Sow or Milk+E2 groups. Microarray analysis identified 130, 253, 125, and 170 differentially-expressed transcripts (±2-fold, P<0.05) between Milk, Milk+E2, Milk+G and Soy groups, respectively, relative to the Sow group. Functional annotation analysis indicated formula feeding alters gene expression in pathways associated with cell proliferation and apoptosis. Additional pathways that were identified, cell morphogenesis and differentiation and hormone signaling were only associated with the Milk+E2 group. We also confirmed several down-regulated microRNAs including miR-128, miR-1 and miR-422b (2.4- to 10.2-fold) in the formula groups compared to the Sow control; these have been implicated in regulation of cellular apoptosis and proliferation. The changes in mRNA expression of Wnt2b, cyclin D and n-myc indicated a heightened proliferative state in mammary glands of all formula groups compared to the Sow group. E2-responsive genes, Pgr, Tgfβ2, Rerg, were significantly upregulated in the Milk+E2 group relative to all other groups. Our data suggest that dietary exposure to soy isoflavones during infant feeding does not elicit an estrogenic response in the mammary gland. Still, formula feeding may initiate proliferative pathways independent of estrogenic signaling.

**2654 Application of Sphingolipids as Biomarkers of Fumonisins Exposure in Kenyan Children**
R. Wangia1, D. Githanga2, K. Xue3, L. Tang3, O. Anzala1, and J. Wang1.
1University of Georgia, Athens, GA; and2University of Nairobi, Nairobi, Kenya.

Fumonisins (FNs), a group of mycotoxins produced mainly by several Fusarium species, are ubiquitous food contaminants, especially for corn and corn products. Fumonisin B1 (FB1) caused severe toxicities in farming animals, induced kidney and liver tumors in rodents and fish, and has been associated with many human adverse health effects, including esophageal cancer. IARC has categorized FB1 as possible human carcinogen (Group 2B). Inhibition of ceramide synthesis and disruption of sphingolipids metabolism have been well studied as the major mechanisms of FB1-induced toxicity. Dynamic changes of sphingolipids, specifically increases in sphinganine (Sa) and decrease in sphingosine (So) levels as well as their ratio have been proposed to be the major indicators of FB1 exposure in human subjects. The primary objective of this study was to determine the feasibility of using sphingolipid analysis as a biomarker for Fumonisin exposure in children. A total of 284 urine samples were collected from children age 1 to 14 years in Kenya, a high mycotoxin exposure region. Exfoliated cells from urine were isolated, processed and sphingolipids quantified by High Pressure Liquid Chromatography with fluorescence detection. Sa and So were detectable in 95.07% and 98.94% of the urine samples respectively. All non-detectable samples were from male subjects. The levels of Sa, So and Sa/So ratio and assessed FN exposure in Kenya children who consume maize as a staple diet. A total of 284 urine samples were collected from children age 1 to 14 years in Kenya, a high mycotoxin exposure region. Exfoliated cells from urine were isolated, processed and sphingolipids quantified by High Pressure Liquid Chromatography with fluorescence detection. Sa and So were detectable in 95.07% and 98.94% of the urine samples respectively. All non-detectable samples were from male subjects. The levels of Sa, So and Sa/So ratio and assessed FN exposure in children. 389

2019 SOT Annual Meeting
2655  Aflatoxin B1-Induced Alterations on Gut Microbiota-Dependent Nutritional Metabolome in F344 Rats

J. Zhou, L. Tang, and J. Wang. University of Georgia, Athens, GA.

Human gut-microbiota serves as the key hub of initial nutritional provision. Our previous study has demonstrated that aflatoxin B1 (AFB1), a major contributor to the AFB1-associated toxic side effects, can be well separated by LemonGlyerol treatment using weighted Unifrac analysis. Furthermore, GMB analysis of the feces at week 4 indicated that the GMB metabolic patterns, with the most prominent difference observed in the treatment groups, were aligned, and 60 of the top 100 differential features were imputatively identified from NIST database. Bioinformatic analysis demonstrated that the major metabolic pathways disrupted by AFB1 include: valine-leucine metabolism, bile acid and steroid synthesis, GTP Synthesis, N-acetyl-D-glucosamine synthesis, and carbohydrate conversion. For data collected with HRLC-LTQ Orbitrap MS, 3925 MS1 features were aligned using MZmine, whereas 2498 MS2 features (234 groups) were aligned using XCMS. A total of 86 metabolites were identified from these features by searching Human Metabolome Database (HMDB), MassBank, and METLIN databases. The major metabolic pathways affected by AFB1 include: retinol metabolism, glycerolipid metabolism, penelope and glucuronate interconversion, glycerophospholipid metabolism, arginine and proline metabolism. The categories of the altered metabolites/nutrients include carbohydrates, amino acids, bile constituents, phospholipids, glycerolipids, and fatty acids. Interestingly, a number of carbohydrates were accumulated in the feces, such as glucose (2.72 fold), rhamnose (3 fold), fructose (3.6 fold), turanose (2.03 fold), galactose (2 fold), galactitol (1.53 fold), glycerol (1.35 fold), ribose (1.26 fold), 3-beta-D-galactosyl-sn-glycerol (1.36 fold), arabinose (1.39 fold), and trehalose (12.23 fold). These abnormal alterations suggest the impairment of carbohydrate associated metabolisms. Taken together, these results indicated that the impairment of gut-microbiota dependent nutritional metabolome may be a major contributor to the AFB1-induced adverse health outcomes in animals and humans.

2656  Modulation of Microbiome, Glucose Homeostasis, Behavior and Cognition in Non-obese Diabetic Mice Following Daily Dosage of Lemonglycerol Dietary Supplement

H. S. Xu, G. Huang, A. Patel, and T. L. Guo. University of Georgia, Athens, GA.

The Lemonglycerol (HGG Research LLC) has been claimed to support gut and brain health by relieving vertigo, dizziness, headaches, dry throats, and nausea. However, no preclinical studies have been conducted to confirm the success of this dietary supplement. We have hypothesized that brain function can be beneficially regulated by Lemonglycerol in order to maintain the gut-brain axis, which states that the gut and the brain can communicate and affect each other in a number of ways, including gut microbiota (GBM) modulation. To test this hypothesis, non-obese diabetic (NOD) mice had been dosed daily with vehicle (water), lemon extract, food grade glycerol solution and LemonGlycerol (0.05 mL per day) for a total of 6 months. In addition to monitoring the body weight and glucose levels, the tail suspension and Y-maze tests, which assess the depression and cognitive behaviors, were conducted. Our findings suggested that there were no significant effects on glucose homeostasis of the mice and the cognitive behavior at week 17. Despite not reaching the level of statistical significance, there was a decreasing trend of the immobilization time in the tail suspension test for the treatment groups, with the most prominent difference observed in the Lemonglycerol group. This suggested a potential decrease in depression. Furthermore, GMB analysis of the feces at week 4 indicated that the GBM could be well separated by LemonGlycerol treatment using weighted Unifrac with increases of Bacteroides, Desulfovibrioionales and Y52, and decreases of Lactobacillales and Streptophyta at the order level. This anti-inflammatory response was further supported by increases in the abundance of the genera Prevotella, Ruminococcus and Staphylococcus. Further analysis of the pathways and functional metagenomics using Tax4Fun may be able to shed more light on this new prebiotic that might help an array of people suffering from various symptoms listed above and reduce the intake of medications with toxic side effects. Supported in part by NIH R41AT009523.

2657  Safety Paradigm for Evaluation of Food Additives/Ingredients Produced Using Genetically-Modified Microorganisms

S. Tafazzoli, R. Simon, K. Finch, and A. Roberts. Intersect Scientific and Regulatory Consultancy, Mississauga, ON, Canada.

The safety assessment of genetically-modified (GM) foods, which contain viable or non-viable GM microorganisms (GMMs), have been discussed extensively among scientific and regulatory bodies; however, these evaluations have explicitly excluded consideration of high purity additives/ingredients produced using GM technology. To date, authoritative safety paradigms for evaluation of these ingredients have not been published. A guiding principle in the evaluation of GM foods produced using GM technology has been the concept of ‘substantial equivalence’, which embodies the idea that, if the food derived from a GMM is demonstrated to be substantially equivalent in composition and nutritional characteristics to its conventional counterpart, the history of safe consumption of the conventional counterpart can be extended to the GM ingredient. While substantial equivalence can serve as a baseline for the risk assessment of a food additive/ingredient produced using GM technology, additional considerations are necessary in the safety evaluation of these ingredients. Accordingly, a safety paradigm has been proposed to evaluate the safety of food ingredients produced using GMMs. The first step in this paradigm involves evaluating the safety of the food ingredient using the same scientific procedures approach that is applied to non-GM ingredients, and where applicable, involves a ‘substantial equivalence’ approach to evaluate ingredients with a conventional counterpart that have a history of use or have been previously evaluated in animal studies. The second step assesses the potential risks of the host organism lineage and the effects of the introduced genetic transformations, e.g., have genetic modifications introduced pathogenic, toxicogenic, or other undesirable phenotypes, such as antibiotic resistance to the strain? The third step focuses on the safety of the recombinant protein expression products produced by the GMM, and includes bioinformatic evaluation of recombinant proteins for homology, immunoreactivity, and allergenicity. Overall, this strategy is particularly applicable to situations where traditional safety studies may not be feasible (e.g., vitamins), and promotes ethical safety evaluation practices to avoid unnecessary and redundant animal testing of GM additives/ingredients that have an equivalent comparator in the food supply.

2658  Exposure Assessment of Glyphosate in Breakfast Cereals in the US

Glyphosate is one of the most widely used herbicides for agriculture and forestry applications, as well as on lawns and gardens in the United States. This broad-spectrum non-selective herbicide inhibits 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase, a key enzyme necessary for protein synthesis in plants. In March 2015, the International Agency for Research on Cancer (IARC) classified glyphosate as a Group 2A "probably carcinogenic to humans" carcinogen. Subsequently, it was listed under California’s Proposition 65 as a chemical “known to the state to cause cancer” in July 2017. However, the US Environmental Protection Agency (US EPA) reported that glyphosate was “not likely to be carcinogenic to humans,” and the Food and Agriculture Organization (FAO) as well as the World Health Organization (WHO) reported that “glyphosate is unlikely to be genotoxic at anticipated dietary exposures.” There have been recent reports indicating concern regarding glyphosate in cereal. The purpose of this study was to assess the potential cancer risks associated with consumption of glyphosate in different grain-based cereals by age groups by comparing to the Office of Environmental Health Hazard Assessment’s (OEHHA) proposed No Significant Risk Level (NSRL) of 1100 µg/day for glyphosate. Glyphosate intake was estimated using the mean and maximum estimates of consumption, reported by the Environmental Working Group (EWG). Glyphosate exposure from consumption of all cereal types (conventional and organic) for all age groups (6 months to >70 years) ranged from 0.0575 to 8.14 µg/day and 0.0575 to 133 µg/day for mean and maximum estimates of consumption, respectively. Overall, mean and maximum glyphosate exposures through cereal consumption were lower in organic cereals (mean = 0.292 - 8.14 µg/day; max = 0.0575 - 2.62 µg/day) than conventional cereals (mean = 0.0575 - 0.161 µg/day; max = 0.0575 - 0.161 µg/day) for all age groups (6 months to >70 years) ranged from 0.0575 to 8.14 µg/day and 0.0575 to 133 µg/day for mean and maximum estimates of consumption, respectively. Overall, mean and maximum glyphosate exposures through cereal consumption were lower in organic cereals (mean = 0.292 - 8.14 µg/day; max = 0.0575 - 2.62 µg/day) than conventional cereals (mean = 0.0575 - 0.161 µg/day; max = 0.0575 - 2.62 µg/day) for all age groups. Daily glyphosate doses associated with mean and maximum cereal consumption rates of all categories of cereals are well below OEHHA’s NSRL. The cancer risk from glyphosate exposure from cereal is not likely to be of concern in the United States. Future studies should focus on characterizing total glyphosate exposure from multiple food sources such as wine, fruit juices, legumes, and honey.
2659 The Effects of Activated Carbon on Vitamin K and Blood Coagulation in Rats
Activated carbon is widely used to treat intoxications caused by toxic chemicals taken orally, toxins generated in the gastrointestinal tract, drug overdose etc. However, activated carbon can adsorb not only toxins but also nutrients including enzymes, vitamins and minerals, and the overdose has the potential for nutrient deficiency. Among such nutrient compositions, vitamin K plays an important role in the maintenance of blood coagulation, and the deficiency of vitamin K can cause hemorrhage. In this study, we examined the effects of activated carbon on vitamin K and blood coagulation in rats. Activated carbon was administered orally (dietary administration) to male and female rats at 0 (control), 1.0 and 5.0 w/w% for 2 weeks (6 animals/group); the high dose provides more than 10- to 100-fold margin of the clinical dose (2 to 20 g/day). Clinical signs, body weight, food consumptions, hematology (prothrombin time (PT) and activated partial thromboplastin time (APTT)), blood chemistry (plasma vitamin K concentration), and necropsy were performed. There were no abnormalities in clinical signs, body weights and necropsy. An increase in food consumption, prolongation of PT and APTT, and a decrease in plasma vitamin K concentration were noted in both sexes of the treated groups with dose-dependent manner. The degree of the change in PT and APTT was larger in male rats than in female rats; it is known that male rats are more susceptible to vitamin K deficiency than female rats. In addition, we confirmed that activated carbon has adsorption capacity for vitamin K in vitro. In conclusion, activated carbon has adsorption capacity for vitamin K and the large excess interference with absorption of vitamin K from diet potentially induces blood coagulation disorder.

2660 Low-Level of Total and Arsenic Speciation of Cereal Grains in South Korea
K. Lee, M. Kim, and S. Choi. Korea University, Seoul, Korea, Republic of.
Sponsor: J. Lee
Arsenic (As) compounds have different toxic effects on human depending on chemical species with unique characteristics. Inorganic arsenic (iAs, iAs = arsenite (As (III)) and arsenate (As (V))) is more toxic than organic arsenic and is known to affect cardiovascular disease and cancer. The most important contributor to dietary arsenic to As is cereals. Cereals are consumed as important foods that can provide calories and protein to human. Nevertheless, there is a lack of research on the concentration of arsenic species in various cereals. In this study, total arsenic (tAs) and six arsenic species (As (III) and As (V), monomethylarsonic acid (MMA), dimethylarsonic acid (DMA), arsenobetaine (AsB), and arsenocholine (AeC)) were analyzed in adlay (n = 5), oats (n = 13), glutinous millet (n = 15) and sorghum (n = 15) samples. South Korea’s Ministry of Food and Drug Safety, MFDS provided a tAs analysis method and a method for separating 6 species of arsenic. For the present study, tAs was analyzed using inductively coupled plasma-mass spectrometry, ICP-MS, and 6 species of arsenic were analyzed by high-performance liquid chromatography coupled with inductively coupled plasma-mass spectrometry, HPLC-ICP-MS. In our study, tAs and iAs concentration were at a low level. It is also interesting to note that a positive correlation was observed between tAs and iAs concentration in cereals. Also, iAs fractions were dominant in all cereal samples. The main arsenic species found in cereals were As (III), followed by As (V), DMA and MMA, AsB and AeC were not detected. The result of this study suggests a valid method for determining exposure and potential risk of arsenic species.

2661 Evaluation of Exposure to Mycotoxins through Fruit Juices Consumption by Chromatographic Methods Coupled to Mass Spectrometry in Tandem
The Rapid Alert System for Food and Feed (RASFF) of the European Union places mycotoxins in the second position according to the total number of hazard notifications. Fruits are susceptible to attack by pathogenic fungi, due to their high sugar content, ideal water activity and nutrient composition. Mycotoxin occurrence in fruits is led by various genera of fungi such as Alternaria, Fusarium, Penicillium, Aspergillus. The objective of this study was to evaluate the presence of 30 mycotoxins (AFB1, AFB2, AFG1, AFG2, AOH, AME, OTA, FB1, FB2, ENNA, ENNA1, ENNB, ENUB, BEA, STG, ZON, aZAL, βZAL, αZOL, βZOL, DON, 3-ADON, 15ADON, DAS, NIV, FUS-X, NEO, PAT-T2 and HT-2 toxins) in fruit juice samples (n=80) by Dispersive Liquid-Liquid Microextraction (DLLME) and determination by gas and liquid chromatography-tandem mass spectrometry. The methods accuracy was evaluated by recovery assays at three concentration levels, and precision, expressed as the intra- and inter-day relative standard deviations (RSD%). Good validation results in terms of recoveries (63-113%), reproducibility (RSDs <15%) and repeatability (RSDs>20%) were reached. Moreover, limits of detection (0.03-2.34µg/L) and quantitation (0.1-7.85µg/L) achieved were lower than the legal limits. Matrix effect was evaluated and matrix-matched calibrations were used for quantitation. Results showed presence of at least one or two mycotoxins in 69% and 8% of analyzed samples. The mean contamination level of AFB1, AFB2, AFG2, OTA, βZAL, PAT, AME and AOH were 9.36, 4.49, 3.75, 5.43, 23.22, 28.63, 8.54 and 207.01 µg/L respectively. The estimated daily intake (EDI) of the child and adult population was assessed using the deterministic approach, through evaluation of mycotoxin data contamination of fruit juices and consumption. EDIs resulted below the TDIs for the selected mycotoxins. The obtained results indicated that mycotoxins are presents in different fruit juice samples and highlighted the need to perform continuous efforts to ensure food safety. Acknowledgements. 2662 Toxic Tall Fescue Grazing during Fluctuating Environmental Conditions: Impact on the Metabolome, Microbiome and Their Interaction
B. S. Mote1, N. S. Hill2, G. Suen2, Z. B. Turner1, Z. P. Sanders1, D. P. Jones3, J. H. Skarlupka4, V. Tran5, D. I. Walker3, and N. M. Filipovic2. 1University of Georgia, Athens, GA; 2University of Wisconsin-Madison, Madison, WI; and 3Emory University, Atlanta, GA.
Fescue toxicosis (FT) is a livestock disease resulting from grazing tall fescue infected with the ergot alkaloid-producing Epiclhoeae coenophialum and it has a billion dollar negative impact to the U.S. beef industry. The adverse impact of heat stress (HS) on livestock production is an increasing concern and it costs an additional $369 million to US beef producers. Although previous studies showed HS (i.e., high temperature-humidity index (THI)) exacerbates FT signs, the effects of FT and changing THI conditions on metabolic homeostasis, microbiota contribution to metabolic perturbations, and metabolome-microbiome interactions, are unknown. Thus, we utilized fecal 16S rRNA sequencing and plasma and urine high-resolution metabolomics to investigate the effects of toxic tall fescue (E+) grazing and fluctuating THI in Angus steers over a 26-day grazing trial. Grazing E+ fescue decreased weight gain and induced significant changes in amino acid, biotinoprotein, and energy-producing metabolic pathways in both plasma and urine across the trial, with significant interactions between glutamate, tyrosine, and tryptophan metabolites affected by E+ grazing. E+ grazing during elevated THI resulted in significantly decreased biotinoprotein and glutathione (plasma) and increased carbohydrate and butyrate (urine) metabolism. E+ grazing had a main effect on the fecal microbiota, namely on the Ruminococcaceae, Lachnospiraceae, and Coriobacteriaceae families, with these families having OTUs significantly correlated with THI (r > 0.4; P < 0.05). Differential network analysis correlated microbial OTUs were significantly associated (r > 0.7; P < 0.05) with metabolites involved in androgen/estrogen and fatty acid metabolism in E+ steers. As revealed by predictive metagenomics, metabolomes involved in bile acid biosynthesis and amino acid metabolism were decreased by E+ grazing. Overall, these data indicate that effects of E+ grazing on the metabolome and microbiome are altered by THI, which may explain differences in signs or severity of FT throughout the calendar year. 2663 In Vivo Genotoxicity Study of Cylindropermopsis by the Comet Assay
L. Diaz-Quijada1, M. Puerto1, M. Llana-Ruiz-Cabello1, A. Jos1, A. M. Camean2, and E. Lopez2. 1University of Sevilla, Sevilla, Spain; and 2University of Murcia, Murcia, Spain. Sponsor: G. Font
Cylindropermopsis (CYN) is a biotoxin produced by different cyanobacteria species which has hepatotoxic, cytokotoxic and neurotoxic effects in aquatic organisms and mammals. Its ability to bioaccumulate in tissues of different organisms intended for human consumption may have implications in food safety. In this sense, according to the recommendation from the European Food Safety Authority (EFSA) for the genotoxic assessment of substances in food, the in vivo approach is needed to confirm the previous contradictory in vitro results obtained. In the present work, the in vivo genotoxicity of CYN in Wistar rats was evaluated in liver, stomach and blood by the comet assay. Male animals were exposed orally by gavage to CYN (7.5, 23.7, and 75 µg/kg body weight), and the assay was performed according to the recommendations of OECD guideline 489. This assay provides information about mecha-
nisms of genotoxicity since it can detect DNA breaks as well as oxidative DNA damage when the modified enzyme-comet assay is used (Endonuclease III (Endo III) and Formamido pyrimidine glycosylase (FPG)). The results for the standard comet assay revealed no significant increases in DNA strand breaks at any dose assayed. Similarly, post-treatment with Endo III or FPG showed no differences between treated and untreated groups. Thus, CYN does not induce genotoxicity in vivo with the comet assay. However, further research is required to cover all genetic endpoints required by EFSA. Acknowledgment: Spanish Ministerio de Economía y Competitividad for the project AGL2015-64558-R, MINECO/FEDER, UE, and for the grant DPI (BES-2016-078773) awarded to Leticia Díez-Quijada Jiménez.

Magnesium Biotinate (MB) is a novel, highly soluble salt of biotin. The genetic toxicity profile of MB was assessed by performing the Ames assay and in vitro micronucleus assay. Additionally, systemic toxicity of MB was investigated using single and repeat dose toxicity studies. No evidence of mutagenicity was observed in the Ames assay. The in vitro micronucleus test showed no evidence of clastogenicity. Acute oral toxicity testing established a LD50 greater than 5000 mg/kg of body weight. No effects on body weight parameters were observed after 14-days of oral administration at doses up to 2500 mg/kg/day; therefore, a 90-day study was conducted at dose levels of 120, 600 and 2500 mg/kg/day. In the 90-day study, one female at 2500 mg/kg/day was euthanized for humane reasons on Study Day 63 and exhibited hunched posture, facial/abdominal/ano-genital staining, diarrhea, red nasal discharge, reduced food consumption, reduced fecal volume, and thin appearance. This animal had macroscopic and microscopic evidence of gastric ulceration and lymphoid and bone marrow depletion. For the surviving animals, there were no clinical or ophthalmic signs. A slight decrease in body weight and body weight gain was observed for males at 2500 mg/kg/day; however, due to the magnitude and lack of correlation with clinical or histopathological findings, the decrease was interpreted not to be adverse. There were no test substance-related changes in coagulation and urinalysis parameters. Slight increases in sodium, potassium and/or chloride were observed in males at all dose levels and in females at greater than or equal to 600 mg/kg/day, but were not associated with changes in other serum chemistry indices by in vitro endpoints of toxicity. Given the hydrophobic nature of most of these compounds, the dose of 100 µM was the highest achievable dose to accommodate the no-observed-adverse-effect-level for MB, administered orally for over 90 days, which was determined to be 600 mg/kg/day.

Chloropropanols are chemical contaminants that can be formed during industriual processing of foods, such as lipids used in commercially available infant formula in the United States. Studies have shown that the most common chloropropanol, 3-monochloropropene-1,2-diol (3-MCPD), and lipid ester derivatives of 3-MCPD may have the capacity to be carcinogenic and induce injury to the kidneys and reproductive organs in animal models. To investigate the safety of the most abundant chloropropanols in infant formula, we asked whether the proximal tubule cells of the kidney would be vulnerable to their effects in a direct exposure model in vitro. Using the established human kidney proximal tubule cell line, HK-2, we performed 24-hour treatments with 3-MCPD and select mono- and di-esters derived from palmitate, oleate, and linoleate. Direct exposure to HK-2 cells at treatment doses ranging from 0 to 100 µM was performed to evaluate effects on cell viability, mitochondrial health, reactive oxygen species (ROS) production, and other endpoints of toxicity. Given the hydrophobic nature of most of these compounds, the dose of 100 µM was the highest achievable dose to accommodate our in vitro cell culture model. For each test compound, cell viability only became compromised at high treatment doses (50-100 µM range; P<0.05). These high dose effects were verified by fluorescence imaging of cells treated and stained with Hoechst 33342 and Propidium Iodide. Our study showed that the mode(s) of cell death may not have directly involved disruption of mitochondrial membrane potential, since mitochondrial integrity was not strongly affected except at high doses of the mono-ester of linoleic acid (1-Li). Moreover, significant production of ROS molecules was only detectable at low doses of the 3-MCPD di-esters of the oleic and linoleic acid combinations (O-Li and L-Li; P<0.05). Since chloropropanols reportedly inhibit cell metabolism through interference with glycolysis, we also tested the extent of this
2672 Influence of Serum Lutein and Zeaxanthin on Determination of L-Lysine by Raman Spectroscopy

E. Holland, and R. Bright, Fort Valley State University, Fort Valley, GA.

The Food and Drug Administration does not regulate dietary supplements meaning the supplement companies are responsible for ensuring there are no dangerous contaminants and have the suggested dosage of active ingredients. This study was to compare the amount of L-Lysine in nine dietary supplements to the amounts on the packages using Raman Spectroscopy. Raman Spectroscopy is a scattering method that measures the vibrational modes of molecules. This method was used as opposed to the other analysis methods due to relative speed of detection. Dietary supplements were chosen based on their availability in nearby stores and by Amazon’s Most Recommended List. For the standards, 1.5 g, 2.0 g, 4.0 g, 6.0 g, and 8.0 g of L-Lysine Hydrochloride were measured into 25.0 mL volumetric flasks. Based on the amounts of L-Lysine claimed on the packings, which were either 500 mg or 1000 mg per pill, the number of pills to deliver approximately 5.0 grams of the L-Lysine were crushed and dissolved. Standards and samples were prepared by either dissolving in distilled water or in 1.0 X 10^{-3} M HCl. HCl was used as a closer approximation to stomach conditions. The supplements were then filtered and scanned by PHARM-ID Raman spectrophotometer. The results showed that supplements dissolved in the water have lower amounts of lysine detected than the supplements dissolved in 1.0 X 10^{-3} M of HCl. Overall, the amounts of L-Lysine in the supplements were 26% higher for water and 34% higher than the stated value for HCl.

2668 Virulence Evaluation of Salmonella enterica Isolates Containing Incompatibility Group I1 (IncI1) Plasmids from Food Animal and Human Sources

P. R. Kaldhone, A. Carlson, B. Khajanchi, Y. Sanad, J. Han, J. Deck, S. C. Ricke, and S. L. Foley, US FDA/NCTR, Jefferson, AR; 3University of Arkansas, Pine Bluff, AR; and 4University of Arkansas, Fayetteville, AR.

Salmonella enterica is a leading foodborne pathogen in the U.S. Mobile genetic elements, such as plasmids, can potentially increase their ability to infect and persist in hosts. IncI1 plasmids are widely distributed in Salmonella from food animal sources. These types of plasmids often encode antimicrobial resistance; however, little is known about their impact on the virulence. To assess the potential impact of the plasmids on virulence, 46 IncI1-positive Salmonella isolates from food animal and human sources were evaluated for their abilities to invade and persist for 48 hours in Caco-2 human intestinal epithelial cells. For the virulence studies, Caco-2 cells were grown to confluence, infected with Salmonella isolates and incubated for both one and 48 hours for the invasion and persistence assays, respectively. Additionally, Salmonella isolates were assessed for their ability to produce colicin toxins and inhibit other bacteria. All isolates infected Caco-2 cells after one hour incubation and persisted in the cells at 48 hrs. Persistent cell counts were observed to be significantly higher than invasion assay cell counts in 26% of the isolates. Overall, by (n=36) of Salmonella isolates were able to inhibit growth of at least one E. coli strain. In this study, isolates carrying IncI1 plasmids were able to invade and persist in elevated levels in the intestinal epithelial cell model and able to produce colicin toxins that may provide a selective colonization advantage. This study provides the foundation for additional studies to refine the contribution of the specific IncI1 plasmid-associated genes to virulence. Identification of genetic determinants relevant for increased virulence and toxin production would help to design screening tools for foodborne pathogens and enhance food safety.

2669 Evaluating the Significance of Immunomodulatory Effects Reported for Food Ingredients Undergoing Generally Recognized as Safe (GRAS) Evaluations

A. Mak, N. Dai, A. R. Lobach, and A. Roberts, Intertek, Mississauga, ON, Canada.

The functioning of the immune system is influenced by several factors including the diet. When food ingredients and functional foods are associated with immune modulation, there is not always a clear understanding as to whether these changes are indicative of an adverse, beneficial, or neutral effect. From a regulatory perspective, the US FDA has received some Generally Recognized as Safe (GRAS) notifications reporting immunomodulation, to which the Agency appears to have responded with questions regarding the safety of these effects. The purpose of the current work was to identify the immunomodulatory changes reported in these notifications and to distinguish which effects should be considered innocuous, versus those that could be indicative of safety concerns. Specific immunomodulatory effects were identified from publicly available and confidential GRAS evaluations. Relevant toxicology data were systematically identified for each immunomodulatory factor to determine their significance in terms of safety in food. Increased numbers of blood dendritic cells, CD8+ cytotoxic T cells, and natural killer cells were identified as common immunomodulatory effects reported in GRAS evaluations of certain probiotic and fungal derived products that were flagged as potential safety concerns. These findings, however, were not accompanied by significant changes in any other safety-related endpoints. Slight increases in cells with inflammatory potential are unlikely to be of immediate physiological significance without supporting evidence such as elevated levels of inflammatory cytokines (e.g., TNFα) or indication of tissue injury (e.g., increased ALT levels). However, it appears that the safety issue relates to the potential long-term consequences of sustained immunostimulation, which is difficult to completely refute with short-term toxicology data. Although GRAS evaluations of certain probiotic and fungal derived products demonstrate a slight increase in the number of cells with inflammatory potential, these effects are unlikely to be of immediate physiological significance. Further investigations on the consequences of sustained long-term low-level stimulation of the immune system from food is warranted to overcome safety concerns.

2670 Determination of L-Lysine by Raman Spectroscopy

E. Holland, and R. Bright, Fort Valley State University, Fort Valley, GA.

The Food and Drug Administration does not regulate dietary supplements meaning the supplement companies are responsible for ensuring there are no dangerous contaminants and have the suggested dosage of active ingredients. This study was to compare the amount of L-Lysine in nine dietary supplements to the amounts on the packages using Raman Spectroscopy. Raman Spectroscopy is a scattering method that measures the vibrational modes of molecules. This method was used as opposed to the other analysis methods due to relative speed of detection. 2671 Dried Pig Faeces: Impacts on Nutrient Utilization, Histology and Haematology of Clarias gariepinus

A. O. Ajiboye, F. Ajiado, B. O. Emikpe, and A. A. Adesanya1. 1Bowen University, Iwo, Nigeria; 2University of Ibadan, Ibadan, Nigeria; and 3Osun State University, Ejobo Campus, Nigeria.

Improper utilization and disposal of pig faeces in pig farms have been a great concern due to their hazards and risks they constitute to the environment. This situation calls for conversion of animal waste to wealth through effective utilization of pig faeces for fish feed formulation. This project was therefore designed to provide information on safe level of Dried Poultry Faeces (DPF) on growth, histology and haematology of Clarias gariepinus. A total number of one hundred and fifty samples of C. gariepinus were collected for the feeding trial experiment. Growth, histology, and haematology of the fish samples were determined according to standard methods. Data obtained were subjected to statistical analysis using ANOVA and Duncan multiple range test was used to separate the means. The Mean Weight Gain revealed a significant increase in T3 (69.40g) among the treatments, while 100% inclusion of DPF exhibited lowest value (21.07%). The Packed Cell Volume, Haemoglobin and Red Blood Cell values obtained decreased with increase in DPF inclusions, while an increase in these parameters were observed in T4 (26.50%). White Blood Cell count was significant in T3 (16,150±2.07g/l) and decreased in T4(15,800±2.10g/l) and T2(12,650±0.85g/l) respectively. Histological results confirmed the absence of lesions in the heart, gills and the intestine of fish samples. Lesions was severed in the liver in T4 and T5. The findings of this study revealed that 50% inclusion of DPF is the safe level for growth and survival of C. gariepinus. Since the histological results also revealed no lesions in all the vital organs, except the liver that had severe lesions, DPF can be recommended as an alternative feed ingredient that could substitute fish meal in the fish diet.

2672 Influence of Serum Lutein and Zeaxanthin on Select Cancer Mortality: An 18-Year Follow-Up Cohort Study

E. Afriyie-Gyawu, P. Shankar, A. Brown, and J. Zhang, Georgia Southern University, Statesboro, GA.

Lutein and zeaxanthin (L&Z) are members of the carotenoid family. Food sources of L&Z include a variety of fruits and vegetables, with green leafy vegetables being the richest source. Observational studies indicate L&Z reduce risk for chronic diseases including cancer. L&Z possess important antioxidant properties, promote anti-carcinogenic effects, and have immune modulatory effects and apoptosis-inducing capabilities. To our knowledge, influence of
L&Z on cancer mortality has not yet been characterized. Thus, our objective was to evaluate potential association between L&Z and all-cancer (i.e., breast, colorectal, lung, and prostate cancers) mortality. This retrospective cohort study was conducted with 14,358 adults who participated in Phase II of the National Health and Nutrition Examination Survey III (NHANES III). The dataset served as baseline and was correlated with the National Death Index database for an 18-year (1998–2006) follow-up study. Hazard ratios (HRs) for cancer-related deaths for individuals with high, medium, and low serum L&Z levels were calculated using the Cox Proportional Hazards Regression Model. Unadjusted HRs of all-cancer deaths associated with low serum levels (25% cutoff) of L&Z were 1.32 (95% CI=1.08-1.62) and 1.00 (ref). Adjusted for multiple risk factors (age, sex, race/ethnicity, education, alcohol intake, and cigarette smoke), HRs for all-cancer deaths were 1.18 (95% CI=0.95-1.45) for low serum levels of L&Z and 1.00 (ref). Adjusted HRs for all-cancer deaths, using a 3-level categorization (not adjusting for fruits and vegetables), were 1.50 (95% CI=1.19-1.90) for low vs. high and 1.40 (95% CI=1.18-1.65) for medium vs. high; colorectal cancer mortality was 2.49 (95% CI=1.44-4.22) for medium vs. high; and lung cancer mortality was 1.69 (1.12-2.54) for low vs. high serum levels of L&Z. Adjusting for fruits and vegetables, HRs for all-cancer deaths were 1.44 (95% CI=1.13-1.83) for low vs. high and 1.36 (95% CI=1.15-1.61) for medium vs. high; colorectal cancer mortality was 2.41 (95% CI=1.40-4.18) for medium vs. high, and lung cancer mortality was 1.62 (95% CI=1.07-2.46) low vs. high serum levels of L&Z. Results suggest serum L&Z can reduce risk of cancer mortality. Not only do L&Z reduce carcinogenesis, they also enhance survival among cancer victims. These findings confirm dietary recommendations that promote intake of a variety of fruits and vegetables to protect health and prevent disease. Further studies are needed to explore the physiological mechanisms of this phenomenon.

2673 Metal Oxide Nanoparticles and Bacteria Alter Brush Border Enzyme Activity in an In Vitro Small Intestinal Model
A. Garcia Rodriguez. Binghamton University, Binghamton, NY. Sponsor: G. Mahler
Models of the gastrointestinal tract (GIT) have gained attention as a useful method for evaluating the digestion and absorption of engineered nanomaterials (ENM) released from food packaging and matrices. The in vitro Caco-2/HT29-MTX intestinal model has been shown to be a high-throughput, cost-effective and relatively fast experimental processes when compared to in vivo models. The human GIT environment, however, is composed of both human cells and the gut microbiota. It is well-known that the intestinal microbiota, which is primarily composed of bacteria, forms a complex ecosystem and plays an important role in the health of the host. The gut microbiota has been shown to be involved in basic human biological processes, including modulating the metabolic phenotype, regulating epithelial development, and influencing innate immunity. The goal of this study was to increase the complexity of the Caco-2/HT29-MTX in vitro model by co-culturing the human cells with two common strains of commensal and opportunistic intestinal bacteria, Lactobacillus rhamnosus GG and a non-pathogenic Escherichia coli strain, respectively. The system was challenged with physiologically relevant doses of pristine or digested zinc oxide (ZnO), iron oxide (Fe3O4), silicon dioxide (SiO2), or titanium dioxide (TiO2) nanoparticles, which are some of the most common ENM added to food and food packaging. To observe and measure the role of bacteria on gut function and to determine how food additives can alter this relationship, we acutely (4 hours) exposed Caco-2/HT29-MTX monolayers cultured with bacteria to metal oxide nanoparticles and analyzed intestinal alkaline phosphatase (iAP), aminopeptidase-N (APN), sucrase isomaltase (SI) and Na+/K+ ATPase activity. Our results showed that following exposure to digested and non-digested ENM, intestinal enzymatic activity was altered. The presence of bacteria may play a protective role, as the presence of bacteria in the model attenuated these effects. Brush border enzymes are known to control many physiological gut processes and activities such as the digestion of peptides and nutrient transport. Changes in their activities may cause chronic disease such as obesity, inflammatory processes and malnutrition.

2674 Comparison of Dietary Exposures to Acrylamide from Intakes of Bread and French Fries to a Proposed New No Significant Risk Level for Acrylamide
L. A. Haighton, K. Ngo, S. Pham, C. Sulaiman, and S. Floyd. Intertek Scientific & Regulatory Consultancy, Mississauga, ON, Canada.
Acrylamide, which formed in foods during frying, baking, or roasting is classified by IARC as a probable human carcinogen (2A) and is on the California (CA) Proposition 65 list of chemicals known to cause cancer or reproductive toxicity. Foods often high in acrylamide include French Fries, cereals, potato chips, breads and baked goods, and also coffee. CA EPA has quantified a no-risk-significant risk level (NSRL) of 0.2 micrograms/day for acrylamide. Under CA Proposition 65, businesses are required to provide a warning if foods contain a listed chemical in amounts that would exceed the NSRL when the foods are consumed (based on mean intakes). The NSRL of 0.2 µg/d was reported to be based on a US EPA oral slope factor of 4.5 mg per mg/kg/d. The US EPA has since revised the oral slope factor to 0.5 mg per mg/kg/d. An NSRL corresponding to this value would be 1.4 micrograms/day (1E-5/(0.5 per mg/kg-d) x 1000 µg/mg x 70kg). While CA EPA has reported that levels of acrylamide in foods are less than amounts believed to cause harmful effects, there have been over 100 notices of violation for acrylamide for potato-based and/or bread products. As a practical exercise, intake modeling was conducted to determine the mean intake of oven-baked fries (=26 g/d), deep-fried fries (=37 g/d) and multigrain bread (=34 g/d). In order to not exceed the NSRL, the concentration of acrylamide in the oven-baked and deep-fried fries must be below 7.7 ppb and 5.4 ppb, respectively, and below 5.9 ppb in bread, based on the mean intake estimates. In the concentration of acrylamide in fries are typically 250 to 450 ppb, and 40 ppb in multigrain bread. While fries are not typically considered a healthy choice, multigrain breads are. If the NSRL were increased based on the new US EPA slope factor, acrylamide concentrations would need to be below 54, 38 and 41 ppb in oven-baked fries, deep-fried fries, and bread, respectively; to not exceed the proposed NSRL. The proposed higher NSRL is unlikely to have any negative implications given that several recent epidemiology studies in large population cohorts have failed to support an association between acrylamide intakes and increased risks of renal cell carcinoma, or of breast, ovarian, endometrial or pancreatic cancer. Based on these findings, it has been suggested that dietary acrylamide was not an important cancer risk factor for humans.

2675 Detecting Genotoxicity within Non-Intentionally Added Substances (NIAS): A Problem Facing the Food Contact Materials Industry
P. Rawlinson, and M. Tate. Gentronix Limited, Alderley Edge, United Kingdom. Sponsor: M. Cumberbatch
Alongside intentionally added substances (IAS), safety assessment of non-intentionally added substances (NIAS) in food contact materials (FCMs) is now required under European law. NIAS may include impurities of IAS, or be by-products of the manufacturing process. NIAS are typically assessed by using solvent extractions of FCMs and concentration of the migrates. Assessing genotoxic risk in complex mixtures from FCM migrations poses a significant challenge, further compounded by the unknown identities and low concentrations of NIAS. To determine best approaches for detection of genotoxicity within FCM migrations, a review of Ames, GADD45a assay and carcinogenicity data was conducted for a number of reference genotoxic substances. Using available carcinogenicity data, a ‘permissible daily exposure’ (PDE) with relevance to human daily intake was estimated for each reference substance, along with estimated PDE equivalent concentrations in FCM migrations. These were compared with in vitro assay lowest effective concentrations (LEC) of the proposed TTC limits for safe exposure of NIAS. Comparison of the simulated PDE FCM migration concentrations and in vitro data demonstrated that whilst bioassays do not provide limits of detection equivalent to or below TTC or PDE daily intake values, they can provide useful detection of genotoxic hazard at or below proposed FCM limits of 90 ppb. This study supports the utility of bioassays for the detection of genotoxic hazard of NIAS within FCM migrations.

2676 Mycotoxins and Endotoxin Content Vary between Commercially Available Grain-Based Diets
S. Radhakrishnan1, M. A. Pellizzon1, P. Greiss2, and M. Ricci1. Research Diets, Inc, New Brunswick, NJ; and 2Random Food Diagnostics, Kearneysville, WV. Sponsor: J. Blum
Diet choice can affect data interpretation and reproducibility in laboratory animals. Indeed, studies have shown that endotoxins (ET), mycotoxins (MT) and antibiotics in the diet independently affect the development and function of the immune system in rodents, and thus, careful diet selection is critical especially while studying immune-system related disorders. Grain-based (GB) diets typically have higher concentrations of ET compared to purified diets which have very low to undetectable levels. However, it is unknown whether there is lot-to-lot variability. In this study, we analyzed levels of ET, antibiotics and MT in commonly used, commercially available laboratory animal diets (4 GB diets or 3 purified diets). Bioassays were analyzed using the limulus amebocyte lysate assay for ET and biochip array (Randox) customized to simultaneously detect 21 antibiotics and 10 MT from a single diet sample. Antibiotics levels were 2019 SOT Annual Meeting
Hepatotoxicity of Cannabidiol in the Mouse

Elevated plasma concentrations of ALT, AST and total bilirubin (~20-fold) were found in 1 sample (965 ppb), whereas ocdrotaxin A (0.4 - 1.3 ppb), zearalenone (60 - 162 ppb), deoxynivalenol (0.52 - 1.1 ppm) and fumonisins (56 - 691 ppb) were found in all GB diet samples tested. T2 toxin was detected in 3 out of 4 GB diets (5.6 - 13.8 ppb). Although the levels detected were low, this indicates that some GB ingredients were contaminated by MT known to have toxic and/or immunosuppressive effects. The interactive effects of multiple MT of the 10 most prevalent we measured (–400 others not measured) in vivo cannot be excluded despite their low levels. While certain GB diets may be lower in these toxins than others, we and others have reported the presence and lot-to-lot variability of other contaminants such as mycotoxins, bisphenol A and heavy metals in these diets. We are currently determining whether, as is the case for ET, if there are lot-to-lot differences in MT and antibiotics in GB diets. As anticipated, purified diets are free from such bioactive ingredients, and therefore, provide a clean background to study the toxicological phenotype in animal models.

2677 Assessment of Efficacy of Oroxylum indicum in Rat Model of Thioacetamide-Induced Hepatotoxicity and Its Safety Profile

A. More1, and K. Apte 2. 1APR Research Foundation, Pune, India; and 2APT Testing and Research Pvt. Ltd., Pune, India.

Thioacetamide (TAA) is being used as a hepatotoxicant in rat model of thioacetamide induced hepatotoxicity that mimics cirrhosis and hepatic carcinoma in humans. Traditionally stem bark, flowers and leaf of the plant had been used as a remedy for jaundice in India. Whole stem aqueous and ethanolic extracts (500 mg/kg) each were administered by oral gavage in Wistar rats (3 rats/group/sex) post four hours of oral gavage doses of thioacetamide (50 mg/kg, s.c.) in 100 ml/kg/day for 10 days post final dose of TAA. Animals were sacrificed on day 46, serum samples and liver tissues were collected for clinical chemistry and gene expression/antioxidant enzymes/histo-pathology analysis respectively. Clinical chemistry (ALT, AST, LDH, GDH, AFP) and antioxidant enzymes (MDA, CAT, GSH, SOD) results showed statistically significant decreases (p<0.05) with a trend towards recovery. RT-PCR results showed statistically significant reduction (p<0.05) in TNFα, IL6 (Inflammatory cytokines) and NFκB, P38 MAPK (key regulators of inflammation, immunity, apoptosis and wound healing). Histopathology analysis indicated decreased severity and incidence of tumor nodules from severe to mild in aqueous and ethanolic extract treated groups. Acute (OECD 423, 2000 mg/kg) and Subacute (OECD 407, 1000mg/kg) oral gavage toxicity studies did not result in any adverse clinical signs and mortality. Ames assay (up to 500µg/plate, maximum feasible concentration) and chromosomal aberration assay (up to 5000µg/plate) were tested. Negative taken. Further fractionation of plant extract is warranted to explore hepatoprotective activity from a single active fraction. Supported by APT Research Foundation, Pune, India.

2678 Hepatotoxicity of Cannabidiol in the Mouse Model

I. Koturbash1, L. Ewing1, C. Skinner1, M. Elsohly2, and B. Gurley1. 1University of Arkansas for Medical Sciences, Little Rock, AR; and 2Elsohly Laboratories, Inc. (ELI), Oxford, MS.

Cannabidiol (CBD) is a non-psychoactive ingredient of Cannabis sativa and is a major component of EPIDIOLEX®, a new drug designed for treating epileptic seizures. Utilization of CBD has progressively increased over the last year due to its increased availability to the general public together with aggressive marketing strategies for managing migraine and other pain-associated conditions. Emerging evidence, however, indicates that CBD poses a risk for hepatotoxicity. The goal of this study was to investigate the hepatotoxic potential of CBD delivered with sesame oil to 8-week-old male B6C3F1 mice. Animals were gavaged with allometrically scaled mouse equivalent doses (MED) of either 0, 20, 60, or 200 mg/kg of CBD (acute toxicity, 24 h) or with daily doses of 0.5, 1.5, or 5 mg/kg (chronic toxicity) over 21 days. In both chronic and acute CBD exhibited signs of hepatotoxicity. Specifically, when administered acutely, 200 mg/kg CBD elicited increases in liver-to-body weight (LBW) ratios accompanied by markedly elevated plasma concentrations of ALT, AST and total bilirubin (~20-fold). In the sub-acute study, 50% of mice gavaged with 50 mg/kg CBD exhibited significant toxic manifestations (i.e., tremor and lethargy) on days 3 and 4. Sub-acute CBD exposure was associated with reduced ALT, AST and total bilirubin. Additionally, hepatotoxicity gene expression arrays revealed over 50 genes differentially regulated in the livers of mice gavaged with CBD.

Further analysis highlighted the involvement of genes associated with the oxidative stress response and lipid metabolism as well as a number of cytochrome P450s responsible for drug biotransformation (i.e., CYP1A, CYP2E, CYP2B). In conclusion, mice gavaged with clinically-relevant MED of CBD exhibited classic signatures of cholestatic liver injury. Furthermore, alterations of numerous biochemical pathways associated with lipid and drug metabolism raises serious concerns about the long-term safety of CBD. Support: NIGMS 1P20GM109005 and T32 GM106999; Arkansas Biosciences Institute.

2679 Kalanchoe Plants Traditionally Used for the Treatment of Skin Wounds and Their Antibacterial Activity

D. M. Gonzalez, and I. Rodriguez Velez. University of Puerto Rico at Humacao, Humacao, PR. Sponsor: D. Gonzalez, American Association for the Advancement of Science

Antibiotic resistance has recently become a matter of public health concern due to the inability of classic antibiotics to keep up with constantly mutating bacteria. Therefore, the discovery and development of novel antibiotic agents able to work against currently resistant bacteria is of the utmost importance. A recent literature revision on the ethnomedical and natural products of the Kalanchoe family, has revealed the diverse biological activities reported for Kalanchoe pinnata. For instance, this succulent plant has been traditionally used for treatment of skin disorders and ear infections in Puerto Rico. However, few research has focused toward the other medicinal species of Kalanchoe plants. In our project, we are currently working with six different species of the Kalanchoe genus. We are very interested in determining the effect of these plants against commonly known bacterial pathogens, especially those present in skin wounds. With this in mind, we used a novel screening method to determine their general antibiotic profile. The Mobile Discovery Kit was used to test their activity against common bacteria found in human saliva. A small sample of the leaves were collected, cleaned and cut to perform the assay. After 24 hrs of inoculation, all six species showed notable to strong antimicrobial activity. Positive and negative controls were included in the screening. Five out of six samples (83%) showed no bacterial growth. The results suggest that the antibiotic profile of these species is not controlled by their potential as source of antibiotics may be indeed great. Polar extracts (methanol and aqueous) from the six species were prepared. Their testing against bacteria typically found in skin wounds, are currently in progress and will be presented. As part of a long term goal, these extracts will be purified and characterized to identify the biologically active agents responsible for the described antibacterial effect. This will allow for a better understanding of the Kalanchoe family potential and future applications for the development of new antimicrobial agents.

2680 Cellular Accumulation of Cocaine Following Osteoblastic Differentiation in MC3T3-E1 Cells

Cocaine is one of the most widely abused drugs. It has been reported that the chronic exposure to cocaine can lead to an adverse effect on skeletal development and caused to accumulation of cocaine and its metabolites in bone in rat experiment. However, the accumulation mechanisms in the bone have not been well documented. MC3T3-E1 cells, a mouse calvaria osteblast-like cell line, can induce osteoblastic differentiation and mineralization by treatments with beta-glycerophosphate (GP) and ascorbic acid. In this study, we investigated the effect of cocaine on cellular proliferation and the changes of accumulation of cocaine and its main metabolite, benzoylecgonine (BE), following differentiation using MC3T3-E1 cells. To examine cell proliferation, cells were exposed to 0-1 mM cocaine and cultured for 2 days. The cell viability assay indicated that cocaine promotes cell proliferation. At the concentration of 500 µM, the viable cell counts were incremented to 1.4 times. Furthermore, to examine whether cellular accumulations of cocaine and BE are changed by differentiation, we compared their cellular concentrations between with and without mineralization. The cells were cultured with or without both 10 mM GP and ascorbic acid in the presence of 0-100 µM cocaine for 10 days. After the culture, ALP activity, a marker of osteoblastic differentiation, and CA deposition were increased with treatments of GP and ascorbic acid, suggesting that the cells were differentiated under this culture condition. LC/MS/MS analyses revealed that concentrations of cocaine and BE increased exposure-dose-dependently. The concentration of cocaine in differentiated osteoblasts was significantly higher than that in undifferentiated osteoblasts.
However, concentration of BE was not affected by differentiation. These results indicate that chronic exposure to cocaine might have an adverse effect on bone development.

2681 Protective Effect of Ethanol Leaf Extract of Vitellaria paradoxa (Gaertn F) on Sodium Arsenite-Induced Toxicities in Male Wistar Rats

Globally, the inadvertent exposure to arsenic has been associated with diverse diseases including cancers, ulceration, neurological and reproductive disorders. Researches on arsenic toxicity are therefore being directed towards reducing exposure and/or intercepting its activities. In this regard, the potency of ethanol leaf extract of Vitellaria paradoxa (ELVpar) medicinal plant with antiadictive and antiproliferative properties used in treatment of entic infections, wounds, leprosy was assessed on sodium arsenite (SA) - induced toxicities in rats after ethical approval (Reference: UI-ACUREC 16/0019). Experimental rats were divided into eight groups of five animals each. Group 1 was given distilled water. Group 2: SA at 2.5 mg/kg, Group 3: vitamin E 100 mg/kg, Group 4: SA + vitamin E while Groups 5 - 8 received extracts alone or SA + extract at 100mg/kg and 200mg/kg respectively. After two weeks of treatments, the animals were sacrificed by cervical dislocation. Treatment with SA alone caused significant increase (p<0.05) in serum ALT, ALP activities, Urea and creatinine and concentration of uric acid compared with its control. When co-administered with ELVpar a significant reduction of approximately 1.3 (ALT), 2.6 (ALP), 2.2 and 1.5 (urea and creatinine) folds respectively and 1.6 (MDA) folds respectively was observed. This result was corroborated with observations from histological analysis of the liver and kidney. In addition, treatment with SA led to mild expression of BCL-2 protein > NF-Kb = p53 in kidney as compared with the control. Activation of nuclear factor-Kb (NF-Kb) a transcription factor that promotes cell proliferation and suppresses apoptosis is most likely due to production of reactive oxygen species by the toxicant. Co-administration of ELVpar increased the expression of p53 and decreased the BCL-2 protein expression. It was concluded that ELVpar have hepatoprotective, nephroprotective and apoptotic properties against sodium arsenite-induced toxicities.

2682 Evaluating the Effects of Essential Oils on Steroidogenesis in a Human Feto-placental Co-Culture System

D. Yancu, and T. Sanderson, INRS-Institut Armand-Frappier, Laval, QC, Canada.

We determined whether 5 common essential oils (EOs), basil, fennel seed, orange, black pepper and sage, interfered with feto-placental steroidogenesis in a co-culture model composed of human fetal-like adrenocortical H295R and trophoblast-like BeWo cells. After a 24h exposure of the co-culture to EO concentrations ranging from 0.005% to 0.005%, only basil and fennel seed oil had effects, significantly increasing production of estradiol, estrone, dehydroepiandrosterone, androstenedione, progesterone and estriol, but not testosterone. Using real-time quantitative RT-PCR, basil and fennel seed oil were shown to significantly alter the expression of several key steroidogenic enzymes, including CYP11A1, 3β-HSD1/2, SULT2A1, and 17β-HSD1, -4, and -5 as well as cholesterol transporter STAR. Particular attention was placed on the promoter-specific expression of aromatase (CYP19), the key estrogen biosynthetic enzyme essential for healthy pregnancy. In the co-culture, basil and fennel seed oil stimulated placental-specific promoter I-1 derived CYP19 expression in BeWo cells, whereas in the H295R cells, there was stimulation of promoter-II specific expression of CYP19. CYP19 catalytic activity, determined by titrated water-release assay, was significantly increased by basil and fennel seed oil in both cell types in co-culture, which correlated with increased mRNA levels. Furthermore, the isomers estragole and trans-anethole, the most abundant chemical constituents of basil and fennel seed oil, respectively, were found to have almost identical effects in the co-culture to those of the complete essential oils. Our results indicate that further study is necessary to determine the potential risks of using basil and fennel seed oils during pregnancy, considering their potential to disrupt steroidogenic enzyme activity and expression in vitro. Investigations into the mechanisms by which basil and fennel seed oil increase STAR expression in the H295R cells in co-culture are currently underway, focusing on the role of increased progesterone production. In BeWo cells in co-culture, STAR expression was significantly decreased by basil and fennel seed oil. As placental cells do not translate STAR into protein, we are studying effects on MLN64, a closely related gene that is suggested to replace the function of STAR protein. Effects of EOs and main chemical constituents on signaling pathways involved in the promoter-specific regulation of CYP19 are also under investigation.

2683 Halogenated Marine Natural Products and Human Health: Exploring the Activity of Halogenated Methyl Bipyroles as Agonists for the Aryl Hydrocarbon Receptor

E. Overton-1,2, D. G. Franks1,3, B. Pedleri4, N. Shaul6, A. Kumar5, W. Fenical1,4, I. L. Aluwihare5, C. M. Reddy5, and M. E. Hahn1,3, Woods Hole Oceanographic Institution, Woods Hole, MA; 4Haverford College, Haverford, PA; 5Woods Hole Center for Oceans and Human Health, Woods Hole, MA; and 6Scripps Institution of Oceanography, La Jolla, CA.

The presence of anthropogenic halogenated aromatic hydrocarbons (AHAs) in the marine environment and their potential impacts on human health through consumption of contaminated seafood have been a concern for half a century. Synthetic AHAs such as polychlorinated biphenyls (PCBs) and polychlorinated diphenyl ethers (PBDEs) are ubiquitous in the environment and their toxicity in animal systems is well known. More recently, a variety of naturally occurring, bioaccumulative AHAs have been identified in the oceans, including in upper-trophic-level animals and, increasingly, in seafood. These halogenated marine natural products (HMNPs) include methylxoylated PBDEs (MeO-PBDEs), halogenated methyl-2,1'-bipyroles (MBPs), and halogenated N,N-dimethyl-2,2'-bipyroles (DMBPs). Many of the HMNPs are structurally similar to anthropogenic AHAs, but their potential toxicity and impacts on human health are poorly understood. Here, we show that some of these compounds are able to bind to and activate the aryl hydrocarbon receptor (AhR), through which many of the synthetic AHAs act to cause toxicity. Several MBPs and DMBPs induced CYP1A1 in human HepG2 cells, although with potencies and efficacies less than those of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), whereas two natural MeO-PBDEs were less active. The MBPs and DMBPs also induced Cyp1a1 in zebrafish larvae in vivo. The results highlight the need to better understand the environmental behavior, biological activity, and potential human health impacts of HMNPs. Supported by P01ES021923, OCE-1314642, P01-ES021921, OCE-1313747, and Sea Grant NA19OAR4170104.

2684 Evaluation of Toxic Effects of Methanolic Leaf Extract of Spigelia anthelina on Wistar Albino Rats

Spigelia anthelina Linn also known as pinkroot is a flowering plant in the family of Loganiaceae. It is a tropical annual weed that grows in every part of Nigeria but used as medicinal plant in South Western part of the country to treat chronic hemelnosis in both humans and animals. The plant has been reported for its use as a laxative, antibacteria, and for the treatment of tumors, cancer, HIV, headache, throbbing pain, common cold, heart diseases, chest pain, as vermifuge and to reduce migraines. It is also used alone or in combination with other plants for toothache, foul mouth odour and fever. The plant is popular for its use as worm expellant or to destroy tapeworm and round worms in the body. Spigelia anthelina is used for chronic catarrh, difficulty in breathing and fierce palpitations. It is also an important remedy in pericarditis and other diseases of the heart. Good as this plant is, some people are afraid of its probable toxic effect on which scanty information is available. This then prompts us to study the toxic effect of its leaf extract. The methanolic leaf extract of the plant was administered per os at 200, 400, and 800 mg/kg to three groups A, B and C of Wistar albino rats respectively for 28 days while the group D which served as control was administered also per os with 3ml/kg of distilled water. The obtained blood samples from anaesthetized rats were then analyzed for hematolgy, serum biochemistry and semen. The results obtained showed no significant effect (p>0.05) on the blood parameters, but significant increase (p<0.05) was observed for alanine aminotransferase, aspartate aminotransferase and alkaline phosphatase for the groups administered with 400 and 800 mg/kg compared with the control. There was also a significant decrease (p<0.05) in the sperm concentration of the rats administered with 800 mg/kg of the extract. It was then concluded that the plant could show some toxic effects at high doses and therefore care must be taken when it's been used at high doses.
2685 Investigating the Effects of Chia Seed Consumption on Phase II Detoxification Enzymes and Lipid Peroxidation in Rat Liver

The demand and consumption of functional food has grown significantly worldwide in recent years as people become more health conscious. Phytochemicals are non-nutrient compounds that can be attained from fruits, vegetables, and grains. Consumption of phytochemicals has been correlated with a reduced risk of certain chronic illnesses; these include cardiovascular diseases, obesity, diabetes, and cancer. As such, use of chia seeds (Salvia hispanica L.) has significantly increased over the years, although it has been a common traditional food in many South and Central American countries for centuries. Chia seeds are a rich source of essential fatty acids—such as ω-3 alphalinolenic acid and ω-6 linoleic acid—which are vital for human health. Although chia seeds are mostly consumed for their rich nutritional value, they may exert benefits beyond their nutritional source due to the phytochemicals they contain. Chia seeds are roughly 9% phenolic and include phytochemicals such as myricetin, quercetin, kaemferol, caffeic acid, flavonol glycosides, and chlorogenic acid among others. In this study, we investigated the levels of Phase-II enzymes, GSH content, and lipid peroxidation in rat livers, while varying the amount of chia seeds in the diet of the subjects. The rats (Sprague Dawley) were fed 1.0%, 2.2% or 4.4% chia seeds/kg body weight for 4 months. The levels of GSH, Glutathione S-Transferase (GST), NADPH Quinone Oxidoreductase (NQO), and Thioctic Acid Reactive Substances (TBARS) levels were determined in liver. To the best of our knowledge, no study measuring the effects of chia seeds on detoxification or antioxidant enzymes is conducted. Our results show that GSH levels were dependent to increasing chia seed intakes. Chia seed supplementation in diet does not seem to affect the levels of GST, whereas the levels of NQO seem to significantly increase with higher doses. These results suggest that the induction in GSH and QR levels by chia seeds may provide substantial protection against toxicities and thus be beneficial to human health. Also, the levels of TBARS remain unchanged in both control and chia seed-fed animals suggesting that the supplement of chia seeds in the diet may not cause oxidative damage in liver tissues.

2686 The In Vitro Antibacterial Activity and Safety of Morinda lucida Leaf Extracts against Salmonella Serovars Relevant in Livestock Infections

1University of Pretoria, Pretoria, South Africa; and 2University of South Africa, Johannesburg, South Africa.

Salmonella infections are of great importance in human and animal health. They cause significant morbidity and mortality worldwide. Infections caused by non-typhoidal Salmonella are either non-invasive, self-limiting enteric infections or invasive systemic infections that require effective antimicrobial therapy. The development of resistant strains has reduced the efficacy of the conventional antibiotics. Therefore, there is an urgent need to develop drug leads or templates with good activity against these pathogens. Morinda lucida is a native tree species of Africa that has been used extensively in African traditional medicine for the treatment of symptoms similar to human typhoid and malaria fever. The aim of this study was to investigate the antibacterial activity of the leaf extracts of eight Salmonella serovars. Acetone and aqueous leaf extracts of Morinda lucida were screened for antibacterial activity against several serovars of Salmonella enterica subsp. enterica including S. enterica serovar Gallinarum (birds), Dublin (birds and ruminants), Choleraesuis (pigs), Braenderup (birds), Ildken (humans and birds), Kottbus (birds), Typhimurium (birds and ruminants) and Enteritidis (birds and humans) using a serial microdilution assay. The cytotoxic potential of the acetone and aqueous extracts against human colon cancer (Caco-2) cells was also determined. The minimum inhibitory concentration (MIC) of the selected plant extracts generally ranged from 0.09 to 1.87 mg/ml with the acetone extract having the best activity against all the tested strains. The levels of positive control, gentamycin, against the tested strains ranged from 0.0002 to 0.01 mg/ml. The LC50 values of the acetone and aqueous extracts against the Caco-2 cells were 0.46 and 0.33 mg/ml respectively. The selectivity index (SI) values of the acetone extract ranged from 1.00 to 6.57 and SI of the aqueous extract ranged from 2.3 to 8.28 indicating that the observed antimicrobial activity was generally not due to toxicity to mammalian cells. The results obtained validate in part the potential usefulness of this plant species as an alternative for treatment of human and animal salmonellosis. However, in vivo data is necessary to further investigate this claim.

2687 Inhibition of Pro-hypertensive Soluble Epoxide Hydrolase (sEH) Activity by Magnolia Bark Extract in a One-Step Inhibition 14,15-DHET ELISA

Soluble epoxide hydrolase (sEH) biotransforms anti-hypertensive epoxyeicosatrienoic acids (EETs) to dihydroxyeicosatrienoic acids (DHETs). Increased sEH activity in kidney, heart and brain cells, which lowers EET levels, has been linked to hypertension, cardiovascular diseases and stroke, respectively. Inhibition of sEH-dependent conversion of 14,15-EET to 14,15-DHET, a major metabolite of sEH, has been evaluated as an approach for the prevention and treatment of hypertension and stroke. The aim of this study is to find whether a Chinese medicine, magnolia bark extract (FDA GRAS food additive), inhibits activity of pro-hypertensive sEH. Previously inhibition of sEH activity has been measured by a two-step inhibition assay consisting of a 30 min incubation step with the sEH enzyme, 14,15-EET and an inhibitor followed by ethyl acetate extraction and quantification of the 14,15-DHET level by ELISA. Using a novel one-step inhibition ELISA developed by combining the inhibition and quantification steps, sEH activity inhibition assays using 12-[(tritylcyclo[3.3.13.7]dec-1-ylamino)carbonyl]alaminododecanoic acid (AUDA, positive control), magnolia bark extract, honokiol (major constituent of magnolia bark), carrot and watermelon juices and vitamin B complex were carried out. A reaction mixture (100 µl) of 80 nM EET, 15.6 nm sEH enzyme and with or without a dietary supplement was pre-incubated for 30 min in 14,15-DHET antibody-coated wells of the 96-well plate to capture 14,15-DHET formed from EET. The levels of 14,15-DHET formation and % inhibition by the dietary supplement were quantified using 14,15-DHET standards after addition of 14,15-DHET-conjugated HRP (100 µl) to the standard or the reaction mixture (100 µl) in each well. The AUDA was a potent inhibitor of the sEH activity. Carrot and watermelon juices and vitamin B complex did not inhibit sEH activity, whereas 4 mg/ml and 10 mg/ml magnolia bark extract inhibited sEH activity by 83% and 96%, respectively, and 1 mM honokiol inhibited the sEH activity by 80%. Honokiol, a bioactive component of magnolia bark, added to human kidney ACHN cell culture media inhibited cytosolic sEH activity. Thus, consumption of magnolia bark extract might lower cellular sEH activity and ameliorate hypertension and heart-related diseases.

2688 Characterization and Formulation of a Black Cohosh Root Extract (BCE) Lot to Be Used in Rodent Toxicology Studies

E. Mutlu1, T. Cristy1, J. Pierfelice1, J. Andre2, B. Stiffler2, B. Burbak2, and S. Waidyanatha1.
1NIHES/NTP, Research Triangle Park, NC; and 2Battelle, Columbus, OH.

Black cohosh (Actaea racemosa) is sold as a dietary supplement for the treatment of menstrual and menopausal symptoms in women. Although it has widespread human exposure, there is limited safety data in rodents and humans. The National Toxicology Program (NTP) is investigating the toxicity of BCE in rodents. The objective of this work was to screen commercially available lots sold as BCE to select an unformulated product for use in NTP studies. Multiple lots of unformulated and formulated products sold as BCE, standard reference materials of BCE and potential adulterants (Chinese, red, and yellow cohosh) were analyzed using a combination of non-targeted and targeted analytical techniques. Authenticity was confirmed by chemical fingerprinting and DNA barcoding. Based on the results, a lot was selected for further characterization. The constituents of the selected lot (actein, 0.47%; 27-deoxyactein, 2.09%; ferulic acid, 0.04%; isoflavonic acid, 0.70%; caffeic acid, 0.28%; cimicifugoside C, 2.13%; 26-deoxyisofagomine, 0.08%; magnoflorine, 0.01%) were determined by LC-MS-MS. Other analyses included moisture content (5.6%), ash (5.8%), and nutritional content (fat, carbohydrate and protein). The lot was also analyzed for contaminants (heavy metals, ≤476ppb; pesticides, ≤0.3ppm; mycotoxins, ≤50ppb; microbial content, ≤10 CFU/g). A method for formulation of BCE in 0.5% methylcellulose was developed and a formulation analysis method was validated to quantify isoflavonic acid. Analytical method was linear (r ≥0.99) and accurate and homogeneous (% relative error, RE ≤ ±10 %). The formulations were stable for multiple markers (actein, 27-deoxyactein, isoflavonic acid and cimicifugoside C) up to 42 days with % RE ≤ ±20 of day 0. These data demonstrate that the BCE lot is suitable and can be formulated to be used in rodent toxicological studies.

2689 Inhibition of Vascular Endothelial Growth Factor-Induced Angiogenic Effects in Human Umbilical Endothelial Cells by Cinnamon Extract

It remains elusive how safe the use of Japanese herbal medicines is during pregnancy and if the herbal medicines do any harm to pregnancy and placentation. Since components of herbal medicines are more complicated than those of modern medicines, the former’s actions may be more complicated than the latter’s. Long-term fetal exposure to herbal medicine may, therefore, adversely affect fetal or postnatal development. Hazard assessment of traditional Japanese herbal medicine for pregnant women is important as herbal medicines are commonly perceived to have fewer side effects than modern medicines. Angiogenesis actively undergoes throughout pregnancy, and the dysplasia of corpus luteum and placenta due to vulnerable angiogenesis results in miscarriage or low birth weight. The present study investigated the effect of cinnamon extract, which is often taken during gestation period as a component of Goreisan or Kakkonito, on the Vascular Endothelial Growth Factor (VEGF)-induced tube formation in vascular epithelial cells. Methods: Human Umbilical Vein Endothelial Cells (HUVECs) were cultured on Matrigel-coated plate and treated with VEGF at 20 ng/mL in absence or presence of cinnamon extract for 20 h. As treatment with cinnamon extract at 50 μg/mL inhibited VEGF-induced tube formation in HUVECs, cinnamon extract was separated into three fractions, chloroform fraction (ChrF), butanol fraction (ButF) and water soluble fraction (WatF), and the effect of each fraction on tube formation in HUVECs was similarly investigated. Results: Of the three separated fractions, ChrF showed an inhibitory effect on tube formation. We separated components of ChrF using column chromatography and identified cinnamic acid as a major component of ChrF using Nuclear Magnetic Resonance (NMR) and mass spectrometry. Cinnamic acid was quantified using thin layer chromatography. The content of cinnamic acid in cinnamon extract was 1.70%. Tendency to inhibit effect on tube formation was similarly observed after treatment with cinnamic acid at 5.7 μM, corresponding to cinnamon extract at 50 μg/mL. The results show that cinnamic acid might be an active principle of cinnamon extract for suppression of VEGF-induced tube formation in HUVEC.

2690 Development and Validation of an Analytical Method for Quantitation of Alpha-Pinene in Rodent Blood by Headspace GC-MS
M. A. Silinski1, J. C. Blake1, J. Licause1, R. A. Fernando1, V. G. Robinson2, and S. Waidyanatha1. 1RTI International, Research Triangle Park, NC, and 2NIEHS/NTP, Research Triangle Park, NC.

Alpha-pinene (AP), produced by pine trees and other plants, is the main component of turpentine and is used as a fragrance and flavor ingredient. Exposure to AP occurs via use of personal care and household cleaning products and in the lumber industry. Despite widespread exposure, the toxicity data for AP are limited. The objective of this work was to develop and validate a method to quantitate AP in rat and mouse mammary tissue, a potential target tissue, in support of the National Toxicology Program toxicokinetic and toxicology studies. Standards were prepared by spiking a ~100 mg aliquot of mammary tissue with 100 μL of spiking solution containing AP and internal standard (IS; AP-d3) in 50/50 ethanol/saline in a 2-mL headspace vial. The vial was sealed with a metal crimp-top cap, equilibrated for 10 min at 60°C, and a 500 μL headspace sample was analyzed by GC-MS using single ion monitoring ([M+H]+ m/z 136 (AP) and 139 (IS)). A DB-5MS column was used with oven temperature ramped from 40°C to 150°C in 9 min. The method was successfully validated in female Sprague Dawley rat mammary tissue over the concentration range 100-5000 ng/g. Matrix standard curves were linear (r ≥ 0.99), and the percent relative error (%RE) values were ≤ ±12% for standards at all levels. Small background peaks were detected in the matrix and method blanks, but the response was low and did not interfere with method performance. Absolute recovery was low (2%) likely due to high lipophilicity of AP. However, the limit of detection, determined from the standard deviation at the lower limit of quantitation (100 ng/g), was 17.7 ng/g, demonstrating adequate sensitivity. Recovery levels were 90% at 900 ng/g for intra- and inter-day precision (% relative standard deviation, RSD) and accuracy (%RE) were ≤5% and ≤7%, respectively, for quality control standards prepared at 250 and 2500 ng/g. Standards as high as 20,000 ng/g could be analyzed using a lower injection volume (20 μL) or by extrapolating the calibration curve beyond 5000 ng/g, with mean %RE ≤ ±1.4% and %RSD ≤3%. Smaller sample sizes (~50 ng) could also be analyzed, with mean %RE ≤ 2.2% and %RSD ≤ 2%. The method was validated for female Harlan Sprague Dawley rat and B6C3F1 mouse mammary tissues; %RE values were ≤ ±5% and %RSD ≤ 2%. These data demonstrate that the method is suitable for the analysis of AP in rodent mammary tissues generated from toxicokinetic and toxicology studies.

2691 Development and Validation of an Analytical Method for Quantitation of Alpha-Pinene in Rodent Mammary Tissue by Headspace GC-MS
M. A. Silinski1, J. Licause1, T. Venoyama1, J. C. Blake1, R. A. Fernando1, V. G. Robinson2, and S. Waidyanatha1. 1RTI International, Research Triangle Park, NC, and 2NIEHS/NTP, Research Triangle Park, NC.

Alpha-pinene (AP), produced by pine trees and other plants, is the main component of turpentine and is used as a fragrance and flavor ingredient. Exposure to AP occurs via use of personal care and household cleaning products and in the lumber industry. Despite widespread exposure, the toxicity data for AP are limited. The objective of this work was to develop and validate a method to quantitate AP in rat and mouse mammary tissue, a potential target tissue, in support of the National Toxicology Program toxicokinetic and toxicology studies. Standards were prepared by spiking a ~100 mg aliquot of mammary tissue with 100 μL of spiking solution containing AP and internal standard (IS; AP-d3) in 50/50 ethanol/saline in a 2-mL headspace vial containing 18 stainless steel beads. The vial was sealed and homogenized for 30 sec for 2 cycles at 1000 rpm. Each vial was equilibrated for 10 min at 60°C and a 200 μL headspace sample was analyzed by GC-MS using single ion monitoring ([M+H]+ m/z 136 (AP) and 139 (IS)). A DB-5MS column was used with oven temperature ramped from 40°C to 150°C in 9 min. The method was successfully validated in female Sprague Dawley rat mammary tissue over the concentration range 100-5000 ng/g. Matrix standard curves were linear (r ≥ 0.99), and the percent relative error (%RE) values were ≤ ±12% for standards at all levels. Small background peaks were detected in the matrix and method blanks, but the response was low and did not interfere with method performance. Absolute recovery was low (2%) likely due to high lipophilicity of AP. However, the limit of detection, determined from the standard deviation at the lower limit of quantitation (100 ng/g), was 17.7 ng/g, demonstrating adequate sensitivity. Recovery levels were 90% at 900 ng/g for intra- and inter-day precision (% relative standard deviation, RSD) and accuracy (%RE) were ≤5% and ≤7%, respectively, for quality control standards prepared at 250 and 2500 ng/g. Standards as high as 20,000 ng/g could be analyzed using a lower injection volume (20 μL) or by extrapolating the calibration curve beyond 5000 ng/g, with mean %RE ≤ ±1.4% and %RSD ≤3%. Smaller sample sizes (~50 ng) could also be analyzed, with mean %RE ≤ 2.2% and %RSD ≤ 2%. The method was validated for female Harlan Sprague Dawley rat and B6C3F1 mouse mammary tissues; %RE values were ≤ ±5% and %RSD ≤ 2%. These data demonstrate that the method is suitable for the analysis of AP in rodent mammary tissues generated from toxicokinetic and toxicology studies.

2692 hTERT Immortalized Adult Dermal Melanocytes: An In Vitro Cell Model for the Study of Skin Pigmentation
L. G. Rodriguez, and C. Zou. ATCC Cell Systems, Inc, Gaithersburg, MD.

Skin pigmentation is a complex process; melanocytes produce melanin and package it into melanosomes that are in turn exocytosed into the surrounding extracellular matrix. Numerous genes play roles in controlling pigmentation at various levels of melanin production. Mutations in these genes are characteristic of multiple skin disorders, including hyperpigmentation, hypopigmentation, and mixed hyper-/hypopigmentation. Additionally, extrinsic factors secreted by the surrounding resident cell types also regulate the melanin expression in adult melanocytes. Human primary cells can be a useful model for elucidating melanocyte biology. However, primary cells have their limitations such as donor variability and limited lifespan. Consequently, a need exists for a more robust human cell model system for the study of skin pigmentation. In this study, we immortalized primary dermal melanocytes by expressing human telomerase reverse transcriptase (hTERT) in cells that were isolated from an adult donor. The immortalized primary melanocytes were cultured continuously for more than 40 population doublings without any signs of replicative senescence, yet retained melanin production. The immortalized primary melanocytes maintained a consistent expression of the melanocyte-specific marker TRP-1, and lacked expression of the fibroblast-specific marker TET7. In addition, we demonstrate the capability of these immortalized primary melanocytes to transfer melanosomes to keratinocytes, the ability to modulate melanogenesis with stimulators and inhibitors, and their capacity to incorporate into a functional 3D human dermal organotypic culture. Taken together, the hTERT immortalized melanocytes provide a versatile in vitro cell model for the study of melanin production and melanocyte:keratinocyte interactions in the dermal environment.
In vitro three-dimensional skin tissue models have become the state-of-the-art approach to studying human skin physiology and pathology with the ultimate goal to reduce and replace animal-based toxicological assessment of chemicals. Any reactive agent must first penetrate the skin’s barrier to elicit a reaction in the epidermis and dermis. Thus, understanding the functional composition of the skin’s barrier is a crucial step in understanding how chemicals can potentially gain access into the skin and subsequently influences all downstream reactions. The lipid composition of both the Phenion Full-Thickness (FT) Skin Model epidermis and the Phenion Open Source Reconstructed Epidermis (OS-Rep) was analyzed with thin-layer chromatography. When analyzed simultaneously, the lipid profiles of both skin models closely matched the profile of native human foreskin epidermis. Ceramides, cholesterol, cholesterol derivatives, triglycerides and phosphatidylcholine were identified in all samples tested. Immunofluorescence analysis of keratinocytes isolated from skin biopsies and the epidermis of both the FT and OS-Rep models revealed the presence of major enzymes found in epidermal lipid metabolism, (ceramidases; serine palmitoyltransferase). When comparing to intact human skin, these 3D models presented with similar lipid patterns and key barrier enzymes involved with human skin lipid synthesis. Taken together this provides strong evidence that the physiological barrier and function of the models, mainly located in the stratum corneum, are compatible with human skin. This confirmation was required prior to conducting substance testing in these skin models, (in vitro skin irritation; penetration studies). Only a functioning and selective barrier can discriminate between chemicals which remain on the tissue surface or those that can permeate the skin and subsequently influence the skin’s vascular systems. Thus, for experiments which require a barrier function both the FT and the OS-Rep models are well-suited as in vitro surrogates for native human skin, or epidermis, respectively.

The aim of this study was to correlate the lipid composition of native human foreskin epidermis and different in vitro skin models, including two 3D models (Phenion Full-Thickness (FT) Skin Model and Phenion Open Source Reconstructed Epidermis (OS-Rep)) with the corresponding lipid composition of human foreskin epidermis. The lipid composition of the 3D models was analyzed by thin-layer chromatography. The results showed that the lipid profile of the 3D models closely matched that of human foreskin epidermis, indicating that these models are suitable for studying skin physiology and pathology.

**Development of new methods to qualify the integrity and the barrier function of the skin is necessary before effecting ex vivo skin toxicity tests in reliable conditions. To avoid unsuitable over-prediction of the dermal absorption by the use of impaired skin preparations, the OECD guidelines 428 and 430 require skin integrity check using reference compounds like caffeine for measurement of transcutaneous passage and of transepithelial electrical resistance (TEER) respectively. Caffeine transcutaneous passage is usually performed to qualify dermal delivery, such as that through the stratum corneum, that is tested with human skin. This confirmation was required prior to conducting substance testing in these skin models, (in vitro skin irritation; penetration studies). Only a functioning and selective barrier can discriminate between chemicals which remain on the tissue surface or those that can permeate the skin and subsequently influence the skin’s vascular systems. Thus, for experiments which require a barrier function both the FT and the OS-Rep models are well-suited as in vitro surrogates for native human skin, or epidermis, respectively.
2697 Dermal Toxicology Application Area Changes as Compared to Theoretical Total Surface Area of Hanford Miniature Swine over 18 Weeks

T. Madsen1, J. Liu2, L. Brown1, D. F. Brocksmith2, and G. F. Bouchard1,2.
1Sinclair Research Center LLC, Auxvasse, MO; and 2Sinclair Bio Resources LLC, Auxvasse, MO.

Dermal toxicity studies are frequently initiated in growing animal models. The test compound is generally applied on a Dermal Application Area (DAA) that is frequently set at certain ratio to total surface area. Since the growth during juvenile period can be significant; the DAA is likely to be impacted during the course of a chronic study. The purpose of this study was to determine the relative proportion of the DAA to Total Body Surface Area (TBSA) will change proportionally over time with the growth of the miniature swine, and 2) to compare three TBSA formulas. The ratio DAA (cm² surface area) to TBSA was calculated from body weight at periodic intervals for 18 weeks in 16 male and 16 female Hanford miniature swine (~4 mo old Hanford miniature swine, averaging ~14 kg at initiation). Two mid-back 5 cm x 5 cm (25 cm²) DAA's, one located on each side of the spine, were used on each subject. The TBSA (m²) was calculated by the well-recognized Spector formula (9.5 x BW(G)0.3710000) as well as the Brodie and Wachtel formulas. Using the Spector formula, the mean ratio DAA to TBSA for week 0 and 8 (N = 32) for an application area was 0.46% ± 0.04 and 0.51% ± 0.06 (MEAN ± SD), respectively. After week 8, subsequent periodic measurements of the ratio of TBSA to DAA remained steady suggesting proportional changes in growth of both DAA and TBSA. The correlation of the three formula ratios was >0.99. Thus, comparable TBSA and DAA/TBSA ratio between the three formulas suggested the well-recognized Spector Method is a valid choice.

2698 Skin Penetration of [3H]Octanoic and [14C]Decanoic Acids after Topical Application of C8910 Formulations to Excised Pig and Human Skin

L. Estigoy, X. Li, and W. Reifenrath, EAG Laboratories, Hercules, CA.

C8910 is a biopesticide consisting of octanoic, nonanoic, and decanoic acids. The objective of this study was to determine the skin disposition (evaporation, skin surface residue and penetration) of two of the fatty acids after topical application of aqueous dilution of three different emulsifiable concentrates in a test system predictive of skin absorption in vivo. Formulations were spiked with tritium labeled octanoic acid and carbon-14 labeled decanoic acid and applied to excised pig or human skin. Data, expressed as percent of applied dose, were statistically analyzed (p = 0.05). Comparing the 3 concentrate dilutions, there were no significant differences in evaporation (approximately 60% for octanoic acid and 40% for decanoic acid), percutaneous penetration (about 20% for octanoic acid and 15% for decanoic acid) and residue remaining on the skin surface (approximately 5% for octanoic acid and 20% for decanoic acid) at 24 hours. These results were compared to a mineral oil formulation previously registered with the US EPA for livestock fly control. While there were no significant differences in evaporation, penetration was significantly higher and skin surface residue significantly lower for the mineral oil formulation. Since the pesticidal activity of the fatty acids is influenced by skin penetration, these results support their formulation in emulsifiable concentrates for livestock fly control.

2699 Solute Partitioning from Formulations to Build Skin LFER Models

J. Hughes-Oliver1, G. Xu2, and R. Baynes3. 1North Carolina State University, Raleigh, NC; and 2Wells Fargo & Company, Charlotte, NC.

Permeation of chemical solutes through skin can create major health issues especially to workers in the metalworking industry. Using the membrane-coated fiber (MCF) as a solid phase membrane extraction approach to simulate skin permeation, we utilized partition coefficients for 37 solutes under 90 treatment combinations that could broadly represent formulations that could be associated with occupational skin exposure. These formulations were designed to mimic fluids in the metalworking process, and include: one of mineral oil, polyethylene glycol-200, soluble oil, synthetic oil, or semi-synthetic oil; at a concentration of 0.05 or 0.5 or 5 percent; with solute concentration of 0.01, 0.05, 0.1, 0.5, 1 or 5 ppm. Linear free-energy relationship (LFER) models were then developed from these data sets to estimate the effect of these multiple variables on skin partitioning. Partition coefficients range from 0.015 to 1279 (-1.820 to 3.107 on the base 10 logarithm scale) and it was somewhat surprising that the smallest partition coefficients were associated with higher concentrations of solute present in the formulation. The improvements in r², Adj-r², Q₁₀₀₀, and Q₁₀₀₀₀ (LOSO = leave one solute out) for the LFERs were quite noticeable. The single LFER model was shown to be inadequate (Q₁₀₀₀₀ = 0.57), but extensions that account for experimental conditions provide important improvements in estimating solute partitioning from selected formulations into the MCF. The benefit of the Expanded Nested-Solute Concentration LFER model (Q₁₀₀₀₀ = 0.88) then compared to the Crossed-Factors LFER model (Q₁₀₀₀₀ = 0.68) was only revealed through a careful LOSO cross-validation that properly addresses the existence of replicates to avoid an overly optimistic view of predictive power. Finally, the partition theory that accompanies the MCF approach is thoroughly tested and found not to be supported under sufficient experimental occupational exposure in the metalworking industry. Our resulting model provides interpretations that are useful for identifying solutes whose chemical structures are consistent with low predicted levels of dermal permeability.

2700 Large Data Sets and Quantitative Risk Assessment (QRA) for Dermal Allergens

The use of quantitative risk assessment (QRA) principles to evaluate the skin sensitization potential of ingredients in consumer products has seen increasing use and development. A key outcome of the QRA is identifying a concentration where the induction of sensitization is not expected in humans, the No Expected Sensitization Level (NESIL). This NESIL is translated to an Acceptable Exposure Level (AEL) for consumers by dividing the NESIL by Safety Assessment Factors (SAFs). These SAFs account for uncertainties in extrapolating from the experimental conditions used to derive the NESIL to a realistic in-use exposure. To address this gap, we utilized data from a Human Repeated Insult Patch Test (HRPT) in a simple vehicle. However, historical databases of HRPTs are often available within consumer product companies on multiple product formulations that contain the same ingredient, in aggregate these datasets can be large encompassing 100s - 1000s of tests. This presents a unique opportunity to provide additional confidence in establishing safe ingredient use levels based on metrics for presence and percent composition of ingredients. Clusters of comparable formulas were identified from this map using graph modularity. These clusters were evaluated to confirm safe use levels and determine the need to apply SAFs across different formula types. For example, citral was included in 44 cosmetic formulas in 3 distinct clusters and no sensitization was observed up to the maximum tested concentration of 0.01%. The clusters were observed to be consistent, members of each cluster contained only similar formula backbones. This consistency confirms the approach to use modularity to identify formula clusters in this map. The separation of the clusters demonstrate that consideration should be given to adequate formulation based SAFs when data is read across between clusters. Using large historical HRPT data sets and QRA shows promise as an approach for cosmetic safety guidance.

2701 Experimental Induction of Allergic Contact Dermatitis in Sinclair, Hanford, and Yucatan Minipigs

A. Stricker-Krongrad. Sinclair Research Center LLC, Auxvasse, MO.

The objectives of this study were to induce and characterize allergic contact dermatitis using 2,4-dinitrofluorobenzene (DNFB) in Sinclair, Yucatan, and Hanford minipigs, and assess the efficacy of corticosteroids in treatment of dermatitis (N = 3 per breed, all males). During acclimation the entire dorsum of the minipig was shaved, washed, and topical dermal challenge sites were marked on the dorsum of each animal. Sensitization Phase: On Day 1, animals were topically sensitized with 10% DNFB distributed among the left and right ears, and left and right medial thighs. Challenge Phase: On Study Days 14, animals were challenged on designated dose sites with 1% DNFB. Dose administration: Approximately 2-4 hours post challenge, dose sites on the right side of the animal were treated with 1% hydrocortisone. Dose Site Scoring: Dose sites were scored for erythema and edema using three point grading scales (maximum total score: 6) during the course of three days post-challenge. Histopathology: Dose sites from one animal of each breed of minipig were processed to slides, stained with H&E, and evaluated by a pathologist for signs of dermatitis (24 hours post-challenge). Results: Mean summed irritation scores peaked at 24 hours in the Yucatan (Mean +/- SEM: 2.6 +/- 0.6), and at 48 hours post-challenge in the Hanford (Mean +/- SEM: 3.6 +/- 0.3) and in the Sinclair (Mean +/- SEM: 1.6 +/- 0.8). At 72 hours irritation was still
present, but moderate in nature (average: Hanford: 1.6; Sinclair: 1.0; Yucatan: 1.0). Hydrocortisone treatments did not affect the severity or the course of the allergic response. Histopathological findings were similar and consistent with lesions associated with contact dermatitis in all three animals, and included minimal to moderate epidermal necrosis and acanthasia, edema, eosinophilic and mononuclear infiltrates in the superficial and deep dermis. Conclusion: Moderate to prominent dermatitis was induced in Yucatan, Hanford, and Sinclair minipigs using 10% DNFB sensitization, followed by 1% DNFB challenge. Treatment of select dose sites with 1% hydrocortisone 2-4 hours post challenge with 1% DNFB did not reduce overall irritation scores in any breed of minipig. Length: less than 2,300 characters, all included but space.

2702 Definition of an In Silico Protocol for Skin Sensitization

C. Johnson1, D. Bower1, K. Cross1, S. Miller1, D. P. Quigley1, R. R. Tice2, C. M. Zwickl3, and G. Myatt1.1Leadscope, Inc., Columbus, OH; 2RT3 Consulting, Hillborough, NC; and 3Transendex LLC, Indianapolis, IN.

In silico assessments are an important component of toxicology. However, standardized protocols for the conduct and interpretation of in silico methods are lacking. A consortium comprising of over 55 diverse organizations has published a general strategy for developing in silico protocols to assess toxicological endpoints such as genetic toxicity, carcinogenicity, acute toxicity, reproductive toxicity, developmental toxicity, neurotoxicity, irritation/corrosion, etc. The purpose of the in silico standardization project is to generate, record, communicate, and archive results in a uniform, consistent, and reproducible manner, while fostering the use and reducing the burden on both industry and regulators to justify the use of these methods. Incorporating standardized principles into the use of in silico methods supports a more transparent analysis of the results and mitigates “black box” concerns. Here, we report on efforts to develop an in silico protocol for skin sensitization. Relevant effects/mechanisms are identified for the skin sensitization endpoint and a hazard assessment framework was established. Rules and principles are defined for integrating in silico predictions with in vitro data to derive a comprehensive assessment of skin sensitization. A) prediction of skin sensitivity, B) events in keratinocytes, dendritic cells, and rodent lymphocytes; and C) skin sensitization in vitro, rodents, and humans. In addition, a new software platform was developed to allow content searching against high-quality specialized databases and integrate models developed in compliance with the published protocols. Statistical models were developed for the Local Lymph Node Assay (balanced accuracy of 82.5%) and Direct Protein Reactivity Assay (balanced accuracy of 81%). Case studies illustrate the utility and flexibility of the hazard assessment framework. Standardization of in silico tool use and interpretation of results greatly reduces the burden on both industry and regulators by providing confidence in and justification for the use of these types of integrated approaches.

2703 Evaluation of OECD Accepted In Vitro Methods for Assessment of Skin Sensitizing Potential of Agrochemical Formulations

J. Ball1, H. Scott1, E. Smith1, S. Bennett2, W. Masinja1, C. Elliott1, M. Tate1, and M. Cumberbatch1.1Gentrixon, Alderley Edge, United Kingdom; 2Alderley Analytical, Alderley Edge, United Kingdom; and 3Syngenta, Bracknell, United Kingdom.

Limited information exists on the predictivity of in vitro methods for the assessment of skin sensitizing potential of complex agrochemical formulations, despite the regulatory requirement for testing of these materials for classification and labelling purposes. The objective of this study was to explore the performance of OECD approved test methods in determining the skin sensitization potential of 7 agrochemical formulations with existing Local Lymph Node Assay (LLNA) and/or Buehler test data. Prior to testing the formulations, the proficiency of the laboratory to perform the Direct Peptide Reactivity Assay (DPRA), KeratinoSens®17C and Human-Cell Line Activation Test (h-CLAT) was confirmed successfully using the proficiency materials as outlined in the OECD Test Guidelines 442C, 442D and 442E, respectively. Of the formulations selected, four were known skin sensitizers (two emulsifiable concentrates [EC], one flowable concentrate for seed treatment [FS] and one suspension concentrate [SC]) and three were non-sensitizers (1 SC, 1 FS and 1 water dispersible granule [WDG]). A single average molecular weight (MW) for each formulation was calculated by considering the MWs of each component (including active/non-active ingredients and approximate MW for polymers), and their individual proportions resulting in MWs for testing ranging from 177 to 2260 kDa. Solvent selection and solubility assessments were performed for each formulation and KeratinoSens®17C and h-CLAT using the MTT assay and formulation doses adjusted to achieve >70% cell viability across much of the dose response curve. As such, starting doses of 1000μM to 2μM and 1.25 to 1.5-fold dilution steps, were applied depending on solubility and cytotoxicity of the formulation. Preliminary data suggest that the approach taken resulted in correct identification of 3/3 non-sensitizers, but only 1/4 sensitizers (formulation SC; IC50 > 0.4μM; IC50 > 2.0μM) due to cytotoxicity/solubility issues and that these issues are likely attributable to the agrochemical-co formulation components. Since keratinocyte activation represents only 1 key event of the skin sensitization Adverse Outcome Pathway, suitability of all 3 OECD accepted in vitro assays is being assessed.

2704 Applying In Silico Approach to Unravel Mechanism of Toxicity of Contact-Sensitizing Hair Dye Components

T. Krismanovic1, K. Jankovic1, D. Mitic Potkrajac2, G. Apic1, and R. B. Russell1.1Metisox Ltd, Cambridge, United Kingdom; and 2Cell Networks, University of Heidelberg, Heidelberg, Germany.

Fifteen to 20% of the general population have allergic contact dermatitis as a clinical manifestation of contact sensitization, making this skin disease a major health problem. Screening for contact-sensitizing chemicals is highly relevant, particularly in dermatology. The use of animal tests for this purpose is constrained by ethical considerations, need for high-throughput screening and legislation (e.g., for cosmetics in the European Union). Although hair dye substances, that are strong or extreme sensitizers, are very common in consumer hair dye products on the European market, dermatitis patients are generally patch tested with one substance only, namely N-phenylenediamine. Therefore, it is not possible to accurately estimate the overall burden of hair dye allergy in dermatitis patients. The goal of the study was to develop knowledgebase and software tool that can be used to predict potentially harmful interactions between chemicals as an alternative to animal test methods. From the public domain and proprietary company datasets we collected data on 303 commercial hair dye formulations and their potential contact sensitizers such as health and beauty aids, household products, drugs and food. Our software generates networks of interacting chemicals, genes, proteins, pathways, and biological effects, providing extensive information on chemicals and their biological effects on organisms. In order to test our approach, we used the three ingredients most commonly used in permanent hair dye formulations (N-phenylenediamine, PPD; Resorcinol, RES and hydrogen peroxide, H2O2). We showed how simultaneous exposure may result in one chemical augmenting the toxic effects of the other. Our computational tool shows that RES and PPD target molecules that are involved in inflammation and allergy reactions like cytochrome P450 protein CYP1A1, CYP3A4, prostaglandin synthase PTGS2, chemokine receptors CXCR4, CCR6 and cytokines IL8, ILS. Further, our system identified correlation between these two chemicals and various skin conditions such as skin sensitization and skin inflammation. Bioinformatics analysis provides the molecular mechanism of how exposure to these hair dye components can induce skin sensitization, and putative explanation of additive and/or synergistic effect observed with these three chemicals.

2705 A Tier-Based Skin Sensitization Testing Strategy for Personal Care Products

E. S. Fung1, D. A. Drechsel2, K. M. Towle1, D. J. Paustenbach3, and A. D. Monnot4.1Cardno ChemRisk, Aliso Viejo, CA; 2Cardno ChemRisk, Boulder, CO; 3Cardno ChemRisk, San Francisco, CA; and 4Cardno ChemRisk, Jackson Hole, WY.

Tier-based testing strategies allow for a comprehensive evaluation of product safety in a cost and time efficient manner. Currently, there is a lack of formal testing requirements and standardized tier-based testing strategies for cosmetics and personal care products, especially for complex mixtures. The goal of this project is to develop a tier-based testing strategy for skin sensitization potential of personal care products. An on-market hair cleansing conditioner containing 23 ingredients was evaluated for skin sensitization potential using a proposed tier-based testing strategy for personal care products. The first tier of evaluation utilized the OECD QSAR Toolbox for an in silico evaluation of the skin sensitization potential of the identified ingredients with defined chemical structures. Subsequently, tier two testing utilized the OECD 442C in vitro guideline test (Direct Peptide Reactivity Assay [DPRA]) to evaluate identified ingredients with skin sensitization potential from tier one. To date, the OECD 442C in vitro guideline test has not been validated for food products. However, tier three testing adapted the OECD 442C in vitro guide- line to evaluate the skin sensitization potential of the total product mixture. The results from tier one in silico testing revealed four structural alerts for skin sensitization: methylchloroisothiazolinone, methylisothiazolinone, panthenol, and stearamidopropyl dimethylamine. Tier two in vitro testing of the individual structural alerts in tier one testing were not sensitizing at the concentrations tested. Tier three in vitro testing was consistent with individual ingredient evaluation; the formulated product was not
sensitizing. Together, the results indicated that although several ingredients were identified as potentially sensitizing, based on structural alerts from in silico testing and subsequent in vitro testing revealed that the individual ingredients and the product were non-sensitizers at the concentrations tested.

2706 An In Vitro Assay Platform to Assess Skin Sensitization Potential of Chemicals in Subset of Tox21 10k Library
Z. Wei1, L. Zhang1, X. Liu1, M. Song1, T. Xu1, R. Huang1, M. Ferrer1, and M. Xia1.1. NIH/NCATS, Bethesda, MD; and 1. NIH/NEI, Bethesda, MD.

Skin sensitization, a toxicological endpoint, is known to be the initiation step of allergic contact dermatitis (ACD). Measurement of sensitization potential is a necessary step in the safety evaluation of both industrial and consumer products. In order to reduce and replace in vivo local lymph node assay (LLNA) gradually being replaced by in vitro cell-based assays. This study used several in vitro assays and 3D skin tissue equivalents to assess skin sensitization potential of topically used compounds. The Nrf2-ARE pathway has a well-established role in the detection of sensitizing chemicals with reactivity towards the cysteine residues in Keap1 protein. A total of 354 topically used compounds from the Tox21 10k library and 128 reference compounds were screened in an Nrf2-ARE-Luc reporter assay. Active compounds identified from Nrf2-ARE-Luc reporter screen were further tested for effects in the inflammation related assays that measure IL8 and IL1B expression in THP1 cells or primary keratinocytes. Finally, selected compounds were tested for concentration-response effects in activating dendritic cells by measuring the induction of cell surface expression of CD86 and CD54 by compounds on THP1 cells, as analyzed by flow cytometry. The ranking order of tested benchmark chemicals revealed that our test battery was able to distinguish strong from weak sensitizers. Some sensitizers tested in this study, such as 2,4-dinitrochlorobenzene (DNCB), methyl-dibromo glutaronitrile (MDBG) and Diphenylcyclopropenone (DPCP) are also contact irritants. We further compared the activity of these compounds in test battery assays with cytokine profiling assays in 3D bio-printed epidermis equivalents. The allergenic properties of the chemicals appeared to dominate over interactive properties since the effective concentration to induce sensitization was one magnitude lower than the irritation threshold. This high throughput test battery of assays provides a relevant tool to quickly detect sensitizers. The data generated from these in vitro assays provide a resource for predictive modeling and hazard identification.

2707 In Vitro Irritation Potential of Cyanotoxins in Reconstructed Human Skin
D. G. Ross, M. F. Hughes, and J. E. Simmons. US EPA, Research Triangle Park, NC.

Cyanobacteria are microorganisms that occur naturally in both fresh water and marine environments. They are found at higher densities in eutrophic waters. Cyanobacteria can rapidly increase under growth-enhancing conditions of sunlight, elevated temperature and increased loading of anthropogenic nutrients such as nitrogen and phosphorus, resulting in harmful algal blooms (HABs). HABs have been detected in all 50 states. Many cyanobacteria are capable of producing cyanotoxins. Microcystins and cylindrospermopsin are some of the classes of cyanotoxins formed, with the microcystins the most commonly detected. Human exposure to cyanotoxins can occur through drinking water, recreational activities (e.g., swimming, bathing), the aquatic food web, terrestrial plants, and food supplements. Human exposure to cyanotoxins are known to cause skin rashes, gastrointestinal, and nervous system, liver and kidney damage. The objective of this study is to assess the in vitro dermal irritation potential of microcystin LR and cylindrospermopsin. The in vitro Epiderm Skin Irritation Test (EPI-200-SIT MatTek, Ashland, MA., USA) is a 3D cell culture (referenced in the OECD Test Guideline 439 for skin irritation) that consists of organized basal, spinous and granular layers, and a multilayered stratum corneum containing intercellular lipid layers arranged in patterns analogous to those found in vivo. The tissue is derived from normal epidermal keratinocytes from neonatal foreskin. This tissue is also known as reconstructed human skin. Tissues (3/dose) were exposed to microcystin-LR (M-LR) at concentrations of 2, 20, 100, 200, 1000, and 2000 µg/L and cylindrospermopsin (CYN) at concentrations of 4, 40, 200, 400, 2000, and 4000 µg/L prepared in sterile water. The highest concentrations were 500-fold US EPA’s recommended recreational criteria or swimming advisory levels using a spectrophotometer. In this assay, at both the 1 and 24 hr timepoints, neither cyanotoxin was determined to be an irritant at any tested concentration. The conditions of this experiment, M-LR and CYN are not dermal irritants This abstract does not represent US EPA policy.

2708 Acute Dermal Irritation Response in White Sinclair and Hanford Minipigs
J. Klein, Sinclair Research Center LLC, Auvassus, MO.

Acute dermal irritation was induced and characterized in white Sinclair and Hanford minipigs using a variety of known human irritants at increasing concentrations (N = 2 per breed, 3-4 months old, all females). During acclimation the areas of the dorsum of the minipig to be tested were shaved, and the topical dermal challenge sites were marked. Animals were administered 0.5 mL of test compound on gauze to a 4 cm² area for 4 hours. Following dose administration, the gauze was removed (time 0) and animals were scored using a Modified Draize Scoring System for erythema (0-4) and edema (0-4), with a maximum score of 8. Scoring was conducted at 1, 24, 48, and 72 hours after test article removal. Materials tested were as follows: sodium hydroxide (0.5, 1, 2, and 4%), formaldehyde (0.8, 2, 4, and 8%), benzenzalkonium chloride (7.5, 15, 30, and 45%), and sodium dodecyl sulfate (20, 40, 60, and 80%). Results: The data indicate that all concentrations of formaldehyde and sodium dodecyl sulfate failed to show irritation in both minipig lineages. All concentrations of sodium hydroxide failed to show irritation in the Hanford minipigs, while 4% sodium hydroxide caused erythema (scores of 1 or 2) starting at 24 hours in both Sinclair minipigs. Benzenzalkonium chloride at 20% was shown to induce edema (scores of 1 or 2) in Hanford minipigs, however, benzenzalkonium chloride at 45% showed no difference between the lineages. Conclusion: When exposed to either sodium hydroxide or benzenzalkonium chloride, two known human irritants, white Sinclair minipigs display more irritation (based on erythema and/or edema scores) when compared to Hanford minipigs. At a certain irritation threshold (e.g. 45% benzenzalkonium chloride), there was no difference between the lineages. Although more testing needs to be performed to confirm the results, these early tests suggest that the white Sinclair minipig may be more sensitive to potential irritation and therefore a better animal model for human responses to chemicals. Length: less than 2,300 characters, all included but space.

2709 Validation Method to Detect Formazan Salt Using High-Performance Liquid Chromatography to Evaluate Irritation and Corrosion Assays in 3D Human Epidermal Model
S. A. Dreossi1, C. A. Mini1, S. S. Maria-Engler2, and D. P. Oliveira1.
1University of São Paulo, Ribeirao Preto, Brazil; and 2University of São Paulo, São Paulo, Brazil.

The disclosure of the 3Rs principle drove to the establishment of a large range of in vitro methods for different applications, especially for the safety evaluation of new chemical compounds. Considering that, OECD has published two widely used guidelines, OECD 431 (2016) and 439 (2015), for skin corrosion and irritation, respectively. For both tests, evaluation of the effect is based on the color produced by the generation of formazan salt, a well-known indicator of cell death. However, colored substances such as hair dyes are difficult to assess due to color interference. The aim of this study was to propose and validate a method for the determination of the salt of formazan in our “in house” Reconstruction Human Epidermis (RHE) model using HPLC according to the US FDA 2018. For that, we used a LC-10AT VP (Shimatzu) with UV-vis detector SPD-10A VP (Shimatzu) and the chromatographic conditions: mobile phase acetonitrile-water (80:20 v/v), Lichrospher 100® RP-18 (5µm) column; LichroCART® 125-4 HPLC-Cartridge, flow rate 1,2mL/min. Chromatograms were processed at a wavelength of 555 nm. For linearity, we prepared a standard solution of formazan in isopropanol with different points (0.5; 2; 20; 50; 100; 200 µg/mL). Precision and accuracy were performed using 3 different concentration and 3 independent calibration curves (intraday and interday assays), using 5 replicates. Solutions of each concentration were dried and resuspended in mobile phase prior to injection. In order to evaluate the matrix effect, we used 5 RHE fortified with 3 concentrations of formazan (2; 20 and 100 µg/mL), followed by the recovery determination. For selectivity, using RHE, an extraction step was necessary to evaluate interference from matrix. As results, we observed a linearity with r =0,99; recovery up to 85%; accuracy and precision with standard deviation <15%. Additionally, the method is validated and suitable for analysis of corrosion and irritation in RHE after exposure to colored compounds. Financial Support: Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) and Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES).
Establishment of Skin Irritation and Decontamination of TMAH Splashes: Genotoxic Effects Induced by Hair Dyes in Development of a Method to Measure Systemic Toxicity. Confirmation with pH with hypertonic, amphoteric solution could limit tissue diffusion and thus of the corrosive base effect of TMAH and of decontamination for returning pH to be ~10 times greater: 140, 250, or 1,100 ml. These studies highlight the role to 2.5, 5, and 25% TMAH, respectively. With tap water, added volumes needed it was necessary to add, 8, 15, and 100 ml of hypertonic, amphoteric solution appears after 600 ml are added. To achieve a physiologically tolerable pH of ~9, decontamination, a precipitate occurs after 18 ml are added and then disapperition, a precipitate occurs and persists. With hypertonic, amphoteric solution permeable membrane more rapidly than the 2.5 and 5% concentrations: 2 vs. either tap water or an hypertonic, amphoteric solution using a dosing tech deposited on the top of the membrane in contact with a 6 ml compartment of diffusion of TMAH concentrations of 2.5, 5, and 25% (Acros; pH =14; pH =13.6) through the skin. 3 drops of the contaminant were deposited on the top of the membrane in contact with a 6 ml compartment of sodium chloride. Simulation of TMAH decontamination was performed using either a single in vitro test or in vitro test can replace accepted animal based results. Significant efforts have been made to employ RhE models as a standalone skin sensitization assay. For example, genmic arrays (eg. SENS-IS) provide powerful tools for key event (KE) genomic based biomarker assessment. Here, we present a proteomic array using electrophoresimecence multiplexing technology as a single assay to assess the regulation of key biomarkers associated with known KE for skin sensitization. Data from concurrent detection and quantification of KE biomarkers is presented as a proof of concept multiplex approach to the assessment of skin sensitization.

Decontamination of TMAH Splashes: In Vitro Experiments

Tetramethylammonium hydroxide (TMAH) is a quaternary ammonium compound and also a strong corrosive base. TMAH is widely used in the semicon- ductor and photovoltaic industries as an etchant and developer. It dissociates into the TMA+ and OH- ions, the latter causing chemical skin/eye injuries and the former felt responsible for systemic toxicity including reported fatalities. It is plausible that dermal injury from the OH- ion may increase tissue penetration of the systemically toxic TMA+ ion. In vitro experiments were performed using a semipermeable cellophane membrane (30 g/ml, 20.8 μm) to mimic diffusion of TMAH concentrations of 2.5, 5, and 25% (Acros; pH =15.6; pH =14; pH =13.6) through the skin. 3 drops of the contaminant were deposited on the top of the membrane in contact with a 6 ml compartment of sodium chloride. Simulation of TMAH decontamination was performed using either a single in vitro test or in vitro test can replace accepted animal based results. Significant efforts have been made to employ RhE models as a standalone skin sensitization assay. For example, genmic arrays (eg. There are a number of approaches to evaluate the safety of a personal care or cosmetic product, including clinical testing. Recently, there have been consumer reports of scalp dermatitis following the use of a commercially available cleansing conditioner. The aim of this study was to evaluate the skin tolerability of 6 commercially available hair cleansing products. A double-blind, randomized, controlled, IRB-approved clinical trial of 6 hair care products (HCPs) using Repeat Open Application Tests (ROATs) and Semi-Open (SO) patch tests was performed. For the ROAT, 150 healthy adult volunteers applied 0.2 ml of product to 6 separate, randomized locations on the forearms per standardized protocol. Exposure time was increased (5-15 minutes) over 5 weeks. Participants and investigators were blinded to product locations. Application was discontinued if a ROAT score $\geq 6$ (10 maximum). SO testing was performed at week 4 and graded at week 5 in a double-blind randomized fashion. Primary outcomes included ROAT and SO scores for each HCP. Of the 150 individuals that have completed the study, 84.7% are female, with a mean age of 48.4 years. 41.3% of the study participants had a history of either atopic dermatitis, asthma, or hay fever. Preliminary analysis (performed with study blind intact) found that 5.3% of participants achieved stopping point (total ROAT$\geq6$) for one HCP. That same product resulted in ROAT scores of $\geq 1$ and SO score $\geq 4$ for 42.7% and 3.1% of participants, respectively. In contrast the remaining 5 HCPs had $\leq 3.3\%$ with ROAT scores $\geq 1$ and $\leq 3.6\%$ with SO score $\geq 4$. There is a significant difference in tolerability of the 6 HCPs evaluated as measured by ROAT and SO.

TNIP1 protein is a widely expressed, cytoplasmic inhibitor of inflammatory signaling initiated by membrane receptors for pathogen-associated and damage-associated molecular patterns (PAMPs and DAMPs) coming from endogenous and/or environmental sources. TNIP1 deficiency occurs in inflammatory skin diseases such as lupus and psoriasis, possibly sensitizing cells to such stimuli. Recently, we published TNIP1 deficiency in keratinocytes sensitizes them to experimentally-defined PAMPs and DAMPs thus promoting hyper-responsive expression and secretion of inflammatory markers (e.g. IL-8, IL-6 and TNFα). Thus, TNIP1 deficiency with subsequent stimulation establishes intrinsic (gene expression) and extrinsic (cytokine milieu) changes which we predict may modulate global tissue events such as wound healing. In this study, we examined the wound healing parameters of cell survival, migration, and expression of other inflammation-related genes. Specifically, we used our cell culture model of TNIP1 deficient keratinocytes to investigate stimulating toll-like receptor 3 with the agonist poly IC, a representative dsRNA PAMP/DAMP. Our studies revealed increased expression of antimicrobial (e.g. $\alpha$100a family) and wound healing (e.g. IL-8, CCN2) associated genes, suggesting potential benefit of increased inflammatory response from TNIP1 deficiency. Unexpectedly, poly IC challenge of TNIP1 deficient cells restricted re-epithelialization and induced cell death as compared to TNIP1 deficiency alone. Intriguingly, we detected not only increased expression for genes associated with cell death and inflammasome activation (e.g. caspase 1, IL-1β) but strikingly also for A20, a protein that represses cell-death signaling downstream of membrane receptors. Despite this compensatory increase in A20 mRNA, we found evidence of a decrease in its protein activity. Thus, an underlying mechanism for the hyper-responsive phenotype of TNIP1 deficient keratinocytes following DAMP/PAMP stimulation involves not only an increase in inflammatory gene expression but also likely includes deficiencies in adequate compensatory responses such A20 activity.
Humans are exposed to ultraviolet radiation (UVR) throughout their lives, which has both beneficial and detrimental effects. UVR is essential for vitamin D synthesis, but high exposure can cause painful sunburns and increase one’s risk of skin cancer due to its high mutagenicity. Sunscreens have been developed to combat UVR’s negative effects, and are even more highly encouraged for at risk populations. While sunscreens have been shown to be effective at reducing the risk of skin cancer, there is evidence to suggest that some UV filters may have hormonal and endogenous compounds, as well as further toxicological studies on these chemicals essential. We hypothesized, based on structural aptitude, that some UVR filters found in sunscreens may be able to modulate Aryl hydrocarbon receptor (AhR) signaling. The AhR is a ligand-activated transcription factor that plays a significant role in the metabolism of various endogenous and exogenous compounds, as well as regulating the immune system. Interestingly, the endogenous AhR agonist 6-formylindolo-3,2b-carbazole (FICZ) is thought to be produced in the skin after UVR exposure. To test our hypothesis, we utilized the H1L1.1c2 mouse hepatoma AhR reporter cell line to screen UVR filters for activity as an AhR agonist or antagonist. While the UVR filters that we have tested thus far show no agonist or antagonist activity towards the AhR, co-treatments of the UVR filter octinoxate and FICZ resulted in a potentiation of AhR activation that was greater than what FICZ alone was able to elicit. We repeated these treatments on an immortalized keratinocyte cell line (HaCaT) and analyzed RNA expression of cytochrome P4501A1 (CYP1A1), a known AhR target gene, via real time PCR (qPCR). Our results showed that this potentiation also occurs in keratinocytes. Based on our results, we hypothesized that octinoxate acts as a CYP1A1 inhibitor, resulting in a reduction in the rate of FICZ metabolism and sustained activation of the AhR. To test this hypothesis, we performed an Ethoxyresorufin-O-deethylase (EROD) assay as well as a biochemical CYP1A1 inhibition assay (Promega). The results of both assays strongly suggest that octinoxate is able to inhibit CYP1A1 activity. While there is more to be done, our research has produced significant evidence to suggest that octinoxate has off-target effects on normal AhR signaling via CYP1A1 inhibition, which has many potential implications for skin function.

2719 Beauty Sleep: Skin Collagens Regulate Sleep in Response to Cell Stress in Caenorhabditis elegans

When animals are sick or injured from an exposure that results in cell stress, they respond by sleeping; such behavior is called sickness or stress induced sleep (SIS). The pathway regulating SIS may be conserved from nematodes to vertebrates. Cellular stress in C. elegans leads to activation of the epidermal growth factor (EGF) receptor on the ALA neuron, which releases neuropeptides. ALA neuropeptides induce SIS behavior, which consists of immobility and feeding quiescence, elevated arousal threshold, and rapid reversibility. While much is known about ALA activation and its downstream mechanisms, the SIS pathway upstream of EGF remains poorly understood. This part of the pathway is the focus of our work. We found that mutants lacking the cuticular collagens DPY-5, DPY-10, or DPY-13 show impaired feeding and movement quiescence following exposures to ultraviolet (UV) irradiation or heat shock. Feeding was measured by counting the number of pharyngeal pumps in 10 seconds. Movement quiescence was measured using machine vision algorithms. The loss of skin collagen genes results in short, fat worms, a morphological phenotype referred to as Dumpy or Dpy. To determine where the dpy mutation acts in the SIS pathway, we crossed each of them into an inducible-EGF background. Each of the three dpy mutants showed normal or enhanced SIS following the induction of EGF, suggesting that these genes act upstream of EGF. To determine if mutants with a Dpy phenotype due to mutations other than collagen genes are important for SIS, we tested mutants in dpy-19, which encodes a C-mannosyltransferase. dpy-19 mutants had normal SIS following both UV and heat shock, suggesting that specifically collagen gene disruption and not the Dpy phenotype explains the impairment in SIS in the dpy-5, -10, and -13 mutants. To determine whether disruption of the cuticle in the absence of a Dpy morphology affect SIS, we tested mutants in bus-8, which encodes a glycosyltransferase that is important for cuticle integrity. bus-8 mutants do not have a Dpy phenotype. We found that bus-8 mutants are not deficient in SIS, suggesting that disrupting the cuticle is not sufficient to impair SIS, but that collagen disruption specifically is important. We conclude that cuticular collagen disruption impairs stress induced sleep. This information informs our understanding of the relationship between skin collagens and fatigue/sleepiness associated with sickness in humans.

2720 Oral Ingestion of a Novel Oxygenating Compound, Ox66, is Non-toxic and Results in Increased Oxidation

F. Zhang, G. Aquino, A. Dabi, W. Nugent, B. Song, and E. Bruce. 1Baylor University, Waco, TX; and 2Song Biotechnologies LLC, Baltimore, MD.

Ox66TM is a novel solid-state oxygenating compound. In order to support the use of Ox66TM as a potential oxygenating supplement to alleviate conditions caused or exacerbated by hypoxia, this study evaluated the safety of Ox66TM, its ability to withstand the conditions of the digestive tract, and its potential to increase oxygenation in the mesentery in rats. The toxicity of Ox66TM was evaluated by performing acute (10-day) and chronic (90-day) feeding studies on rats. The stability of the compound in the digestive tract was evaluated via ex vivo simulated digestion and subsequent CFDA viability assay on gut epithelial cells. Its capacity for oxygenation in the mesenteric microcirculation was determined by interstitial fluid pressure (P,interstitial) and oxygen measurements upon injection into the small intestine of rats. No toxicity was found associated with acute or chronic oral administration of the compound in rats, and the compound was able to withstand the environment of the digestive tract in vivo. Based on the animal feeding study, the NOAEL was considered to be 1000 mg/kg/day. This proof-of-concept study further demonstrates the potential of Ox66TM to function as an oxygenating supplement that might be useful for treating either pathological hypoxic-related conditions or to improve oxygenation levels during or after exercise under healthy conditions.

2721 Application of New Approach Methodologies (NAMs) to Address Data Gaps in Human Risk Assessment: 2-Amino-2-Methylpropanol (AMP) Case Study

P. Sura, and P. Spencer. ANGUS Chemical Company, Buffalo Grove, IL.

2-amino-2-methylpropanol (AMP™) is an organic chemical widely used as a dispersant and neutralizer in the paints and coatings, and personal care industry. In previous evaluations, high oral doses of AMP in rat and dog repeat-dose studies induced liver steatosis and an early post-implantation loss in an OECD 422 developmental screening study in rats. As a result, several regulatory agencies have requested additional animal studies to better characterize the risk to human health. The current work utilized New Approach Methodologies (NAMs), in silico and in vitro approaches, to address uncertainties in the human risk assessment. To leverage existing human data on a widely used over-the-counter (OTC) diuretic drug Pamabrom, the ability to read-across was substantiated by conducting a bioequivalence study with AMP and Pamabrom. This, in tandem with in vitro methods combined with in vivo to in vivo extrapolation (IVIVE) to estimate an in vivo human point of departure, was conducted to strengthen the human risk assessment and address the data gaps raised by the regulatory bodies. The human data from the Pamabrom and the in vitro/IVIVE work addressed the uncertainty in the risk assessment process, with respect to extrapolation of results from animal studies to humans, as well as the differences in sensitivity to effects on target tissues between species. This additional data strengthened the weight of evidence regarding the overall safety of the chemical having a long history of safe use, thus preventing additional animal testing for hazard assessment of chemicals.

2722 Next Generation Products Induce Lower Biological Activity Than Combined Cigarettes: A Comparison of Aerosol Chemistry and In Vitro Toxicity

K. Rudd, R. Wieczorek, E. Trelles-Sticken, J. Pani, O. Dethloff, L. Simms, and M. Stevenson. 1Imperial Brands plc, Bristol, United Kingdom; and 2Reemtsma Zigarettenfabriken GmbH, Hamburg, Germany.

Tobacco smoking has long been recognised as a major cause of disease. While public health bodies recommend complete cessation as the best action smokers can take to improve their health, some organisations begin to recognise the harm reduction potential of alternative products to smokers who are unwilling or unable to quit. There are many next generation products (NGPs) commercially available aiming to provide an alternative to smoking, with a significant reduction in harm. The study objective was to compare the chemical composition and in vitro toxicological activity of different NGP aerosols with conventional cigarette smoke. Products investigated were the Kentucky reference cigarette (3RAF), a tobacco heated product (THP), a hybrid product (THY) and a myblu™ vapour product (1.6% [w/w] nicotine; tobacco flavour). The smoke/aerosols were generated using the Health Canada Intense smoking regime for 3RAF and THP (55mL/2s/30s) and the CORESTA Recommended
Method No. 81 (55mL/3s/30s; square wave puff profile) for HYB and mybelle\textsuperscript{a}. The collected whole smoke and aerosols were tested under the CORESTA regulatory in vitro toxicity assays: neutral red uptake (BEAS-2B) for cytotoxicity, Ames (TA98, TA100) for mutagenicity and in vitro micronucleus assay (V79) for genotoxicity. Chemical analysis of all the NGP aerosols tested revealed substantial reductions in aerosol constituents when compared with conventional cigarette smoke. For example, the WMO 9 priority toxicants were below the level of detection in mybelle\textsuperscript{a} aerosol corresponding to a >99% reduction compared to 3RAF. All NGP aerosols demonstrated marked cytotoxicity reductions compared to cigarette smoke on a per puff basis. 3RAF smoke was highly mutagenic in the Ames test and induced significant genotoxicity after 1 puff. This cross-section represented a significant response in TA98 only, and induced genotoxicity after 24 puffs. In contrast, neither HYB nor mybelle\textsuperscript{a} aerosols were mutagenic or genotoxic (up to 100 puffs) under the test conditions. The data shows clear differences between 3RAF cigarette and NGP emissions and in vitro toxicity. NGPs should be considered to have the potential to reduce smoking-related disease risks.

### 2723 Use of Alternative Test Methods to Assess the Sensitization Potential of Commonly Used Botanical Extracts Found in Cosmetic Products

Z. Wang, C. Avonto\textsuperscript{1}, R. Verma\textsuperscript{1}, S. I. Khan\textsuperscript{1}, A. G. Chittiboyina\textsuperscript{2}, I. A. Khan\textsuperscript{2}, and N. Sadrieh\textsuperscript{1}\textsuperscript{1} US FDA, College Park, MD; and \textsuperscript{2}University of Mississippi, University, MS.

Botanical ingredients are increasingly used in cosmetic products. Because of increasing limits internationally on animal testing, the sensitization potential of such ingredients will depend more heavily on alternative test methods. We have undertaken a study to evaluate the skin sensitization potential of a number of botanical extracts and ingredients from 	extit{Matricaria chamomilla} (German chamomile), a commonly used botanical in skincare products, using \textit{in chemico}, \textit{in silico}, and \textit{in vitro} methods that have previously been developed and/or validated for decision-making. Initially, (quantitative) structure-activity relationship (Q)SAR models built on human data as well as murine local lymph node assay (LLNA) data were applied to screen 246 chemical constituents of German chamomile for their skin sensitization potential, and the results were combined in a weight-of-evidence (WoE) predictions. Based on these (Q)SARs (\textit{in silico}) WoE prediction results, 30 compounds were chosen for further \textit{in chemico} and \textit{in vitro} testing using the Direct Peptide Reactivity Assay (DPRA), KeratinoSens\textsuperscript{TM}, the human Cell Line Activation Test (h-CLAT), as well as a recently developed chemical high-throughput assay using dapsyl cysteamine (HTS-DCYA). Among the compounds tested to date, 2,5-dihydroxybenzoic acid, quercetin, epicatechin, luteolin and caffeic acid were found to be reactive both in the DPRA and HTS-DCYA, which are both designed to simulate the molecular initiating event in the skin sensitization adverse outcome pathway. The phenolic constituents appear to be more reactive than the terpenoids constituents of chamomile. On the other hand, the lipophilic compounds such as guaiazulene, herniarin and bisabolol, were not chemically reactive but they did elicit an increase in the expression of at least one of the two protein markers on the cell surface in the hCLAT assay. Future testing of these assays including KeratinoSens\textsuperscript{TM} will be performed to investigate the ability of German chamomile constituents to activate inflammatory responses mediated by the Kep-ARE-Nrf2 pathway in keratinocytes.

### 2724 Improving Safety Assessment Weight-of-Evidence with Poison Center Data

A. Maier\textsuperscript{1}, M. Vincent\textsuperscript{1}, J. Colvin\textsuperscript{2}, A. Quinones-Rivera\textsuperscript{3}, and J. Arbogast\textsuperscript{3}.

\textsuperscript{1}Cardno ChemRisk, Cincinnati, OH; \textsuperscript{2}Cincinnati Children’s Hospital Drug and Poison Information Center, Cincinnati, OH; and \textsuperscript{3}GOJO Industries, Inc., Akron, OH.

Safety assessments rely on weight-of-evidence (WoE) analyses to integrate human effects and toxicology information. Human effects data are often limited. Poison Centers (PCs) respond to millions of calls each year, including accidental and intentional misuse of various consumer products. Such data might support evaluation of exposure concentrations, dose-response, and severity of health effects. PC records were evaluated for alcohol-based hand sanitizer (ABHS). Details from 2521 PC calls regarding exposure to ABHS were evaluated for information on the route of exposure, estimation of the amount consumed, presence and severity of health effects, patient characteristics (e.g., age, weight), product characteristics (e.g., brand, color, scent), packaging characteristics (e.g., dispenser type, package size), and formulation characteristics (e.g., active ingredient type, concentration). Retrospective evaluation of the case narratives allowed for descriptive and trend analyses, but many of the (Q)SAR predictions could not be verified due to gaps in data collection during the initial PC consult and a lack of consistent follow-up to confirm patient outcomes. Reported clinical effects and severities suggest that accidental ingestions are inconsequential and do not result in serious health complications. Accidental ingestions of ABHS demonstrated a similar patient outcome profile to traditional hand soaps, with a lower rate of clinical effects when compared to ethanol-containing mouthwashes. These findings add to the WoE from studies of other ethanol-based consumer products of the retrospective analysis identified characteristics or scenarios that are more likely to lead to accidental or intentional misuse. 82% of ABHS cases were children ≤ 5 years of age and most (74%) ingested only a small amount (0-4 ml), defined as a “taste”. Children were 4.5 times more likely to consume more than a “taste” if they had direct access to the ABHS. However, much of the retrospective information is limited for use in quantitative dose-response analysis. Design and implementation of a prospective analysis would fill identified data gaps and improve the reliability of data capture for safety assessment through standardization of questions asked during PC calls and attempted follow-up on all reported incidents.

### 2725 Evaluating the Phototoxic Potential of a Hair Cleansing Conditioner

D. A. Drechsel\textsuperscript{1}, E. S. Fung\textsuperscript{1}, K. M. Towle\textsuperscript{2}, J. F. Paustenbach\textsuperscript{3}, and A. D. Monnot\textsuperscript{1}.

\textsuperscript{1}Cardno ChemRisk, Boulder, CO; \textsuperscript{2}Cardno ChemRisk, Aliso Viejo, CA; \textsuperscript{3}Cardno ChemRisk, San Francisco, CA; and \textsuperscript{4}Cardno ChemRisk, Jackson, WY.

Phototoxic dermal reactions may be produced by topical administration of exogenous chemicals. Chemicals that cause phototoxicity absorb ultraviolet (UV) light and transfer this energy to other molecules or form reactive free radicals that result in adverse reactions such as redness and blistering. No standardized test for phototoxicity is required under current US FDA regulations for personal care and cosmetic products; however, if UV exposure is anticipated following product use, evaluation for phototoxic potential may be necessary. The goal of this study was to utilize a validated phototoxicity test to evaluate the phototoxic potential of three on-market hair cleansing conditions to demonstrate this assay’s applicability to personal care and cosmetic products. The OECD 432 in vitro guideline study was utilized to evaluate the phototoxic potential of the hair cleansing conditioners. The hair cleansing conditioners were evaluated by a UV-visible light (VIS) spectral scan to ensure no significant absorption between 280 and 400 nm. Subsequently, Balb/c 3T3 mouse fibroblast cells were exposed to the hair cleansing conditioners and controls for one hour. Following the incubation, one set of treated 3T3 cells were irradiated with 4 minutes of 5 J/cm\textsuperscript{2} Solar Simulated Light (SSL), containing wavelengths of UVA and visible light with more than 99% of UVB blocked out. A duplicate set of treated 3T3 cells were kept in the dark. After UV irradiation, 3T3 cells were washed and incubated for 24 hours and cell viability was determined by neutral red uptake. The difference in cell viability between the SSL exposed and non-exposed 3T3 cells were used to determine the phototoxicity of the hair cleansing conditioners. Under the conditions tested, the hair cleansing conditioners were not phototoxic in the 3T3 neutral red uptake phototoxicity test, while the positive control was significantly phototoxic. Taken together, these results demonstrate that the tested hair cleansing conditioners did not have phototoxic potential.

### 2726 An Inter-species Comparison of the Triclopyr In Vitro and In Vivo Toxicokinetic Properties, for Risk Assessment Purposes

Triclopyr is a synthetic auxin, a broad-weed herbicide, used in pasture and rice. Hence, external human exposure is possible via dietary and non-dietary route. Herein, we present a multi-faceted approach, utilizing newly generated data from \textit{in vitro} systems and existing internal data from \textit{in vivo} studies. This project includes academic and volunteer research volunteers, as well as \textit{in silico} predictions of systemic exposure to recapitulate oral gavage and dietary exposure profiles in various species, including humans. The oral absorption of triclopyr was complete in mammals as well as in human volunteers and, \textit{in vitro}, in a CaCo-2 cells experiment. \textit{In vitro} comparative metabolite usage under dietary and \textit{in vivo} confirmed lack of metabolism in humans, similar to other species. Excretion mechanisms, previously investigated in \textit{in vivo} renal clearance study in dog, are unique to that species, while a more rapid renal elimination in rat and human would correlate with known lower systemic levels compared to dog. Comparative \textit{in vitro} plasma protein binding confirmed that the plasma free fraction available for glomerular filtration is

2019 SOT Annual Meeting 406
higher in dogs compared to rat and humans. Renal clearance was additionally investigated in primary proximal tubule cells to determine direction, magnitude, and transporters involved in mammals’ tubular excretion/resorption fluxes. Overall the results of these studies will be utilized to confirm that the triclopyr toxicokinetic profile of rats is more similar to humans, while dogs present a very species-specific excretion system of organic acids. These data are key to interpret toxicity features in rats. In addition, since the point of departure for triclopyr risk assessment are based on rat studies, the similarities between these two species greatly reduce uncertainties (and, possibly, safety factors) for the use in human health risk assessment.

**2727 Safety Testing of Bacteria: Challenges and Approaches to Translocation Testing in Studies Conducted in a High-Throughput Vivarium**

A. B. Pater-Faranda, J. Roper, P. Mukerji, and F. Burns. DuPont Haskell Global Center for Health Sciences, Newark, DE.

Safety assessments for live microbial products, such as bio pesticides and probiotics, present unique experimental challenges for an in vivo testing laboratory. Among these is the assessment of potential for translocation - the migration of an organism from the gut to other parts of the body. For assessment of translocation endpoints during probiotic safety evaluation in 90-day rat gavage studies, blood samples and selected tissues are collected in the vivarium setting at necropsy, transported to a laboratory with biosafety cabinets, homogenized, and the homogenate plated and analyzed using appropriate conditions. Colonies are counted, scored by 8 morphological criteria, and sub cultured for subsequent molecular identification. A critical variable for analysis of translocation from the gut to the tissues is the potential for environmental contamination during tissue harvest. Even with the strict sanitization protocols of a modern, high-throughput vivarium, absolute sterility can be difficult to achieve. This is especially true when large numbers of animals are processed quickly to collect the many samples required for a thorough safety evaluation. During three recent 90-day rat gavage studies with probiotic test substances, techniques designed to minimize environmental microbial contamination were implemented but not evaluated by limit implemented. Enhanced vivarium practices included aseptic blood collection techniques, whole-animal and tissue sanitation procedures, and prioritization of tissue collection for translocation assessment over tissues intended for other endpoints. In addition to enhanced vivarium practices, it was determined for solid tissues that briefly submerging the samples in a sodium hypochlorite solution prior to homogenization provides effective surface decontamination without affecting identification and quantification of microbes within the tissue. In sections of chicken liver with application of a bacterial indicator strain, hypochlorite pretreatment reduced surface contamination by greater than one log in the absence of a statistically significant reduction in detectable bacteria injected into the liver. Implementation of these practices facilitates accurate and reliable evaluation of microbial translocation in large, multi-endpoint safety studies.

**2728 Effect of Percent S9 Fraction on Bacterial Background Lawn Assessment in Ames Assay Using 35mm Plate Spread Technique**

S. K. Bhatti1, B. Kallam2, and M. W. Fariss2.1, Enthalpy Analytical, Henrico, VA; and 2ToxSynergy LLC, Midlothian, VA.

The Ames assay is commonly used to evaluate the mutagenic potential of pharmaceutical and tobacco products for regulatory purposes. A significant increase in the number of His+ revertant colonies observed in agar containing Salmonella bacteria and a test chemical indicates mutagenicity. To assess cytotoxicity in this assay, thinning of the background bacterial lawn is microscopically determined. With the development of new in vitro exposure systems that permit continuous cell exposure to aerosols or smoke, the Ames assay method required modification by spreading the bacterial solution on top of agar in a 35 mm plate. Using this technique, we observed reproducible thinning of the bacterial lawn by limiting the amount of histidine/biotin (nutrients) in the absence of the S9 fraction. However, in the presence of 10% S9, background lawn thinning could not be seen. We hypothesized that a reduction in the amount of S9 in the spread solution on the agar plate would allow the microscopic assessment of lawn thinning while providing adequate metabolic activation. Therefore, the objective of this work was to determine if microscopic analysis can detect thinning of the bacterial background lawn on top of the agar with 5% S9 fraction. The Ames assay was performed using a 35 mm agar plate spread technique with a bacterial solution in the absence or presence of 5 or 10% S9. Salmonella strains (TA98, TA100, TA102, TA1535, TA1537 and TA97a) were used to determine the number of His+ revertants and lawn thinning after 48 hours of incubation. The effect of 5 or 10% S9 fraction on the positive and negative control values for revertant colonies were also determined. We observed the reproducible thinning of the background lawn by limiting the amount of histidine/biotin in the absence and presence of 5% S9 but not with 10% S9 fractions. Using 5% S9, the positive and negative control values for revertant colonies were within historical control ranges (similar to 10% S9) for all strains. We conclude that thinning of the background bacterial lawn was clearly observed in all strains using the Ames assay with spread techniques and presence or absence of 5% S9 and microscopic analysis. The use of 5% S9 fraction with the 35 mm plate spread technique should permit the assessment of both mutagenicity and cytotoxicity in vitro aerosol or smoke exposure.

**2729 Oral Toxicity Testing of the Novel Green Insensitive Munitions Explosives, 2,4-Dinitropropyrazole (DNP) and 2,4,6-Trinitro-3-bromoanisole (TNBA)**

The US Department of Defense (DoD) utilizes Composition B, which includes 2,4,6-trinitrotoluene (TNT), in artillery and mortar rounds. TNT has known occupational toxicity concerns and is a possible human carcinogen. Exposure to TNT can exhibit a variety of toxicities to the liver, blood, immune system, and reproductive system. Additionally Composition B does not meet current insensitive munitions (IM) requirements mandated by the DoD. As such, the focus of the Green Insensitive Munitions Explosive (GriMex) program is to develop an alternative IM formulation containing novel replacements for TNT that present fewer concerns to occupational exposures of TNT. 2,4-dinitropyrazole (DNP) and 2,4,6-trinitro-3-bromoanisole (TNBA) have progressed through this program as potential replacements for TNT. Dose verification and stability measurements determined that both compounds are stable in corn oil at room temperature for at least 5 weeks. The toxicity of these two compounds was tested via acute and 14-day subacute oral gavage dosing in Sprague-Dawley rats using corn oil as the vehicle. Acute dosing via the Stagewise Adaptive Dose Method resulted in LD50 values 444 (95% CI: 364-542) mg/kg and >2000 mg/kg for DNP and TNBA, respectively. Subacute dosing at 5 different dose levels for each compound produced a variety of compound-related toxicities. The results of this study will provide vital information in the effort to identify suitable replacements for TNT.

**2730 The US FDA Animal Rule and Standard for Exchange of Nonclinical Data (SEND)**

The Standard for Exchange of Nonclinical Data (SEND) is the newly required format for submissions of nonclinical data to the US Food and Drug Administration (US FDA) for carcinogenicity studies, and single and repeat dose toxicity studies. The framework of SEND was modeled off the older Standard Data Tabulation Model (SDTM) used for clinical submissions; both were created by the Clinical Data Interchange Standards Consortium (CDISC) with the goal of standardizing and digitizing data for the US FDA reviewer. SEND is not currently required for Animal Rule studies, however there is an increasing desire to use the SEND format for data visualization and warehousing purposes. Under the current SEND modeling paradigm, animal rule studies introduce several complications during the formulation and review of the dataset. For example, SEND has no ability to include Day 0, which is counter to the traditional design of many animal rule studies that use Day 0 for challenge doses (i.e., day of radiation, day of infection, etc). Additionally, modeling the challenge agent and test article within the Trial Domains are not demonstrated within the current guidelines, making best practices and standardization across different studies and sites unachievable. Since the current 3.0 guidelines do not allow the introduction of non-defined domains, information regarding challenge agent dosing, medical history, medical countermeasures, and microbiology samples will have to be included in existing domains, which will stretch their original purpose and incorporate non-controlled terminology. A CDISC Animal Rule team is currently working on drafting a guidance standard for Animal Rule studies. This guidance standard will be subject to US FDA and public input prior to being issued as a requirement.
Chemical Alternatives Assessment of Selected Phthalate Substitute Plasticizers: Carboxylates, Adipates, Citrates, and Trimellitates

M. Zachary, and M. H. Whittaker, ToxServices LLC, Washington, DC.

Phthalate esters are primarily used as plasticizers for flexible polyvinyl chloride (PVC) which, in turn, is used in many consumer products. Certain members of this chemical class, such as di-(2-ethylhexyl)-phthalate (DEHP), have been shown to cause reproductive and developmental toxicity. Because of their health concerns, six phthalate esters are now restricted from use in children’s products. As a result, a number of substances have been identified as alternative PVC phthalate plasticizers such as carboxylates, adipates, citrates and trimellitates. Although many of these alternatives show promising application potential, data regarding their potential toxicity are discordant and/or incomplete, and with limited studies conducted to characterize their environmental fate and toxicity. Towards this, we evaluated the human health and environmental hazards of nine commonly used non-phthalate ester plasticizers from various chemical classes. Their toxicity hazard profiles were compared to DEHP and a lower molecular weight phthalate, dimethyl phthalate (DMP). We utilized the GreenScreen® for Safer Chemicals (GS) tool to assess and compare hazard profiles of these plasticizers and identify critical data gaps. The GS assesses chemicals for 18 human health and environmental hazard endpoints to assign an overall benchmark (BM) score ranging from 1 (High concern) to 4 (Safe). A GreenScreen summarizes endpoint scores in a hazard summary table to allow for ease of visualization. Based on our investigation, two plasticizers were demonstrated to be good alternative to DEHP as they have the best GS BM scores (i.e., minimum BM score except for a data gap). These substances are bis(2-ethylhexyl) terephthalate (DEHT), the isomer of DEHP, and epoxidized soybean oil (EBSO), a vegetable oil-based plasticizer. Tributyl O-acetylcitrate (ATBC), a citrate-based plasticizer, also demonstrates low toxicity for human health endpoints. However, it poses a hazard for aquatic toxicity. The remaining investigated plasticizers including DMP all have a GS BM score of 2 due to their potential human health and environmental toxicity. To this end, this poster will outline the GS methodology and present in detail the results of the GS assessments for the assessed plasticizers including their chemical identities. This visual communication of hazard information for phthalate ester plasticizers will help formulators select less hazardous plasticizers and recognize important data gaps in each alternate chemical's dataset.
JP-8, a petroleum-based jet fuel, is currently the primary fuel used in US Air Force aircraft. Because the US Government is interested in lowering dependence on crude oil for military use, alternative fuels have been developed that would be either combined with or used in place of JP-8 for military operations. This study investigated the sensory irritation potential of the inhalation of aerosols and vapors from Amyris C15, an alternative fuel that is produced by a direct sugar to hydrocarbon process and is mostly the alkane farnesane. Sensory irritation is the most common harmful effect of inhaled airborne chemicals, and irritancy can be quantitatively measured in mice by reflex inhibition of respiratory rate. The concentration of a chemical that induces a 50% respiratory depression is termed the LD₅₀, and describes the sensory irritancy potential of that chemical. The testing method that was used followed the American Society for Testing and Materials guideline: Standard Test Method for Estimating Sensory Irritancy of Airborne Chemicals. Briefly, separate cohorts of Swiss-Webster mice were exposed nose-only to five concentrations of an Amyris aerosol/vapor mixture for 30 minutes. Respiratory rates were measured with a body plethysmograph during the exposure and 10 minutes post-exposure and compared to a pre-exposure baseline. Amyris exposure did not induce a respiratory rate depression at least 50% at any of the concentrations tested.

Several recent reviews and risk assessments have addressed the potential for cosmetic talc to cause disease, particularly ovarian and lung cancer and mesothelioma. These studies have generally focused on epidemiology studies (including studies of industrial talc-exposed populations) that have evaluated whether talc or its potential contaminants might cause these diseases. The issue of what (if any) contaminants might be found in cosmetic talc has been the subject of intense study for decades. There has not been a recent critical integrated effort to determine whether animal studies support a potential disease link between talc and/or its contaminants and cancer. We evaluated 17 animal studies of talc, identified through a combination of literature searches and compilation of previous reviews. In addition, we synthesized data from other animal studies that evaluated whether characteristics (e.g., fibrous form, length, dimensions, etc.) of some talc particles or contaminants might be a factor too in the cancer risk. Our critical review of talc-specific animal studies did not support that exposure to cosmetic talc products would result in an increased risk of cancer. Analysis of animal studies that evaluated whether potential contaminants of cosmetic talc such as fibrous talc or other non-asbestiform elongate mineral fibers (regardless of dimensions) also did not support an increased risk of cancer. The animal studies support the premise that high doses of cosmetic talc and/or its contaminants could be associated with non-cancer respiratory effects, such as inflammation and fibrosis. These observed effects are consistent with the type of health effects observed in animal studies of other nuisance dusts, and human reports that have found evidence of talcosis in cosmetic talc miners and millers with high exposures.

PCB 11 has been detected in air, water, sediments and human serum. PCB 11 has not been identified in any of the commercial PCB mixtures. Its presence in many cases is likely to be through products containing pigments in which the PCBs are inadvertently produced. Little information is available on the toxicity of PCB 11. The present study examines the effects of PCB11 on hepatic nuclear receptor activation in primary human hepatocytes. In addition, the effects of PCB 11 are compared to PCB77, 95, 126, 153 and Aroclor 1016 and 1254. Cryopreserved primary human hepatocytes (PHHs) cultures were exposed for 48 hours and subsequently measured for cytotoxicity, gene expression of CYP1A2, CYP2B6, and CYP3A4, and mRNA expression of TNF, IL8, NQO1 enzymes levels. Cryopreserved PHHs were exposed to chemicals at nominal concentrations of 0.2, 0.4, 0.9, 2.4, 9, 20, 40, 90, 200 μM (PCB 77, 126, 153 and Aroclors 1016 and 1254) or 2, 4, 9, 20, 40, 90, 200 μM (PCBs 11 and 95) or DMSO vehicle control. All concentrations were run in triplicate in three replicate plates. Cell viability was decreased at the highest concentration for all chemicals. All chemicals but PCB 95 induced CYP1A2 with a rank order of potency of PCB77 > PCB153 > PCB126 > Aroclor 1254 > Aroclor 1016. All chemicals except PCB126, a model Ah Receptor (AhR) activator, produced a 50-70-fold induction of CYP1A2. PCB11 only resulted in a 2-5 fold induction of CYP1A2 at concentrations of 90μM or higher, suggesting minimal AhR receptor activation. CYP3A4 was induced by all chemicals evaluated with a rank potency of PCB153 > CITCO > PCB95 > Aroclor1016 > PCY3A4 > PCB126. Aromatase (Arom) and CYP1A1 enzymes levels indicate these effects result in an increased risk of cancer. Analysis of animal studies that evaluated whether potential contaminants of cosmetic talc such as fibrous talc or other non-asbestiform elongate mineral fibers (regardless of dimensions) also did not support an increased risk of cancer. The animal studies support the premise that high doses of cosmetic talc and/or its contaminants could be associated with non-cancer respiratory effects, such as inflammation and fibrosis. These observed effects are consistent with the type of health effects observed in animal studies of other nuisance dusts, and human reports that have found evidence of talcosis in cosmetic talc miners and millers with high exposures.

The Cramer decision tree, published in 1978, is a procedure developed to estimate the toxic potential of a substance based on its chemical structure. Based on the structural functionalities present, a chemical is parsed into Class I of oral toxicological concern, Class II of intermediate toxicity and Class III where a presumption of safety cannot be assumed. The Cramer decision tree was incorporated into the Threshold for Toxicological Concern (TTC) approach for the risk assessment of chemical substances, in circumstances of relatively low exposure, for which toxicological data is not available. The TTC approach is used by both the European Safety Authority (EFSAS) and the World Health Organization (WHO) Joint Expert Committee on Food Additives (JECFA) in their evaluation of flavoring ingredients for use in food. In a 2016 workshop report, EFSAS and WHO noted that minor changes to the Cramer decision tree could reduce ambiguity and make it more adaptable to use within silico tools. With this in mind, the goal of this study was to develop an update to the original Cramer decision tree that reflects current metabolic and toxicologic knowledge, that expands the chemical space covered, but that also has a simplified structure relative to the original Cramer decision tree. The revised approach relies more heavily upon chemical structure-based questions to move compounds into classes. This approach enhances the ability of in silico tools to correctly apply the decision tree when assigning substances to various classes of toxicological potential. Toxicological poten-

Primary human hepatocytes (PHH) are the gold-standard for preparing in vitro 3D liver models but are limited by their scarcity and their vulnerability to freeze-thaw cycles. In recent years, the more readily available HepaRG cells (hepatoma progenitor cell line able to differentiate into hepatocytes) have shown to be more similar to PHH, showing comparable stable metabolic competence and inducibility, with the added advantage of data consistency over multiple thawing. HepaRGs are a novel liver 3D model consisting in encapsulated differentiated HepaRGS, able to make spheresoid within 5 days post-encapsulation. Viable over 5 weeks, they respond to various Cytochrome P450 (CYP) inducers (CYP1A2, 2B6 and 3A4), while maintaining ≥2-fold induction along their lifespan. We demonstrated by LC-MS/ MS the functionality of phase I enzymes (CYP1A2, 2D6, 2B6 and 3A4) by studying the hydroxylation of Phenacetin, Dextrometorphan, Bupropion and Midazolam. Furthermore, HepaRGs display polarity features as demonstrated by the efflux of fluorescent probe (CDFDA) in intercellular biliary pockets and by measuring hepato-specific functions, such as albumin and urea synthesis over 5 weeks. Using the radio-HPLC method, we next investigated the metabolism of different radiolabelled xenobiotics - testosterone (TE), 7-hydroxycon
marin (7-HC) and 7-ethoxycoumarin (7-EC) at increasing concentrations - by HepaRGs after 48h incubation. The detection of different TE metabolites proves the in vitro metabolic phase I functional key enzymes (CYP2C19, 2C9 and 3A4). Interestingly, HepaRGs were able to metabolize TE in 68-hydroxytestosterone without any saturation of the CVP involved in this process by contrast to 2D monolayer where a plateau was reached. Moreover, the metabolism of 7-EC and 7-HC demonstrated phase I and phase II (glucoroni
dation and sulfation) enzyme activity, respectively. In addition, we assessed the hepatotoxicity on HepaRGs with 6 drugs with known hepatotoxic potentials for acute (24h, 48h) or chronic (14 days) exposure and demonstrated their efficient prediction ability for toxic or non-toxic compounds. HepaRGs represent a stable and reproducible in vitro liver-mimicking tool for the study of compounds metabolism, drug-drug interactions and hepatotoxicity.

T. Clipson, J. Rutkiewicz, and M. Whittaker. ToxServices LLC, Washington, DC.

The European Commission’s Cosmetic Regulation No. 1223/2009 (EU 2009) requires cosmetics marketed in the European Union (EU) to be safe for their intended use. EU regulations require each cosmetic formulation have a Product Information File (PIF), which includes a Cosmetic Product Safety Report (CPSR). A CPSR assesses toxicological endpoints for a cosmetic, including an evaluation of potential health risks of each cosmetic raw material, including impurities. A CPSR assessment evaluates each ingredient and impurity against a minimum of ten different toxicity endpoints, including acute toxicity, skin and eye irritation, skin sensitization, phototoxicity, genotoxicity, repeated dose toxicity, reproductive toxicity, and carcinogenicity, and assigns a point of departure (POD) for the overall risk evaluation of each chemical undergoing assessment. Ideally, the POD is the no-observed-adverse-effect level (NOAEL) from a repeated dose animal study that is 90 days or greater in length. Most ingredients and impurities in cosmetics have limited in vivo data for one or more of the toxicological endpoints, and the availability of toxicity data is further limited by the Cosmetic Regulation’s ban on animal testing. Therefore, application of data gap filling approaches is required to meet regulatory requirements. For example, despite a very limited dataset for the essential oil Litsea cubeba fruit oil, ToxServices was able to prepare a CPSR ingredient assessment by reviewing the literature and identifying citral, the primary constituent of the oil, as a surrogate to fill data gaps for the eye irritation, skin sensitization, phototoxicity, repeated dose toxicity, and reproductive toxicity endpoints. Ferulic acid (an antioxidant in skin care formulations) also has a limited dataset, and has no suitable surrogate with data to assess skin irritation, eye irritation, and skin sensitization endpoints. ToxServices employed a suite of modeling programs including Toxtree, VEGA, and OECD QSAR toolbox, to estimate toxicity and fill the data gaps for these endpoints. Examples and considerations for data gap filling approaches for the ten toxicity endpoints assessed in a cosmetic ingredient risk assessment will be illustrated and discussed, including use of read-across methods and goodness of fit indices to select chemical surrogates and assign a POD, suffi
ciency of in silico modeling to predict endpoints such as genotoxicity, and the importance of correct selection of methods validated by the European Centre for the Validation of Alternative Methods (ECVAM).

D. Butler, E. Weaver, and S. Hsieh. Trinity Washington University, Washington, DC.

To determine what chemicals can be inhaled during an everyday use of hair care products for African American women, 9 brands of products (4 hair relaxers, 6 shampoos, 6 conditioners, 2 conditioning treatments, 1 leave in condi
tioner, 1 hair masque, 6 hair lotions, and 1 hair serum) were analyzed for vol
tile organic compounds (VOCs). Each product was purchased at local beauty supply store and some came packaged as a kit. Only one of each type of prod
cut was tested; replicates were not purchased. Samples were analyzed by GCMS (gas chromatography mass spectrometry) with headspace sampling. To approximate what VOCs could be emitted upon use, samples were incubated at 37°C, and the vapor injected into the GCMS. Compounds were iden
tified by matching mass spectra to those in a chemical library (NIST). Since the purpose of this work was a screening to find VOC identities, concentrations of the VOCs were not determined. Over 100 compounds were detected and identified. They included terpenes / terpenoids (15), alcohols (12), hydrocarbons (57), chlorinated (3), hydrocarbons (57), ethers, diethers (6), esters (23) and aldehydes (5). Some compounds would not have been expected given the listed ingredients, and they include substances that are suspected carcinogens, for example 1,4-benzen, styrene, and benzene. Because mixtures of chemicals have more adverse health effects than individual components, preliminary experiments were conducted to test emissions from a subset of products for their toxicity. Four products were used: one hair relaxer, one shampoo, one conditioner, and one hair lotion. Each product was applied to a filter paper on the lid of the petri dish, and Escherichia Coli and Bacillus Subtilis were exposed to product vapors for 24-hours. These preliminary re
sults show no inhibition of bacterial growth.

Exposure data is a major challenge in the field of safety assessment process of cosmetic products. For many years, the European Scientific Committee on Consumer Safety (SCCS) has provided, through its Notes of guidance and opinions, a number of quantitative data about use frequ
cency, amounts of products applied, areas of application and expo
sure to some categories of cosmetics. However, all the data reported are related to the “Adult” exposure and no information about “realis
tic” exposure assessment to cosmetics in children from birth is available. In this context, the SCCS has stated to adjust the default assessment factor of 100 for children (from birth to 10 years old) by multiplying this factor by the difference in Skin Surface Area (SSA) over Body Weight (BW) ratio (SSA/BW) between adults and children. Thus, the difference between the SSA/BW ratio has been set at 2.3 for children from birth. Based on these elements, it seems interesting to check if this additional safety factor is sufficiently reliable to cover the exposure to cosmetics and their ingredients in children from birth. Through an exhaustive review of the exposure data available in literature for children from birth, a comparison has been performed between the P90 val
cues for children from birth versus adults for the same product categories. The exposure data have been chosen on the basis of relevant criteria such as: date of the study, type of sampling and analytic method, method of collecting data etc. Following this analysis, it has been found that some ratios calculated are higher than 2.3. Such results imply that the safety factor of 2.3 may not be sufficient to cover the exposure in children from birth for a number of cosmetic products. This difference highlights the importance of taking into account the most “realistic” exposure for some cosmetics instead of applying additional factor which may lead to an underestimation of the risk expected. The final goal of this work is always to ensure the safety of cosmetic products under normal or reasonably foreseeable conditions of use for all the populations.
Safety Assessment of Cosmetic Ingredients and Chemicals for Skin Sensitization Using QSAR In Silico Tool

S. Martin1, D. Thomas1, F. Bree1, A. Sharma1, and D. Steen2, 1 Eurosafe, Saint Grégoire, France; and 2 Biopredic International, Saint Grégoire, France.

Skin sensitization methods are developed to protect workers and consumers from chemical exposures. These methods are well adopted in OECD 6 Test Guideline (TG) addressing 5 Key Events (KE) of the skin sensitization Adverse Outcome Pathway (AOP) such as 442C (Direct Peptide Reactivity Assay, DPRA); OECD TG 442D (Keratinosens™) and, 7 OECD TG 442E (human Cell Line Activation Test, h-CLAT). The two biomarkers based test SENS-15 and the Genomic Allergic Detection Test 10 (GARDs) are under consideration by the OECD for the development of the respective TGs. Here, our study aimed to test the practicability of in silico predictions using (QSAR) tools i.e. Toxtree and VEGA HUB to evaluate their use as a time- and cost-effective alternative to relate measured and calculated physical-chemical properties of chemical compounds to their sensitization potential. The 25 compounds have been selected from literature under non-sensitizer, weak, moderate, strong and extreme category with LLNA and Sens-15 prediction. These predictions are taken as benchmark for our QSAR analysis. VEGA predicted the skin sensitization potential of these compounds with 96% accuracy. However, Toxtree predicted the skin sensitization potential of 76% accuracy. The details, as well as forward and backward searches. Studies were selected for inclusion using PECO (Population, Exposure, Comparator, Outcome) criteria and evaluated for reporting quality, risk of bias, and sensitivity using a domain-based approach. Then each study was rated as high, medium, or low confidence. Evidence was synthesized and strength of evidence was summarized into categories of robust, moderate, slight, indeterminate, or compelling evidence of no effect, using a structured framework. Findings in the liver included changes in liver weight, changes in clinical chemistry, and histopathological findings suggestive of liver damage. The evidence for liver effects was considered moderate, based on consistent changes in liver weight in medium and high dose studies. The strongest evidence of an effect on liver enzymes and histopathological changes was observed in exposures to low doses of DEP over long durations; however, these studies were generally considered to be low confidence due to risk of bias concerns. Conversely, no histopathological effects were observed at higher doses in medium or high confidence studies. Differences in animal models, route, and study design between the lower and higher dose studies may contribute to the inconsistent pattern of findings. These conflicting findings suggest that additional research needs to be conducted on DEP following low dose exposures, which are more likely to be relevant to humans. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA.

Use of Cross-Route Extrapolation to Develop an Oral Cancer Slope Factor for Isoprene and Its Application in a Drinking Water Risk Assessment

J. Fleischer, and M. H. Whittaker, ToxServices LLC, Washington, DC.

According to the National Toxicology Program’s 14th Report on Carcinogens, isoprene is reasonably anticipated to be a human carcinogen. Although no reliable human epidemiology data are available, prolonged inhalation of isoprene causes tumors at multiple sites, including the liver, lung, pituitary gland, kidney, mammary gland, and Harderian gland in rats and/or mice. Isoprene can be found in drinking water as a result of leaching from rubber materials. Due to its volatility, few oral-route toxicity studies have been conducted. We performed cross-route extrapolation on benchmark dose modeling data that had served as the basis for a previously-published inhalation unit risk value to obtain an oral cancer slope factor (CSF) for isoprene. Cross-route extrapolation is justified because isoprene causes neoplastic and non-neoplastic effects at multiple distal sites; the most sensitive neoplastic effect is at a distal site (the liver); and measured and modeled toxicokinetic data are available to assess differences in route of exposure. Moreover, it is plausible that oral exposure to isoprene could result in a spectrum of neoplastic and non-neoplastic effects that is similar to what has been observed following inhalation exposure. We developed an oral CSF for isoprene using the lower bound EC10 (i.e., the LECO10 of 78.5 ppm (equivalent to 238.7 mg/m³) for liver tumor development in male mice as the point of departure. Using reference inhalation rate and body weight values for male B6C3F1 mice and a body weight ratio-based dosimetric adjustment factor, we converted the 238.7 mg/m³ LEC10 to a human equivalent dose of 1.42 mg/kg-day and then to an oral CSF of 0.0704 (mg/kg-day)⁻¹. We then used this oral CSF to identify an acceptable level (10⁻⁶ risk) of isoprene in drinking water. Because isoprene may act through a mutagenic mode of action, we applied age-specific drinking water ingestion rates to the oral CSF to obtain life-stage specific drinking water unit risk values, which were then summed across age groups to derive the total lifetime drinking water unit risk of 5.31 x 10⁻⁵ (μg/L)⁻¹. Applying this unit risk value to an acceptable cancer risk level of 10⁻⁶ yields an allowable concentration of 1.9 μg/L isoprene in drinking water.
Application of Toxicogenomics for the Risk Assessment of the Food Contaminant Acetamide

Michigan State University, East Lansing, MI; 1-Michigan Biotechnology Institute, Lansing, MI; 2-Scitovation, Research Triangle Park, NC; 3-Syngene International, Bengaluru, India; 4-Eurofins Advins, Bengaluru, India; 5-Exponent, Menlo Park, CA; and 6-Indiana University Bloomington, Bloomington, IN.

Acetamide (CAS 60-35-5) is detected in common foods including milk, eggs, beef, and roasted coffee beans. Chronic rodent bioassays using high doses (≥1000 mg/kg/day) suggest acetamide is a group 2B possible human carcinogen due to the induction of liver tumors. Weight-of-evidence indicates acetamide is not genotoxic, and therefore a threshold response is expected. We used a toxicogenomics approach in male Wistar rats gavaged daily for 7 days at doses of 30, 100, 300, and 1000 mg/kg/day (mkd) to determine the benchmark dose (BMD), and investigate its mode of action. No treatment related changes in terminal body weight, clinical chemistry, or histopathology were observed at doses of 30, 100, or 300 mkd. At 1000 mkd, the dose reported to elicit carcinogenesis, liver weights decreased 1.3-fold with the presence of single cell necrosis, hepatocyte vacuolization, and increased mitotic activity consistent with a 4.2 fold increase in the cell proliferation index. Accordingly, plasma ALT and AST were increased 2.0- and 2.2-fold, respectively. RNA-seq analysis identified 1 differentially expressed gene at 300 mkd, and 2,685 at 1000 mkd (fold-change ≥1.5 and FDR ≤ 0.05). Down-regulated genes were associated with lipid metabolism while up-regulated genes included cell signaling, immune response, and cell cycle functions. Collectively, these results revealed a no-observable adverse effect level (NOAEL) and no-observed-transcriptional effect level (NOTEL) at 300 mkd, warranting further investigation at doses between 300 and 1000 mkd to identify the benchmark dose (BMD). Function enrichment studies indicate that perturbations of cell cycle and lipid metabolism, though a more refined dose-response evaluation will be needed to demonstrate dose-dependent effects related to the MOA of acetamide. Funding by the Bill and Melinda Gates Foundation (OPP142801).

Sulfuryl Fluoride-Induced Neurotoxicity: Potential Direct Brain Access via the Intranasal Route

Sulfuryl fluoride is a fumigant registered to control structural and commodity pests such as termites, bedbugs, and the saw-toothed grain beetle. It kills insects by anoxia and interfering protein synthesis. As a consequence of ongoing evaluation of human health risks of fumigants, the California Department of Pesticide Regulation completed a risk assessment of sulfuryl fluoride in 2006 and an update to that risk assessment in 2018. The most current database includes registrant-submitted studies, open literature studies, and a physiologically based pharmacokinetic model in humans, acute inhalation exposure to high levels of sulfuryl fluoride causes respiratory irritation, pulmonary edema, renal injury, central nervous system depression, brain necrosis, and even death. Short-term or chronic inhalation exposures result in brain, respiratory system, dental, and kidney effects in both humans and laboratory animals. Fluoride is considered the active principal in sulfuryl fluoride-induced toxicity and it is commonly thought to work through either a systemic or portal of entry mode of action (MoA). Common neurotoxic effects in mice, rats, rabbits, and dogs were malacia (necrosis) and vacuole formation in the basal ganglia, also generally considered to have a systemic MoA. However, from our analysis of the updated toxicity database, we suggest that neurotoxicity may instead be mediated via direct entry through the nasal cavity, bypassing the blood-brain barrier. This novel MoA for sulfuryl fluoride neurotoxicity is supported by the following: 1) a fluoride brain-to-plasma (T/P) ratio for acute inhalation studies that is approximately 20-fold higher than T/P ratios from oral, intra-venous, or intraperitoneal studies with sodium fluoride (NaF); 2) sulfuryl fluo- ride-induced brain lesions are confined to the basal ganglia after inhalation exposure, but not after oral NaF exposure; and, 3) evidence of direct intranasal absorption for other chemicals. In conclusion, future studies should explore the possibility of a direct access to brain via the nasal epithelium, which would influence the calculation of reference concentrations.

Health Risks of Chemicals in Consumer Products: A Review

D. Li1, and S. Suh2. 1-University of Nevada Reno, Reno, NV; and 2-University of California Santa Barbara, Santa Barbara, CA.

Increasingly diverse chemicals are used in consumer products, while our understanding of their exposure pathways and associated human health risks still lags behind. This study aims to identify the dominant patterns of exposure pathways and associated health risks of chemicals used in consumer products reported in the peer-reviewed literature. We analyzed 342 articles covering 202 unique chemicals, and distilled the information on the functional use/product application combinations, including plasticizers, polymers/monomers, and flame retardants used in food contact products, personal care products, cosmetics, furniture, flooring, and electronics. We also published over the past decade, facilitating an updated MoA analysis for nasal tumors. These new data include analytical results discerning endogenous and exogenous biomarkers of exposure to formaldehyde and negative results from in vivo genotoxicity assays in target tissues of rats, as well as in genetically susceptible mice (including a recent NIEHS study conducted in p53-/- mice). Herein, we conduct a MoA analysis with special emphasis on studies published over the past decade. These data support a MoA involving exceed-
Antibiotic resistance (ABR) has become a global public health threat, as antibiotics used to treat diseases, including common infections, are increasingly becoming ineffective. Spread over 380 square kilometres in Himachal Pradesh’s Solan district, the Baddi-Barotwala-Nagarbar (BBN) industrial area is one of India’s largest pharmaceutical manufacturing hubs. The region hosts around 500 small, medium and large pharma units and accounts for 35 per cent of Asia’s total medicine production. But rapid industrialisation and a lax attitude towards safe disposal and management of pharma waste have raised concerns about the effects of pollution on the environment and health. Due to such practices, the BBN region remains prone to antibiotic pollution. They are among environmental persistent pharmaceutical pollutants which have not degraded completely during treatment. They may influence the genetic makeup of bacteria, leading to the survival of resistant bacteria and spread of antimicrobial resistance (AMR), a public health threat. Samples were collected from different area of BBN and they were identified for antibiotics resistant of bacteria in environment in laboratory. Antibiotics and resistant bacteria are present in the environment. Antibiotics could favour resistant bacteria. As in other environments, the significance of this process depends on the antibiotic concentration, its bioavailability and other constraints. This varies in water, sewage sludge, soils, and sediments, because the concentration of antibiotics, the physicochemical constraints and the mobility of bacteria as well as their resistance genes vary. The ability to take up DNA from the environment is widespread among natural isolates. To understand the interaction of antimicrobial compounds and bacteria in the environment and for a sound risk assessment, the use of test systems and field studies is crucial. For developing countries such as India, inadequate policy framework, limited stakeholder awareness, ineffective monitoring, limited focus on infection prevention and control, inadequate sanitation and hygiene, limited data on AMR surveillance and dearth of technology and resources have been the major challenges. Our study shows how improper disposal of pharmaceutical industry waste from Baddi, Himachal Pradesh, one of the largest pharmaceutical manufacturing hubs in India, could become a potential reason for emergence and spread of ABR.

Environmental stressors and contaminants can lead to Adverse Outcomes (AOs) in both human health and ecological receptors. Evaluating risks of AOs across multiple organisms in a community is crucial to characterize the cumulative impacts of stressors and contaminants; but is challenging due to species-specific differences in exposure pathways, behavior, physiology, and toxicity mechanisms. This work addresses some of these challenges by developing a quantitative source-to-outcome approach using the Aggregate Exposure Pathway (AEP) and Adverse Outcome Pathway (AOP) frameworks. We demonstrate this approach using a case study of a hypothetical site contaminated by a molecule that competitively inhibits iodide uptake into the thyroid at the sodium-iodide symporter (NIS), and TOP effects established AOPs. External exposure pathways were quantified in an AEP network describing chemical movement through the site. This network was used to predict NIS-inhibitor exposure for humans, fishes, and small herbivorous mammals under mild, moderate, and high contamination scenarios. Network analyses were applied to describe source apportionment for each species. Exposures were linked to an AOP network for NIS inhibition using physiologically based pharmacokinetic models, then combined with mechanistic dose-response data to calculate a hazard index (HI) for each potential AO in each species. The analysis predicted that surface water contamination was the largest contributor to source apportionment of exposure in fishes, while groundwater contamination was the largest contributor in humans and small herbivorous mammals. HI results predicted small herbivorous mammals to have the highest risk of AOs in all scenarios, while the relative risk of AOs in scenarios between humans and fishes differed by exposure pathway. This work demonstrates how the AEP-AOP construct can link environmental transport and transformation, exposure, toxicokinetics, and toxicodynamics; as well as inform cumulative risk assessment, by 1) organizing mechanistic data, 2) identifying data gaps, 3) quantifying uncertainties, and 4) facilitating simultaneous evaluation of risk in human health and ecological endpoints. The views expressed in this poster are those of the authors and do not necessarily reflect the views or policies of the US Environmental Protection Agency.
Using Evidence Mapping to Focus and Refine the Evaluation of Reproductive Endpoints in a Systematic Review of PCBs

Systematic review will often reveal a wide range of health outcomes associated with exposure to a chemical of interest. This is particularly true for chemicals that have thousands of studies available, such as polychlorinated biphenyls (PCBs). From a pragmatic perspective, a systematic review of all of these studies is not feasible. In such cases, it may be helpful to focus the systematic review on the outcomes identified as most impactful for protecting public health. Here, we describe the application of evidence mapping as an organizational principle for refining a large and complex database, using animal toxicology studies on the reproductive effects of PCBs as an example. A systematic review of PCB-related health effects identified >400 animal toxicology studies that evaluated reproductive toxicity. These studies were extracted into a literature inventory designed to capture relevant experimental design and health outcome details. The endpoints evaluated in each study were categorized according to type of outcome (e.g., fertility/fecundity, hormone levels, organ weights). To identify the most relevant adverse health outcomes to move forward for further evaluation, major considerations will include the number and types of studies evaluating each outcome, the severity or biological significance of each outcome, and the relative sensitivity of each outcome to PCB exposure. Once the most relevant adverse health outcomes are identified, studies reporting these outcomes can proceed through the systematic review process, where they will undergo study evaluation and further analysis. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US Environmental Protection Agency.

Identification of Points of Departure for Trimethylamine Exposure Guidance Levels

D. Petersen, P. McGinnis, and S. Milanez. US EPA, Cincinnati, OH; TERA, Cincinnati, OH; and ORNL, Oak Ridge, TN.

Trimethylamine (TMA) is produced on a large-scale in the manufacturing of numerous products including dyes and herbicides and has been involved in several unanticipated releases. Toxicity information was used in the weight of evidence for identifying critical effects and points of departure (PODs) that could be used to derive exposure guidance values for TMA for 24-hour, 30-day, and 90-day durations of exposure. The highly alkaline corrosive nature of TMA is manifested by immediate portal of entry effects after oral or inhalation exposures. Longer-term systemic effects, produced by either oral or inhalation routes of exposure involve neurotoxicity and pathological changes in the liver and kidney. The respiratory tract is the primary target for inhaled TMA toxicity with endpoints ranging from sensory and pulmonary irritation, epithelial tissue damage, increased airway resistance, to lethality via pulmonary edema. Effect levels corresponding to the Acute Exposure Guideline Level (AEGL) 1, 2, and 3 Tiers respectfully, representing thresholds for mild/ reversible effects; serious/irreversible effects; and lethality, were identified. Inhalation POD values for the 24-h duration Tier 1 was 8 ppm from a human occupational study. Tier 2 was 918 ppm, used with an adjustment for severity, and Tier 3 was 918 ppm, the latter two levels derived from a 14-d rat study. All PODs were time-adjusted to 24-h following a C∞/t relationship. The POD for 30-d Tier 1 effects was 8 ppm, again from the human occupational study and the Tier 2 POD was 190 ppm from the 14-d rat study. A Tier 3 POD was not determined because of a lack of data. A 90-d Tier 1 POD used the previous human study while the 90-d Tier 2 and Tier 3 PODs could not be established due to a lack of relevant data. For oral exposures, in humans initial nausea and vomiting are followed by an initial inflammatory phase, with prolonged exposures resulting in necrosis with gastrointestinal and respiratory stenosis and stricture formation. The 24-h Tier 1 POD was 4.0 mg/kg-d, based on a human study, while the Tier 2 POD was 200 mg/kg-d, and the Tier 3 POD was 464 mg/kg-d based on rat studies. The 30-d POD values for Tiers 1, 2, and 3 were based on a rat developmental study, with values of 40, 200 and 200 mg/kg-d respectively. The 90-d Tiers 1, 2 and 3 PODs used 30-d data, subjected to a duration adjustment. These PODs can be used to develop exposure guidelines useful to the emergency response community and State and local public health departments in the case of unanticipated releases. This abstract may not represent the views and policies of the US Environmental Protection Agency.

Semi-automated Data Extraction Workbench for Environmental Health

B. Howard, A. Maharana, A. Tandon, and R. Shah. Sciome LLC, Research Triangle Park, NC.

Systematic review, already a cornerstone of evidence-based medicine, has recently gained significant popularity in several other disciplines including environmental health and evidence-based toxicology. One critical and time-consuming process that must occur during systematic review is the extraction of relevant qualitative and quantitative raw data from the free text of scientific documents. The specific data types extracted differ among disciplines, but within a given scientific domain, certain data points are extracted repeatedly for each review that is conducted. To that end, Sciome has begun research and development of a semi-automated data extraction workbench for use in this context. We are focusing our research on three specific goals. First, we are using deep learning to build novel data extraction models to extract data elements of interest to those conducting systematic reviews in the domain of environmental health. Second, we are building a web-based data extraction software platform specifically designed for usage in the domain of systematic review. And finally, we plan to introduce new protocols to standardize the extraction process further for both humans and models, to help ensure that we report our results so far, including the performance of more than 20 novel data extraction components of relevance to environmental toxicology, created and tested on an annotated dataset from NTP. Performance varied widely among data types with some tasks inherently more difficult than others. For certain simple data types, like sex of the experimental animal, we achieved F-scores in excess of 95%; for more difficult entities, we were still often able to achieve an F-score of 65% or more, given sufficient training data. Because accurate data extraction can be a challenging problem, and given that current methods rarely achieve 100% accuracy, we are integrating our methods into a spell-checking system that combines machine and human intelligence in a manner that is superior to either in isolation. The system will: highlight extracted terms in a pdf; automatically populate extraction forms with extracted data; allow humans to intervene and correct the results; and learn from the corrections to continually update the model. The resulting system will meet both systematic reviewers and modelers’ needs more efficiently and less expensively to maintain, greatly accelerating the process by which scientific consensus is obtained in a variety of health related disciplines having great public significance.

The Escalating Severity of Boron Trifluoride Inhalation Effects Necessitates Prompt Emergency Response Actions

J. C. Lipscomb, C. Troxel, G. Henningsen, and M. McClanahan. US EPA/ORD/NHSRC, Cincinnati, OH; CM Tox, Lander, WY; Front Range Environmental Toxicology, Monument, CO; and CDC (Retired), Chambles, GA.

Boron trifluoride (BF3; CASRN 7637-07-2) is an industrial catalyst existing as a colorless gas with a readily detected odor. It is also used as a fire retardant and in various nuclear science applications. NASA estimated that 50,000 workers are potentially exposed annually; industrial and transportation accidents can result in additional unanticipated and uncontrolled exposures. Toxicity at both the portal of entry and systemic tissues occurs following inhalation exposures. High concentrations cause acute lethality from direct pulmonary effects, while prolonged exposure to lower concentrations can cause lethality from renal effects. Inhalation studies covering durations to 13 weeks demonstrate concentration responses for pulmonary and renal effects, and lethality. Acute Exposure Guideline Level (AEGL) values are available for up to 8 hours, but no values exist for longer durations. BMD 50 and BMD 05 values for 4-h lethality differed by only 1.5-fold. Because inhalation exposures may persist beyond 8 hours and the concentration-response for lethality is steep, data for multiple effects for durations beyond 8 hours were examined in the context of AEGL tiers 1, 2 and 3, representing thresholds for mild and reversible effects; more serious irreversible or escape-impairing effects; and lethality, respectively. Tiered points of departure were discriminated for acute exposures (ranging 4-fold) by no effect levels, respiratory irritation and death; for short-term exposures (ranging 8-fold) by urinary biomarkers, organ weight changes and death; and for subchronic exposures (ranging 8-fold) by urinary biomarkers, renal histologic changes and death. The narrow range of POD values for these effects further underscores the need for prompt characterization and control of exposures from unanticipated BF3 releases. This abstract may not represent the views and policies of the US Environmental Protection Agency.

An Integrated Approach to Evaluate Common Mechanisms of Toxicity in Pesticides to Support Cumulative Risk Assessment

In 2016, the United States Environmental Protection Agency’s (US EPA) Office of Pesticide Programs published a guidance framework for establishing candidate common mechanism groups (CMGs) and conducting cumulative risk assessment (CRA) weight-of-evidence-based screenings. A candidate CMG is a group of chemicals that share characteristics such as structure, apical endpoints, and mechanistic data that indicate a common mechanism of toxicity may exist. Although a candidate CMG lacks sufficient data for establishing all key events in an adverse outcome pathway, it requires less data to be established than a full CMG and, as such, it allows the US EPA to more efficiently screen pesticides for CRA purposes. In the current study, a multi-tiered approach was used to investigate mode of action through literature review, and to analyze in vivo toxicity data, in vitro Toxicity Forecaster (ToxCast) data, chemical structural features, and physicochemical properties of dinotroaniline pesticides currently registered in the United States. This analytical approach was used to determine whether nine dinotroaniline compounds or a subset of those listed compounds may form a candidate CMG. The pesticidal mode of action for dinotroanilines involves disruption of root and bud microtubules of plants. Despite a high degree of structural similarity among at least three dinotroanilines and shared target organs that were identified for some of the chemicals based on effects observed in in vivo studies, there were no consistencies among the groups, suggesting lack of a common mechanism when all available data were considered together. For example, two compounds with a high degree of structural similarity and thyroid/liver in vivo effects were not found active in any ToxCast assays. Everything considered, the weight-of-evidence is insufficient to support the testable hypothesis that dinotroanilines could form a candidate CMG, and highlights the importance of establishing a consensus among multiple analyses prior to CRA. Disclaimer: The views expressed in this presentation are those of the authors and do not necessarily reflect the views or policies of the US EPA.

Application of a “One-to-Many” Analog Approach with Consideration of Toxicokinetics in Consumer Product Safety Assessments

B. Lampe. NSF International, Ann Arbor, MI.

A “one-to-many” read-across approach, in which data from a tested compound is read across to multiple structurally-related untested, target compounds, can be used when for risk assessment of structurally and functionally related chemicals. Using a case-study of octylphenyl glycol ether (OGE) surfactant ingredients in several consumer products, including cosmetics and detergents, data relevant to 4-tert-octylphenol (4-OP) was read-across to two other OGEs, which are structurally identical to 4-OP except with three to six ethoxy units in place of the hydroxyl group. 4-OP is weakly estrogenic, binds to the estrogen receptor, and has been shown to result in various reproductive effects at doses exceeding the metabolic saturation threshold at doses between 50 and 200 mg/kg/day. Crucially, the presence of the ethoxy chain in the target compounds is anticipated to reduce the toxic potency of the OGEs compared to the source compound, 4-OP. Twenty-four repeated dose and reproductive toxicity studies on 4-OP were evaluated, and seven were deemed reliable for assessment. The key study selected for the point-of-departure (P0D) was a two-generation reproductive feeding study in rats, in which exposure to 240 mg/kg/day of 4-OP resulted in an 18% reduction in relative uterine weight and 16% decrease in the mean body weight of the F1 pups. The corresponding human-equivalent non-human equivalent effect level (NOAEL_{h}) of 5.1 mg/kg/day was the lowest P0D among the seven studies considered, with the exception of a four-week repeated dose study that was potentially confounded by gavage-specific irritative effects. Few published risk assessments in the literature utilize a one-to-many read-across approach and relatively little guidance is available for doing so. Here, we have shown one way in which the one-to-many approach could proceed, in which it can be clearly shown that the source compound is likely to be more toxicologically potent than all the source compounds. Such an approach is likely to be health-protective, but overly-conservative.

Derivation of a Total Allowable Concentration for Methyl Acetate

S. M. Cotti, K. Licko, and M. H. Whittaker. ToxServices LLC, Washington, DC; and Water Quality Association, Lisle, IL.

Methyl acetate (MeOAc) is a volatile solvent that has been detected as a leachate from drinking water systems. This poses the potential for a total allowable concentration (TAC) for MeOAc in drinking water following NSF/ANSI Standard 61 (Drinking Water Components: Health Effects) risk assessment guidelines. NSF/ANSI Standard 61 Standard 61 defines a TAC as the maximum concentration of a nonregulated contaminant allowed in a public drinking water supply. MeOAc has low acute oral toxicity. Acute inhalation exposure in humans may cause transient narcotic effects, blindness, and optic nerve damage. No animal repeated-dose oral toxicity studies were identified. A 28-day inhalation study in rats identified a NOAEC at 1,057 mg/m³ and a LOAEC at 6,040 mg/m³ based on impaired body weight (BW) gain, decreased food consumption, and pathological changes in the olfactory epithelium. MeOAc is not mutagenic or clastogenic based on negative results in two bacterial reverse mutation assays, and a micronucleus assay in rats. The US EPA evaluated the toxicity of MeOAc in a health and environmental effects profile published in 1986 and a provisional peer-reviewed toxicity value document published in 2010. Due to the lack of oral repeated dose toxicity data for MeOAc, US EPA relied on data for methanol (MeOH), the immediate in vivo hydrolysate product of MeOAc, to evaluate MeOAc’s toxicity in both documents. In 2010, US EPA established a screening peer-reviewed r-PID of 1 mg/kg/day for MeOAc by adjusting the MeOH r-PID of 0.5 mg/kg/day by the molecular weight (MW) ratio of MeOAc and MeOH. The MeOH r-PID of 0.5 mg/kg/day was derived using an oral NOEL of 500 mg/kg/day based on changes in serum chemistry and decreased brain weights in 90-day oral rat studies, and adjusted by a composite uncertainty factor of 1,000 (10 for interspecies extrapolation, 10 for intraspecies extrapolation, and 10 for subchronic to chronic extrapolation). However, in 2013, the MeOH r-PID was updated from 0.5 mg/kg/day to 2 mg/kg/day, based on an oral NOEL of 500 mg/kg/day after changes in serum chemistry and decreased brain weights in 90-day oral rat studies, and adjusted by a composite uncertainty factor of 1,000 (10 for interspecies extrapolation, 10 for intraspecies extrapolation, and 10 for subchronic to chronic extrapolation). In 2015, the MeOAc screening r-PID of 1 mg/kg/day is outdated. New toxicity data that would impact the US EPA’s assessments of MeOAc or MeOH was identified. Therefore, using US EPA’s r-PID for MeOH to calculate an r-PID for MeOAc is still appropriate. ToxServices derived an oral r-PID of 4 mg/kg/day for MeOAc by adjusting the data to support the use of a 20% relative source contribution factor, a BW of 70 kg, and 2 L/day drinking water intake, results in a TAC of 30 mg/L for MeOAc.

Comparison of Dam Toxicogenomic and Dam/Embryo-Fetal Apical Points of Departure in a Rat Ketoconazole Developmental Toxicity Study

K. Johnson, E. Costa, A. Venkatraman, S. Sriram, V. Marshall, and J. LaRocca. Corteva Agriscience, Agriculture Division of DowDuPont, Indianapolis, IN; Corteva Agriscience, Agriculture Division of DowDuPont, Mogi Mirim, Brazil; Corteva Agriscience, Agriculture Division of DowDuPont, Johnston, IA; and Dow Chemical Company, Midland, MI.

Toxicity testing paradigms for novel molecules take several years of investment and require extensive animal usage. There is promise that leveraging alternative techniques, such as toxicogenomics, may be able to replace traditional testing strategies for risk characterization while reducing animal use and maintaining protection for human health. The objective of this study was to generate in vitro data to support the use of a transcriptome benchmark dose (BMD)-based point of departure for developmental and reproductive toxicity (DART) by comparing transcriptome to traditional apical points of departure. Ketoconazole, a fungicide with established embryotoxic and fetotoxic properties, was used for proof-of-concept in a rat developmental toxicity study. Ten rats/dose group were exposed daily to vehicle control or ketoconazole with seven dose levels ranging from 0.63 to 40 mg/kg/day from gestation day (GD) 6-21. On GD 21, embryotoxicity and fetotoxicity was evaluated with standard endpoints from the OECD 414 guideline, and whole-genome long RNA (mRNA) sequencing was performed on dam liver and placenta samples. Lower confidence limits of BMDLs (BMDLs) were generated on apical endpoints using BMDS software and normalized gene expression data using BMDEXpress2.2 software. Dam apical BMDLs ranged from 0.42 to 13.88 mg/kg/day, with placenta histopathology as the most sensitive endpoint. Fetal apical BMDLs ranged from 13.97 to 20.35 mg/kg/day, with postimplantation loss as the most sensitive and stenogene delayed ossification as the least sensitive endpoints. Dam liver and placenta pathway-level BMDLs were 1.0 and 1.8 mg/kg/day, respectively. These BMDL values were roughly ten times more sensitive than any embryo-fetal toxicity apical endpoint evaluated in the study but more closely approximated the most sensitive dam apical endpoint BMDL (placenta histopathology at 0.42 mg/kg/day). These
data support the concept that labor- and animal-intensive DART studies could potentially be replaced with streamlined studies that employ transcriptomic data to identify a point of departure (in theory utilizing the liver as a sentinel organ), which would not only be protective of human health but also reduce animal use.

**2766 The Utility of Informative Prior in Benchmark Dose Modeling for Animal Reduction**

K. Shao, W. A. Chiu, and A. Shapiro, Indiana University, Bloomington, IN; Texas A&M University, College Station, TX; and Independent Consultant, Durham, NC.

The benchmark dose (BMD) method has a number of important advantages over the traditional NOAEL/LD50 (no/lowest observed adverse effect level) approach, however, the substantial potentials of the method have been considerably limited by prevailing dose-response modeling strategies and practice. The recently developed Bayesian benchmark dose (BBMD) modeling framework not only provides a useful tool for probabilistic dose-response assessment, but also offers an opportunity to reduce animal use in experimental testing while maintaining the similar accuracy in BMD estimation. This study focuses on investigating how empirical informative prior (IP) derived from toxicological data in regulatory risk assessments may impact the accuracy of BMD estimated using various animal sample sizes. Commonly used dose-response models (e.g., Logistic, Multistage) were fit to simulated dose-response data generated with different sample size from a few assumed “true” dose-response curves with different shapes. Such simulation study design allows us to explore situations where the empirical IP may or may not be compatible to the true dose-response relationship. How likely the estimated confidence interval (CI) of BMD will cover the true BMD and the width of the CI were estimated from datasets with a typical toxicological study design (e.g., four doses with 50 animals in each level) using uninformative prior, and compared with the counterparts estimated using empirical IP with reduced sample size. Results show that more than 40% reduction in animal use can be achieved when the IP is compatible with (i.e., having similar DR shape as) the “true” curve. However, the accuracy of BMD estimates can be impaired due to the limited flexibility of model shape imposed by the IP when the compatibility is weak. The results highlight the importance to use toxicologically based informative prior in dose-response assessment.

**2767 Assessing Somatic and Psychosocial Health Risks of Water Body Contamination on Human Communities in the Niger-Delta, Nigeria**

B. C. Akpunne, Redeemer’s University, Osun State, Nigeria.

Researches exist on the environmental consequences of oil extraction. The somatic and psychosocial health risks of Water Body contamination on humans in the Niger Delta region of Nigeria have however not received adequate research attention. 226 participants, purposively drawn from five Niger Delta communities, responded Water Body Contamination Scale (WBCS), General Health Questionnaire (GHQ-12) and Mental Health Continuum-Short Form (MHC-SF). Perceived prevalence of the effects of the domains of Water Body Contamination (WBC) are Nature/Environment Risk (NER) 54.0%, Life Style Disruption (LSD) 50.9%, Physical Health Risk (PHR) 53.4%, Mental Health Risk (MHR) 52.6%, Perceived Ability to Control Effects (PACE) 37.2% and WBC 58.6%. Observed prevalence of severe psychological distress include inability to concentrate (17.3%), insomnia (13.6%), feeling not useful to society (5.5%), confusion/indecision (2.8%), being constantly under strain (7.3%), inability to overcome difficulties (18.3%), do not enjoy normal activities (5.5%), inabil-

**2768 Systematic Review and Literature Mapping of Naphthalene Adverse Health Outcomes**

Since the posting of the 1998 naphthalene assessment by the US EPA’s Integrated Risk Information System (IRIS), the human and animal study naphthalene literature base has been significantly updated. The goal of this project is to evaluate the new evidence to help guide the research assessment to focus on the appropriate health outcomes. It is important to evaluate the new evidence across evidence streams for evaluating biological plausibility and human relevance on naphthalene-induced toxicities. A systematic review and literature map was used to summarize the literature characteristics in broad categories of evidence streams and health outcomes. Firstly, a broad-based literature search was conducted utilizing four online databases (PubMed, Web of Science (WOS), Toxline and Toxic Substances Control Act Test Submissions (TSCATS)) and additional search strategies that identified 15,935 studies. An initial electronic screen followed by title/abstract and full text screening identified 129 relevant citations based on Populations, Exposures, Comparators, and Outcomes (PECO) criteria that were mapped to human health (n=31), animal toxicology (n=86), and physiologically-based pharmacokinetic models (n=10) studies. Health outcome mapping revealed that the top five human health outcome categories included reproductive (n=9), immunological (n=7), hematological (n=3), hepatic (n=3), and endocrine/exocrine (n=3) systems. Mapping of the animal toxicology literature identified hepatic (n=22), immunological (n=20), reproductive (n=13), renal (n=12), and immunological (n=12) systems as the top five health outcome categories. These evidence maps are critical for prioritizing study evaluation and data extraction efforts that shape the evidence synthesis and integration, and dose-response analysis needed for health assessment.

**2769 Development of Aggregate and Cumulative Risk Assessment System of Hazardous Substances in Agricultural Environment in South Korea**

1National Institute of Agricultural Sciences, Jeollabuk-do, Korea, Republic of; 2K&A Consulting, Co., Yongin, Korea, Republic of; and 3National Institute of Agricultural Sciences, Jellabuk-do, Korea, Republic of.

Establishment of an ongoing monitoring in agricultural environments and rapid risk assessment system of hazardous substances for human would make the risk management in agricultural environment more efficient. In South Korea, a systematic approach started with the need of rapid and accurate risk assessment, which might take advantages of using even national-wide big data on hazardous substances. Agricultural Products Risk Assessment System (APRAS) developed by National Institute of Agricultural Sciences (NIAS) has been set up to evaluate human exposure and risk based on the residual monmoranic and hazardous substances in the agricultural environment, such as pesticides, heavy metals, and environment persistent pollutants in the agricultural environment. APRAS deals with aggregate assessment that includes all assessable pathways to the substance-specific exposure, and cumulative assessment of the group of substances with the same toxicity mechanism. In addition, it covers probabilistic evaluation function to reflect the national characteristics of Korean population. As a result of evaluating the aggregate and cumulative risks for dioxins with the same toxic mechanism through APRAS, it was confirmed to be very safe not only for the whole Korean adults but also for infants. The results of this system has been mutually verified with the results from the commercial probabilistic evaluation model and other risk assessment models developed in the developed countries, which can ensure the reliability of the system. APRAS can be applied to establish research directions or present policy proposals for more efficient management of hazardous substances in agricultural environment, for example, setting up the criteria of agricultural products or soil remediation.
Benzo(k)fluoranthene (BkF) and indeno(1,2,3-cd)pyrene (IP) are two polycyclic aromatic hydrocarbons (PAHs) that have extracted from several consumer products. Both PAHs are classified by US EPA (2010) as probable human carcinogens (B2), based on no human cancer data and limited animal data, and are on California’s Proposition 65 List. In order to develop No Significant Risk Levels (NSRLs) for these compounds, a relative potency factor (RPF) approach was utilized. The method involves calculating the relative potency factor (IP/BkF) as the ratio of carcinogenic potency of the compounds containing chemicals listed on Proposition 65 must include these chemicals on a warning label. However, Proposition 65 chemicals may be exempt from these requirements if a discharge or exposure is below the chemical's respective.

The US EPA and OEHHA have selected BaP as the index PAH because it has a robust toxicological dataset, including numerous rodent studies in which the carcinogenic potencies of BaP are shown to be equal to or greater than those of other PAHs. The US EPA determined cancer potencies of 3 and 7% for BaP and IP, respectively, compared to BaP. These potencies are based on positive results in rat lung implantation studies. OEHHA has derived a NSRL of 0.06 µg/day for BaP using an oral cancer slope factor of 1.2 x 10^-11 mg/kg-day^1 derived from gastric papillomas and squamous cell carcinomas in Swiss Webster mice fed 50-200 ppm BaP for 4-6 months. Therefore, screening-level NSRLs for BaP and IP were derived by applying RPFs for BaP and IP to the NSRL for BaP. The equation used to calculate screening-level NSRLs for PAHs is: BkF NSRL / PAH RPF = PAH NSRL. Applying the RPF of 0.03 for BkF gives a NSRL of 0.06 µg/day / 0.03 = 2 µg/day. Applying the RPF of 0.07 for IP gives a NSRL of 0.06 µg/day / 0.07 = 0.85 µg/day. Screening-level NSRLs for BaP and IP can be used in a safe harbor assessment to evaluate whether products that contain these PAHs may be exempt from California Proposition 65 labeling requirements.

The federal Agency for Toxic Substances and Disease Registry (ATSDR) released a 3-compartment Shower and Household Water-use Exposure (SHOWER) model (v1.0) in May 2018 that estimates inhalation and dermal exposure to chemicals in household water. The model predicts exposure for various showering and bathing schedules, including contaminants from other sources, such as dishwashers, clothes washers, toilets, and faucets. Model outputs include average daily human exposure concentrations and dermal doses for households with 1, 2, 3, and 4 persons. The model predicts air concentrations in a shower stall, bathroom, and main house throughout the day and accounts for chemicals entering a compartment either directly from sources within the compartment or indirectly from other compartments. Exposure is calculated by tracking contaminant air concentrations in relation to the activity pattern of the person in the house. Results are provided for the most highly exposed person in the household, usually the person taking the last shower in the home. For example, for a scenario consisting of a combination of multiple showers and carbon tetrachloride in water at 100 ppb, the model predicts average daily human exposure concentrations of 8, 15, 20, and 25 µg/m³ for households with 1, 2, 3, and 4 persons, respectively. The predicted concentrations are below ATSDR’s Minimal Risk Level and US Environmental Protection Agency’s (US EPA) Reference Concentration for carbon tetrachloride. The model-predicted dermal doses range from 0.37 µg/kg/day for adults to 0.68 µg/kg/day for children aged 1 to 2 years and are below US EPA’s Reference Dose. ATSDR used experimental data from US EPA to verify the model. The simulated concentrations are in good agreement with the experimental data considering the complexity of the model and the uncertainty associated with the experimental data. Using methods pioneered by Julian Andelman, Tom McKone, and others, the ATSDR SHOWER model advances the science of and provides a convenient platform for assessing inhalation and dermal exposure from contact with contaminated household water. Advantages of using the model include 1) assessing exposure for households with up to four members, 2) evaluating exposure from being home all day or away 10 hours, and 3) including other household activities that use water. The SHOWER model is available as a desktop application upon request at showermodel@cdc.gov.

Deriving human health risk estimates for environmental chemicals has traditionally relied on toxicity data from humans and/or experimental animals. In the absence of in vivo toxicity data, new approach methods (NAMs) such as read-across have the potential to fill regulatory data gaps. This case study applied an expert-driven read-across approach to assist in screening-level assessment of non-cancer oral toxicity for p,p'-dichlorodiphenyldichloroethane (p,p'-DDD), a data-poor chemical known to occur at contaminated sites in the U.S. Three potential analogues with existing non-cancer oral reference values were identified and evaluated for suitability based on three primary similarity contexts (structural, toxicokinetics, and toxicodynamics). Furthermore, in vitro high-throughput screening (HTS) assays from ToxCast were evaluated for evidence in support of the similarity justification for read-across. Analysis of ToxCast assay results revealed similarities in the bioactivity profile of the target, p,p'-DDD, which argues with a relative potency factor (RPF) of 0.07 for IP, demonstrated values (e.g., dose-effect relationships) in rat pulmonary systems, which is a potential influence of metabolism in the detoxification/bioactivation of environmental chemicals are often unaccounted for in in vitro systems, and should be considered in the interpretation of ToxCast assays when evaluating analogues for read-across. The views expressed in this abstract are those of the author and do not necessarily reflect the views and policies of the US EPA.

Characterization of safe use for spray and aerosol products includes the development of physical characterization and generation rate data, exposure estimations with consideration to chemical physical properties, and identification or derivation of safety thresholds for data-rich and data-poor chemicals for systemic and local endpoints. Multiple risk assessment techniques and tools are required to achieve confidence in a comprehensive safety conclusion. These include tools for exposure estimation (e.g., ConsExpo) and demonstration of safety using (Q)SAR to identify structural alerts and Cramer class with application of the Threshold of Toxicological Concern (TTC) for data-poor chemicals, specified or derived No Expected Sensitization Induction Level (NESIL) values to identify Acceptable Exposure Limits (AELs) for dermal sensitization, and reference to systemic or Low Observed Adverse Effect Levels (NOAEL or LOAEL) identified or derived through published literature search. A framework approach is presented (that highlights methodologies with lower confidence to inform future research needs) using case studies for common fragrance ingredients (e.g., linalool, β-pinene, and isoeugenol with maximum use rates of 1%, and the minor ingredient isobutyl methacrylate estimated at a maximum of 0.018%) and formulary components (e.g., dipropylene glycol and ethoxylated lauryl alcohol at maximum use rates of 10%). Overall, total estimated local and systemic exposure using default parameters resulted in Margin of Safety (MOS) > 1 over the Acceptable Daily Intake (ADI), AEL, or TTC, and Margins of Exposure (MOE) > 100 over NOAELs for all components except for α-pinene, where MOE values of 5.3 and 2.2 for adults and children, respectively, were identified based on a NOAEL of 0.36 mg/kg-day identified from a recent (2016) 90-day inhalation study in rats with a LOAEL of 25 ppm (LOAEL, γ = 3.6 mg/kg-day), thus indicating a recommended maximum use level of 0.02% within the context of this evaluation. Product specific rates and fraction of generated airborne particulate would further refine the assessment.
Rapid Evidence Mapping (rEM) (Lam et al. 2018) has been developed as a resource-efficient approach for rapidly compiling a high-level view of the available evidence using rigorous, transparent and explicit methodological approaches. Here we have applied the rEM approach to a case study mapping the evidence available with respect to possible adverse effects of feminine care products (FCP). This exercise illustrates how rEMs can be quickly created with the assistance of software tools using a much-reduced level of effort compared to what is typically required to produce a detailed evidence map or scoping study. Specifically, we examined the categorizations of included studies, binned by FCP type, biological exposure, and health outcome and the intersections of these categories. The resulting evidence map was developed to: identify areas where the most research has so far been conducted; identify potential evidence gaps where more research is needed; and target areas where sufficient information may exist for pursuing a systematic review. We identified 16,425 abstracts from a PubMed search and screened references in SWIFT-Active Screener, utilizing the software’s built-in machine learning model that identified 13,241 papers. Of these, 94% were relevant. Among the remaining 12,622 references, Active Screener software predicted that <6% would be relevant; this was confirmed with a small amount of additional screening. After screening was complete, 1,309 relevant studies were ultimately included. We identified research areas having a large body of evidence where a follow-up review, such as a systematic review, may be informative (e.g., human exposures to staphylococcus and toxic shock) as well as areas where literature is lacking (i.e., biological exposure linkages with sprays, wipes, intravaginal washing, herbal product types; ingredient linkages with douches, herbal medicine, sprays, sanitary pads; and general linkages between FCP types and health outcomes). The resulting Rapid Evidence Map provides a useful tool that can be used to quickly review the evidence base for multiple decision-making points and serve to illustrate how, when combined with the expertise of a review team, rEMs can provide an efficient form of knowledge synthesis.

**2775 Benchmark Dose (BMD) Modelling Analysis of In-Field Data of Human Respiratory Epithelium (MucilAir) to Establish a Toxicological Point of Departure (POD)**

L. Li, P. Mosquin, and D. J. Brambilla. *RTI International, Research Triangle Park, NC. Sponsor: P. Hinderliter*

The utility of conventional in vivo animal studies to characterize toxicity associated with repeated inhalation exposures to irritants is limited by the complexity of extrapolation to humans, as well as by animal welfare concerns. An in vitro model of the human upper airway epithelium (MucilAir™) is a functional model of the human respiratory tract and accurately represents potential effects in vivo. This model was used in the evaluation of human toxicity for an irritant chemical. A number of endpoints were assessed, including Trans-Epithelial Electrical Resistance, Lactate Dehydrogenase Release and Resazurin metabolism which serve as markers of the surface irritant effect. Ten exposure concentrations ranging from 2 and 200 mg/L were evaluated in human respiratory epithelial cells as six replicates from five donors. A Hill model was fitted to the data using the BMDS software developed by the US EPA. Our assessments of model fit strongly favoured the Hill model over alternative polynomial models. Different definitions of the benchmark response (BMR) with various values of the benchmark response factor were evaluated, including the relative change BMR of 10% in the mean response over the control group, the one standard deviation BMR and the point BMR. The estimated Hill models well captured the patterns of dose-response curves. The BMD estimates were comparable across donors and endpoints, and their ranges and the 95% lower limits were used as the POD to determine chronic inhalation risk assessment values. Assessment of this POD against tissue-level exposure values demonstrated the safety of the assessed uses of this compound. This in vitro model is a fit for purpose alternative method for quantitative risk assessment of inhalation exposure to irritant materials.

**2776a Fipronil Hazard Identification for Occupational and Residential Exposure**

**2776 Comparison of Lung Cancer Risks from Environmental Exposures to Arsenic and from Those Associated with Medical Monitoring Criteria for Smokers**

The Agency for Toxic Substances and Disease Registry (ATSDR) may request medical monitoring as a follow-up to health evaluations at contaminated Superfund sites. Despite the general medical monitoring criteria outlined by ATSDR, it is sometimes difficult to determine whether potential disease risks among individuals who might have been exposed to specific environmental contaminants (e.g., arsenic in soil or water) at or near Superfund sites may warrant medical monitoring. In contrast, detailed criteria for lung cancer screening based on smoking history are available (i.e., lung cancer screening is only recommended for older individuals who have smoked in the past 15 years with at least 30 pack-years of cumulative smoking). Here, we present a case study comparing theoretical lung cancer risks from exposures to arsenic in drinking water and smoking, eligible for medical monitoring. We first calculated lifetime excess lung cancer risks for adults and children using a hypothetical arsenic concentration in soil, applying exposure assumptions used to derive the United States Environmental Protection Agency (US EPA) residential soil Regional Screening Levels, as well as more plausible exposure assumptions, and an oral lung cancer-specific cancer slope factor (CSF) for arsenic of 1.6 and 2.1 per mg/kg-day, for men and women, respectively. This CSF assumes a linear dose-response relationship, although evidence supports a threshold. Assuming an arsenic in soil concentration of 225 mg/kg and US EPA default exposure assumptions, the hypothetical lifetime excess lung cancer risks were 3.3 x 10⁻⁴ (0.03%) and 4.5 x 10⁻⁴ (0.05%) for men and women, respectively. For calculating the cumulative lung cancer risks of heavy smokers eligible for lung cancer screening, we relied on published absolute and relative lung cancer risks estimated from nearly a million men and women in the US during 2000–2010. Considering age- and sex-specific absolute lung cancer risks, relative lung cancer risks specific to smoking behaviors and history, and assuming various ages at which individuals started smoking, we calculated excess lung cancer risks due to smoking to be at least 2.8% and 1.6% for men and women, respectively. In conclusion, potential lung cancer risks from exposure to arsenic in soil at a concentration of 225 mg/kg are at least 3-fold lower than those of lower smokers if US EPA default exposure assumptions are applied, and potentially up to 200-fold lower if more plausible exposure assumptions are applied and, thus, do not warrant lung cancer screening.

**Fipronil Hazard Identification for Occupational and Residential Exposure**

Fipronil is a phenylpyrazole insecticide that blocks gamma-aminobutyric acid-gated chloride channels leading to central nervous system excitation and death. It is used to kill ticks and fleas on companion animals and for public health-related pest control. Clinical symptoms of exposure include seizures, dizziness, sweating, nausea, vomiting, diarrhea, blood pressure, eye and throat irritation, headache, coughing, and tremors. In acute toxicological studies in rats, mice and rabbits, fipronil caused convulsions, seizures, tremors, gait abnormalities and lethargy. In chronic studies, fipronil targeted the liver, thyroid and kidney. It is oncogenic in rats (thyroid) and mice (liver). In rats, over 80% of orally administered fipronil is absorbed; a significant portion is reabsorbed via enterohepatic circulation. Fipronil has a high log Kow partitioning into fat, and is expected to bioaccumulate. Dermal absorption is ~4.3%. The critical acute oral no observed effect level (NOEL) of 0.02 mg/kg/day was derived from a combined rat chronic toxicity-oncogenicity study. A statistically significant, 25% decrease in serum thyroxine (T4) occurred in males by Day 7 at the lowest observed effect level (LOEL) of 0.06 mg/kg/day. The critical acute oral NOEL was used for acute dermal and inhalation routes, as T4 (the most sensitive endpoint) was not monitored in route-specific studies. The critical subchronic and chronic oral NOEL of 0.02 mg/kg/day was based on sustained T4 decreases, convulsions, and death at the LOEL (0.06 mg/kg/day) after 23-50 weeks. Fipronil induced thyroid tumors in rats at high doses (13-17 mg/kg/day) that resulted from increased hepatic clearance of T4, leading to activation of the hypothyalamic-pituitary-thyroid axis. This mechanism is only relevant in rats, as humans have tighter T4 buffering. As such, a risk calculation based on T4 effects would presumably protect against thyroid tumors in humans. There have been numerous reports of adverse human health effects following fipronil exposure. These reports, coupled with concerns about in utero T4 deficiencies that could lead to mental retardation, hearing loss, and bone growth deficits -- and what role fipronil exposure may play in the development of these effects prompted a comprehensive human health...
A Review for the Best Practices for the Application and Preparation of SEND Data Sets

C. McPherson, Z. Bei, S. McPherson, and Z. Chengen, Wuxi AppTec, Suzhou, China.

Since December 18, 2016 Standard Exchange of Nonclinical Data (SEND) data sets have been required for New Drug Applications (NDA), abbreviated new drug applications (ANDA), and certain biologics license applications (BLA) and since December 18, 2017 SEND was required for nonclinical data contained in all Investigational New Drug Applications (INDAs). The preparation of these data sets is an additional step in the process for submission. As always timing is crucial for submissions with sponsors looking for the most aggressive timelines to reach the market and gain market competitiveness. This article will look at the key steps to optimize delivery of these SEND data sets. This optimization starts with alignment of terminology and the internal scheduling and processing; so that the draft and final SEND data sets can be sent to the client within days of issuance of the definitive reports. The internal processing and scheduling works too, for legacy studies or studies run by a client at a different CRO. The key factor here is effective and proactive communication with the Sponsor to define the format of the data and thereby reduce or minimize the need for any data re-entry or manual manipulation of data. This presentation will illustrate the processes for formatting send data sets based on experiences learnt to date when preparing SEND data sets for US FDA submission, and looking forward March 2019, some Safety Pharmacology will be included, with SENDIG3.1.

Recent Insights into the New ECHA/EFSA Endocrine Disruptor Guidance

New European Union (EU) Guidance on evaluation of chemicals for endocrine disruption was published in June 2018. This is particularly applicable to pesticides and biocides since for these, endocrine disruption is (under legislation) a hazard-based exclusion criterion, and therefore a major regulatory hurdle. The Guidance requires a comprehensive documentation of all endocrine-related measurements, across all studies including published literature, is notably time-consuming and prone to input error. The minimum base dataset for a sufficient endocrine evaluation includes a modern (post-2001) OECD 416 multigeneration study or OECD 443 Extended One-Generation Reproductive Toxicity Study (EGrRTS), and therefore will require new data generation for the majority of chemicals, since the dataset for many pesticides pre-dates the 2001 guidelines and must be supplemented. Hence the Guidance in effect sets new data requirements beyond existing EU legislation, and will result in an increase in animal testing. Some data can be provided by way of in vitro receptor binding assays, including ToxCast estrogen (but not androgen or thyroid) receptor data. The data most suited to endocrine evaluation are generated in mammals, but environmental effects in non-target species must also be assessed and a conclusion reached. Early feedback from some authorities is that mammalian data will not entirely reassure on potential environmental endocrine effects. There is a limited number of guidelines suitable for assessment of endocrine effects in environmental species, and Guidance recommends the OECD 240 Medaka EGrRTS and OECD 241 Larval Amphibian Growth and Development assays, with few laboratories currently offering these assays. It remains uncertain if thyroid hormone depletion will be concluded as endocrine disruption, or a secondary consequence. Experience to date indicates that considerable resources and time are required to conduct evaluations according to the Guidance particularly with respect to Appendix E, which then offers limited value to the process of assembling and integrating lines of evidence. Some regulators are requesting these evaluations with unrealistic short deadlines.

Oregon’s Approach to Systematically Select Toxicity Reference Values for a Program to Regulate Toxic Air Contaminants

D. Farrer, S. Wegner, M. Poulsen, S. MacMillan, K. Johnson, and G. Goldfarb. Oregon Health Authority, Portland, OR; and Oregon Department of Environmental Quality, Portland, OR.

The State of Oregon recently adopted a risk-based approach to regulating toxic air contaminants from industrial sources. The approach, called Cleaner Air Oregon (CAO), requires source-specific risk assessments that consider exposures and associated risk to neighbors. With over 200 regulated toxic air contaminants, state agencies needed a streamlined method to select toxicity reference values (TRVs) for use in source-specific risk assessments. State agencies identified four federal and state program-specific authoritative sources of chronic toxicity information on toxic air contaminants: US Environmental Protection Agency’s (USEPA) Integrated Risk Information System, US EPA’s Provisional Peer Reviewed Toxicity Value program, the Agency for Toxic Substances and Disease Registry (ATSDR), and California’s Office of Environmental Health Hazard Assessment (OEHHA). For acute toxicity information, state agencies looked primarily to ATSDR and OEHHA. These agencies were identified as authoritative sources because they have the resources to conduct comprehensive literature reviews that consider the overall weight of scientific evidence, degree of consensus in the scientific community, and the quality of underlying studies when establishing toxicity information. In many cases multiple authoritative sources had toxicity information on the same toxic air contaminant. Initially, state agencies addressed this by establishing a hierarchy of authoritative sources, selecting toxicity information from sources higher in the hierarchy over other sources. In response to public comment, this approach was modified in the case of chronic TRVs such that the most recently published chronic toxicity information from among the authoritative sources was selected as the chronic TRV. State agencies continued to use a hierarchy of authoritative sources for selection of acute TRVs because some authoritative sources used averaging times that more closely matched CAO’s desired averaging period (24 hours) than others. The hierarchy of authoritative sources for acute TRV selection was ATSDR’s acute minimal risk levels (MRLs), OEHHA’s acute reference exposure levels, and ATSDR’s intermediate MRLs. As other states move towards risk-based regulation of toxic air contaminants, Oregon’s approach may serve as a helpful model.

Automated Data Visualization Tool to Map FDA-CDER’s Public-Private-Partnership Deliverables

One of the primary charges of the US Food and Drug Administration (US FDA) is to advance public health by streamlining drug development. Public-Private-Partnerships (PPPs) are collaborations between regulatory agencies and other stakeholders that make it possible to address areas of unmet need that are not the purview of any single organization. This project uses a tool developed from the D3JS (Data-Driven Document JavaScript) visualization library, to identify the activities and deliverables of the PPPs associated with US FDA’s Center for Drug Evaluation and Research (CDER), and assesses how they map to US FDA’s and CDER’s public health mission and congressional mandates. The aggregated PPP data are stored in a queriable PostgreSQL database and visualized via an interactive dashboard. The tool has been built with the goal of developing an automated platform for data visualization that can display organizational activities and their progress towards addressing specific public health needs.

Use of Dog Studies in US FDA’s Safety Assessments for Food Additives and Color Additives

The Center for Food Safety and Applied Nutrition (CFSAN) of the US FDA conducted a review to determine the impact of studies conducted in dogs on decisions regarding the safe use of food and color additives that have been the subject of petitions submitted to the Office of Food Additive Safety (OFAS). The Toxicological Principles for the Safety Assessment of Food Ingredients (Redbook 2000) provides guidelines for conducting toxicology studies in rodents (rats or mice) and dogs. We searched our database of food additive (FAPS) and color additive petitions (CAPs) with one or more dog studies and
identified 87 and 75 petitions, respectively. Dog studies were determined to be decisive in making a safety decision for 32% of FAPs and provided supportive information for 36% of FAPs. Dog studies were determined to be decisive in making a safety decision in 48% of CAPs and provided supportive information for 15% of CAPs. These preliminary findings indicate that dog studies have contributed to safety assessments of food and color additives; however, there has been a significant decline since the year 2000 in the number of dog studies submitted to US FDA for this purpose. Further analyses are aimed at identifying factors (e.g., study design, etc.) that influence the value of dog studies in regulatory decisions. US FDA is interested in identifying alternatives to the dog study that can be incorporated into safety testing strategies for food additives and color additives and that are consistent with US FDA’s goal of modernizing toxicology.

**2782 Pharmacology/Toxicology Review of Related Grades of Excipients in Generic Drug Products: Successful Practices and Common Pitfalls**

S. Rayavarapu, R. T. Dorsam, S. T. King, R. Houghtling, M. Mueller, and S. Goel. US FDA, Silver Spring, MD. Sponsor: S. Goel, American College of Toxicology

US FDA’s Office of Generic Drugs (OGD) evaluates excipient safety to ensure that excipients in generic drugs maintain a similar safety profile to their respective reference listed drugs (RLDs). Sometimes the excipients used for pharmaceutical formulations may exist in various grades (i.e. subtle differences in their physical and or chemical characteristics). On occasion, generic drug applicants may submit a justification that relies on safety information from a related grade of an excipient that differs from the proposed grade in either physical or chemical characteristics. Such excipient grades, and their differences, require evaluation to determine whether their physical, chemical, and toxicological characteristics are relevant to support the safety of the proposed formulation. The authors surveyed 32 Abbreviated New Drug Application-Pharm/Tox reviews to identify trends in submissions, review considerations, successful practices and common pitfalls in excipient safety justifications. Of the reviews surveyed, data gaps were identified in approximately 33% of the submissions. These data gaps resulted in a non-approval and warranted additional information from the applicant. Data gaps consisted of incomplete reports, lack of relevant data to justify the safety of specific grade in question, or failure to address the drug’s context of use (i.e. local toxicity), safety of target population (e.g. pediatrics), duration of use (e.g. chronic). Additionally, applications received a deficiency if excipient grades could not be compared due to incomplete information on the physical, chemical and toxicologic characteristics of the grades. Successful safety justifications included similarities and differences in the physical and chemical characteristics across excipient grades, available safety information for both the proposed and the related excipient grades, and scientific justification for how the available data addresses the safety of the grade in question. Successful justifications also established the relevance of the available safety information to the context of use of the proposed generic drug product. Overall, this work highlights successful practices and common pitfalls in safety justifications to continually improve first-cycle generic drug approvals.

**2784 Better Ways Than the Bioassay: Weight-of-Evidence Approach to Assess Carcinogenicity Potential of Food-Use Pesticides**

G. M. Hilton¹, A. J. Clippinger², S. Papineni³, R. Buesen³, S. Melching-Kollmus¹, T. Kolmos⁴, N. Ryan⁵, D. C. Wolf⁶, R. C. Peffer⁷, and A. W. Hayes⁸. ¹PET International Science Consortium Ltd, London, United Kingdom; ²Corteva Agriscience, Agricultural Division of DowDuPont, Indianapolis, IN; ³BASF Corporation, Ludwigshafen am Rhein, Germany; ⁴Bayer Crop Science LP, Research Triangle Park, NC; ⁵Syngenta Crop Protection, LLC, Research Triangle Park, NC; and ⁶University of South Florida College of Public Health, Tampa, FL.

Rodent cancer bioassays have been used for decades to identify chemicals that may be carcinogenic to humans. However, numerous retrospective analyses and reviews of data collected from the bioassay over the past 40 years have raised questions about the relevance and regulatory need for the bioassay to assess risk to human health. As a result, a working group comprised of different sectors and stakeholders have developed case-examples using a weight-of-evidence (WoE) mechanistic-based approach to determine the appropriateness of waiving rodent cancer bioassays in the context of crop protection chemical registration. The WoE approach was used to evaluate exposure, mode-of-action, physiochemical properties, and toxicological data from defined endpoints. Selected pesticides that represented different classes of chemistry were reviewed using the WoE approach to evaluate available information on pesticide mode of action, indication for use, metabolic profile, toxicokinetics, genetic toxicology, histopathology from dose-response studies, tumour formation, hormonal perturbation, immune response, read-across, margins of exposure, uses, human exposure scenarios, and other relevant endpoints used in risk assessment. These data were collated to determine if there would have been sufficient information to perform a health protective chronic risk assessment without performing rodent cancer bioassays. Additional analyses are being conducted of a much larger set of pesticides to ensure adequate coverage of chemical space. The results of these analyses will be used to establish the criteria for when the mouse and/or rat cancer bioassay can be waived with sufficient confidence to protect public health.

**2785 California Law First in North America to Require Non-Animal Safety Substantiation of Cosmetic Ingredients**

E. Baker and K. Sullivan. Physicians Committee for Responsible Medicine, Washington, DC.

Growing public pressure on cosmetics companies is pushing the industry away from animal tests and towards greater uptake of in vitro and in silico methods. Although the US Food and Drug Administration does not require specific tests for cosmetics, many multi-use ingredients may be tested in vivo to meet regulatory requirements in other sectors or for non-required product stewardship reasons. Other products are subject to regulatory requirements in other countries. In 2018, California joined the European Union and other regions in severely restricting the sale of cosmetics products or ingredients that have been tested in animals. Starting January 1, 2020, no cosmetic may be sold within the state if it, or its ingredients, was tested on animals after January 1, 2020. Exemptions are allowed for testing conducted in response to a requirement by a state, federal or foreign regulatory body under certain conditions. Furthermore, the law requires that companies selling cosmetics or ingredients tested on animals under one of the exemptions use nonanimal
methods to substantiate the safety of the cosmetic or ingredient. Because the law applies to cosmetics companies as well as any third party suppliers or contractors, many ingredients manufacturers will now be required to use in vitro or in silico methods to substantiate the safety of their products, even if they are also conducting an in vivo study for the same endpoint to support the ingredient in another sector. Training and outreach efforts must be conducted to ensure ingredients suppliers are ready to comply with new regulations. Indeed, there are numerous non-animal methods available for assessing the potential hazards of cosmetics ingredients. This presentation will outline the legislative requirements and the available tools and resources to abide by them.

2786 PBT Assessment Criteria—Critical Tool or Policy Anachronism? An Analysis of Regulatory Approaches for Selection of Chemicals for Expedited Action

P. C. DeLeo¹, and S. Hartigan². Integral Consulting Inc. Annapolis, MD; and “American Chemistry Council, Washington, DC.

In June 2016, amendments designed to improve the Toxic Substance Control Act (TSCA), the primary chemicals management law in the United States, were codified into law. These included in new authorities in Section 6(h) that required the US Environmental Protection Agency (US EPA) to take expedited action on chemicals that are persistent, bioaccumulative and toxic (PBT). Unfortunately, the basis US EPA is initially using for identifying PBTs is a 2014 Agency prioritization document (the TSCA Work Plan) that did not rely upon rigorous collection or analysis of data. It also excluded from consideration any US EPA identified five chemicals for expedited risk management action by June 22, 2019: Decabromodiphenyl ethers (DecaDBE), Hexachlorobutadiene (HCBD), Pentachlorophenol (PCP), Phenol, isopropylated, phosphate (3:1; PIP 3:1), and 2,4,6-Tris-(tert-butyl) phenol (2,4,6-TTBP). An evaluation of the US EPA assessment of the use and exposure of the chemicals found that PBT criteria alone were not good measures of the need for expedited action. For example, no company had reported manufacture and/or import to the U.S. of two of the substance (HCBD and PCTP) in recent years, and nearly the entire market volume of another substance (2,4,6-TTBP) was consumed as chemical intermediate (methodology A) and a fuel antioxidant (6%). The evaluation of selection of chemicals for expedited action is particularly timely as US EPA is currently considering the next group of at least 20 chemicals which will be selected for risk evaluation, and US EPA has recently released a proposal for prioritization of the entire TSCA Inventory of active chemicals in commerce (approximately 30,000 chemicals). In light of the use and potential exposures for the TSCA Section 6(h) PBT chemicals, policy recommendations on approaches for selection of chemicals for risk evaluation and prioritization of the TSCA Inventory will be provided.

2787 The Nonclinical Innovation and Patient Safety Initiative (NIPSI): Supporting Human-Based Nonclinical Approaches through Advances in Regulation, Policy, Science, Education and Training

E. Baker. Physicians Committee for Responsible Medicine, Washington, DC.

The integration of modern and state-of-the-art nonclinical approaches for assessing drug safety, efficacy and disease modeling are expected to improve drug development. Recent advances, such as the US Food and Drug Administration’s (US FDA) Predictive Toxicology Roadmap and the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) Strategic Roadmap for Establishing New Approaches to Evaluate the Safety of Chemicals and Medical Products in the United States, represent a fundamental shift in how drugs will be developed and regulated. Regulators now state the need to move away from animal testing towards new approach methodologies that can be expected to be more predictive for humans, and have mapped their plans for doing so. The Nonclinical Innovation and Patient Safety Initiative (NIPSI) formed to foster stakeholder collaboration - among federal agencies, the private sector, and patient, health and research organizations - that supports innovative human-based science and addresses the factors that impede the uptake of modern, predictive approaches. Stakeholders initially met at a full-day NIPSI roundtable in January 2017 in Washington, D.C., then a growing group met during ancillary meetings of the Society of Toxicology Annual Meetings in March 2017 and March 2018. This presentation outlines NIPSI recommendations for advancing the uptake of human-relevant nonclinical approaches. One project aims to change US Food and Drug Administration (US FDA) regulations from requiring “animal” data to “nonclinical,” which encompasses animal in vivo and human and animal-based in vitro and in silico approaches. Another project involves lobbying the United States Congress to increase funding allocated for human-based science. The presentation will also include results from a recent review of NDAs for approved drugs that found no inclusion of “tissue chips” or “microphysiological systems” in US FDA submissions for approved drugs. Results will be updated for the Annual Meeting.

2788 Comparing Safe Intakes of Elements Established by the Food and Nutrition Board of the Institute of Medicine versus Those Established by the US Environmental Protection Agency

J. Ryer-Powder¹, and L. Ausman². ¹Environmental Health Decisions, Ladera Ranch, CA; and ²Tufts University, Boston, MA.

The Food and Nutrition Board of the Institute of Medicine (FNB) establishes Tolerable Upper Intake Levels (UL) for nutrients, defined as “the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects to a given individual in the general population.” The US Environmental Protection Agency (US EPA) establishes oral reference doses (RfD) for chemicals in the environment, defined as “an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime”. The objectives of this study are to (1) compare ULs with RfDs for elements, (2) examine the basis for the levels, and (3) determine if results support establishing a uniform approach to setting safe levels for elements in food and the environment. Current ULs and RfDs for male adults were obtained from the National Institutes of Health (NIH) toxicology database and US EPA website. Tolerable ULs were compared with RfDs and a ratio was developed to calculate differences in these values. For each element, selection of (1) the studies relied upon, (2) the critical adverse health effect, (3) the no observable adverse effect level (NOAEL) or lowest observable adverse effect level (LOAEL), and (4) uncertainty factor (UF) for RfD were evaluated to assess differences in levels. The difference in UL/RfD ratios ranged from 0.7 to 5.7. The largest differences were seen with copper, fluoride, molybdenum, and vanadium. The bases for the differences were selection of studies, critical adverse health effects, selection NOAELs or LOAELs, and UF. The FNB and US EPA rely on similar methodologies to set “safe” levels for intake of elements. Both procedures select relevant studies, derive a NOAEL or LOAEL, and divide the level by an UF to account for uncertainties (e.g., extrapolation from animals to humans and susceptibility to adverse effects). Although the intent of ULs and RfDs is to use the weight of the evidence to define a safe upper limit of exposure, different results were obtained for certain elements. It may be prudent for agencies to harmonize the setting of safe levels of nutrients for exposure via the diet and environment.

2789 A Case Study on Parabens Shows the Applicability of New Generation Risk Assessment Based on New Approach Methodologies

B. Desprez¹, S. Grégoire², C. Malvy², S. Tozer², M. Dent³, G. Kenna³, A. Schepl¹, C. Ellison¹, H. Rose³, D. Keller³, M. Klar³, N. J. Herbst³, J. Eilstein³, and G. Oukkastra³. ¹Cosmetics Europe, Brussels, Belgium; ²L’Oréal, Aulnay Sous Bois, France; ³Procter & Gamble Company, Egham, United Kingdom; ¹Unilever, Sharnbrook, United Kingdom; ²Gerry Kenny Consulting, Macclesfield, United Kingdom; ³Beiersdorf AG, Hamburg, Germany; ³Procter & Gamble Company, Cincinnati, OH; ³Coty, Darmstadt, Germany; and ³Henkel, Düsseldorf, Germany.

The Long Range Science Strategy (LRSS) is Cosmetics Europe (CE) research programme on new generation risk assessments (NGRA) based on new approach methodologies (NAMs). It includes a series of case studies, and one of them is on parabens. We use a tiered workflow, coming from the formed Seurat-1 programme and published by the OECD. The goal is to perform a safety assessment of parabens with long or branched lateral chain based on existing information from the parabens that have short lateral chain and for which toxico-kinetics and toxico-dynamic information are available, in combination to aggregate exposure evaluation. At Tier 0 we collected information for agencies to harmonize the setting of safe levels for exposure via the diet and environment.

Although the intent of ULs and RfDs is to use the weight of the evidence to define a safe upper limit of exposure, different results were obtained for certain elements. It may be prudent for agencies to harmonize the setting of safe levels of nutrients for exposure via the diet and environment.

The long-range science strategy (LRSS) is Cosmetics Europe (CE) research programme on new generation risk assessments (NGRA) based on new approach methodologies (NAMs). It includes a series of case studies, and one of them is on parabens. We use a tiered workflow, coming from the formed Seurat-1 programme and published by the OECD. The goal is to perform a safety assessment of parabens with long or branched lateral chain based on existing information from the parabens that have short lateral chain and for which toxico-kinetics and toxico-dynamic information are available, in combination to aggregate exposure evaluation. At Tier 0 we collected information on use scenario and chemical features. Parabens are Cramer Class I, but the exposure exceeds by far the threshold of toxicological concern (TTC) value. Read across shows most studies available with a need to prioritize developmental and reproductive toxicities. In Tier 1 we focused on determining the bioavailability of the parabens, and thus the systemic concentration. We used in vitro experiments (e.g., plasma protein binding, hepatic clearance in human hepatocytes) to parametrize a physiologically-based kinetic (PBPK) model. These data have the potential to be used for a conclusion based internal Tier (i.e., Tier 2) and, if this is relevant, to also explore modes of
action and toxicodynamic (e.g., docking studies, ToxCast® data, endocrine-receptor assays, transcriptomics). The conclusion on the safety, here, is based on read across using both chemical and biological similarities.

### 2791 Characterizing In Vitro Tests Co-Culture for Safety Assessment: Characterization of Testes Longitudinal Cellular Dynamics In Vitro

Y. P. Suh, and E. Faustman, University of Washington, Seattle, WA.

To improve chemical evaluation and identification of potential adverse health effects in humans, we are designing in vitro methods. In vitro cell cultures derived from a single cell type are limited. Using a 3 dimensional organotypic approach allows us to evaluate systematic interactions between cells and reduces the need for in vivo assessments. This organotypic, in vitro model of testicular development mirrors the development shown by in vivo studies. Isolated testicular tissue was harvested from C57BL/6 male mice on post-natal day 9 and digested into a single cell suspension and co-cultures were maintained for up to 16 days in 24 well plates with data collection on days in vitro (DIV) 3, 7, and 16. These times represent “windows of potential susceptibility” for testes development. Markers for Sertoli cells (Vimentin), Leydig cells (3β-HSD), Germ cells (DAZL, SCP3 and c-kit), and proliferation (PCNA) were quantified. For each well, we used an immunofluorescence dual staining technique with Scanning Laser Image Cytometry (iCytoS) to observe the percentage of cell type changes among the population and distribution of each cell population. Our observations in vitro demonstrated concordance of changes in Sertoli cells, Leydig cells and Germ cells throughout testicular development with similar trends in vivo. This project is supported by US EPA (RD 83573801, RD 83451401), the NIEHS (SP01ES009601, SP03ES00703, T32ES015459), and US FDA (1U01FD004242). The views expressed in this paper are those of the authors and do not necessarily reflect the views of the US EPA.

### 2792 Tiered Approach to Chemical Screening Using Both Hazard- and Exposure-Based Evaluation

S. Dubrow1, S. Risotto1, and M. Ciarlo2, 1American Chemistry Council, Washington, DC; and 2EA Engineering, Science, and Technology, Inc., PBC, Hunt Valley, MD. Sponsor: S. Dubrow, Society of Environmental Toxicology and Chemistry

With growing interest in the chemistry of everyday products, there is a greater need for methods of product safety assessment. There are a number of alternatives assessment frameworks that screen products and ingredients using scoring methodologies based on a chemical’s inherent hazard. However, risk is a function of both hazard and exposure. Potential for exposure is often dependent on whether the chemical is released from a product and the level of individual exposure. Comprehensive risk assessments that consider both hazard and exposure generally require substantial data input as well as quantitative models that may be time consuming to apply. Thus, there is a need for streamlined alternatives methods that allow efficient screening of products to prioritize those calling for comprehensive risk assessment versus those where exposure levels and hazards are expected to be of low concern. ACC’s Sustainability and Market Outreach Division has developed a tiered approach to chemical screening that provides a simple, yet science-based method for evaluating the potential for chemical exposure from a product. This more holistic framework for alternatives assessment can be used to introduce the concept of risk and exposure into existing hazard-only methodologies. The approach begins with an initial identification of relevant exposure scenarios and pathways based on product use, as well as identification of product components. The first tier of the approach screens ingredients using basic information on chemical hazard. The second tier screens ingredients based on an understanding of how product form and ingredient chemical and physical characteristics influence exposures. The third tier provides a risk scoring methodology that combines information on the intended use of the product and additional information on hazard. The final output is a risk matrix that users can employ to prioritize their actions and resources towards the highest risk scenarios. ACC performed a pilot test of 10 generic, unbranded formulations to identify the benefits and challenges of the approach, and potential opportunities for improvement or refinement. ACC is currently working to implement recommendations developed as a result of the pilot test.

### 2793 Active Machine Learning for Information Retrieval in Systematic Literature Reviews: Addressing Bias and Appropriate Use

Systematic reviews in toxicology and human health risk assessments involve the retrieval and structured examination of information from all relevant sources related to a research question of interest. Systematic reviews commence with a broad-based literature search that is designed to be comprehensive and therefore tends to return a high proportion of non-relevant articles. Text analytics and natural language processing technologies are now widely used to save time and increase efficiency in the information retrieval and prioritization steps of a systematic review by automatically discarding non-relevant articles. For example, supervised machine learning approaches rely on a training dataset (a set of documents labelled, for instance, as relevant or not to a topic of interest) to build models that go on to automatically classify a larger set of unclassified documents. Recently, “active” machine learning was proposed as a solution that limits the cost of creating a training dataset by sequentially focusing on training only the most informative documents. We simulate active machine learning by using a set of approximately 7,000 abstracts from the scientific literature related to the chemical arsenic that was previously classified by subject matter experts with regard to relevance to mode of action. We examine the performance of alternative sampling approaches to sequentially expanding the training dataset, specifically looking at uncertainty-based sampling and probability-based sampling. We discover that while such active learning approaches can potentially reduce training dataset size by up to 60% compared to random sampling (regular supervised machine learning), active machine learning-based predictions of model performance potentially suffer from bias that negates its potential benefits. Without correction, we find that active sampling can result in biased performance metrics up to a level of 25 percentage points. We discuss statistical approaches and the extent to which the bias resulting from skewed sampling can be compensated. We find that the use of independent validation methods can help reduce but not eliminate bias in active learning. We propose a useful role for active learning in contexts where accuracy metrics are not critical and/or where it is necessary to rapidly retrieve a subset of relevant literature.

### 2794 Using Interactive Media to Explore and Explain Hazard Assessment Data

C. Skuce1, A. Williams2, P. Hartman3, G. Aygeman-Badu2, K. Osborn1, and C. Henning2, 1ICF, Columbia, SC; 2ICF, Durham, SC; and 3ICF, Fairfax, SC. Sponsor: J. Wignall

Technological and methodological advancements in systematic review allow us to gather, screen, and characterize large literature bases supporting hazard assessment, risk assessment, and risk management at an increasing rate. Properly assessing and interpreting these data and presenting them to the public in a transparent manner becomes increasingly important as the risk assessment process faces increased scrutiny from scientific, political, and public communities. This is particularly important for hazard assessment, when health and human lives may be dependent on data interpretation. Data visualizations can address these areas of need by helping viewers perceive, understand, and assess the displayed information easily and quickly. Recently, more government agencies are leveraging new kinds of data visualizations in public reports, some of them web-based and interactive. In this analysis we explored how online systematic review tools such as HAWC and DRAGON ONLINE provide methods to rapidly capture trends and findings in a literature base with the aim of identifying best practices for implementing visual and interactive media. We also used visualization software and packages such as Tableau and R Shiny, which facilitate creation of interactive dashboards that viewers can manipulate to ‘zoom in’ on specific parameter values, to create ‘Evidence Maps’ for scooping available literature and dose-response, hazard, margin-of-exposure, and uncertainty range data. We present recommendations for the use and display of these maps, including key features and examples, and lessons learned from using them in risk assessment. We will also discuss how incorporating interactivity into visualizations is a highly effective method of targeting visualizations for use in two contexts: 1) Exploring data - allowing risk assessors to examine complicated datasets for scoping and analysis, and 2) Explaining data - increasing the transparency and clarity with which data and analysis are presented to risk managers and the public.
There is increasing need to rapidly determine chemical hazards in the DOD. However, questions surround the application of new approach methodologies (NAM) for rapid hazard assessment. To address this, DOD is developing a strategy for using NAMs to rapidly and accurately assess chemical hazards. We identified six key areas to address in develop in a roadmap: 1. DOD needs are different from other Federal agencies; DOD needs to understand hazards of new materials, chemical weapons, chemical spills, balance use with health hazards, and under diverse conditions (climate, urban, suburban, high altitudes). 2. Barriers to using NAMs to be addressed: Lack of acceptance by US EPA or OECD, unfamiliarity, hesitancy to work with developers of NAMs, no DOD service policy supporting use during acquisition process. 3. Increase technical acceptance of NAMs: verify and validate NAM performance, collaborate with others that promote regulatory acceptance, demonstrate NAMs in case studies, define technical and assay/model uncertainty in predicting human or standard model endpoints, explain limitations/relevance, use of NAMs is not an all or nothing strategy (2R1 + 1R). 4. Identify technology/innovation gaps and solutions: Gaps include inter-individual and laboratory variability, dose-response extrapolations, systems toxicology approaches, extrapolation to human relevance, few ecotoxicology NAMs and understanding mixture effects. Solutions include: new in silico techniques, leveraging Federal efforts, collaborate with non-DOD facilities, archived tissues to develop endpoints for analysis (e.g. `omics), foster tissue on chip/synthetic systems. 5. Education and outreach will be required support use of NAMs including better coordination of efforts across DOD and Federal agencies. 6. Develop an implementation plan and identify policy arising from roadmap implementation. A draft road map has been authored addressing these issues and is undergoing further review by DOD and other Federal partners. We expect that the roadmap will accelerate the ability of DOD services to understand chemical health hazards, protect DOD personnel and respond to emergency chemical situations.

Toxicological Review of Inorganic Arsenic

The Integrated Risk Information System (IRIS) Program is developing an updated Toxicological Review of Inorganic Arsenic. Given the size and complexity of the existing reference database, the National Research Council recommended US EPA conduct analyses to further prioritize among its three tiers of health outcomes. To prioritize outcomes for dose-response, US EPA conducted an analysis that considered strength of evidence of the epidemiological evidence for hazard (either by relying on conclusions from other assessments or by conducting new systematic reviews of the literature). Human studies containing exposure- or dose-response data were evaluated to assess aspects of internal validity (risk of bias) of study findings based on study design and conduct for hazard identification using an approach adapted from the Office of Health Assessment and Translation (OHAT). Identified strengths and limitations were considered to reach a study confidence classification of High, Medium, or Low confidence, or Uninformative for a specific health outcome. Judgments regarding the strength of the human evidence were made considering risk of bias, study sensitivity, consistency, strength, biological gradient, and coherence. Datasets from outcomes judged to have a "robust" or "moderate" evidence base were further evaluated for their suitability for dose-response analysis and included in a margin of exposure (MOE) screening level dose-response. More than 250 separate datasets were modeled using US EPA's Benchmark Dose Software. Points of departure based on the maximum likelihood estimate of the dose that increased the relative risk by 20% (RRD) were compared with an estimate of the general US population exposure to inorganic arsenic to derive MOE values for each dataset. The utility of dose-response analyses for economic benefit-cost analysis was also considered. MOE analysis results were used to inform the selection of health outcomes for further dose-response analysis. Animal and mechanistic studies are considered supplementary. Based on the strength of evidence evaluation and MOE analysis the arsenic assessment focuses on the following six health outcomes (out of fifteen): bladder cancer, lung cancer, diseases of the circulatory system, pregnancy outcomes, neurocognitive effects, and diabetes. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA.
in NHANES and the effect levels reported in the human health effects literature. Our conclusions show the machine learning techniques that we used were found to be comparable to expert review of literature and increased efficiency, and we present preliminary results from our investigations of 5 environmental chemicals as an example of how this type of screening-level approach may qualitatively inform public health considerations and cumulative risk decisions. The duration of the exposure is contingent on product use, life-cycle, and exposure control decisions.

---

**2800 Detection of Public Health Risk Levels for Contaminants in Consumer Products**

B. J. Hughes, V. S. Bhat, and K. D. Cox. NSF International, Ann Arbor, MI.

NSF, as a third party certifying body, determines when very high levels of chemicals extracted from certified products present a significant public health that may warrant immediate risk management measures (e.g. product holds or recalls). Existing paradigms lack sufficient chemical- and product-specific exposure context. Chemical identification/characterization, product life-cycle, population(s) affected, mechanistic and toxicological data need to be considered when deriving health-protective and scenario-specific guidelines. This phase of the pipeline identified 97% of duplicate groups with a precision of 52%. After accounting for manual review to remove false positives from the machine-identified duplicates pile, the combined pipeline realized a 99% efficiency gain. We normalized these results based on maximum possible efficiency gains (which depends on the proportion of duplicate groups in the original dataset) to estimate a normalized efficiency gain of 94%. Finally, we utilize text analytics to analyze the distribution of keywords across a combined set of references to inform refinements in search strategies. We show how iteratively streamlining search keywords based on their retrieval characteristics could reduce manual labor by an additional 15% downstream in the systematic review process.

---

**2801 Comparison of NTP OHAT and US EPA TSCA Study Quality Criteria: Trichloroethylene (TCE) and Congenital Heart Defects (CHDs) as a Case Study**

As part of developing best practices in systematic review (SR) for toxicity and risk assessment, tools are being designed or refined to accommodate evidence bases which include many different types of studies (i.e., experimental, in vitro, and observational studies). This is necessary as such tools were originally designed for different evidence bases (i.e., clinical trials). In this case study, two tools available to appraise data quality are compared as means of providing an understanding of the practical application of available approaches. Using the evidence base for TCE and CHDs, data were appraised using two tools: (1) the US EPA TSCA draft guidance for study quality evaluation SR principles, and (2) the NTP-OHAT Risk of Bias tool. Nine observational studies, 10 experimental animal studies, and 20 mechanistic studies were assessed representing a diverse range of study designs (in vivo, in vitro, and in vivo), durations, and exposure routes. The application of TSCA metrics to the TCE-CHD literature demonstrated some similarities with the NTP-OHAT criteria [e.g., none of the human studies were considered high quality (TSCA score <1.7 or OHAT Tier 1), and within the experimental animal studies, the inhalation animal studies were determined to be of higher quality than the oral studies]. However, there were more differences than similarities. Most notably, strict adherence to the TSCA metric criteria definitions resulted in designations of many human and mechanistic studies as “unacceptable” (and subsequently not considered in the risk assessment). A key difference between the tools and resulting quality characterizations is how the absence of reporting a metric is appraised. This was particularly impactful for several mechanistic studies, as several study design elements (e.g., cell plating and maintenance, cytotoxicity, etc.) were not often reported. Additional differences can be attributed to the thoroughness and specificity of the TSCA approach, as well as breadth of the TSCA criteria (includes multiple aspects of study validity), relative to NTP-OHAT. This case study demonstrates the need for continued refinement of critical appraisal tools to assess study quality.
There are some criticisms of the US and EU approaches about the environmental (Risk) Assessment (E(R)A) of medicinal products. They only consider one a particular medical product at a time, and ignore the fact that some compounds can cause additive or even synergistic toxic effects when in the presence of other APIs with similar Mechanism of Action (MoA). Recent evidence strongly supports the fact that amongst the pharmaceuticals in use today, steroidal pharmaceuticals merit particular attention for their adverse effects on the environmental compartment, i.e. glucocorticosteroids (GC). Synthetic GCs have been designed to have higher glucocorticoid potency, reduced mineralocorticoid effects and a longer duration of action. Synthetic GCs share the same biochemical backbone as endogenous cortisol, but in most of the tissue-specific biodynamics, H in the 9th carbon is substituted by F or CI to increase the stability of these compounds in the human body. Therefore, it is anticipated that the corticosteroids with F or CI substitution could resist degradation in sewage treatment plant (STP). Experimental data show that GCs disrupt metamorphosis in anuran amphibians by complex modes of action and suppress reproductive functions in fish as an adaptive response to divert metabolic building blocks away from biosynthetic pathways. Moreover, in fish GCs cause follicular atresia, advance or delay oocyte maturation and ovulation or affect egg size, fertilization success. GCs are classifiable as endocrine disruptors. Interestingly, under EU law if the medicine has endocrine disrupting properties the applicant is required to perform an E(R)A. Conversely, US law does not consider the risk posed by endocrine disrupters to aquatic species. It is very likely that pharmaceuticals with similar MoA will act in an additive manner, and therefore it can be argued that the total concentration of GCs in the environment, rather than the concentration of each individual GC, is of most relevance to the risk assessment of GCs on aquatic organisms. Therefore, in order to overcome the cocktail effects, we recommend that E(R) A is performed for groups of APIs with similar MoA. This would enable a more accurate E(R)A and a reduction of test organisms. The group approach for E(R) A can lead to a reduction of costs for all the companies marketing APIs with similar MoA.

Guidelines for determining a safe, oral dose for a compound in humans using laboratory animal test data differ based on the source of exposure (e.g., drug or therapeutic, drinking water contaminant, food substance, or dietary ingredient). A lack of harmonization between methodologies introduces confusion and variations in the application of regulatory guidance and determinations of safe, oral doses in humans. For orally administered drugs, US FDA recommends converting any observable adverse effect levels (NOAELs) established in lab animals to NOAEL human equivalent doses (HEDs) using body surface area conversion factors (BSA-CFs) to normalize for differences in body surface area between the test animal and humans. An uncertainty factor (UF) (e.g., default of 10) is then applied to the NOAEL_HED to derive Maximum Recommended Starting Doses (MRSDs) in clinical trials. Similarly, US EPA guidance recommends calculating oral reference doses (RFDs) by applying the appropriate composite UF to a NOAEL_HED. The US EPA converts a NOAEL in lab animals to a NOAEL_HED by physiologically based-toxicokinetic (PBTK) modeling or chemical-specific information. Absent such data, dosimetric adjustments are made to the RFDs. However, when considering exposure to multiple substances, the PDE values obtained in 5 groups (being differentiated by the selection of preferred values) was summarized in a memorandum generated by members of US EPA’s Office of Land and Emergency Management Human Health Regional Risk Assessors Forum Toxicity Workgroup (and with support from the Superfund Technical Support Center). After discussion and resolution of the toxicological issues for these chemicals by the Toxicity Workgroup, changes will be proposed to management for inclusion into the RSLs and baseline risk assessments.

The “Regional Screening Levels for Chemical Contaminants at Superfund Sites” are calculated from human health toxicity values and national default exposure parameters, and used by all US EPA regions to aid in decision-making at Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) sites. Human health toxicity values in the RSLs are selected based on a recommended hierarchy of sources, namely 1) US EPA’s Integrated Risk Information System (IRIS); 2) Provisional Peer-Reviewed (PPRTVs); and 3) other (“Tier 3”) values. However, the hierarchy provides flexibility to encourage risk assessors to select values according to the “best science” available. In some cases (for 11 inhalation toxicity values and 21 oral toxicity values), a subchronic toxicity value from the hierarchy of sources is lower than its corresponding chronic toxicity value. To evaluate and select a definable toxicity value for inclusion in the RSLs and baseline risk assessment, information was compiled that includes the source and the basis of the toxicity value, the critical effect(s), the point of departure (POD), the composition uncertainty factor (UF), and the resultant toxicity value. Differences among subchronic and chronic toxicity values (for the same chemical) were attributed to changes in: 1) the selection of a principal study (e.g., newer assessments based on a more recent publication); 2) methodology (e.g., the use of benchmark dose (BMD) modeling instead of a NOAEL/LOAEL approach, and the application of uncertainty factors or dosimetric adjustments); or 3) a combination of these factors. Based on evaluation of the data, preferred toxicity values were selected for each chemical. The values and rationale for the selection of preferred values was summarized in a memorandum generated by members of US EPA’s Office of Land and Emergency Management Human Health Regional Risk Assessors Forum Toxicity Workgroup (and with support from the Technical Support Center). After discussion and resolution of the toxicological issues for these chemicals by the Toxicity Workgroup, changes will be proposed to management for inclusion into the RSLs and baseline risk assessments.

Guidelines for determining a safe, oral dose for a compound in humans using laboratory animal test data differ based on the source of exposure (e.g., drug or therapeutic, drinking water contaminant, food substance, or dietary ingredient). A lack of harmonization between methodologies introduces confusion and variations in the application of regulatory guidance and determinations of safe, oral doses in humans. For orally administered drugs, US FDA recommends converting any observable adverse effect levels (NOAELs) established in lab animals to NOAEL human equivalent doses (HEDs) using body surface area conversion factors (BSA-CFs) to normalize for differences in body surface area between the test animal and humans. An uncertainty factor (UF) (e.g., default of 10) is then applied to the NOAEL_HED to derive Maximum Recommended Starting Doses (MRSDs) in clinical trials. Similarly, US EPA guidance recommends calculating oral reference doses (RFDs) by applying the appropriate composite UF to a NOAEL_HED. The US EPA converts a NOAEL in lab animals to a NOAEL_HED by physiologically based-toxicokinetic (PBTK) modeling or chemical-specific information. Absent such data, dosimetric adjustment factors (DAFs), based on body weight scaling, are applied to the NOAEL in animals to calculate the NOAEL_HED. In contrast, HEDs are not included in US FDA regulations or guidance for food substances or dietary ingredients. When assessing the safe use of a food substance under the conditions of intended use (i.e., Generally Recognized as Safe (GRAS) dossier or Food or Color Additive Petition), NOAELs are identified in lab animals, then the NOAEL from the most sensitive laboratory species is commonly selected, and an UF (e.g., default of 100) is applied to the NOAEL to determine the Acceptable Daily Intake (ADI) in humans. It is common for the NOAEL in a lab animal species to be extrapolated to humans based on body weight alone (1:1), to determine the margin of safety (MOS) between the (extrapolated) NOAEL in humans and estimated daily intake (EDI). For dietary supplement ingredients, an ADI may also be determined through the identification of a NOAEL in lab animals and application of a composite UF, without consideration for allometric scaling. These differences afford the opportunity for inconsistencies and variations in translating safe, oral doses, highlighting the need for additional education within the scientific community, and consensus and harmonized guidelines between US regulatory bodies.

The EMA/CHMP/SWP/10430/2012 document introduced a new criteria to define the limits of exposure to establish the risk in multiproduct GMP pharmaceutical facilities and to manage the possible cross contamination issues. This involves the determination of exposure limits according to toxicological criteria based on the inherent characteristics of each substance (substance-based approach). The procedure followed for determination of health based exposure limits for substances for a Technical Support Center (TSC). After discussion and resolution of the toxicological issues for these chemicals by the Toxicity Workgroup, changes will be proposed to management for inclusion into the RSLs and baseline risk assessments.
Systematic review approaches in human health assessment includes the integration of evidence from experimental, epidemiological, and mechanistic studies. The process of screening and evaluating evidence can be challenging due to the diversity of research models, methods, outcomes, and the variety of known mechanistic pathways resulting in chemical-induced toxicity. The Ten Key Characteristics of Carcinogens provide a useful method for searching and screening mechanistic information on chemical-induced carcinogenesis. The goal of the current project was to identify a set of key characteristics that can be used to analyze mechanistic evidence which may inform the potential pathways/networks associated with chemical-induced male reproductive toxicity. The proposed key characteristics were identified through a review of established mechanisms for chemical-induced male reproductive toxicity. An expert workshop was convened in March 2018 at the University of California-Berkeley to determine whether the key characteristics approach can also be applied to non-cancer effects including male reproductive toxicity. Eight key characteristics were identified and include alterations in: 1. germ cell functions, 2. somatic cell functions, 3. reproductive hormone levels/production, 4. hormone receptors, 5. DNA damage, 6. epigenetic modifications, 7. oxidative stress, and 8. inflammation. As a proof of principle, the key characteristics were used to evaluate evidence from mechanistic studies on the PCB mixture Aroclor 1254. A database was developed to capture experimental design information and mechanistic outcomes from the available studies. The resulting database can be used to qualitatively evaluate mechanistic and toxicological evidence as part of a hazard characterization analysis. Disclaimer: The views expressed are those of the authors and do not necessarily represent the views or policies of the US EPA.
Nephrotoxicity is among the top five reasons for clinical attrition of compounds. Current in vitro models for detecting and de-risking nephrotoxicity are often inadequate as they lack apical and basolateral transporters responsible for compound uptake and disposition. Additionally, animal models suffer from poor predictivity for their human counterparts. Thus, better and more predictive models are needed which can be used for safety assessment of nephrotoxic compounds. Herein, we evaluated the utility of freshly isolated human primary proximal tubule cells (aProximate™) seeded on TransWell plates for de-risking nephrotoxicity using kidneys from multiple different donors. Freshly isolated proximal tubule cells retained many of the key transport and metabolism functions that are both critical for toxicity and lost during cryopreservation. To assess the utility of aProximate cells, a variety of 30 mechanistically distinct pharmaceuticals were screened using translational safety biomarkers such as KIM-1, NGAL, and Clusterin to detect toxicity in vitro in addition to non-specific end points such as ATP depletion, LDH leakage, and TEER. NGAL showed the highest predictivity with a specificity of 85%, specificity of 75% and area under the ROC curve of 0.86. Importantly, the model was able to correctly rank-order compounds from the same chemical class according to their clinical risk of causing drug-induced kidney injury. Using the cut-offs generated by the 30-compound dataset, an additional 10 Takeda internal compounds were screened, and the assay could distinguish nephrotoxic compounds from benign thus validating the predictivity of the current platform. This in vitro model shows potential as a robust platform for safety assessment of nephrotoxic compounds.

2811 Freshly Isolated Primary Proximal Tubule Cells as an In Vitro Platform for Nephrotoxicity Testing

2812 Lead (Pb2+)-Induced Increases in Calcium Oxalate Crystal Formation Is Ameliorated via IP3-Receptor Knockdown

A. J. Branco, and G. M. Landry. Massachusetts College of Pharmacy and Health Sciences, Boston, MA.

Calcium oxalate (CaOx) accounts for 75-80% of kidney stone composition with a high recurrence rate. Genetic predisposition, gender, geographic region, diet, and low fluid intake all contribute to disease pathogenesis. However an important contributor to CaOx crystal formation that remains insufficiently studied is chronic exposure to environmental pollutants, specifically nephrotoxic metals. Lead (Pb2+) is of particular interest as epidemiological data indicate that low-level, chronic exposure (BL = 0.48-3.85µM) confers a 35% increased risk of developing CaOx nephrolithiasis. However, the mechanisms underlying association between kidney stone formation and lead exposure have yet to be elucidated. Interestingly, Pb2+-induced increases in inositol 1,4,5-trisphosphate (IP3) with subsequent IP3 receptor (IP3R) activation mobilizes free Ca2+ in rat proximal tubule cells. Drosophila provide a useful genetic model where major renal pathophysiology, particularly specific nephrotoxic-mediated pathways, can be efficiently studied. Anterior Malpighian tubules (MT) were isolated from either w1118 or IP3R knockdown female flies (n=13-15) and treated with oxalate (5mM) ± Pb2+ (2µM) for 1h. Following exposure, MTs were imaged using differential interference microscopy (DIC), and crystals quantified using ImageJ. CaOx crystal number and total area were significantly increased (~5-fold) in Pb2+-treated MTs compared to oxalate-exposed MTs when compared to oxalate alone controls. However, CaOx crystal number and total area in Pb2+-treated MTs were significantly decreased (~3-fold) indicating a role for IP3R-mediated Ca2+ mobilization as a mechanism for Pb2+-induced increases in CaOx crystallization. Future studies will determine whether IP3R transgenic flies reared on a Pb2+-containing diet mimic these in vivo results.

2813 Diglycolic Acid, the Toxic Metabolite of Diethylene Glycol, Affects Calcium Homeostasis, Mitochondrial Respiration, and the Aspartate–Glutamate Carrier Citrin in Human Proximal Tubule Cells

C. N. Jamison, and K. E. McMartin. Louisiana State University Health Sciences Center Shreveport, Shreveport, LA.

Diethylene glycol (DEG) is an organic compound that is found in household products, including brake fluid, but can also be an adulterant in medicines by acting as counterfeit glycerin. DEG poisonings affect the liver and nervous system, but have been characterized predominately by acute kidney injury and specifically necrosis of the proximal tubule cells. Diethylene glycol is metabolized to two primary metabolites: 2-hydroxyethyoxycetic acid (2-HEAA) and diglycolic acid (DGA). In human proximal tubule (HPT) cells, DGA is the metabolite that produces concentration-dependent cell death by decreasing the production of ATP and substrates involved in the electron transport chain, downregulating this energy-producing pathway. In other studies using cells with sub-threshold concentrations of DGA were conducted using primary human proximal tubule cells. Cells treated with DGA and BAPTA-AM, a calcium-specific chelator, were harvested and analyzed using the ratiometric calcium indicator dye Fura 2-AM. Additionally, HPT cells were treated in a DGA time-course with either additional calcium or a calcium ionophore to see if the effects of DGA on oxalate transporter phosphorylation could be attenuated. This oxygen consumption rate was measured using the Seahorse XF24 Analyzer. Citrin expression in DGA-treated HPT cells over time was also measured via western blot analysis. DGA treatments showed an increase in intracellular calcium at 25 mM at 36 and 48 h, but the BAPTA-AM-treated cells at varying concentrations were inconclusive. DGA decreased OCR in a time-dependent manner, lending support to the effects of DGA on energy production. Citrin expression was decreased with DGA incubations compared to control at the 36 and 48 h timepoint. These data suggest that DGA increases total HPT intracellular calcium levels, but more studies using other calcium sensing techniques need to be performed to determine the location and other targets of this effect.

2814 Efflux Pathways of Diglycolic Acid in Primary Human Proximal Tubule Cells

J. Dagenhardt, C. Robinson, and K. McMartin. Louisiana State University Health Sciences Center Shreveport, Shreveport, LA.

Diethylene glycol (DEG) is an industrial solvent, generally found in brake fluid and lubricants, implicated in mass poisonings worldwide. The predominant metabolites of DEG are 2-hydroxyethyoxycetic acid (2-HEAA) and diglycolic acid (DGA). Exposure to DEG causes proximal tubular necrosis, as well as hepatoxicity and a delayed peripheral neuropathy. DGA has been implicated with the metabolite responsible for the renal and hepatic toxicity seen in these poisonings, as it is shown to accumulate in the organs. Due to this accumulation, transport of DGA into and out of kidney cells is of interest. Initial experiments focused on both the organic anion transporter (OATs) and the sodium-dependent dicarboxylate transporters (NADCs). Results from these experiments showed that stimulation of OATs did not enhance DGA efflux. However, primary human proximal tubule (HPT) cells have been reported to lose OATs activity over time in culture. Therefore, it was important to determine if OATs were functioning in our cell model. We hypothesized that preloading the cells with dicarboxylate substrates of OAT1 and OAT3 would cause an increase in uptake of the typical OAT substrate para-aminom hippurate (PAH). HPT cells were grown on inserts until confluent, then loaded apically with succinate, DGA, glutarate, α-ketoglutarate, or control buffer. After incubations, cell lysates were counted on a scintillation counter to determine PAH uptake. Loading with succinate was able to increase the PAH uptake, while DGA was not able to increase PAH uptake. We concluded that OAT1/3 were functional in our cell model and that DGA was not likely removed from the cells for exchange for PAH.

2815 Development of Human Proximal Tubule-Chip for Assessment of Potential Renal Transporter-Based Drug-Drug Interactions

The kidney plays a key role in elimination of xenobiotics and endogenous compounds through its complicated and efficient uptake and efflux transport systems. An investigation of drug interactions with renal transporters and in upregulating drug disposition and toxicity, and more importantly, predict potential drug-drug interactions in human. However, currently available cell-based models often failed to predict renal transporter activity and not scalable to a predictive clinical outcome due to in vitro in vivo discrepancy. Our aim was to develop a human Proximal Tubule-Chip for assessment of renal transporter-based drug-drug interactions. Our Proximal Tubule-Chip is a microengineered microphysiological system where human proximal tubule cells and glomerular microvascular endothelial cells were cultured under continuous medium flow and mechanical forces. Human primary proximal
tubular epithelial cells were cultured in the tubular channel on top of the porous membrane whereas glomerular microvascular endothelial cells were cultured on the opposite side of the same membrane in the vascular channel under continuous physiological flow to form functional Proximal Tubule-Chip. The Proximal Tubule-Chip maintained polarized proximal tubule cell morphology for up to 15 days, exhibited tight junctions, barrier function (inulin leakage), demonstration of proximal tubule cell marker proteins including aquaporin-1 and Na/K-ATPase, revealed gene expression by real-time quantitative polymerase chain reaction of renal transporters including glycoprotein, multidrug and toxin excision (MATE) 1, MATE2-K, organic anion transporter (OAT) 1 and 3, and organic cation transporter (OCT2). We also demonstrated that the functional activities of proximal tubule cells, para-aminomuconic acid mediated by OAT1/3 and creatinine mediated by OCT2. These results suggest that the Proximal Tubule-Chip represents a physiologically relevant system for drug discovery and development applications.

2816 Supplementation of Growth Media of Cultured Renal Cells with the Energy Substrate Acetoacetate Impacts Energy Metabolism and Response to Toxins

T. Denoon, and S. M. Ford, St. John’s University, Jamaica, NY.

The proximal tubule of the kidneys is a metabolically active tissue with a high energy demand which makes it susceptible to factors that interfere with oxidative metabolism. Cultured kidney cells such as LLC-PK1 possess many functions of the proximal tubule, however their energy metabolism differs from the highly oxidative tubule metabolism in vivo. This may impact its reliability in predicting toxicity. Modulating the growth media composition has been shown to shift cultured liver and muscle cells from high glycolytic activity to increased oxidative metabolism and enhanced ATP production, but little is done on renal cells. This study is designed to examine the influence of culture media composition on the energy metabolism of LLC-PK1 cells and their responses to mitochondrial toxins. Cells were grown to confluence in SFDM media containing 3% FBS and 5 mM glucose or 5 mM glutamate supplemented with 10 mM acetoacetate (0.5) increased for cells grown with acetoacetate (30.6 ± 4.11 pmol O2/min/μg DNA compared to 20.9 ± 2.22 for 5 mM glucose alone). Other measures of mitochondrial function were also significantly increased for cells grown with acetoacetate including basal respiration, maximal respiration, ATP-linked respiration, and coupling efficiency. No significant changes in measures of glycolysis were detected between the two treatments. Two compounds which have been shown to affect mitochondrial function were examined to determine whether the culture media would influence their toxicity. Cells treated with the antifungal clotrimazole for 24 hr exhibited significantly lower LC50 (17.3 ± 3.7 μM) compared to cells grown in glucose alone (34.1 ± 3.9 μM). In contrast, cells treated with the NSAID diclofenac for 24 hr showed no effect of media composition. These results indicate that the composition of the growth medium influences the energy metabolism of cultured renal cells which may affect the responses of the cells to toxicants.

2818 Development of Predictive In Vitro Cross-Species Proximal Tubule Models for Drug Transporter and Nephrotoxicity Studies

G. Chung1, L. Armstrong2, M. Nichols1, and C. Brown1,2, Newcells Biotech Ltd, Newcastle upon Tyne, United Kingdom; and 3Newcastle University, Newcastle upon Tyne, United Kingdom.

Currently there is no in vitro platform that enables cross-species comparisons of renal drug transport or nephrotoxicity, which is one of the reasons for the high incidences of drug attrition. Our solution to this is to develop and characterise novel assay platforms using primary renal proximal tubule cells (PTCs) derived from key model species. Here we report the extension of the aProximate™ assay platform to include non-human primate (NHP) and canine PTC models. PTCs were isolated from fresh kidney cortex using a collagenase/enzymedigested protocol. NHP and canine PTCs grown on Transwells formed confluent monolayers and produced average TEER value of more than 90 Ω.cm² after 7 days in culture, similar to human and rat PTC monolayers. At the mRNA level, NHP and canine PTCs expressed key drug transporters including MDR1, MRP4, BCRP, OCT2, OATP4C1 and lower levels of OAT1. Functionally, a net digoxin secretion across NHP monolayers; 10μM digoxin, the apical to basolateral flux (J+ apical to basolateral flux (J+ apical to basolateral flux (J+ apical to basolateral flux (J+ apical to basolateral flux (J+) of 3.3±0.2 pmol/cm²/h) significantly smaller than the basolateral to apical flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J− apical to basolateral flux (J−) of 15.8±0.2 pmol/ cm²/h. Net secretion of digoxin was significantly inhibited by triiodothyronine (10μM) or estrogen-3-sulfate (10μM) at the basolateral membrane, or GF120918 at the apical membrane. Similar data was generated for canine PTC monolayers. These results were consistent with OATP4C1-mediated uptake of digoxin and apical efflux of digoxin mediated by MDR1. To test the utility of NHP monolayers as predictive models of nephrotoxicity, cells were challenged with a range of nephrotoxins using KIM-1 level, TEER, and cell viability as endpoints. In response to cisplatin challenge (10μM), KIM-1 release increased significantly alongside a significant decrease in cell viability to 34.4±4.4%, and TEER to 16.3±3.1 % of control values respectively. In addition to cisplatin-induced toxicity, a significant increase in KIM-1 release was found in response to challenge with 10μM cyclosporin, 10μM methotrexate, 200μg/ml polymyxin B or 200μg/ml gentamicin. Both cyclosporin and gentamicin had no effect upon either TEER or cell viability. Methotrexate and polymyxin B challenge resulted in a significant fall in both TEER and cell viability. These results report the successful production of primary NHP and canine PTC platforms which, similar to our human and rat aProximate™ PTC models, may prove useful as predictive in vitro PTC models of drug transport and drug toxicity.

2819 Preventive Effect of Sulforaphane on Type 2 Diabetes-Induced Diabetic Nephropathy via AMPK-Mediated Glucose/Lipid Metabolism Improvement

Z. Li1, G. Hua1, T. Ma2, L. Miao2, Z. Zhang2, and L. Cai1, 1University of Louisville, Louisville, KY; and 2Jilin University, Changchun, China.

Diabetic nephropathy (DN) is the leading cause of end-stage renal failure worldwide. Sulforaphane (SFN) was reported to prevent DN along with the activation of nuclear factor erythroid-2 related factor 2 (Nrf2) and AMP-activated protein kinase (AMPK). Dyslipidemia plays a crucial role in DN in type 2 diabetes (T2D)-induced DN. AMP-activated protein kinase (AMPK), particularly AMPK-α2 isoform, can attenuate the nephropathic alterations by improving lipid metabolism. To study if SFN can protect T2D-induced DN by activating AMPKα2 and Nrf2-mediated anti-oxidative pathways, male C57BL/6J and AMPKα2 knockout (AMPKα2-KO) mice were fed high-fat diet (HFD) for 3 months to induce T2D and treated with single or multiple short-term treatment with sulforaphane (STZ) to hyperglycemia as a T2D mouse model. Control mice were fed with normal diet without STZ. T2D and control mice were treated with or-with
suggesting that the MCLR-induced glomerular change was attenuated in HHFC-induced NASH. In contrast, 30 µg/kg MCLR increased casts and proteinuria in both control and HHFC, but to a greater magnitude in HHFC, suggesting that HHFC animals were more susceptible to these toxicities. The MCD group was refractory to MCLR-induced renal histopathological changes. Compared to the vehicle treatment within each diet, the 30 µg/kg MCLR dose decreased PP2A protein levels in both NASH groups, whereas the 10 µg/kg MCLR dose decreased PP2A protein levels only in the MCD group. MCLR bound to protein was detected only in the 30 µg/kg dose and is mostly observed at ~25-kDa in the control and HHFC groups, whereas in the MCD group most is observed at ~35-kDa. Control animals adapted to repeated MCLR exposure by increasing the urinary excretion of MCLR and MCLR-cysteine at the end of the study, whereas this adaptation was attenuated in HHFC animals. These data indicate that the mechanisms of altered MCLR-induced proteinuria and casts in HHFC-induced NASH may be associated with differential MCLR urinary elimination and modulation of PP2A and apoptosis. Collectively, these data suggest that NASH patients may be more susceptible to certain aspects of MCLR-induced renal toxicity and may contribute to the burden of chronic kidney disease in NASH patients. Funding: 4RO00E520455.

2820 Cisplatin Renal Cytotoxicity in Human Proximal Tubular Epithelial Cells Is Modified by Resveratrol Protection of Mitochondrial Function

M. A. Valentovic, K. C. Brown, M. Dial, and R. McGuffey. Marshall University School of Medicine, Huntington, WV.

Cisplatin is a cancer chemotherapeutic agent used in treating testicular, ovarian, and cervical cancer. Cisplatin usage is associated with adverse effects that include neurotoxicity and nephrotoxicity. The frequency of these serious adverse effects increases with dose and cycles of treatment. Resveratrol (RES) is a polyphenolic compound that promotes apoptosis in some cancer cell lines and reduces tumor size in clinical studies. Part of the mechanism for reducing cisplatin toxicity by RES may be mediated by preserving mitochondrial function and diminishing cisplatin induced oxidative stress. Cisplatin targets renal proximal and distal tubules. HK-2 cells were selected for this study as they are a human renal proximal tubular epithelial cell line (HK-2). Our hypothesis is that RES will diminish mitochondrial impairment by cisplatin in HK-2 cells. HK-2 cells were plated for 48 h followed by a 1 h pretreatment with RES or 1% DMSO (vehicle). Renal cells were subsequently exposed to cisplatin at a final concentration of 0.50 µM for 24 h. Viability was assessed using MTT and trypan blue exclusion cell counts. All studies were conducted a minimum of 3 independent experiments. Cells pretreated with 10 µM RES were protected from cisplatin cytotoxicity at 24 h. Cisplatin caused a concentration dependent decline in MTT viability after 24 h exposure to 0.75 and 1.5 µM cisplatin. RES pretreatment for 1 h with 10 or 15 µM RES increased HK-2 viability relative to cells exposed only to RES Vehicle (DMSO). Additional studies examined whether RES stimulated cell growth as part of the mechanism for cellular protection. RES did not increase cell number as part of its protective mechanism. Mitochondrial function was evaluated at 24 h using a Seahorse XFp analyzer. Basal and maximal mitochondrial respiration were monitored in RES and cisplatin treated cells. Western analysis detected an increase in protein carbonylation with 24 h cisplatin exposure which was reversed by RES. Mitochondrial function was diminished by cisplatin and partially reversed by RES. RES protects human epithelial cells from cisplatin cytotoxicity, preserves mitochondrial integrity and mitochondrial respiration. Supported by NIH Grant INBRE R20GM103434 and a WV NASA Undergraduate Research Fellowship to MD and RM.

2821 Microcystin-LR Renal Toxicity in Nonalcoholic Fatty Liver Disease

T. Arman, K. Lynch, M. Gastecki, M. J. Goetteken, and J. Clarke. 1Washington State University, Spokane, WA; and 2Rutgers, The State University of New Jersey, Piscataway, NJ.

Non-alcoholic fatty liver disease (NAFLD), an advanced stage of NASH, nonalcoholic steatohepatitis (NASH), increases systemic exposure to microcystin-LR (MCLR), potentially increasing kidney exposure and toxicity. We hypothesize that MCLR will exacerbate renal toxicity in NASH. Sprague Dawley rats were fed either a control diet, a methionine or choline deficient (MCD) diet, or a high fat/high cholesterol diet (HHFC) (NASH) for 10 weeks. After 6 weeks of diet, animals were administered either vehicle, 10 µg/kg, or 30 µg/kg MCLR via i.p. injection every other day for 4 weeks. MCLR-induced NASH increased the glomerular change histopathology score (control=0.0±0.0, HHFC=1.0±0.0). After 30 µg/kg MCLR exposure, this score increased in both control and HHFC groups to ~1.5, sug-

2822 3D NephroScreen: High-Throughput Drug-Induced Nephrotoxicity Screening on a Proximal Tubule-on-a-Chip Model

Renal toxicity remains a major issue in clinical trials, and stresses the need for more predictive models fit for implementation in early drug development. Here, we describe a perfused, leak-tight renal proximal tubule cell (RPTec) model cultured within a high throughput microfluidic platform (Mimetas' OrganoPlate®), along with recent results from a 12-compound nephrotoxicity screen performed within the "NephroTube" CRACK IT consortium in collaboration with sponsors. Human monolayer, RPTec cells (Sigma) were grown against a collagen I ECM in a 3-channel OrganoPlate®, yielding access to both the apical and basal side. Drug-induced toxicity was assessed by exposing kidney tubules to 4 benchmark and 8 blinded compounds with known clinical effects supplied by the sponsors for 24 and 48h. The tightness of the barrier was evaluated by diffusion of a dextran dye from apical to basal compartment. Parallel to this, cell viability with a WST-8 assay and the presence of LDH in the supernatant were assessed. Finally, kidney tubules were lysed, and RNA was extracted for gene expression analysis of acute kidney injury markers. Upon perfusion flow, RPTec form leak-tight confluent tubular structures against the collagen I ECM in the OrganoPlate®. The NephroScreen revealed significant decreases in barrier tightness and cell viability of 7 out of 12 compounds. Furthermore, the release of LDH was significantly increased in 9 out of 12 compounds. An increased expression in HMOX1, TNFα and NGAL compounds. Furthermore, the NephroScreen revealed significant decreases in barrier tightness and cell viability of 7 out of 12 compounds. 2824 Circulating microRNA Biomarkers for Drug-Induced Tubular and Glomerular Injury in Rats
T. Yokoi, T. Kagawa, T. Zárybnicky, Y. Shiraz, and S. Oda. Nagoya University Graduate School of Medicine, Nagoya, Japan.

Acute kidney injury is an important clinical concern. For the early phase detection, the present study focused on circulating microRNA (miRNA) as a novel biomarker for kidney injury. Through next-generation sequencing analysis, we aimed to identify specific plasma miRNAs that can enable prediction and discrimination of tubular and glomerular injuries. Six-week-old male Sprague-Dawley rats were intravenously administered cisplatin (CSP) and gentamicin (GEN) to induce tubular injury. To make glomerular injury models, uranyl oxycromic (PUR) and doxorubicin (DOX) were intravenously administered. Small RNA-sequencing was performed to analyze time-dependent changes in the plasma miRNA profiles. The sequence data was firstly mapped to the mature miRNA sequences of rats. The sample normalization was performed with DESeq package of R software. Considering that the PUR- and DOX-induced glomerular injury models were accompanied by tubular injury, the specifically changed miRNAs among PUR and DOX models were defined as glomerular injury specific miRNAs. In the differential analysis, we focused on miRNAs with following criteria: (1) |log2(ratio)| > 2 and FDR < 0.05; (2) the earlier responses to the kidney damage, and (3) the level of changes in the normalized read counts. Through the analysis, several miRNAs such as miR-148a-3p and miR-143-3p were commonly down-regulated in all of the models, and miR-122-3p and miR-192-5p were specifically down-regulated in the glomerular injury models. Our data indicated that the combination of several specific miRNAs in the plasma may enable the early and sensitive detection of tubular and glomerular injuries. The present study suggests the potential utility of plasma miRNAs in the early and type-specific detection of kidney injury.

2825 Modeling the Effects of Proteinuria on a Human Renal Proximal Tubule Using a 3D Microphysiological System
1University of Washington, Seattle, WA; 2Seattle Children’s Hospital, Seattle, WA; and 3Kidney Research Institute, Seattle, WA.

Proteinuria is a pathological cause of progressive renal impairment in chronic kidney disease. Changes in ultrafiltrate composition during glomerular dysfunction may promote or exacerbate tubulointestinal lesions by activating pro-inflammatory, pro-fibrotic, and vaso-modulatory signaling in proximal tubule epithelial cells (PTECs). To better understand how serum-filterate components drive PTECs toward an activated phenotype, we treated a 3-dimensional microphysiological model of the human renal proximal tubule with human serum. Exposure of PTECs to 2% human serum for 48 hours increased secretion of kidney injury molecule 1 (KIM-1) and expression of proliferation marker protein Ki-67 (K167), both of which are events that occur during tubular wound healing. In vivo. Transcriptomic profiling by RNA-seq revealed the expression of 820 genes were significantly affected. Ingenuity Pathway Analysis software identified transforming growth factor beta (TGF-β) and tumor necrosis factor alpha (TNFα) as the primary upstream regulators mediating the observed transcriptional changes. Many of the affected genes have roles in matrix remodeling, immune cell modulation, and endothelial activation. These data suggest that our microphysiological system reproduces the pathophysiological response of the proximal tubule to serum and has utility in exploring the mechanisms of PTEC activation as well as potential therapeutic interventions. Future efforts include evaluating the impact of inhibiting TNFα or SMAD signaling on PTEC response to human serum.

2826 Time-Dependent Regulation of Calbindin Expression in Cisplatin Kidney Injury

Calbindin is a cytosolic calcium-binding protein expressed in distal tubules and collecting ducts of the nephron. Since the discovery that calbindin is released into urine after kidney injury, there has been growing interest in using calbindin as an early and sensitive biomarker of nephrotoxicity. However, very little is known about the intrarenal regulation of calbindin turnover. We therefore sought to characterize the time-dependent regulation of renal calbindin release and expression in the kidneys during cisplatin nephrotoxicity, a well-established model of acute kidney injury. Male C57BL/6J mice were treated with vehicle or cisplatin (20 mg/kg, i.p.), and urine, plasma, and kidneys collected at 24-hour time points. Urinary calbindin and kidney injury molecule-1 (Kim-1) concentrations were elevated by 11.6-fold and 2.5-fold, respectively by day 2. Serum creatinine and blood urea nitrogen, traditional markers of renal injury, increased in cisplatin-treated mice by day 3, confirming the presence of acute kidney injury. Concurrently, time-dependent decreases in intrarenal calbindin protein were observed on days 3 and 4. Additionally, a 200-fold up-regulation of both calbindin (Calb1b) and Kim-1 miRNA was seen on day 3. These data suggest that early release of calbindin from the kidneys into the urine initiates the compensatory induction of miRNA expression at later time points (days 3 and 4). Interestingly, Calb1b up-regulation paralleled an increase in the mRNA expression of the apical TRPV5 calcium channel and a decrease in the basolateral sodium-calcium exchanger NCX1. These data suggest a coordinated response to modulate ion and calcium transport, which may be required to maintain renal integrity. In summary, an improved understanding of the regulation of renal calbindin during cisplatin nephrotoxicity enhances its utility as a potential biomarker of kidney damage. Supported by P30ES050522 and T32ES007148.

2827 Effects of the SGLT-2 Inhibitor Canagliflozin on Adenine-Induced Chronic Kidney Disease in Rats
B. Ali1, S. Al-Salam2, Y. Al Suleimani1, M. Al Za’abi1, A. Abdelrahman1, N. Schupp1, and A. Nemmar2.
1Sultan Qaboos University, Al Khod, Oman; 2United Arab Emirates University, Al Ain, United Arab Emirates; and 3University of Düsseldorf, Düsseldorf, Germany.

SGLT-2 inhibitors have been shown to be nephroprotective in diabetes. Here, we examine if one of these drugs could also ameliorate non-diabetic chronic kidney disease (CKD). Six groups were used: control, adenine-fed, and canagliflozin (10 or 25 mg/kg, by gavage), each with or without adenine. Rats fed adenine showed the typical features of CKD that included elevation of blood pressure, decreased food intake and growth, increased water intake and urine output, decrease in creatinine clearance, and increase in urinary albumin/creatinine ratio, liver-type fatty acid binding protein, N-acetyl-beta-D-glucosaminidase, and plasma urea, creatinine, uric acid, calcium, indoxyl sulfate and phosphorus concentrations. Adenine also increased concentrations of several biomarkers of inflammation such as neutrophil gelatinase-associated lipocalin, interleukin-6, tumor necrosis factor alpha, clusterin, cystatin C and interleukin-1β, and decreased some oxidative biomarkers in kidney homogenate, such as superoxide dismutase, catalase, glutathione reductase, total antioxidant activity, and urinary 8-isoprostane and urinary 8-hydroxy-2-deoxyguanosine. Adenine significantly increased the renal protein content of Nrf2, caused renal tubular necrosis and fibrosis. Given alone, canagliflozin at the two doses used did not significantly alter any of the parameters mentioned above. When canagliflozin was given concomitantly with adenine, it significantly and dose-dependently ameliorated all the measured adenine-induced actions. Canagliflozin ameliorated adenine-induced CKD in rats, through reduction of several inflammatory and oxidative stress parameters, and other indices of acute toxicity. Moreover, the increase in the renal content of the transcription factor Nrf2. The drug caused no overt or significant untoward effects, and its trial in patients with CKD may be warranted.

2828 The Regulation of Mitochondrial Fusion in Cold Storage Kidney Preservation

A major hurdle in the field of renal transplantation is the shortage of suitable donor kidneys. A large gap remains between graft survival of renal allografts from deceased donors versus living donors. Kidneys from deceased donors...
must undergo cold preservation before transplantation to allow time to find a suitable recipient. Even though cold storage greatly extends the window of opportunity for transplanting kidneys, it also leads to mitochondrial injury impairing overall graft outcome. The goal of this study is to investigate the role of key proteins that regulate the mitochondrial fusion machinery during cold storage injury using an in vitro kidney transplant model. In our studies we show that key mitochondrial proteins (OMA1, YME1L, and OPA1) involved in mitochondrial fusion machinery are impaired after cold storage. Furthermore, we show that OMA1 knockdown combined with cold storage restores OPA1 processing suggesting that OMA1 loss may have a protective effect against cold storage induced mitochondrial injury by restoring normal fusion. We also show that OMA1 sRNA increases in ATP-dependent cell viability during cold storage. Additionally, our lab has developed a novel assay for measuring OMA1 enzymatic activity using fluorescence resonance emission technology. Taken together, this data suggest that OMA1 may be a promising therapeutic target for improving the function of kidneys transplanted after cold storage exposure.

2829 Cytotoxicity, Mitochondrial Function, and Endoplasmic Reticulum (ER) Stress Associated with the Radiocontrast Agent Diatrizoate (DA) in a Human Proximal Tubular Cell Line

D. Ward, K. C. Brown, and M. Valentinovic. Marshall University School of Medicine, Huntington, WV.

Contrast-Induced Acute Kidney Injury (CI-AKI) is the third most common cause of hospital associated kidney damage. Contrast agents are necessary for many diagnostic procedures such as arteriography, venography, and whole body CAT scans. The mechanisms of contrast-induced renal impairment are not entirely known but oxidative stress, diminished renal hemodynamics, and direct cytotoxicity have all been hypothesized. The hypothesis for this study is that diatrizoate (DA) induces direct cytotoxicity to human proximal tubule epithelial (HK-2) cells via oxidative stress, diminished mitochondrial function, and induced endoplasmic reticulum (ER) stress. HK-2 cells were plated for 48 h to equilibrate followed by a 24 h exposure to DA (0-30 mg/mL). All studies were run with a minimum of 3 independent experiments. Viability was measured at the end of the 24 h period using Cell Countess Trypan Blue exclusion and MTT conversion to formazan. Oxidative stress and ER stress were monitored using Western blot analysis for protein expression. Mitochondrial function was monitored using an Agilent Seahorse analyzer. Agilent Seahorse Cell Mito Stress Tests and Cell Glycolysis Stress Tests were performed on HK-2 cells exposed for 24 h to DA. Diminished cell function was evident within 24 h beginning with 2 mg I/mL DA as measured by the MTT assay. Western blot analysis indicated a rise in protein carbonylation as a biomarker of oxidative stress following DA exposure relative to vehicle (p<0.05). Biomarkers for ER stress included a rise in caspase 12 in the DA group relative to vehicle. Basal Oxygen Consumption (OCR) and maximal OCR were diminished by 15 mg I/mL DA relative to control (p<0.05). DA impaired HK-2 cells by inducing a rise in oxidative stress and diminishing mitochondrial function. Supported by NIH INBRE BP20GM10343 and a WV NASA Graduate Fellowship to DW.

2830 Confirmed Biphenyl-Dependent Formation of Calculi Observed in SD Rats Have Been Shown to Initiate Bladder Tumors in Rodents Only

J. Thomas, J. Klappac, B. R. Hannas, C. L. Zablotsyn, W. Faber, S. M. Green, and S. Marty. Dow Chemical Company, Midland, MI; Corteva Agriscience, Newark, DE; WFTC, LLC, Victor, NY; and Eastman Chemical Company, Kingsport, TN.

Biphenyl (BP) is an aromatic chemical used as a synthesis intermediate and in heat transfer fluids. The rich toxicological dataset, with a number of rodent companies, suggests that diatrizoate (DA) induces direct cytotoxicity to human proximal tubule epithelial (HK-2) cells via oxidative stress, diminished mitochondrial function, and induced endoplasmic reticulum (ER) stress. HK-2 cells were plated for 48 h to equilibrate followed by a 24 h exposure to DA (0-30 mg/mL). All studies were run with a minimum of 3 independent experiments. Viability was measured at the end of the 24 h period using Cell Countess Trypan Blue exclusion and MTT conversion to formazan. Oxidative stress and ER stress were monitored using Western blot analysis for protein expression. Mitochondrial function was monitored using an Agilent Seahorse analyzer. Agilent Seahorse Cell Mito Stress Tests and Cell Glycolysis Stress Tests were performed on HK-2 cells exposed for 24 h to DA. Diminished cell function was evident within 24 h beginning with 2 mg I/mL DA as measured by the MTT assay. Western blot analysis indicated a rise in protein carbonylation as a biomarker of oxidative stress following DA exposure relative to vehicle (p<0.05). Biomarkers for ER stress included a rise in caspase 12 in the DA group relative to vehicle. Basal Oxygen Consumption (OCR) and maximal OCR were diminished by 15 mg I/mL DA relative to control (p<0.05). DA impaired HK-2 cells by inducing a rise in oxidative stress and diminishing mitochondrial function. Supported by NIH INBRE BP20GM10343 and a WV NASA Graduate Fellowship to DW.

2831 Effect of 4-Methylpyrazole on Acetaminophen-Induced Hepatotoxicity

H. Orhan, J. Y. Akakpo, A. Ramachandran, and H. Jaeschke. University of Kansas Medical Center, Kansas City, KS.

Acetaminophen (APAP) hepatotoxicity is the leading cause of acute liver failure in the United States, and a significant proportion of APAP overdose patients also develop hepatotoxicity. While mechanisms of APAP-induced liver injury have been well studied, molecular mechanisms involved in APAP-induced kidney injury are not well characterized. We have previously demonstrated that 4-methylpyrazole (4MP), an US FDA approved antidote against methanol and ethylene glycol poisoning, can provide significant protection against APAP-induced liver injury by inhibition of cytochrome P450-mediated generation of the reactive APAP metabolite, N-acetyl-p-benzoquinone imine (NAPQI). To determine the kidney protective effect of 4MP, we used a chemical model of acute kidney injury induced by cytochrome P450, this study explored whether 4MP could also prevent APAP-induced kidney damage and thus have a dual benefit in APAP overdose. Male C57BL/6J mice were treated with 300mg/kg APAP with or without 4MP for 2, 6 or 24h, followed by analysis of APAP metabolites (2h) and cell injury (6 and 24h) within the liver as well as kidney. Western blots for cytochrome P450 2E1, demonstrated comparable enzyme expression in both livers and kidneys, whereas APAP-protein adduct measurement indicated significantly elevated levels in the liver when compared to the kidney. Treatment with 4MP essentially eliminated adduct levels in both organs. Analysis of APAP metabolites at the 2h time point indicated that 4MP inhibited formation of APAP-GSH, APAP-NAC and APAP-Cys in the liver, while APAP-Cys was significantly decreased in the kidney. However, APAP-sulfate levels were increased by 4MP treatment in the kidney. Interestingly, estimation of JNK activation, which is a hallmark of APAP-induced liver injury, indicated no activation in kidney, while the liver showed robust activation, which was inhibited by 4MP as expected. In conclusion, the data suggests that there is appreciable expression of cytochrome P450 in the kidney and some APAP metabolism does occur in the organ. In addition to its effect in the liver, 4MP treatment can also inhibit the oxidative metabolism of APAP in the kidney. However, in contrast to the liver, the signaling mechanism of cell injury in the kidney may be independent of JNK.

2832 Effect of Levosimendan, an Inodilator, on Cisplatin-Induced Nephrotoxicity in Rats

Levosimendan is a positive inotropic agent with vasodilating properties. It increases the sensitivity of troponin C to calcium in cardiac cells, causes vaso-dilation by opening the (ATP)-sensitive potassium channels in smooth muscle cells and possesses anti-inflammatory and antiapoptotic effects. We investigated the effect of levosimendan on cisplatin (CP)-induced nephrotoxicity in rats. Rats were randomly divided into four groups (n = 6). The first and second groups received normal saline (control) and intraperitoneal (i.p.) cisplatin (6 mg/kg) on day 7, respectively. The third and fourth groups were given a single intraperitoneal (i.p.) injection of CP on day 7 and levosimendan (1 mg/kg/day) or vehicle for 10 days, respectively. At day 11, animals were anaesthetized and blood collected and kidneys removed. Another four groups were treated the same as the previous four groups to measure renal blood flow. CP significantly increased plasma urea, creatinine and neutrophil gelatinase-associated lipocalin (NGAL) levels. In addition, CP increased urinary albumin/creatinine ratio, N-Acetyl-β-D-Glucosaminidase (NAG) activity and reduced creatinine clearance. CP also significantly increased the plasma concentration of plasma tumor necrosis factor-α (TNF-α) and significant changes in reduced antioxidant indices (catalase and superoxide dismutase (SOD)) and increased malondialdehyde (MDA) levels. Histopathologically, CP caused remarkable renal damage compared with control. Moreover, CP reduced renal blood flow. Levosimendan significantly ameliorated CP-induced biochemical, histopathological and hemody-
**Analytical Methods Impact Estimates of TCE’s GSH Conjugation and Risk Assessment**

Trichloroethylene (TCE) is enzymatically conjugated with glutathione (GSH) to form S-(1,2-dichlorovinyl)-glutathione (DCVG), which is further metabolized to 5,6-dichloro-1,2-dihydroxyacetylenic (DHA) and dichloroacetylglutathione (DCVC). These GSH conjugates have been implicated in kidney toxicity and kidney cancer in rats from TCE exposure. Studies have reported very different levels of these metabolites in subcellular fractions and tissues, depending on the method used: HPLC-UV (high performance liquid chromatography-ultraviolet) or HPLC-MS (HPLC-mass spectrometry), with values being much higher for the HPLC-UV method. To examine these differences, spiked concentrations of DCVG and DCVC were measured side-by-side in rat and human tissues using HPLC-UV or HPLC-MS/MS (HPLC-Tandem MS). Following derivatization of DCVG and DCVC with dimethyl sulfoxide (DNS), DCVC eluted at the solvent front with the HPLC-UV method and could not be quantified. DNS-DCVG, however, was quantified in rat kidney, heart, and liver, but not in human kidney, heart, or liver. Collagen IV, fibronectin, and PCNA increased in kidneys of 4-week-old and 36-week-old female OVE26 mice, while the protein levels of PCNA increased in kidneys of both male and female OVE26 mice, but the protein levels of p53 were approximately two-fold higher in male OVE26 mice compared to female OVE26 mice. In addition, the mRNA and protein expression levels of apoptosis-related markers were significantly increased from those of individual treatment. To further elucidate the mechanism of combined toxicity in kidney and liver, both quantitative real-time PCR and Western blot were applied to confirm mRNA and protein expression levels of DCVG and DCVC in both kidney and liver. In this study, we investigated the combined toxicity of OTA and AA in the kidney and liver cells. The cell viability with the treatment of OTA and AA was checked to determine the concentration at which the synergistic effect occurs between OTA and AA. The toxicity of the combination of both substances showed synergistic effects regarding cell viability and ROS production. In addition, mRNA and protein expression levels of apoptosis-related markers were significantly increased from those of individual treatment. To further elucidate the mechanism of combined toxicity in kidney and liver, both quantitative real-time PCR and Western blot were applied to confirm mRNA and protein expression levels of DCVG and DCVC in both kidney and liver. The mRNA and protein expression levels of collagen IV, fibronectin, and PCNA were significantly increased from those of individual treatment. To further elucidate the mechanism of combined toxicity in kidney and liver, both quantitative real-time PCR and Western blot were applied to confirm mRNA and protein expression levels of DCVG and DCVC in both kidney and liver. The toxicity of the combination of both substances showed synergistic effects in renal cells.
which are either publicly available (e.g., the NIST/EPA/NIH Mass Spectral Library) or private/custom-built. Further, the action of making a “positive” match of an identity to a detected substance relies on expert judgement, which often incorporates database search software and scoring algorithms. While definitions may be found in USP 1663 for the various levels of confidence in identification (e.g., tentative, confident, and confirmed), such terminology is not uniformly applied and, therefore, open to interpretation. The goal of the current research is to assess the results of identification of untargeted analysis in one testing scenario. Samples of 0.25% ZDBC in PVC and HDPE were extracted at 6 and 12 cm²/mL for 24 h at 37 °C and 50 °C in isopropanol. An Agilent Technologies 7890B GC/MS was used to analyze 1 µL injection volumes of samples, utilizing a DB-5MSUI column, and heating profile of 50 °C (3 mins), then 12 °C/min until 315 °C, followed by a 15 min hold. Analysis was conducted using Agilent MassHunter Unknows Analysis software version B.08.00. Peaks were detected using deconvolution mode and searched in the NIST 1A v17 library with scores adjusted to match the NIST dot product match factor algorithm. Samples were blank subtracted, and then manually curated to remove hits not considered true peaks or that were below the reporting threshold (500 ppb). A 500 ppb mix of seven reference standards was utilized, and the lowest response factor (RF) of the seven was used as the manual RF. Reference standard RFs ranged by 28-fold, indicating high response factor variability. The average number of identification matches within 10 points of the true identity of the reference standards ranged from 1 to 7 and averaged 3.3. Of 36 samples analyzed, 15 contained extractable substances above the reporting threshold, containing an average of 1.6 +/- 0.5 substances at levels of 0.79 +/- 0.13 µg/mL. The average match score for the most abundant substance in a sample was 83 +/- 3 with generally 7 or more alternative identifications within 10 match factor points of the top candidate. These results illustrate a potential for variability in substance identification and will be addressed by additional studies.

2839 Derivation of Short-Term Threshold of Toxicological Concern Values for Extractable Chemicals from Medical Devices

P. Alwin¹, M. Cabonce², V. Haase¹, J. Lyons¹, B. Moeller¹, K. Ohneswere¹, S. Parker¹, and F. Wang¹. WuXi AppTec Inc., St. Paul, MN; and²Fresenius Medical Care, Waltham, MA.

The increased reliance on chemical characterization and risk assessment for assessing the potential toxicological risks from medical devices and materials necessitates the use of Threshold of Toxicological Concern (TTC) values to prioritize the evaluation of extractable chemicals. The TTC approach is based on the concept that chemical structures can define the potential for toxicity, and that common structural features can be used to group substances into various categories of toxicological concern. Current TTC values derived for lifetime exposure are overly conservative when used to evaluate the potential for systemic health hazards associated with limited (<24 hours) and prolonged (>24 hours and <30 days) exposure durations, leading to an overestimation of the relevant risks. To investigate the methodology for short-term TTC derivation, a database for short-term toxicity was produced from extractable chemicals commonly identified in medical devices. Organic chemicals with structural alerts or data suggestive of carcinogenicity were excluded, and systemic effect levels were identified from multiple endpoint subacute, subchronic, and reproductive toxicity studies. Developmental effects were investigated as a separate descriptor. Tolerable intakes (TI) were derived in accordance with ISO 10993-17 and then fit to a distribution curve, from which 5th percentile values were calculated for limited and prolonged exposures. The derived TI values were discordant with the anticipated Cramer classification (ToxTree, Version 3.1.0), and similar thresholds of toxicity were observed for both class I and III chemicals. Variation among the derived TI values for Cramer I chemicals suggests the need for additional refinement of the predicted toxicity for this class. The results overall suggest the ability to integrate structural knowledge of extractable chemicals from medical devices into a threshold evaluation approach to prioritize the evaluation of potential systemic health risks for short-term exposure to these chemicals.

A Case Study: Solvent Extract Analysis as a Way to Bridge Biocompatibility Data for a Material Change

Y. Zhou¹, M. Posga³, D. Malek², and R. Przygoda¹. Johnson & Johnson, Cincinnati, OH; and¹Maleck Toxicology Delaware LLC, Greenville, DE.

ISO 10993 requires test article extracts to be observed pre- and post-extraction for color changes, presence of particulates and test article degradation. It is not uncommon to observe particulates in the extract sample. Current standards (USP 788 and AAMI TIR42) address particulates evaluation associated with intravenous medical device only. US FDA Color Additive (CA) Policy requests supplemental CA information if the extract has particulates. This case study gives an example of a new device biological evaluation when particulates found in extracts. A given device is used for saline (NS) irrigation, and classified as an externally communicating device in contact with tissue, bone and dentin for < 24 hrs. The test article polar (NS) and non-polar (sesame oil) extracts (50°C for 72 hrs) were tested for cytotoxicity (37°C for 24 hrs MEM extract only), sensitization, irritation and acute systemic toxicity per ISO 10993 with acceptable results. However, orange particulates were in all NS extracts (the origin was identified to be from a 303 stainless steel (SS) component), and white particulates were in some sesame oil extracts. Orange particulates were identified by scanning electron microscope to be iron/chromium/oxygen, and were caused by oxidation. White particulates were identified by infrared spectroscopy to be polycarbonate, which was attributed to the sample cutting process. Oxidation was also observed in clinically relevant condition (NS, 37 °C for 12 hrs), which was attributed to the machining process. Agitation options on 303 SS were investigated to improve its corrosion resistance, but was not an effective alternative. A material change from 303 SS to 304 SS was then proposed and evaluated. No oxidation on 304 SS components was observed for the NS extraction up to 72 hrs at 37 °C. No further biocompatibility testing was performed on the finished product following the material change. The US FDA 510(K) was cleared based on the initial biocompatibility testing (303 SS), particulates identification, and corrosion testing of 304 SS in a simulated-use extraction. No CA information was required when the identified particulates were not CA related. This case study indicates using chemical analysis to bridge biocompatibility data for a material change is well accepted by US FDA. It saves time, cost, and animals for device evaluation.

Establishing a Tolerable Intake Level for a Medical Device Extractable Using Methyl Isobutyl Ketone as a Surrogate

M. Boylan, B. Wang, and M. H. Whittaker. ToxServices LLC, Washingon, DC.

As specified in ISO 10993-17:2002, “The determination of the suitability of a medical device for a particular use involves balancing any identified risks with the clinical benefit to the patient associated with its use. Among the risks to be considered are those arising from exposure to leachable substances arising from medical devices.” After tert-butyl isopropyl ketone (TIBK) was detected during extraction testing of a permanent implant, a risk assessment was performed to calculate a tolerable intake (TI). A TI is defined as the estimate of the average daily intake of a substance over a specified time period that is considered to be without appreciable harm to health. As no chemical-specific toxicity data were identified for TIBK, the structurally similar methyl isobutyl ketone (MIKB) was identified as a potential surrogate. ToxMatch calculated a Tanimoto coefficient of 0.9 between the target compound and MIKB, which above the cutoff of 0.6 and indicates that TIBK is structurally similar to MIKB. Therefore, chronic toxicity data on MIKB were used to derive a TI for TIBK. A number of tumors were reported in rats and mice following long-term inhalation exposure to MIKB. The kidney tumors in male rats are likely associated with α2μ-globulin toxicity, and liver neoplasms in male and female mice are likely the result of constitutive androstane receptor (CAR) activation, discounting their use in derivation of a TI for medical device applications. Although a positive trend in the increased incidence of mononuclear cell leukemia in rats was reported following chronic exposure to MIKB, statistical significance was only reached at the highest dose group; this neoplasm is common in mouse control groups, and the strength of response was too weak for NTP to conclude that it was associated with MIKB exposure. Therefore, TIBK was evaluated as a non-carcinogen using a NOAEL of 1,026 mg/m³ that was used to derive the US EPA’s MIKB reference concentration. Using default parameters in ISO 10993-17:2002 for an inhalation rate of 20 m³/day and default body weight of 70 kg, MIKB’s NOAEC, was converted to a solid dose of 293 mg/kg/day. Applying uncertainty factors to account for inter- and intraspecies variability, inhalation to solid dose, and use of a surrogate yields a TI of 2,442 mg/kg/day for TIBK.
2941 Risk Assessment of Leachable Substances from a Drug Coated Balloon Catheter Classified as a Combination Product

A case study is presented for a toxicological risk assessment for a drug coated balloon catheter. The device is classified as a combination product under the US FDA Office of Combination Products as subject to the safety requirements for medical devices (under CDRH) and drug products (under CDER). Due to the complexity of issues that can arise, the overall study design required early coordination among toxicologists, chemists, and US FDA. The device is used in angioplasty, to provide mechanical dilation of arteries, while the drug coating provides an ancillary effect of reducing restenosis. Therefore, the risk assessment evaluated potential exposure to leachables arising from the device as well as impurities/degradation related to the drug component (which is released and absorbed onto the artery walls). An extractables analysis was conducted separately for the drug-coated balloon and the uncoated balloon. Ex Extractions were conducted with purified water, 50% isopropyl alcohol, and hexane at 50K Number 8728C for an exhaustive duration. The total extractable amount of each substance was viewed as an estimate of a one-time exposure. Exposure estimates were compared to a Threshold of Toxicological Concern (TTC), which eliminates substances present below levels of any toxicological concern. Substances above the TTC were compared to a Tolerable Exposure (TE) level derived from repeated dose animal studies. To avoid overly conservative risk estimates, a Proportional Exposure Factor, defined as in ISO 10993-17, was used to modify the TE, considering the differences between chronic and acute exposure. If a TE could not be derived for substances lacking published toxicological studies, exposures were compared to a modified TTC or a Qualification Threshold (QT) for impurities or degradants in drug products. Chemical structure was used to identify potential degradants. In summary, three toxicity thresholds (TTC, TE, and QT) were used to establish safety thresholds for leachable substances, and the benefits derived from therapeutic efficacy were considered when assessing drug product degradants.

2942 Role of Device Extraction Methods in Biocompatibility Assessment. Differential Effects of Latex in the Bacterial and Mammalian Test Systems

Safety assessment of medical devices usually involves collecting the extract per ISO 10993-12 and applying it to in vitro/in vivo test systems. Sometimes, the results are dependent on how the test samples are prepared during extraction as described in the following case studies. A vascular introducer Sheath, when tested for biocompatibility, showed particulates in the extract. So, the extraction procedure was repeated using intact (uncut) devices with no evidence of visible particulates. This shows that during normal clinical use the device is safe in patients and formation of particulates is an experimental artifact. In the second case, a cardiovascular catheter with stainless steel blade was evaluated for PITT. Two samples showed the time to form blood clot was 24% of negative control instead of the US FDA limit of > 80%. Upon further investigation, the failed test samples were found to contain tubing made with natural rubber latex. This latex component is in the proximal non-patient contacting portion of the device and was not supposed to be included in the biocompatibility testing. However, in the interest of patient safety, the catheter was further tested in an in vivo porcine model under simulated clinical use condition, thus confirming the lack of thrombogenic risk to patients. Finally, a nephrostomy catheter showed cytotoxicity test failure. But other in vivo assays such as irritation, sensitization, systemic toxicity and rabbit pyrogenicity have all showed passing data. During genotoxicity testing, both polar/non-polar extracts have passed the Ames bacterial mutagenicity assay. In contrast, there was a significant increase of mutation frequency in mouse lymphoma (L5178Y) cultures treated with RPMI extract in the absence of S9 but not in the presence of S9. A detailed examination of the study revealed that a latex cuff (located outside the patient’s body) was included in the extraction mixture which may have led to the positive mutagenic response. Repeating the mouse lymphoma assay without latex cuff confirmed the mutagenic response is indeed due to the presence of latex. Though the effects of natural rubber latex on cytotoxicity and coagulation are known, this is the first demonstration of the differential effects of latex on genotoxicity parameters. In summary, during biocompatibility assessment it is always better to ensure only patient contacting components are included and if necessary the extraction procedure is conducted under clinically relevant conditions.

2943 Proposal for the Application of Threshold Potency and Severity of Harm When Assessing Toxicological Risk of Non-Cancer Systemic Toxicity of Medical Device Constituents

A. Hood. *US FDA, Silver Spring, MD.*

Toxicological threshold values are numbers derived by toxicological risk assessors to make informed judgments whether exposure to chemicals/compounds will present tolerable toxicological risk. Systemic toxicity threshold values are applied to chemicals/compounds with known or suspected systemic toxicity potential. We investigated whether potency and severity categories of non-cancer medical device chemicals/compounds might be useful when assessing the non-cancer systemic toxicological risk. Toxicological threshold values for medical device chemicals/compounds was obtained from the US EPA IRIS and ECHA Registered Substances databases. The toxicological thresholds were mined for non-cancer systemic oral subchronic/chronic toxicity thresholds. The potency of the selected toxicological thresholds were categorized as low (high potency) or high (low potency) based on the non-cancer threshold of toxicological concern (TTC) values of 1.5 (Cramer Class III) or 30 (Cramer Class I) micrograms per kilogram body weight per day, respectively. Severity of harm categories were defined as low (No observable functional change), intermediate (medical intervention not required), or high (medical intervention could be required). Results of our analysis are the following: (a) 86.6% - 93% of the chemicals have a toxicological threshold >0.03 mg/kg bw/day (Low Potency), (b) 2.1% - 5.4% of the chemicals have a toxicological threshold between 0.0015 and 0.03 mg/kg bw/day (Intermediate Potency), and (c) 9.9% - 8% of the chemicals have a toxicological threshold <0.0015 mg/kg bw/day (High Potency). All of the chemicals/compounds with a high potency toxicological threshold value were inorganics. Toxicological thresholds for organic chemicals/compounds were categorized as low (Cramer Class II) to intermediate (between Cramer Class I and III) potency. There was no difference in the number of Cramer Class I and II low potency organic chemicals/compounds categorized as low or intermediate severity. There were more low potency Cramer Class III chemicals/compounds categorized as high severity. Assigning non-cancer systemic toxicological thresholds into potency and severity categories may be useful for making expert judgments when conducting toxicological risk assessments of medical device chemicals/compounds.

2944 Predicting Exposure and Toxicity to Nickel Released from Cardiovascular Devices Using Multi-scale Modeling

D. Simon, D. Saylor, V. Chandrasekar, S. Skoog, P. Turner, and E. Sussman. *US FDA, Silver Spring, MD.*

Many cardiovascular device alloys contain nickel, which if released in sufficient quantities, can lead to adverse health effects. However, in vivo nickel release from implanted devices and subsequent biodistribution of nickel ions to local tissues and systemic circulation are not well understood. To address this uncertainty, we developed a multi-scale (material, tissue, and system) biokinetic model. The model links nickel release from an implanted cardiovascular device to concentrations in serum and urine, which can be readily monitored, as well as in peri-implant tissue. The model was parameterized for a specific cardiovascular implant type, nitinol septal occluders, using in vitro nickel release test results, studies of ex vivo uptake into heart tissue, and in vivo and clinical measurements from the literature. Our results show that the model accurately predicts nickel concentrations in peri-implant tissue in an animal model and in serum and urine of septal occluder patients. The congruity of the model with these data suggests it may provide useful insight to establish nickel exposure limits and to interpret biomonitoring data. Additionally, we use the model to predict local and systemic nickel exposures during peri-implant device use. We find that nickel release per device surface area does not exceed 0.074 µg/cm² and is less than 32 µg/d in total. Finally, the local nickel exposure predictions can be utilized with in vitro cytotoxicity assessments to characterize cellular responses to expected in vivo concentration.
Biological evaluation of medical devices often includes chemical characterization (as described in ISO 10993-18). Device materials are subject to extraction where by materials, processing additives, residues, as well as material breakdown products may be released. These extractables have potential consequence on the biological response to the device during its use. Chemical characterization studies are followed up by toxicological risk assessments which evaluates potential harm from exposure to the extractables. In some cases, evaluation of material equivalence of similar device materials is required. Following extraction, chemical analysis is performed by various methods, such as GC/MS, FTIR, and LC/UV/MS. Current technology in high resolution mass spectrometry may improve these analyses. This presentation discusses development of improved data analysis methods to probe chemical analysis data from two materials’ equivalency. Two batches of two medical device materials, polyether block amide (commonly known as Pebax) and polypropylene, were analyzed. Multiple rounds of extractions (24 hour at 50°C 200 rpm) were used to obtain non-volatile residue. Test extracts were introduced to different instruments: a GC/MS (7890B/5977B Agilent) and an UHPLC-QTOF-MS system (6540 UHD- Agilent). Amounts of extractables were estimated semi quantitatively by comparing to a set of internal standards. Standards of various polymer additives were prepared and analyzed by LC-PDA-MS system where the UV absorbance and MS data were acquired together. Processed and raw Pebax materials were extracted by water and hexane, the total non-volatile residues on the order of 60 mg/g 5 g sample. GC/MS analysis revealed minor amounts of extractables (less than 20 μg/l 1 g sample). The GC/MS data were also processed for identification of analytes using the 2017 NIST Mass Spectral Library. Preliminary results showed more than 20 compounds tentatively identified. Ongoing work includes the use of Q-TOF MS with greater resolution (~40,000) for unknown identification using a commercial E&L Database. A scoring scheme for binary comparison of the data was utilized using Pearson correlation. The current results indicate Pearson correlation can be used to compare multi-dimensional data in binary steps. However more data mining is needed to ascertain material equivalency.

Materials to Probe Material Equivalency

2University of Montreal, Montreal, QC, Canada. Sponsor: P. Singh

Micro-computed tomography (Micro-CT) represents a non-destructive high-resolution imaging modality in which CT is performed on small samples such as explanted tissues. Typical image resolutions of 1-40μm/voxel can be generated and a three-dimensional (3D) model of the sample can be reconstructed. When applied to implanted medical devices, this technique can contribute to histology and histomorphometry of in vivo samples. It can fully evaluate the safety and performance of the medical device and to provide a full volume analysis rather than only limiting the analysis to the plane of the histology slide. The technology was applied to evaluate the resorption of magnesium implants. Yucatan miniswine coronary arteries implanted with magnesium scaffold were imaged by micro-CT and a thresholds band on density was applied to the images. Those thresholds were compared to specialized histology using Raman and infrared spectroscopy combined with X-ray diffraction analysis. Low-density material was then identified as magnesium hydroxide and high-density as intact magnesium. Volumetric evaluation of these two forms magnesium cage was performed using a commercial E&L Database. A scoring scheme for binary comparison of the data was utilized using Pearson correlation. The current results indicate Pearson correlation can be used to compare multi-dimensional data in binary steps. However more data mining is needed to ascertain material equivalency.

Correlation of Micro-CT Imaging with Histology Sections, an Important Tool for Understanding the Structural Function and Biological Response to Implantable Medical Devices

In Vitro Sensitization Assays for Medical Device Industry per ISO-10993-10: Challenges and Opportunities

B. R. Alzuia, S. Howard, and Y. Chen, American Preclinical Services, Minneapolis, MN.

A challenge in developing in vitro alternatives for sensitization testing is addressing multiple events in the adverse outcome pathway. While a number of approaches have been developed within the last ten years, they have mainly been applied only to chemical test articles. The main challenge in translating these tests to medical devices is the heterogeneity of materials present and the number of controls that need to be applied in the extraction process. To address this disparity, we performed a series of studies to investigate the sensitivity and suitability of in vitro sensitization assays in testing medical device extracts. We assessed methods which could investigate three of the key events in the Adverse Outcome Pathway (AOP) describing skin sensitization. The initiating step involves chemical reactions between sensitizers and skin proteins. The Direct Peptide Reactivity Assay (DPRA) measures the depletion of synthetic peptides when exposed to test chemicals by high performance liquid chromatography. We performed experiments to assess the sensitivity of this method compared to the standard in vivo assay, the Guinea Pig Maximization Test (GPMT), and concluded that the test may be unsuitable to measure sensitizers present at the low concentrations typically found in medical device extracts, underscoring the need to further develop in vitro sensitization assays. We examined the next step of the AOP, the activation of keratinocytes. The Keratinosens test method is a recently developed luciferase-reporter based method. We examined the sensitivity of the Keratinosens method by testing titrations of several previously identified sensitizers, and performed feasibility testing to screen for potential positive and negative controls for extraction. We measured the final key step in the AOP, activation of dendritic cells, using the Human Cell Line Activation Test (hCLAT). This flow cytometry platform detects changes in cell surface marker expression. We determined that concentrations of positive control 2,4-dinitrochlorobenzene (DNCB) nearly 10-times lower than those used in the GPMT could induce a significant positive result. Based on this high sensitivity, we also attempted to determine positive and negative controls for extraction for use with the hCLAT. Overall we have evaluated the relative sensitivity of the three assays, GPMT, DPRA and hCLAT.

In Vitro Sensitization Assays for Medical Device Industry per ISO-10993-10: Challenges and Opportunities

### 2948 Extended Applicability Domain for GARD with Vehicles for Medical Device

Allergic contact dermatitis is induced by certain substances, sensitizers, and the symptoms can severely affect quality of life. To prevent individuals from exposure, chemicals and materials must be safety tested. The biological evaluation of Medical Devices includes skin sensitization assessment (ISO 10993-10:2010) and this commonly involves in vivo assays. However, there is a growing public and economic demand for animal-free models. The GARDTM platform is an in vitro state of the art test developed for the assessment of e.g. skin or respiratory sensitizers. The assay is based on a human myeloid cell line, SenzaCell, and depending on the safety hazard to be assessed, tailor-made gene expression panels are analysed. During the development of GARD, DMSO and water were chosen as standard test item solvents. However, the standard for Medical Device extracts (ISO 10993-12:2012) requires both polar and non-polar extraction vehicles; the latter being a challenge for in vitro assays. In this study it is shown that GARDskin is compatible with both. Initially, the compatibility of GARDskin with saline (0.9% NaCl), G-Biosciences and five selected oils, used as extraction vehicles, was assessed. Saline, Super Refined Sesame Oil (CRODA) and Sesame Oil (Acros organics) did not induce cytotoxicity while two other oils, Highly Refined Sesame Oil (CRODA), Super Refined Olive Oil (CRODA) and Sesame Oil (Acros organics) did not induce cytotoxicity while two other oils, Highly Refined Olive Oil (Sigma) and Ph Eur Olive Oil (Sigma), did. Subsequently, the GARDskin prediction signature (GPS) was analysed for the non-cytotoxic extraction vehicles. The GPS result did not predict sensitization for saline and Super Refined Olive Oil, while the results for Super Refined Sesame Oil showed a minor sensitization signal and Sesame Oil resulted in a major signal. The GARDskin prediction signature is a useful method which detects changes in cell surface marker expression. We determined that concentrations of positive control 2,4-dinitrochlorobenzene (DNCB) nearly 10-times lower than those used in the GPMT could induce a significant positive result. Based on this high sensitivity, we also attempted to determine positive and negative controls for extraction for use with the hCLAT. Overall we have evaluated the relative sensitivity of the three assays, GPMT, DPRA and hCLAT.
to detect sensitizing leachables from spiked materials in both polar (saline) and non-polar (Super Refined Olive Oil) extraction vehicles. This broadens the applicability for GARDskin to include Medical Device testing.

**2949 Alternative Tests to Replace Ocular Irritation Animal Test in Medical Device Using Reconstructed Human Corneal Epithelium**

S. Yang1, J. Kwon1, J. Ryu2, C. Pelleveoisin3, K. Lim3, B. Kim4, I. Kim5, and K. Kim1. 1Yonsei University College of Dentistry, Seoul, Korea, Republic of; 2EPISKIN, Lyon, France; 3Ewha Womans University, Seoul, Korea, Republic of; 4Keimyung University, Daegu, Korea, Republic of; and 5Korea Testing and Research Institute, Jeollanamdo, Korea, Republic of.

The alternative methods to ocular irritation animal test in medical devices were evaluated using irritant and non-irritant polymer samples with an in vitro eye irritation test using three dimensionally reconstructed human corneal epithelium (SkinEthic HCE) models produced by EPISKIN. The results were compared with the in vivo rabbit Draize eye irritation test, as well as other alternative test to animal study, the BCOP. Test samples were prepared in polymer form to mimic the state of the medical devices. The 5 irritant polymer samples were examined which were Genapol X-80 in PVC, 15% SDS in silicone, 4% Genapol X-100 in PVC, 25% Heptanoic Acid in silicone and 0.75% ZDEC Polyurethane that contained irritant chemicals in the form of solid polymer. The 3 non-irritant polymers were used which were Silicone Cured Rubber, Elasthane 80A and High Density Polyethylene (HDPE). All the test samples were extracted using polar (saline) and non-polar (sesame oil) vehicles. Extracts of irritant polymer samples were subsequently analysed by ICP-OES and LC-MS. As a result, SkinEthic HCE models yielded a consistent decision for irritant and non-irritant extracts. The results were similar in BCOP, with the exception of non-polar extracts of Genapol X-80 in PVC and polar extracts of 25% Heptanoic Acid in silicone in BCOP, for which no prediction could be made. Also, all the test samples' extracts were non-irritant results in the in vivo test. The analyses of polar extracts of 15% SDS in silicone and 4% Genapol X-100 in PVC showed that the concentration of irritant chemicals were 54.626 mg/l and 196.16 mg/l, respectively. Consequently, these observations suggest that the human corneal epithelium (SkinEthic HCE) could be considered as alternative tests to replace ocular irritation animal test in medical devices.

**2950 Development and Validation of a RHE Model with Impaired Barrier Function to Assess Class IIIb Medical Device Biocompatibility**

S. Balzaretti, L. Ceriotti, F. Carriero, and M. Meloni. VitroScreen, Milan, Italy. Sponsor: E. Dufour

Medical devices (MD) composed of substances belong to a large heterogeneity of products intended by the manufacturer to be used, alone or in combination, for specific human medical purposes and which do not achieve their principal intended action by pharmacological, immunological or metabolic mechanical means. The EU Medical Device Regulation n. 2017/745 (MDR) indicates that the physical and functional properties of the skin barrier are discriminating factors for MD classification: MD applied to intact skin are classified as IIIa while MD that come into contact with injured skin or mucous membranes are IIIb. In order to address the biocompatibility of substance based MD that are intended to come into contact with injured skin (IIIb), a reproducible epidermal injured model with impaired barrier function has been developed by using a commercially available and standardized reconstructed human epidermis model (RHE, EpiSkin Lyon). The injured model has been induced by a mechanical abrasion targeting the epidermal physical barrier, the stratum corneum (SC) and the tight junctions (TJs) associated to granular layer without involving deeper epidermal structures. The model presents an impaired barrier function at the moment of MD application even so in a context of tissue homeostasis. A multiple endpoint analysis (MEA) approach has been adopted to characterize the injured model at 1h and 24h from injury. The results in presence of negative and positive controls (saline solution, Sodium Lauril Sulfate and Lactic Acid) have shown that the cellular viability quantified by MTT was not affected; on the contrary, the injured RHE model has shown an increased permeability to caffeine during the first hour and the impairment of TJs with significant reduction of TEER (Trans-Epithelial-Electrical-Resistance) values. The most interesting result to confirm the impairment of the barrier after 1h and up to the final readout of 24h has been the biotin assay that has shown an increase of biotin quantified by immunofluorescent detection related to the increased barrier permeability also confirmed by H&E staining. The reproducibility of the results has been assessed in n=6 different batches of the RHE model suggesting the interest of the use of this RHE model with impaired barrier function to assess the irritation potential of MD or derma-pharmaceutical products on fragile skin with impaired barrier function. The model seems a robust and predictive tool to assess the biocompatibility of Class IIIb MD taking into account the classification requirements of the MDR.

**2951 Assessment of Thrombogenicity of the CardioGard Gen2 Emboli Protection Cannula in a Fully Anti-coagulated Swine Cardiopulmonary Bypass Model**

J. Heitke1, D. Post2, Y. Chen3, T. van Valkenburg4, M. Beckel5, and M. F. Smith1. 1American Preclinical Services, Minneapolis, MN; and 2Cardiogard, Medford, MA.

Thrombogenicity testing for blood contacting medical devices is required by ISO 10993-4 for regulatory approval. Issues arise when devices are complex in design; not simple catheters suitable for intravenous (IV) deployment. There is also a desire to assess device thrombogenicity in models that mimic clinical use. We designed an in vivo thrombogenicity assay for a dual lumen aortic cannula, the CardioGard Emboli Protection Cannula-Gen 2, a device specifically designed for use in cardiopulmonary bypass. The device is intended for use only with clinically relevant anticoagulation and is not amenable to IV deployment in either standard in vivo models or in vitro blood loop designs. Differential blood flow rates through the dual lumens of the cannula is a feature in the clinical use of the device and were also deemed critical when simulating clinical use. As a result, we deployed the device in the aorta of three swine on cardiopulmonary bypass for 6 hours with anticoagulation and ACT management and then assessed acute thrombogenicity. After thoracotomy, each animal was placed on cardiopulmonary bypass using the CardioGard as the arterial supply cannula. Once each animal was successfully implanted, the heart was arrested and bypass was maintained for 6 hours with a flow rate of 5 L/min outlet and 1 L/min inlet. Heparin was administered throughout the study to maintain ACT between 400 and 600 seconds. Complete blood counts, and coagulation parameters were also monitored. At the conclusion of the bypass duration, the animals were euthanized and the devices were removed for visual scoring of surface thrombus. Semi-quantitative thrombus assessment was performed by visual inspection of the CardioGard cannula and a lumen of the aorta of ascending aorta. The CardioGard return line filter was also visually assessed for thrombus deposition. All evaluated device surfaces and filters had no formed thrombus and scored “0” for thrombogenicity (no visible surface thrombus deposition). All device surfaces that were visually assessed for thrombus formation had no deposition evident. There was also no evidence of thromboembolism in the brain, kidneys and liver when examined grossly. Overall this study demonstrated the capability of a complex surgical procedure to suitably evaluate the potential thrombogenicity of an extravascular blood contacting device in a manner consistent with clinical practices and compliant with ISO 10993-4 for regulatory review and approval.

**2952 Investigation of Neonatal IPA Exposure from IPA-Filled Caps Used to Disinfect Luer Valves**

H. Shin, B. Oktem, and A. Hood. US FDA, Silver Spring, MD.

IPA-disinfection cap products are commonly used in neonatal intensive care units (NICUs) and exempted from US regulatory approval. Sauron et al. (2015) reported isopropyl alcohol (IPA) filled caps used to disinfect luer valves can potentially result in excessive IPA exposure (i.e. intravenous) to neonatal patients. Sauron et al. (2015) simulated the worst-case clinical use conditions of commercially available IPA-filled disinfection caps and needle-free luer valves and reported (a) luer valves (normally clear) become opaque after simulated use with IPA-filled disinfection caps and (b) newborns/neonates are at risk of exposure to potentially harmful levels of IPA from the disinfection caps. After review of the general scientific and toxicological merit of the Sauron et al. (2015) report, we concluded the reported level of IPA is not small; however, inadequacies of the reported analytical and toxicological risk assessment methods limits further consideration. We conducted investigations on the impact of IPA-filled disinfection caps on needle-free luer valves and observed (a) luer valves (originally clear) become cloudy within 24-hours of contact with IPA solution or IPA-filled disinfection caps and (b) needle-free luer valve seal integrity became compromised based on an air leak test. These preliminary findings support a potential interaction between the IPA in the IPA-filled disinfection cap and the needle-free luer valve. Further investigation is required to understand potential IPA exposure to neonates in NICUs from the use of commercially available IPA-filled disinfection caps and luer valve combinations. Reference: Sauron et al. (2015) Using isopropyl alcohol impregnated disinfection caps in the neonatal intensive care unit can cause isopropyl alcohol toxicity. Acta Paediatr 104, e489–e493.
2953 Synergistic Toxicity of a Dental Monomer and Nicotine

J. Samuelsen1, T. Tanner2, S. Usvlok1, H. V. Rukke1, and R. Becher1,3.
1NIOM, Oslo, Norway; 2University of Oulu, Oulu, Finland; and 3NIPH, Oslo, Norway.

Tobacco products as well as nicotine containing replacements contain relatively high levels of nicotine. Research investigating the toxic potential of nicotine has to a large extent focused on interaction with nicotinic cholinergic receptors. Recent studies, however, indicate that nicotine interact with autophagy. The latter could be due to the reported lysosomotropic property of nicotine that may impair lysosome function. The monomer 2-hydroxyethyl methacrylate (HEMA) is one of the major components of many resin-based restorative materials and dental patients are exposed during and after treatment. HEMA has a cytotoxic potential in vitro, and studies suggest that cells adapt to HEMA exposure by increasing the autophagic capacity. The aim of this study was to compare the isolated and combined exposure to HEMA and nicotine on cell viability. As HEMA seems to rely on protection through autophagy and nicotine may impair this pathway, combined exposure could result in synergistic toxicity. A human oral squamous carcinoma cell line PE/CA-PJ49 was exposed to HEMA (0-2 mM) and nicotine (0-10 mM). The cell viability was measured by MTT assay. Western blotting was used to quantify the autophagy related protein p62/SQSTM1 (p62), a protein that is degraded during autophagy. During increased requirement for autophagic flux, p62 synthesis increases. Exposure to nicotine or 2 mM HEMA for 24 h had no measurable effect on cell viability. In contrast, combined exposure to 2 mM HEMA and nicotine reduced the cell viability to less than 50% of control. Cells exposed to nicotine for 16 h showed significant increased p62 level. This level increased further when cells were exposed to both nicotine and 2 mM HEMA. HEMA alone, however, had no measurable effect on the p62 level. In summary, our results show that combined exposure to HEMA and nicotine cause synergistic toxicity. The effect of HEMA and nicotine on p62 further support that this effect is caused by the hypothesized effects on autophagic flux. Increased autophagy caused by HEMA may not affect the level of p62 as both synthesis and degradation increase. Combined exposure to HEMA and nicotine will increase p62 synthesis and block degradation, resulting in higher p62 levels than nicotine alone. Simultaneously, the presence of damaged cellular molecules may explain the increased toxicity. Our results suggest that combined exposure to nicotine and HEMA result in synergistic toxicity and that inhibition of autophagic flux by nicotine is a key event causing this synergy.

2954 Chemical Characterization of Acrylonitrile Butadiene Strene 3D Printed Medical Devices

K. Naher, E. Sussman, B. Oktem, and S. Wickramasekara. US FDA, Silver Spring, MD. Sponsor: P. Goering

Additive manufacturing, otherwise known as 3D printing, research has become exceedingly popular in the recent years. According to a recent Reuters news report, 3D printing has provided a new avenue for medical application-based anatomic surgical models and medical devices. While 3D printing is becoming relevant in medical devices, a variety of factors can affect the biocompatibility of a medical device. Chemical characterization of medical device extractables by mass spectrometric techniques has emerged as a more selective alternative to traditional biocompatibility testing of medical devices, which utilizes biological test systems. We investigated the extractables profile of two specific Acrylonitrile Butadiene Strene (ABS) feedstocks. These feedstocks were then 3D printed into casts. The aim was to determine whether the extractables profile would be altered by 3D printing and thereby potentially affect the biocompatibility. Forearm casts were manufactured from biocompatible Stratasys-M30i and commercial PushPlastic filaments by Fused Filament Fabrication (FFF). Materials tested included the filaments prior to printing, a 3D printed cast for each filament, and a post processed 3D printed cast made from the PushPlastic filament. Sample extraction was performed with 3 different solvents (water, isoproply alcohol and hexane) at 50°C for 24h with gentle agitation. The solvent 7890B GC/MS was used to determine volatile/semi-volatile extractables with NIST 2017 spectral database for compound identification. GC/MS analyses tentatively identified over 60 extractables in isopropanol and hexane extracts of all materials, including extractables such as acetonphenone, and styrene-acrylonitile (SAN) trimers. No water soluble extractables were found by GC/MS. Prints made of M30i filament showed fewer unique identified extractables than the prints made of PushPlastic filament based on the volatile extractables from hexane and isopropanol extractions. Further, the finished PushPlastic 3D print contained fewer identified compounds than the unfinished PushPlastic 3D print. This analysis determined that the printing process utilized herein either introduces new compounds or makes otherwise unextractable analytes available. Ongoing work includes rapid analysis of extractables and leachables by DART-MS, as well as performing a toxicological risk assessment on the identified extractables.

2955 Aerosol Dispersion Measurement of Lung Mixing Volume

M. McCawley, T. Petitte, R. Sangani, and S. Hadique. West Virginia University, Morgantown, WV.

Delivery of aerosolized medication to the lung assumes a mixing volume based on simple measures of inhaled volume. However, using a Chemical Engineering approach for evaluating stirred reactor vessels, it is possible to measure the actual volume involved in the mixing of an aerosol bolus. In theory, the actual volume should inform delivery of aerosolized medication to better calculate dose and, the dose of aerosolized medication should penetrate into the lung to a volume equivalent to the inhaled volume. However, in the case of airway obstruction it is not uncommon to supplement aerosol delivery with Heliox to achieve greater penetration into partially obstructed areas. Thus, a measure of penetration might, additionally, quantitatively inform treatment by providing a measure of penetration. Physician-scheduled pulmonary function testing were offered the opportunity through informed consent to perform aerosol dispersion testing. A patient breathed a $0.7\mu$m corn oil aerosol in a 50 ml bolus to a depth of approximately 400 ml into the patient's lungs. Concentration and volume data were fit to a previously tested sequential series stirred reactor vessel equation. The solution to the equation provided two parameters defined as the equivalent mixing volume and as the mixing coefficient or Peclut number. The ratio of the two parameters can also be used to delineate asthmatic subjects from asymptomatic subjects ($p<0.05$). Asthmatic patients displayed a range of equivalent mixing volume values between 25 and 100% of the one liter tidal volume. Those with the lowest percent predicted values for spirometry as seen in subjects with fixed airflow obstruction, were also the most likely to have lower equivalent mixing volumes. In patients with COPD the equivalent mixing volume appeared to be greater than 150% of that predicted by the actual inhalation volume due to increased airways’ time constants resulting in longer emptying times. Previous work with smoking subjects and current work with patients with COPD and asthma reveal different trends in the change of equivalent mixing volume with worsening symptoms. As a general trend, the equivalent mixing volume appears to increase as obstructive airways’ time constants increase with asthma. Therefore, equivalent mixing volume may also be used to differentiate between asthma and COPD. This indicates that there is a need for methods to evaluate increased penetration of nebulized medication in patients with obstructive airway lung diseases.
Bioabsorbable polymers such as poly(lactic acid), poly(glycolic acid), and poly(lactic-co-glycolic acid) are widely used in medical devices. Although lactic acid and glycolic acid, the final degradation products, are biological compounds found naturally in the human body, high concentrations in the local microenvironment may result in adverse biological effects. The goal of this study was to evaluate the effects of different concentrations of lactic acid and glycolic acid as well as changes in pH on cellular responses and hemocompatibility. Human coronary artery endothelial cells (HCAECs) were exposed to different concentrations of lactic acid and glycolic acid (0.25 mg/mL to 5 mg/mL). Cellular responses were evaluated using the MTT assay (viability), the DCFDA reactive oxygen species assay, and morphological assessment. Hemocompatibility was evaluated using in vitro assays for hemolysis, coagulation cascade activation, and platelet aggregation. After hemolysis testing, polymer degradants were exposed to human whole blood (5 U/mL heparin) diluted to a hemoglobin concentration of 125 mg/dL, with PBS and evaluated using red blood cell counts from an automated cell counter. For coagulation cascade activation, pooled human plasma was treated and assessed using the activated partial thromboplastin time assay. Finally, platelet aggregation and platelet activation were analyzed after exposure of human platelet rich plasma (200K platelets/μL; 1 U/mL heparin) to lactic acid and glycolic acid. Platelet aggregation was analyzed by platelet count using an automated cell counter. For platelet activation, the expression of P-selectin (CD62P) was investigated using flow cytometry. HCAECs exhibited significant cytotoxicity (<70% viability) after exposure to 1.25 mg/mL glycolic acid and 1.75 mg/mL lactic acid. No significant increase in ROS was observed at any concentration. Adverse blood responses including hemolysis, platelet activation, platelet aggregation, and coagulation were also observed after treatment with certain concentrations of lactic acid and glycolic acid. These results suggest that high concentrations of polymer degradants in the local microenvironment may result in adverse biological responses.
2962 Predictive Capacity of Vitrigel-EIT (Eye Irritation Test) Method

H. Yamaguchi1,2, H. Kojima3, and T. Takezawa4. 1National Agriculture and Food Research Organization, Tsukuba, Japan; 2Kanto Chemical Co., Inc., Isehara, Japan; and 3National Institute of Health Sciences, Kawasaki, Japan.

Background: The Vitrigel-EIT method is an in vitro eye irritation assay using a human corneal epithelium model fabricated in a collagen vitrigel membrane (CVM) chamber. Widespread eye irritancy of chemicals is predicted by analyzing the time-dependent changes of trans-epithelial electrical resistance (TEER) values for 3 minutes after exposing chemicals to the culture models. In this study, we aimed to define the applicability domain of the Vitrigel-EIT method by testing a total of 114 chemicals. Also, we estimated the predictive capacity of the test method under the applicability domains. Methods: The eye irritant potential of test chemicals was judged by the Vitrigel-EIT method as irritant or non-irritant, and subsequently the correlation with GHS classification was evaluated. Also, the applicability domain of Vitrigel-EIT method was defined by investigating the physicochemical properties of false-negative chemicals. Results: Discussion: The classification by the Vitrigel-EIT method was in accordance with the GHS categories on 85 test chemicals in the total of 114 chemicals, indicating the accuracy of 74.6%. Meanwhile, eight chemicals were predicted as false-negatives, indicating the false-negative rate of 12.9%. In addition, 21 chemicals were predicted as false-positives, indicating the false-positive rate of 40.4%. Six of the eight false-negative chemicals were acidic, and one of the two non-acidic false-negative chemicals was a water-insoluble solid easily separated from a culture medium. Therefore, we concluded that chemicals with a logP value of 2.5 or more and a density of either less than 0.95 g/cm³ or over 1.10 g/cm³ from the original 114 chemicals. Under the applicability domain, false-negative positive rates were respectively 20.0%, 39.2%, and 79.4%, respectively. These results suggest that the eye irritant potential of chemicals was accurately judged by incorporating the applicability domain into Vitrigel-EIT method.

2963 Implementation of In Vitro Eye Irritation Test Method Using SkinEthic HCE and Between-Laboratory Reproducibility Evaluation in China

N. Li1, Y. Yang2, G. He3, Y. Liu4, P. Wu5, J. Wu6, Q. Qin7, and Z. Cai8. 1L’Oréal Research & Innovation, Shanghai, China; and 2Guangdong Province Center for Disease Control and Prevention, Guangzhou, China. Sponsor: E. DuFour

SkinEthicTM reconstructed human corneal epithelium (HCE) in vitro eye irritation test method was adopted by OECD as one of Validated Reference Methods (VRMs). In 2017, following the adoption and commercialization of SkinEthicTM HCE model in China in 2018, the present study was aimed to implement SkinEthicTM (HCE) in vitro eye irritation test method in China according to TG 492. In phase I, 11 chemicals (including one reference chemical from TG 492) as training set was assessed by two operators in each laboratory (Number 1: 100% positive rate and accuracy of 12.3%, Number 2: 20% positive rate and 30% accuracy). In phase II, remaining 14 reference chemicals from TG 492) as training set was assessed by two operators in each laboratory. In phase I, 11 chemicals performed by two operators in each laboratory obtained high within-lab reproducibility, showing Number 1: 100% sensitivity and 86.5% (36.3/42) accuracy. In conclusion, SkinEthicTM HCE in vitro eye irritation test method was successfully transferred in China using the model produced in this country, showing high predictivity and good within-lab reproducibility. The current study provides solid scientific and technical foundation to enable the implementation of in vitro eye irritation test, also further supports and promotes application of alternative methods in China.

2964 Comparing Therapies to Reduce Ocular Sulfur Mustard-Induced Injuries

D. Durante1, R. Hahn2, P. Zhou3, and M. Gordon4. 1Pennsylvania State University, University Park, PA; and 2Ernest Mario School of Pharmacy, Piscataway, NJ.

Sulfur mustard, a chemical weapon used in World War I, the Iraq-Iran War, and in the 2015 Syrian conflict, is a vesicant that injures the eyes, lungs and skin. Ocular exposure leads to corneal microblistering, ulceration, and possibly loss of the corneal epithelium from its stroma, neovascularization, scarring, and a long term possibility of developing dry eye disease. Separation of the corneal epithelium from its stroma can cause a loss of vision. No drugs are as yet US FDA approved for ocular mustard injury. Here two US FDA-approved drugs for other ocular injuries, oxetertacycline and Restasis, were tested as therapies for ocular mustard injury. Used on unjured corneal organ cultures these drugs showed no adverse effects. Other corneal organ cultures were exposed to nitrogen mustard (NM) for 2 hr, followed by recovery for 22 hr. During the 22 hr recovery, some corneas received no therapy, others received Restasis (one drop every 12 hr), and others received oxetertacycline treatments 3 times in 24 hr by preparing a solution where 40 µL delivered 0.2 mg oxetertacycline. After the exposures and treatments, corneas were collected and sectioned to examine the histology of the microscopic injury. The images with either drug showed a reduction in NM-induced ocular damage compared to eyes receiving no drug after exposure, as assessed by the degree of epithelial-stromal separation. These data supported further testing of the therapies on in vivo rabbit ocular organ cultures using sulfur mustard (SM). The same ocular tests were performed at 24 hr after a 2 hr SM exposure. Restasis was applied every 12 hours, as was done in the organ cultures, but the in vivo oxetertacycline experiment included only 2 applications per day rather than 3. Both the histology of organ cultured corneas and in vivo exposed corneas indicated that Restasis was more effective for attenuating ocular injury from NM and SM. Future work includes adding an antiangiogenic to Restasis to see if this reduces neovascularization.

2965 Regulators of Toxicant-Induced Cornea Epithelial Injury Identified by High-Throughput siRNA Screening

Some toxicant exposures to the eye produce a transient injury, while others produce delayed and progressive corneal injury which compromises vision. These injuries often share similar clinical features such as corneal ulceration, opacity, and neovascularization. Studies have shown that there may be some common cellular and molecular mechanisms that drive these delayed progressive clinical features. Although some of these mechanisms have been described, they are not fully understood even for high risk ocular toxicants. In cases where there are common mechanisms for delayed injuries, chemicals with different toxicological properties are likely to elicit different molecular responses early after exposure. It is important to understand these responses as they may present opportunities for early intervention. We have performed siRNA high throughput screening (HTS) in an effort to understand the molecular mechanisms of toxicant-induced corneal injury. We selected hydrogen fluoride (HF) and chloropicrin (CP) for study by cross-referencing Chemical Terrorism Risk Assessment list agents with the ToxNet reports of industrial accidents to find chemicals that present the greatest risk of ocular injury via vapor exposure. Two immortalized human corneal epithelial cell lines were used for study: SV40 immortalized corneal epithelial cells and telomerase immortalized corneal epithelial cells. Microarray data from HF- and CP-injured mouse corneas were mined and used to select 3120 targets from preconfigured Dracmacon Human Drugable siGENOME SMARTpool libraries. The endpoints assessed for HTS were IL-8 levels in cell culture medium and cell viability. Targets were down-selected into validation studies which utilized phenotype restoration and endpoints such as multiplex cytokine analysis and high content analysis to understand toxicant effect and target function. The list of validated siRNA targets that regulate HF- and CP-exposed cell viability and IL-8 production includes molecules such as transcriptional regulators, kinases, phosphatases, solute carriers, and metabolic proteins just to name a few. However, our results show that there is little to no similarity in the molecular responses to these two toxicants. These findings suggest that some early interventions for toxicant ocular injury may need to be toxicant-specific.
Distinctive Roles of NURR1 in Modulating Inflammation, Autophagy and Cell Migration in Human Retinal Pigment Epithelial Cells

P. Yao, and G. Malek, Duke University, Durham, NC.

Age-related macular degeneration (AMD) is the leading cause of vision loss in the elderly, occurring due to degeneration and/or dysfunction of the retina and supporting retinal pigment epithelium (RPE). Though multi-factorial, in which genetic and environmental factors play a role, epidemiological studies indicate that the two established risk factors for AMD are aging and cigarette smoking. Phenotypically, it is characterized by accumulation of lipid- and protein-rich extracellular deposits below the RPE and degeneration of the photoreceptors. These degenerative changes are thought to be due to a lack of autophagy, a process of recycling intracellular components, and 50% of patients with neovascular AMD are treated with anti-vascular endothelial growth factor (VEGF) agents. Therefore, therapies that could induce autophagy as a means to clear toxic deposits and protect RPE cells may be of therapeutic benefit.

NURR1 is a nuclear receptor that is a transcription factor and has a crucial role in maintaining the function of the RPE, which is a single layer of cells that serves as the barrier between blood vessels and the photoreceptors in the retina. NURR1 is known to regulate the expression of several genes involved in autophagy and is recently studied to be a potential therapeutic target for AMD.

In this study, we characterized the role of NURR1 in autophagy and cell migration in human RPE cells. Using a novel small molecule CSE, we observed a dose-dependent increase in intracellular NURR1 expression and autophagy, as measured by increased LC3-II expression and increased RPE cell migration in human RPE cells. These observations suggest that NURR1 may be a viable target to improve the health of RPE cells. In support of this, we found that over-expression and/or ligand activation of NURR1 increased intracellular expression of pro-inflammatory cytokines including interleukin-6 and monocyte chemotactic protein-1 in normal human RPE cells, regardless of age. CSE induced NURR1 expression and activity in human RPE cells as evidenced by qPCR, western blots and NURR1-luciferase reporter activity assays. This activation was more pronounced in RPE cells isolated from aged donors, implicating that aged RPE cells expressing less NURR1 are more susceptible to environmental stimuli. CSE also enhanced LC3-II expression in human RPE cells, indicative of induced autophagy. Ligand activation of NURR1 modulated LC3-II expression in human RPE cells, suggesting the involvement of NURR1 in autophagy. Finally, while ligand activation of NURR1 inhibited cell migration in human RPE cells as assessed in wound-healing assays, over-expression of NURR1 attenuated TNFα-induced migration in human RPE cells. Combined, these novel observations demonstrate that the relative expression level of NURR1 is critical for the autophagic and migratory functions of human RPE cells. The inhibitory effect of activating or over-expressing NURR1 on modulating migration in human RPE cells implicates a potential therapeutic application for AMD patients.

Ocular Toxicity Associated with a Structurally Related PI3Kβ Selective Inhibitor

F. Arjmand1, A. Tomkinson1, S. Perreault1, P. Thomford2, J. Detert2, P. Miller2, J. Ver Hoeve3, P. Miller3, and L. Burns-Naas4. 1Gilead Sciences, Inc, Foster City, CA, 2Covance, Madison, WI, and 4OSOD, Madison, WI.

The toxicology profile of a novel candidate phosphoinositide-3 kinase beta (PI3Kβ) selective inhibitor, C-377C, was evaluated in a 7 day repeat dose dog study. In addition to routine ophthalmic exams, detailed ocular assessments of electroretinography (ERG) and optical coherence tomography (OCT) were included based on the microscopic finding of retinal degeneration observed in a previous study with a structurally related compound. Male beagle dogs (3/group) were dosed daily with C-377C at 0 (vehicle), 10, 40 and 100 mg/kg/day. Based on poor tolerability, high dose animals were euthanized after the second dose on Day 2. Dosing was suspended in the 40 mg/kg/day group on Day 4, and resumed on Day 5 at 30 mg/kg/day. Ocular toxicity, characterized by both structural and functional effects, was present at the low and mid dose levels and was considered likely irreversible. Clinical observations indicated decreased response to visual stimuli, dilated pupils, red conjunctiva and ocular discharge in all animals beginning on Day 4 through the end of the study. Ophthalmic evaluations, ERG and OCT were conducted pre-dose and on Day 6. ERG assessment following dark-adaptation indicated that all dogs in the 10 and 40/30 mg/kg/day groups had no response to single light flashes of 0.01, 0.06, or 2.5cd/s.m-2. Ophthalmic evaluation (slit lamp biomicroscopy/indirect ophthalmoscopy) revealed decreased tapetum in 2/3 dogs at 10 mg/kg/day with complete loss of tapetum in 3/3 dogs and retinal detachment in 2/3 dogs at 40/30 mg/kg/day. OCT imaging confirmed the tapetal changes and retinal detachment. Additional effects noted with OCT included photoreceptor layers appearing as an indistinct single hyper-reflective band and swelling of the optic nerve in the 10 and 40/30 mg/kg/day administration group. No change was reported to be synchronized with circadian rhythms and peak at 2 hr after light onset. In our previous experiment, UNC569, a specific MerTK inhibitor, induced morphological changes in the RPE and photoreceptor cells in the retina in mice. To investigate the influence of dosing time on UNC569-induced retinal toxicity, UNC569 at 100 mg/kg was orally administrated to male mice at Zeitgeber time (ZT; the time of the biological clock in 12/12-hour light-dark cycle where the start time of the light and dark cycle is ZT 0 and ZT12, respectively) 5.5 or ZT22 for 28 days. Electron microscopy was conducted at ZT22 after the final dosing. Additionally, the visual cycle components (11-cis-retinol, 11-cis-retinal, all-trans-retinal, and all-trans-retinol) which play an important role in maintaining retinal homeostasis were quantified by LC/MS/MS. As results, ultrastructurally, the number of phagosomes and phagolysosomes in the RPE increased in both ZT5.5 and ZT22 administration groups, while endoplasmic reticulum dilatation of RPE and chromatin aggregation of photoreceptor nuclei were observed in the retina administered with the drugs. This study was performed in all the components of the visual cycle, indicating that the involvement of the visual cycle on the changes might be low. The present result suggested that the lesion was deteriorated by the absence of physiological MerTK phosphorylation started at ZT2, resulting in severer changes in the ZT22 group.

Evaluation of AAV-Based Gene Delivery to Retinal Cells in Histological Sections in Animal Toxicity Studies

G. Bondarenko, S. D. Sorden, B. J. Christian, S. Webster, and A. Sharma. Covance Inc, Madison, WI.

Gene transfer with adeno-associated virus (AAV) vectors is extensively used for retinal gene therapy applications in preclinical studies and clinical trials due to prolonged expression, low immunogenicity, and established record of safety and efficacy. To allow the direct visualization of vector trafficking and protein localization in transduced cells, green fluorescent protein (GFP) is widely used as a gene expression reporter and a molecular and cellular tag. Previously we have demonstrated the efficacy of multiple methods of GFP detection in histological sections. The purpose of this study was to investigate and establish reliable and reproducible methods for evaluation of GFP expression and to analyze AAV trafficking through tissue biodistribution of gene transduction, protein synthesis and secretion, in an experimental ocular toxicity study. Female C57BL/6NTac mice were administered a commercially available AAV vector containing a gene for GFP (AAV2-GFP) via subretinal injection in the eye. Group 2 animals also received anti-inflammatory therapy to investigate effects of ocular inflammation on the efficiency of vector transduction in different retinal cell types. Animals were euthanized 43 days following injection. Histological sections of formalin-fixed paraffin-embedded eyes were examined microscopically. Detection of GFP reporter was performed on serial sections by immunohistochemistry (IHC) and RNA in situ hybridization (ISH). IHC and ISH staining were evaluated using H-score and a modified RNAscore® scoring system respectively. Commercially available tissue and cell lines stably expressing GFP were used as controls and to evaluate the specificity and sensitivity of the methods. Microscopic findings in both groups were attributed to the subretinal dosing procedure. IHC for GFP revealed negative to minimal labeling in inner and outer nuclear layers and minimal to moderate labeling in the photoreceptor (PHR) layer. In retinal pigment epithelium (RPE), labeling usually occurred in groups of approximately 2-10 adjacent cells. Similar findings were noted with RNA ISH. Statistical analysis of semi-quantitative IHC and ISH found no significant differences between groups 1 and 2, although there was a slight apparent increase in IHC GFP labeling and in the number of transduced cells detected by ISH in the PHR and RPE in group 2 in comparison to group 1. Our study demonstrates approaches for evaluation of IHC and ISH by semi-quantitative scoring systems that allow interpretation and reporting of results in toxicity studies.
Arsenic is wide spread in the environment and is a class I human carcinogen. Chronic arsenic exposure causes lung, skin, and bladder cancer. Paradoxically, arsenic is a potent chemotherapeutic against hematological and solid tumors, and can potentiate the cytotoxic effects when used in combination with other DNA damaging chemotherapeutics, such as hyperthermia and cisplatin. Approved by US FDA, arsenic is a therapeutic for treating acute promyelocytic leukemia (APL). Unfortunately, the use of arsenic is limited among APL patients because up to half experience respiratory events early in the course of the disease, including potentially fatal acute lung injury (aka acute respiratory distress syndrome). Surfactant protein B (SFTPB) plays a critical role in maintaining proper alveolar surface tension and the functionality of healthy lungs, and its absence leads to alveolar collapse that can progress to acute lung injury. SFTPB expression is regulated by Nk2 homeobox 1 transcription factor (Nkx2-1, aka thyroid transcription factor 1, TTF1). In mice, Sftpb transcription is also regulated by SWI/SNF related, matrix associated, actin dependent regulator of chromatin, subfamily a, member 4 (SMARCA, aka BRG1) a chromatin remodeling complex protein that interacts with Nkx2-1. In this study, we demonstrate that arsenic decreases SFTPB transcripts in vivo and in vitro, which can be rescued by dexamethasone. In human alveolar epithelial cells transfected with SFTPB promoter-reporter, arsenic decreased human SFTPB promoter activity. Arsenic also enhances the methylation status of Nkx2-1, thus the transcript level is reduced. A methylation inhibitor, 5-aza-2’-deoxycytidine, rescues the reduction of SFTPB gene promoter activity and SFTPB transcripts caused by arsenic. In summary, we determine that arsenic impairs alveolar surfactant protein B biosynthesis, in part, through Nkx2-1 hypermethylation. These findings could be useful in reducing adverse pulmonary events during arsenic chemotherapy.

How an epigenome’s sensitivity to chemical exposure changes with age is not fully understood. This is particularly significant for the germline where the genome is kept relatively silent through repressive epigenetic marks such as H3K9me3 (histone 3 lysine 9 trimethylation) and H3K27me3 (histone 3 lysine 27 trimethylation). To investigate the relationship between age and epigenetic sensitivity we first used immunofluorescence to quantify changes in the levels of H3K9me3 and H3K27me3 with age in C. elegans germlines. C. elegans are a useful model organism for studying aging because they have a short generation time, are transparent which enables microscopy, and share many canonical age-related pathways with humans such as the insulin-like growth factor signaling pathway. We age-synchronized worms and performed immunofluorescence for H3K27me3 and H3K9me3 at days 1, 3, 5, and 7 of adulthood. We performed 5-7 replicates and for each replicate we quantified the fluorescence intensity of nuclei in 3-4 gonads (10 mid-late pachytene nuclei per gonad). We averaged nuclei area and nuclei intensity for each gonad as well as for all gonads on the same slide. The mean nuclei area decreases with age, the normalized H3K9me3 intensity decreases slightly with age, though the trend becomes weaker at day 7, and variation in H3K27me3 intensity between gonads on the same slide increases with age. The decrease in H3K9me3 intensity could be correlated with the degradation of the nuclear periphery and loss of heterochromatin that occurs with age (Sen et al., 2016). The increased variation in H3K27me3 intensity could be correlated with the increased transcriptional noise and cryptic transcription seen with age (Sen et al., 2015). Next, we will expose worms to the global histone methylation inhibitor 3-deaxaneplanocin A (DZNep). Comparing H3K27me3 and H3K9me3 intensities of the DZNep-exposed gonads to the water-exposed gonads will allow us to investigate changes in epigenetic sensitivity with age. A deeper understanding of how epigenetic sensitivity changes with age will allow us to more effectively test chemicals before they are used in consumer products.

Arsenic pollution in drinking water is a serious public health problem in the world, which affects approximately 150 million people in over 70 countries. People in the affected areas are exposed to arsenic through ingestion of contaminated drinking water and diet on a daily basis. Many human diseases, including neurodegenerative disorders, are engendered by the malfunctioning of proteins vital for important biological processes elicited by protein misfolding. We or in protein quality control during translation. Over the last two decades, it has been proposed that arsenic could affect protein folding and translation, resulting in the proteotoxic stress. Several epidemiological studies have revealed that higher incidence rate of neurodegenerative disorders in a population is correlated with chronic arsenic poisoning. However, the detailed molecular mechanism underlying the arsenic-induced proteotoxic stress is largely unknown. Here, we propose that arsenic could lead to proteotoxic stress through impairing the cotranslational protein quality control pathway by downregulating the E3 ubiquitin ligase activity of ZNF598. We showed that arsenic could interact with ZNF598 in cells, and arsenite could substitute the zinc ions bound with the RING finger domain of the protein through competitive binding. Additionally, our LC-MS/MS-based proteomic data revealed that a 24-hour exposure of 5 μM NaAsO\text{2} resulted in the decrease of specific lysine residues on the specific ribosomal proteins (i.e. 138/139 in RPS10 and K4/8 in RPS20) which are mainly ubiquitylated by the E3 ubiquitin ligase ZNF598. Together, our results support that arsenite could bind to the RING finger domain of ZNF598 by competing zinc ions, thereby impairing the regulatory ubiquitination on RPS10/20 and compromising the co-translational protein quality control pathway. Our study suggests a novel mechanism underlying the arsenic-induced proteotoxic stress in human cells.

How an epigenome’s sensitivity to chemical exposure changes with age is not fully understood. This is particularly significant for the germline where the genome is kept relatively silent through repressive epigenetic marks such as H3K9me3 (histone 3 lysine 9 trimethylation) and H3K27me3 (histone 3 lysine 27 trimethylation). To investigate the relationship between age and epigenetic sensitivity we first used immunofluorescence to quantify changes in the levels of H3K9me3 and H3K27me3 with age in C. elegans germlines. C. elegans are a useful model organism for studying aging because they have a short generation time, are transparent which enables microscopy, and share many canonical age-related pathways with humans such as the insulin-like growth factor signaling pathway. The decrease in H3K9me3 intensity could be correlated with the degradation of the nuclear periphery and loss of heterochromatin that occurs with age (Sen et al., 2016). The increased variation in H3K27me3 intensity could be correlated with the increased transcriptional noise and cryptic transcription seen with age (Sen et al., 2015). Next, we will expose worms to the global histone methylation inhibitor 3-deaxaneplanocin A (DZNep). Comparing H3K27me3 and H3K9me3 intensities of the DZNep-exposed gonads to the water-exposed gonads will allow us to investigate changes in epigenetic sensitivity with age. A deeper understanding of how epigenetic sensitivity changes with age will allow us to more effectively test chemicals before they are used in consumer products.
2974 Effect of Smoking and Air Pollution on Peripheral Blood RNA Modifications in the Beijing Truck Driver Air Pollution Study

A. Kupsc,1 G. Gonzalez,2 Y. Zheng,2 S. Wang,2 D. Chang,2 J. Schwartz,2 L. Hou3, Y. Wang2, and A. A. Baccarelli.1 1Columbia University Mailman School of Public Health, New York, NY; 2University of California Riverside, Riverside, CA; 3Northwestern University Feinberg School of Medicine, Chicago, IL; 4Peking University Health Science Center, Beijing, China; 5China Institute of Industrial Relations, Beijing, China; and 6Harvard T.H. Chan School of Public Health, Harvard University, Boston, MA.

Post-transcriptional modifications of RNA play a fundamental role in regulation of the human transcriptome. The so-called epitranscriptome is critical for health and disease, and can be modulated by cellular stress. However, effects of environmental toxicants on the epitranscriptome remain unclear. Our objective was to examine associations between tobacco smoking and air pollution with 10 RNA modifications in whole blood. Using the Beijing Truck Driver Air Pollution Study, we investigated 10 total RNA modifications in peripheral blood collected from 111 subjects in Beijing, China in 2008. We measured 1-methyladenosine (m1A), N6-methyladenosine (m6A), 2'-O-methyladenosine (Am), N6,2'-O-dimethyladenosine (m2Am), 3'-methylcytidine (m3C), 2'-O-methylcytidine (Cm), N6-acetylcysteine (acC), pseudouridine (Ψ), 5'-methyluridine (m5U), and 2'-O-methyluridine (Um) with nLC MS5. We examined associations between smoking variables (ever/never smoker, pack years (none<3.8 years/3.8 years), environmental tobacco smoke (light/heavy), and smoking on day of visit (present/absent)) and personal air pollution exposure (black carbon (BC) and PM2.5 as measured with a portable monitor over 8 hours) with each modification using linear models. Ever/never smoking and pack years were significantly associated with a 13% decrease in m6A methylation (95% CI: -22.2, -5.6). Smoking on the day of the visit was significantly associated with a 17%-59% increase in m1A, m3C, and m2Am, while m3C, m4C, and m5C were inversely associated with short-term smoking, suggesting a more transient effect. Furthermore, BC was positively associated with m3A. These results provide early evidence into the impacts of environmental toxicants on RNA modifications.

2975 Comparative Analyses of MicroRNA Profiles of E-cigarette Vapour Condensate and Cigarette Smoke Extract-Challenged A549 Cells

G. Kaur, and S. Batra. Southern University and A&M College, Baton Rouge, LA.

Since their introduction in the United States (US) markets, electronic cigarettes (E-cigs) have become extremely popular amongst people of all ages. As of 2012, 1.76 million students in grades 6 to 12 have been reported e-cigarette users which marked a significant increase in US adolescents. While there is a large body of literature suggesting the risks associated with cigarette smoking, not much information is available regarding effects of e-cigarettes. Considering this, a detailed analysis of the microRNA profiles on cigarette smoke and e-cigarette vapour exposure could uncover essential details regarding the affected genes and regulatory pathways. MicroRNAs (miR) are small RNA molecules that function to regulate gene expression post-transcriptionally. There is evidence of dysregulation of miR expression on cigarette smoke exposure. Similarly, transcriptome profiling of human bronchial epithelial cells exposed to-tobacco und e-cigarette smoke using commercially available miRNA PCR Array (Inflammation and Autoimmunity). Our results demonstrate downregulation of 12 miRs; while upregulation of 3 miRs in TF-ECVC challenged A549 cells. Contrarily, 8 miRs were found to be downregulated on CSE challenge. Two miRs, i.e. hsa-miR-181b-5p and hsa-miR-29a-3p, showed significant fold variation on challenge with TF-ECVC. The hsa-miR-181b-5p has been shown to positively regulate p38 MAPK cascade, while hsa-miR-29a-3p negatively regulates proliferation and apoptosis. Our investigations, thus far reveal that TF-ECVC and CSE exposure impacts a distinct set of miRNA populations which may be responsible for the differences in the nature and intensity of inflammatory responses following the exposures. Support: LBRN Summer Award; Young Clinical Scientist Award (FMARRI-123253, YCSA, Faculty); NIH R15 (7 R15 ES023151 02) and Southern University Foundation Grant (FY17-COSC0015; FY18-020).

2976 Low-Dose Developmental Dieldrin Exposure Alters DNA Methylation at Genes Related to Parkinson’s Disease in the Mouse Midbrain

J. Kochmanski, S. VanOeveren, and A. Bernstein. Michigan State University, Grand Rapids, MI.

Human and animal studies have shown that exposure to the organochlorine pesticide dieldrin is associated with increased risk of Parkinson’s disease (PD). Despite previous work showing a link between developmental dieldrin exposure and increased neuronal susceptibility to MPTP toxicity in male C57BL/6 mice, the mechanism mediating this effect has not been identified. Here, we tested the hypothesis that developmental exposure to low-dose dieldrin increases neuronal DNA methylation via genome-wide changes in DNA methylation. Starting at 8 weeks of age, female C57BL/6 mice were exposed to 0.3 mg/kg dieldrin by feeding every 3 days for 30 days prior to mating; maternal dieldrin exposure then continued for the duration of gestation and lactation until weeks of age, pups were sacrificed and brains were dissected. Offspring DNA was then isolated and dieldrin-related changes in DNA methylation were measured via reduced representation bisulfite sequencing (RRBS). We identified a number of significant differentially methylated CpG sites (DMCs) and differentially methylated regions (DMRs) by developmental dieldrin exposure (FDR<0.05). Furthermore, stratification by sex showed that dieldrin exposure had distinct effects on the male and female epigenome. In the male mice, we found dieldrin-related differential methylation within the gene body of the imprinted Grb10 locus. Grb10 encodes an adaptor protein that interacts with Grb10-interacting GYF Protein 2 (GIYF2), a protein encoded in the PARK11 locus that may play a role in PD-related neurodegeneration. Meanwhile, in the female mice, gene ontology pathway analysis showed an enrichment for differential methylation at genes related to central nervous system development. These genes clustered together in an interaction network, and one of the identified loci - Nr4a2 - encodes a transcription factor that has previously been implicated in PD pathogenesis and development of motor dysfunction and motor phenotypic phenotype. In targeted RNA-sequencing analyses, a protein-coding Nr4a2 transcript showed marginally significant differential expression by dieldrin exposure in female mice (p=0.06). Combined, these data suggest that developmental dieldrin exposure can establish a poised epigenetic state at genes related to PD, and that sex-specific epigenetic changes at these loci may contribute to the development of neurodegenerative disease.

2977 Persistent DNA Methylation Linked to Latent Carcinogenesis after Short-Term Chemical Exposure in Mice

B. Chorley, L. Wehmas, S. Hester, B. Bennett, P. Bushe, C. Chamberlin, C. Wood, and G. Carswell. 1US EPA, Durham, NC; and 2NIH, Durham, NC.

Early-life environmental factors can influence later-life susceptibility to cancer. Previously, we showed that exposure to dichloroacetic acid (DCA) increased liver cancer in mice 84 weeks after continuous or early life exposures similarly. Mechanistic findings did not support direct cytotoxic, mitogenic, or genotoxic modes of action. Here, we proposed that prior DCA exposure mediates carcinogenic activity through persistent epigenetic effects. Gene expression was measured by targeted RNA sequencing analyses, a protein-coding Ntr4a2 transcript showed marginally significant differential expression by dieldrin exposure in female mice (p=0.06). Combined, these data suggest that developmental dieldrin exposure can establish a poised epigenetic state at genes related to PD, and these sex-specific epigenetic changes at these loci may contribute to the development of neurodegenerative disease.
DCA exposure. Any direct influence of methylation changes on gene expression or specific oncogenic pathways likely occurred during the lifespan of the mouse. This abstract does not represent US EPA policy.

**2978** An Obesity-Associated Gut Microbiome Reprograms the Intestinal Epigenome and Leads to Altered Colonic Gene Expression

Y. Qin, J. Roberts, S. Grimm, F. Lih, L. Deterding, R. Li, K. Chrysovergis, and P. Wade. **NIH5, Durham, NC.** Sponsor: P. Wade, American Association for Cancer Research

The gut microbiome, a key constituent of the colonic environment, has been implicated as an important modulator of human health. The eukaryotic epigenome is postulated to respond to environmental stimuli through alterations in chromatin features and, ultimately, gene expression. How the host mediates epigenomic responses to gut microbiota is an emerging area of interest. Here, we profile the gut microbiome and chromatin characteristics in colon epithelium from mice fed either an obesogenic or control diet, followed by an analysis of the resultant changes in gene expression. The obesogenic diet shapes the microbiome prior to the development of obesity, leading to altered bacterial metabolite production which predisposes the host to obesity. This microbiota-diet interaction leads to changes in histone modification at active enhancers that are enriched for binding sites for signal-responsive transcription factors. These alterations of histone methylation and acetylation are associated with signaling pathways integral to the development of colon cancer. The transplantation of obesogenic diet-conditioned microbiota into germ free mice, combined with an obesogenic diet, recapitulates the features of the long-term diet regimen. The diet/microbiome-dependent changes are reflected in both the composition of the recipient animals' microbiome as well as in the set of transcription factor motifs identified at diet-influenced enhancers. These findings suggest that the gut microbiome, under specific dietary exposures, stimulates a reprogramming of the enhancer landscape in the colon, with downstream effects on transcription factors. These chromatin changes may be associated with those seen during colon cancer development.

**2979** Epigenetic Effects of Cannabinoids on Bronchial Epithelial Cells

M. S. Doldron, Z. Jia, and R. Bhandari. **University of North Carolina Greensboro, Greensboro, NC.**

Cannabis sativa, commonly known as Marijuana, is one of the most commonly used illicit drugs in the USA, with a reported estimate of 6% of the population aged 26 and older having used marijuana in 2015, for a total of 22.2 million users overall. Therefore, the question of the impact of its use on human health becomes critical. Since inhalation is a major route of exposure, the effect of cannabinoids on bronchial epithelial cells also becomes relevant. The current study investigated the epigenetic effects of chronic cannabinoid exposure as well as the set of transcription factor motifs identified at diet-influenced enhancers. These findings suggest that the gut microbiome, under specific dietary exposures, stimulates a reprogramming of the enhancer landscape in the colon, with downstream effects on transcription factors. These chromatin changes may be associated with those seen during colon cancer development.

**2980** Placental Metals and Expression of miRNAs That Target TGF-β Pathway

P. Bommarito, K. Boggess, and R. Fry. **University of North Carolina at Chapel Hill, Carrboro, NC.**

Pre-eclampsia (PE) is hypothesized to arise from impaired trophoblast invasion into the maternal decidua, giving rise to shallow placentation. In vitro, trophoblast invasion is impaired when exposed to toxic metals. This effect may be mediated by metals-induced changes in microRNA (miRNA) expression. Specifically, miRNAs that target the transforming growth factor beta (TGF-β) pathway have been previously implicated in PE development. We hypothesized that placental toxic metal levels are associated with the expression of miRNAs that target the TGF-β pathway and that these associations may be modified by placental essential metals. Placenta samples were collected from participants in a case-control study of 172 women participating in the Maternal Oral Therapy to Reduce Obstetric Risk (MOTOR) cohort. We quantified placental metals (arsenic [As], chromium [Cr], Cd, lead [Pb], mercury [Hg], selenium [Se], and zinc [Zn]) using inductively coupled plasma-mass spectrometry, and miRNA expression (miR-26a, miR-101, miR-193b, and miR-199b-5p) using a qPCRs-based assay. The association between individual metals and miRNA expression was examined using multivariable linear regression models. Interactions between toxic and essential metals were assessed using interaction-based models. After accounting for potential confounders, placental As and Cr levels were positively associated with the miR-26a, miR-101, and miR-1990-5p expression, and negatively associated with miR-193b expression. There were no associations between placental Cd, Pb, or Hg levels and miRNA expression. Placental Se and Zn levels were associated with lower miR-193b expression and placental Se was positively associated with miR-101 expression. We also identified significant antagonistic interactions between placental Se and several toxic metals, including As, Pb, and Hg, with respect to miR-26a and miR-193b expression. Placental metal levels are associated with the expression of TGF-β-targeting miRNA. Antagonistic interactions between placental Se and toxic metals indicate that lower placental Se may increase susceptibility to metals-associated changes in miRNA expression.

**2981** Comparison of Mouse Liver and Blood DNA Methylation after Gestational Exposure to Lead

DNA methylation is a key epigenetic mechanism linking early developmental environment to long-term health outcomes. Human population-based epigenetic studies are most often limited to easily obtainable, surrogate sources of DNA, including blood. However, the extent to which toxicant-induced changes in DNA methylation in surrogate tissues mirror those in the target tissues is unclear. The Toxicant Exposures and Responses by Genomic and Epigenomic Regulators of Transcription (TaRGET II) consortium was established by the National Institute of Environmental Health Sciences to address the utility of surrogate tissues as proxies for toxicant-induced epigenetic changes in target tissues. In this study, we compared the methylation of liver and blood in 5-month-old male (N=6) and female (N=6) mice that were perinatally exposed to lead. Experiments were performed using genetically invariant mice 93% identical to C57BL/6J. Two weeks prior to mating, dams were assigned to control or lead-acetate (32ppm) water. To assess DNA methylation, we used enhanced reduced-representation bisulfite sequencing. Differentially methylated regions (DMRs) were identified with an FDR cutoff <0.05 and a methylation difference >10%. Although lead exposure ceased at 3 weeks of age, this analysis revealed thousands of stably modified, sex-specific DMRs in the adult blood (n=1535 and n=1404) and liver (n=1740 and n=3342) of exposed females and males, respectively. Overall, 3 DMRs overlapped between liver and blood in females, and 6 in males. The direction of methylation change with exposure was not concordant between blood and liver at all sites; however, in males, Grfn was hypomethylated, and Mirt135 and Plekhg3 were hypermethylated in both liver and blood of exposed mice. Together, these data demonstrate that perinatal exposure to lead induces sex-specific changes in DNA methylation that persist into adulthood, some of which are consistent across target and surrogate tissues. Ongoing studies in TaRGET II will provide additional exposure-specific insights, and include other epigenetic marks that will enable further refinement of the design and analysis of human studies where target tissues are inaccessible.
2982 Whole Genome Assessment Reveals Altered Methylation in DNA Methylation of Polycomb Repressive Complex 2 Components in Effector/Memory CD4+ T Cells after Continuous and Discontinuous Developmental Exposure to Trichloroethylene

S. Byrum1, C. L. Washam, J. D. Patterson1, K. Vyss1, R. Reifeld2, K. M. Gilbert1, and J. S. Blossom1. 1University of Arkansas for Medical Sciences, Little Rock, AR, and 2Colorado State University, Fort Collins, CO.

Trichloroethylene (TCE) is an industrial solvent and water pollutant that promotes autoimmunity/hypersensitivity in both humans and rodents. In auto-immune-prone female MRL +/- mice, adult-only exposure to occupational-level-relevant levels of TCE from the drinking water (500 μg/ml) promoted changes in DNA methylation in regulatory components of the polycomb repressive complex 2 (PC2) in effector/memory CD4+ T cells. These DNA regions bind EZH2, Mtf2, and Jarid2 that are important in CD4+ T cell differentiation and activation, and may regulate autoimmune disease. Developmental exposure to the same dose of TCE during gestation, lactation and early life until postnatal day (PND) 154 generated autoimmunity at PND 259. Since removal of TCE from the drinking water did not prevent disease, we predicted that alterations in DNA methylation of PC2 components would be maintained when TCE was removed from the drinking water. In the current study, whole genome reduced representation bisulfite sequencing (RRBS) was used to compare methylation changes in the CD4+ T cells with noncoding RNA sequences. Results suggest that PC2 methylation in regulatory elements altered by TCE exposure during gestation and lactation could impact methylation in noncoding RNA expression and chromatin modifications. In this study, we characterized the effect of pre-conceptional exposure to PC2 methylations, a persistent organic pollutant, on gene expression to help determine if methylation alterations are promoting transcriptomic alterations, as well as investigate if these findings are tissue-specific or persistent later in life.

2983 Epigenetic Effects of Environmental Chemicals: Integrative Effects on DNA Methylation and Noncoding RNAs

N. Aluru and J. Engelhardt1,2. 1, Woods Hole Oceanographic Institution, Woods Hole, MA; and 2University of Leipzig, Leipzig, Germany.

Epigenetic mechanisms such as DNA methylation, chromatin modifications and noncoding RNAs together comprise the “cellular epigenome” and these mechanisms play an important role in the regulation of gene expression. Environmental factors such as diet, psychological stress and chemical exposure have been shown to modify the epigenome particularly during sensitive windows of development such as embryogenesis and gametogenesis. Some of these effects have been shown to be transmitted to subsequent generations. Most of the previous studies have investigated the influence of environmental factors on epigenetic mechanisms in cell lines. Emerging evidence suggests that there is a role for DNA methylation, noncoding RNAs and chromatin modifications in the development of complex diseases, including neurological system processes, chemical stimuli in senescence, and immune response. From the CD3+/CD8+ T cells, we were able to further gate the cells into CD3+/CD8+/CD16+, CD3+/CD8+/CD56+, CD3-/CD8+ and CD3-/CD8-. Interestingly, only the CD3+/CD8+ populations showed a significant increase (3.97%; p = 0.016) in smokers. Previous studies have demonstrated a role for Gm1 and Prf1 producing CD8+ T cells in the development of atherosclerotic plaques in mice. Taken together, this increased in latent effector CD8+ (CD3+/CD8+/CD16+) T cells might represent an intermediate stage in smoking-induced atherosclerosis.

2984 Using Mass Cytometry to Identify Leukocyte Population Changes from Cigarette Smoke Exposure

M. R. Campbell, S. N. Martos, M. A. Iannone, G. S. Pittman, M. Wan, and D. A. Bell. NIEHS, Research Triangle Park, NC.

Exposure to cigarette smoke has been found to impact immune response, leukocyte subtypes, DNA methylation, and expression from human whole blood. To identify cell populations affected by smoking and possibly connect observed immune cell changes with smoking-associated diseases, we characterized gene expression profiles and cell surface marker phenotypes from primary peripheral blood mononuclear cells (PBMCs) from 5 nonsmokers and 5 smokers by single cell RNA sequencing (scRNA-seq) and mass cytometry (CyTOF). scRNA-seq identified a population of Natural Killer (NK)-like CD8+ T cells in smokers which shared gene expression profiles with both NK cells and CD8+ T cells including an increase in FCGR3A (CD16), GZMB (Granzyme B), and PRF1 (Perforin). In order to determine further which subpopulation increased in NK-like CD8+ T cells, we used CyTOF with a 26 marker phenotypic panel to evaluate over one million viable cells from the same individuals profiled in scRNA-seq analysis. As a result, we identified a population of NK-like CD8+ T cells that shared gene expression profiles with both NK cells and CD8+ T cells.

2985 Perinatal Lead (Pb) Exposure’s Effect on DNA Methylation in Human Umbilical Cord Blood

C. A. Rygiel1, J. M. Goodrich1, W. Perng2, T. R. Jones1, M. Solano3, H. Hu4, M. M. Tellez-Rojo5, K. E. Peterson7, and D. C. Dolinoy1. 1University of Michigan, Ann Arbor, MI; 2Colorado School of Public Health, Aurora, CO; 3National Institute of Public Health, Cuernavaca, Mexico; and 4University of Washington, Seattle, WA.

Early life exposure to lead (Pb) can influence health through epigenetic modifications including DNA methylation. The aim of this study is to identify differentially methylated CpG positions associated with prenatal Pb exposure in human cord blood leukocytes. The Early Life Exposures in Mexico to Environmental Toxics (ELEMENT) project utilizes a series of longitudinal birth cohorts to examine the impact of Pb exposure during sensitive periods of development. In this study, we selected 97 ELEMENT participants with archived umbilical cord blood samples for methylation analysis via the Infinium MethylationEPIC BeadChip, which quantifies total methylation at ~850,000 CpG sites. Maternal blood lead levels (BLLs) at each trimester (T1: 6.56 ± 5.27 μg/dL; T2: 5.89 ± 4.83 μg/dL; T3: 6.20 ± 4.48 μg/dL), umbilical cord BLLs (4.82 ± 2.37 μg/dL) and maternal blood lead levels one-month post pregnancy were measured. Differentially methylated positions (DMPs) by Pb level were identified using linear regression, controlling for sex and estimated umbilical cord 

hypomethylates TE and this leads to increased expression of pIRNAs. We will discuss the functional implications of these alterations as a potential mechanism of multigenerational effects of environmental toxicants. Supported by NIH R01ES024915.
Tobacco smoke exposure is a risk factor for many human diseases and the global disease burden is attributed to it. In addition to DNA damage, smoking-induced epigenetic changes may contribute to etiology of complex smoking-associated diseases. Smoking alters the epigenome and transcriptome of human blood leukocytes. However, interpretation of bulk genomic approaches is limited because changes could indicate altered cellular mixtures or subpopulations. To characterize smoking-related gene expression changes in primary immune cells, we performed single cell RNA sequencing on human peripheral blood mononuclear cells (PBMCs) from smokers (n=4) and non-smokers (n=4). Transcripts of 45,965 cells (78,183 reads per cell) revealed an altered population of Natural Killer (NK)-like T lymphocytes in smokers. Compared to NK cells, the NK-like T cell cluster had elevated expression of CD8A, CD8B, CD3D, CD3E, CD3G, CD6, and CD2, indicative of CD8+ T lymphocytes. Recently rare in non-smokers (2.2%), the transcriptionally unique subset of CD8+ T cells comprised 8.7% of PBMCs in smokers. Among CD8+ T cell subtypes, the increase in NK-like CD8+ T cells (Mann-Whitney p = 0.03) corresponded with a decrease in Naïve CD8+ T cells (p = 0.03). We did not observe changes in the frequencies of two additional CD8+ T cell clusters or in the overall frequency of CD8+ T cells. Mass cytometry of a 26-antibody leukocyte panel confirmed no differences in the frequencies of total CD8+ T (CD3+CD8+ or CD8+ NK (CD3−CD8+)) or CD8+ NKT (CD3+CD8+) cells between smokers and non-smokers. This suggests smoking is associated with an increased number of CD8+ T cells that share characteristics with NK cells, but are not NKT cells. Consistent with an NK-like phenotype, altered effector CD8+ T cells had elevated expression of genes reported to be upregulated in NK cells reprogrammed toward NK cells. Compared to other effector CD8+ T cells, altered effector CD8+ T cells had reduced IL7R and increased FCGR3A (CD16), IFNG (interferon gamma), GZMB (granulysin B), and PRF1 (perforin) expression. In mice, granzyme B and perforin expressing CD8+ T cells contribute to the development of atherosclerotic plaques. Our data highlights a potential link between smoking-induced functional changes in human CD8+ T cells and atherosclerosis.
2990 Continuous Exposure to Morphine Sulfate Alters Genomic DNA Methylation in Mouse Embryonic Stem Cells

P. Panthagani, A. J. Chintalapati, and F. A. Barile. College of Pharmacy and Health Sciences, St. Johns University, Queens, NY.

Epigenetic changes alter heritable phenotypes without modifying DNA sequences and account for individual variability related to drug metabolism and response. This is particularly valid for drugs with addictive properties. Methylation and demethylation of genes also regulates organogenesis in mammalian cells. We have previously shown that morphine sulfate (MS) exposure for 24-hr induces hypomethylation of DNMT1, SA and 3B; i.e. methytransferases responsible for methylation of DNA under various conditions. In this study, we hypothesize that exposure to opioids for longer duration during fetal development affects pre-programmed genomic methylation and demethylation patterns associated with organogenesis, eventually leading to developmental abnormalities. To evaluate the epigenetic mechanism of action of morphine on the differentiation process of proliferating mouse embryonic stem (mES) cells, we monitored cytotoxicity, DNA methylation and cell viability after exposure to MS for 1-, 3-, 5- and 7-days. Cell viability using the MTT assay indicated cytotoxicity at a concentration of at least 1000 µM on day 1. A constant decrease in viability was observed for days 3, 5 and 7 at 1, 10, and 100 µM respectively. Further exposure of mES cells to the standard 10 µM resulted in hypomethylation for all time points evaluated. To confirm if these changes were heritable, cells were allowed to recover for 3 days in the absence of MS after each exposure period. Genomic methylation analysis after the recovery period revealed a reversal of MS-induced hypomethylation. Interestingly, hypermethylation of DNA was observed following 7-day exposure and 3-day recovery. Overall, the results disclose that MS induces heritable epigenetic changes with prolonged exposure at concentrations that do not significantly affect cell viability. Since DNA methylation is essential for maintaining embryonic progression and expansion of stem cells, our results suggest that MS negatively influences developmental progress by shifting DNA methylation patterns in differentiating cells.

2992 Fetal Epigenetic Reprogramming in Response to Early-Life Exposure to Phenols

Maternal exposure to environmental toxicants, including bisphenol-A (BPA), bisphenol-S (BPS), and bisphenol-F (BPF), during early pregnancy can impact an infant’s risk of later-life disease. Persistent changes in DNA methylation are a proposed mechanism through which the prenatal environment can impact lifetime health trajectory. In the Michigan Mother Infant Pairs (MIMP) Cohort, we assessed associations between maternal first-trimester urinary phenol concentrations and DNA methylation profiles in infant umbilical cord blood leukocytes (N=53). We used the Illumina Infinium MethylationEPIC Beadchip to quantitate DNA methylation across the epigenome at 822,609 CpG sites that passed quality checks. Urinary BPA, BPS, and BPF were adjusted for specific gravity (SG). BPS and BPF were dichotomized as detected versus non-detected, because 51% and 43% of samples had detectable concentrations, respectively. Models of single-CpG-site DNA methylation with BPA (continuous) or BPS and BPF (dichotomized) were adjusted for infant sex, maternal covariates, and estimated cord blood cell type proportions. In addition, differentially methylated regions (DMRs) were identified using DMRcate. Analysis with BPA revealed 47 CpG sites significant at a 5% false discovery rate, half of which exhibited less methylation with increasing BPA concentrations. Gene ontology revealed immune system processes, metal-sulfur cluster assembly, regulation of lyase, and succinate dehydrogenase activity as pathways enriched with differentially methylated genes. One DMR in the HOXA3 gene was associated with maternal BPA exposure. Analysis of maternal BPS and BPF exposure resulted in zero CpG sites below the 5% false discovery rate and zero DMRs associated with maternal BPF or BPS exposure. Thus, maternal exposure to BPA, but not BPF or BPS, was associated with differential methylation at the CpG and gene-region levels in infant cord blood. This analysis will be expanded to include DNA methylation profiling of matched placenta samples to evaluate tissue-dependent effects of phenols on the epigenome.

2993 Epigenetic Effects of Maternal Arsenic Exposure on Mice through Drinking Water

Both epidemiological investigations and animal studies have reported that long-term exposure to arsenic from drinking-water and food is associated with cancer, skin lesions, diabetes and developmental effects. However, a thorough understanding is lacking for how epigenetic patterns are perturbed by arsenic exposures. Thus in the present study, to characterize whether and how arsenic affects epigenetic patterns, 10 ppb arsenic were administrated to pregnant C57BL/6 mice until weaning through drinking-water. Body weight and liver function of the 5 months old offsprings were recorded. The results showed that maternal exposure to arsenic alter the body weight of the offspring, and significantly change their liver alamine aminotransferase activities. Transcriptome profiling by using mRNA sequencing revealed that 1222 genes were up-regulated and 614 genes were down-regulated in the offspring’s liver after maternal exposure to arsenic. Gene ontology analysis showed that these differentially expressed genes were enriched in immunological functions. Further examination on chromatin accessibility by using transposase-accessible chromatin sequencing (ATAC-seq) showed that open chromatin regions were significantly changed in the offspring upon maternal exposure to arsenic. Collectively, our investigation identified maternal arsenic exposure actually alters the offspring’s transcriptome via disrupting chromatin’s opening status.

2994 Investigation of the Effects of Zearalenone and Its Metabolites in the Genes Related to Energy Metabolism In Vitro: Relation with the Epigenetic Alterations

E. F. Karaman1, M. Zeybek2, and S. Ozden3. Istanbul University, Istanbul, Turkey; and KOC University, Istanbul, Turkey.

Zearalenone (ZEA), produced by various Fusarium species, is a non-steroidal estrogenic mycotoxin. It contaminates cereals such as corn, wheat, oat and soybean. However, it has no negative effects on human health. In our study, we investigated the effects of ZEA and its metabolite α-ZOL on epigenetic modifications and metabolic pathways have been investigated in HepG2 cells in order to elucidate the possible relationship between metabolic dysfunctions. According to the MTT and NRU tests, the IC50 values were determined as 143.35 and 60.45 for ZEA and 111.42 and 35.72 µM for α-ZOL, respectively. At

2019 SOT Annual Meeting
the concentrations of 1-50 µM of ZEA and α-ZOL exposures for 24 h were significantly increased cell proliferation by BrdU assay in the rates of 7.2-41.71% for ZEA, 11.78-44.33% for α-ZOL, respectively. 50 µM of ZEA and α-ZOL exposure caused significant alterations in the expression levels of nuclear receptor genes (AhR, LXRα, PPARα, PPARγ), alteration in PPAR expression and promoter DNA methylation significantly. Low Gestational Age Newborn (ELGAN) cohort. Our results highlight CpG methylation of critical genes including many that showed sex difference in placental CpG methylation in regards to prenatal acetaminophen exposure.

Reactive oxygen species (ROS) are direct regulators of many vital cellular and developmental processes. However, if left unchecked, excessive ROS can directly damage cellular macromolecules, so cells must maintain tight regulation of ROS. Following exposure to ROS, transcription factors (TFs) are activated and regulate the expression of a myriad of genes in an attempt to protect the cell from ROS-mediated damage and adapt to new environmental conditions. Such changes in gene expression patterns are highly dependent on the ability of TFs to bind DNA, and thus are directly impacted by the local chromatin state and DNA accessibility at target binding sites. For instance, some genes may be located in highly accessible chromatin regions that would allow for immediate ROS-responsive TF binding and gene activation, whereas others may require initial changes in DNA accessibility to allow for activation after long term ROS exposure. Our current models of ROS-induced changes in gene expression and DNA accessibility are fragmentary. Thus, we aimed to fill this gap in knowledge by exposing human MCF7 cells to two different ROS-inducing compounds (menadione [MEN] and tert-butyl hydroperoxide [tBOOH]), followed by transcription and DNA accessibility profiling at 0, 1, 8, or 24 hours. For measurement of gene expression we performed RNA-seq, and for DNA accessibility we utilized the Assay for Transposase-Accessible Chromatin followed by high throughput sequencing (ATAC-seq). We found that MEN exposure resulted in significant changes in expression (FDR-corrected $p < 0.05$) of 38 genes after 1 hour of exposure, an additional 1676 genes at 8 hours, and another 937 genes at 24 hours. Using fine mapping and computational methods to determine transcription factor binding, we identified 38 genes with increased TF binding and DNA accessibility after MEN exposure and opening and closing of chromatin due to ROS exposure. In contrast to the dramatic and dynamic changes in gene expression, we detected a comparatively small number of significant changes in DNA accessibility (<50) across the genome. Similar trends in both gene expression and DNA accessibility were observed with tBOOH treatment. These results suggest that large scale changes in chromatin remodeling is not necessary to mount ROS-induced oxidative stress. Instead, we found that DNA accessibility changes are necessary for transcriptional response to oxidative stress. In summary, our data support a model in which transcription factors are recruited to perform transcriptional reprogramming by oxidative stress. Instead, our data support a model in which transcription factors are recruited to perform transcriptional response to oxidative stress.
the liver. This, although it might be depend on the characteristics of drugs, suggests that eye-drop administration does not always induce more severe genetic changes in corneas than in systemic target organs.

2999 Potential Candidate Genes Driving Cancer Stemness and Their Regulation by Novel Triterpenoids in Triple Negative Breast Cancer

R. Winner, N. Shan, M. Bak, A. Minden, and N. Suh. Ernest Mario School of Pharmacy, Piscataway, NJ.

Triple negative breast cancer (TNBC) is a subtype of breast cancer that is prone to metastasis and high rates of recurrence. Cancer stem cells, responsible for metastasis and resistance to chemotherapy, have been shown to be highly enriched in TNBC. Therefore, treatment of cancer cells with novel pharmacologic agents targeting cancer stemness have the potential to mitigate TNBC’s aggressive phenotype. CDDO-Imidazole (CDDO-I, 1-(2-cyano-3,12-dioxoooleana-1,9-diene-28-yl) imidazole) is a synthetic triterpenoid previously shown to reduce cancer stemness in TNBC cells. The purpose of this study was to identify potential candidate genes important in cancer stemness, and whether CDDO-I treatment would regulate the expression of those genes to inhibit TNBC. The human TNBC cell line SUM159 was used to prepare mammospheres, which are designed to enrich for cancer stem cells. To identify potential candidate genes driving stemness, RNA sequencing analysis was performed on SUM159 cells in monolayer culture, mammospheres, and mammospheres treated with CDDO-I. The samples were subjected to GSEA analysis along the gut-brain axis. The AhR and its ligands also inhibit colon cancer stem cells include TNFa, TGF-β, HIFa, and EGF, all of which are integral to proliferation. Additional novel genes found to be upregulated with enriched cancer stem cells include LOXL2, which promotes cancer cell stemness and stemness in breast cancer, and SLC2A3, which has a role in self-proliferation in embryonic stem cells, and these genes are downregulated when treated with CDDO-I. One of the major pathways downregulated when cells were treated with CDDO-I was the TNFa pathway via HMox1, which was further validated by quantitative PCR analysis. These results suggest that several novel genes may have a significant role in regulating cancer stemness in TNBC, as well as the potential of CDDO-I to reduce the cancer stem cell phenotype of TNBC, and therefore potentially provide better therapeutic outcomes.

3000 The Aryl Hydrocarbon Receptor Is a Tumor Suppressor-Like Gene in Glioblastoma

U. Jin1, K. Karki1, S. K. Michelhaugh2, S. Mittal3, and S. Safe1. 1Texas A&M University, College Station, TX; and 2Wayne State University, Detroit, MI.

The aryl hydrocarbon receptor (AhR) plays an important role in maintaining cellular homeostasis and in pathophysiology, and the interplay between the gut microbiome and microbial-derived AhR ligands protect against inflammation along the gut-brain axis. The AhR and its ligands also inhibit colon carcinogenesis, whereas it has been reported that the AhR and its ligand kynurenine enhance glioblastoma (GBM). In this study, we have re-examined the role of kynurenine and the AhR in GBM using established and patient-derived GBM cells at the functional, molecular and genomic levels. In all the cell lines, kynurenine did not modulate AhR-mediated gene expression and did not affect invasion of GBM cells. Moreover, based on results of transient and stable (by CRISPR/Cas9) AhR knockdown in GBM cells, we observed that loss of AhR enhanced GBM cell and tumor growth, enhanced GBM cell invasion, and increased expression of pro-invasion/pro-migration genes as determined by IPA analysis of RNAseq data. Thus, the AhR is a tumor suppressor gene in GBM and therefore a potential drug target for patients that express this receptor.

3001 Remodeling of Plasma Membrane Proteolipid Composition by Environmental Chemicals and Membrane-Targeted Dietary Bioactives

N. Fuentes1, M. Mihl1, J. Karpač1, I. Corbin2, and R. Chapkin3. 1Texas A&M University, College Station, TX; and 2University of Texas Southwestern Medical Center, Dallas, TX. Sponsor: R. Chapkin, American Association for Cancer Research

Abrupt activation of signaling through the epidermal growth factor receptor (EGFR)/Ras pathway is implicated in many cancers. EGFR and Ras signaling originates from transient nanoscale compartmentalized regions of the plasma membrane composed of specific proteins and lipids. The highly specific lipid composition of these nanodomains, termed nanoclusters, facilitates receptor recruitment and therefore influences signal transduction. This suggests that nanocluster proteolipid composition and formation could represent a site of action for environmental chemicals and a novel target for future chemoprevention interventions. Exposure to the environmental chemical bisphenol A (BPA) can activate EGFR/Ras signaling, while consumption of fish containing long-chain n-3 polyunsaturated fatty acids (n-3 PUFA) such as eicosapentaenoic acid (EPA, 20:5n-3, 8,11,14,17) and docosahexaenoic acid (DHA, 22:6n-3,7,10,13,16,19) can reduce EGFR/Ras signaling, yet the mechanism underlying these effects is unknown. We hypothesize that environmental chemicals that activate EGFR/Ras signaling, modulate the proteolipid composition of EGFR and Ras nanoclusters and that n-3 PUFA can block this effect. Here we demonstrate that dietary n-3 PUFA reduce the lateral segregation of cholesterol-dependent and -independent nanoclusters, suppressing phosphatidic acid-dependent oncogenic KRas effector interactions, via their physical incorporation into plasma membrane phospholipid. This results in the inhibition of oncogenic Ras-driven colonic hyperproliferation in both Drosophila and murine models. Future studies will characterize the effect of BPA on EGFR nanocluster formation. These findings demonstrate the unique properties of dietary n-3 PUFA in shaping plasma membrane nanoscale proteolipid complexes and support the emerging role of plasma membrane-targeted therapies.

3002 Vitamin D Receptor Expression Modulates the Angiogenic Properties of Endothelial Cells through Suppression of Oxidative Stress and Inflammation

Y. Song, C. M. Sorensen, and N. Sheibani. University of Wisconsin-Madison, Madison, WI.

Vitamin D is an important modulator of angiogenesis and tumor growth. We previously showed the active form of vitamin D, 1,25(OH)2D3, is a potent inhibitor of retinal neovascularization. How vitamin D inhibits retinal neovascularization and whether these activities are mediated through vitamin D receptor (Vdr) remains of significant interest. Vitamin D receptor (VDR) is a nuclear receptor that mediates the majority of molecular events associated with vitamin D action. However, the role of VDR expression in retinal angiogenesis, and more specifically in retinal endothelial cell (EC) function remain unknown. Here we demonstrate that VDR expression in retinal EC function remain unknown. Here using retinal EC prepared from wild type (Vdr+/+) and Vdr-deficient (Vdr-/-) mice, we investigated the impact of VDR expression in retinal EC function. Lack of VDR had a significant impact on endothelial cell-cell and cell-matrix interactions. Vdr-/- retinal EC showed altered levels of vascular endothelial cadherin and occludin-1, affecting the formation of adherens and gap junctions. However, the ability of Vdr-/- retinal EC to undergo capillary morphogenesis on Matrigel was minimally affected. Vdr-/- retinal EC proliferated at a slower rate than their wild-type counterparts. Vdr-/- retinal EC exhibited increased expression levels of inflammatory markers including osteopontin and monocyte chemoattractant protein-1. Vdr-/- retinal EC also showed increased reactive oxygen species generation following hydrogen peroxide challenge. These changes were attributed, in part, to sustained activation of mitogen-activated protein kinase (MAPK) pathways, enhanced nuclear localization of NF-κB, and down-regulation of endothelial nitric oxide synthase expression in Vdr-/- retinal EC. Taken together, our results indicate that VDR expression has a significant impact on oxidative stress and inflammation, which contributes to regulation of angiogenic properties of EC.

3003 Decoding Aryl Hydrocarbon Receptor-Mediated Differential Gene Expression

A. Joshi, and C. Elferink. University of Texas Medical Branch, Galveston, TX.

The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor that is primarily studied as a regulator of xenobiotic metabolism, most notably through the activation of cytochrome P450 1A1 expression in response
Triclosan (TCS) is a popular wide-spectrum antimicrobial agent. While TCS was recently banned from several consumer products such as hand soaps, it remains in a top-selling toothpaste and in other household items. TCS inhibits the functions of both mast cells and also of mitochondria. Mast cells are found in most human tissues and play important roles in a wide array of biological processes and diseases. Through investigating the mechanisms by which TCS disrupts mitochondrial and mast cell signaling, the Gosse lab found that TCS depolarizes the mitochondrial membrane and disrupts cellular Ca\(^{2+}\) dynamics. However, triclosan’s effects on mast cells and mitochondria disappear when its ionizable hydroxyl group is not present. These findings suggest TCS to be a proton ionohore capable of not only uncoupling mitochondria, but also possibly capable of disrupting the plasma membrane electrochemical potential (PMP). In this study, we have utilized a fluorescent, genetically-encoded voltage indicator called ArcLight A242 to probe TCS effects on mast cell PMP. Utilizing this method for the first time in mast cells, we observed plasma membrane depolarization in the presence of gramicidin, using confocal microscopy coupled with image analysis. Using these newly-developed methods, preliminary results show that TCS indeed inhibits PMP of mast cells. TCS disruption of PMP could provide a mechanistic explanation of triclosan’s disruption of Ca\(^{2+}\) influx, mast cell function, and a host of other cellular processes dependent on PMP.
Currently mechanistic understanding of drug-induced liver injury (DILI) is still lacking and therefore hard to predict during drug development. Some DILI compounds are known to induce endoplasmic reticulum (ER) perturbations. During chronic ER stress, activation of the adaptive unfolded protein response (UPR) is insufficient and will activate apoptotic pathways mediated by CHOP leading to hepatotoxicity. This switch from adaptive to adverse signaling is poorly understood. To improve mechanistic understanding of the UPR, we aimed to identify novel key regulators of CHOP. First, the suitability of the HepG2 CHOP-GFP reporter for evaluating CHOP induction was determined using a concentration range of various ER stress inducers. Secondly, the most optimal ER stress condition was defined where a concentration of 6 μM of tunicamycin was found most optimal to study CHOP induction perturbations by siRNA-mediated knockdown. Using these conditions, we applied an imaging-based RNA screen of the druggable genome targeting 3457 genes (including kinases, ubiquitinases, transcription factors and epigenetic factors) in HepG2 CHOP-GFP cells to identify novel regulators of the tunicamycin-induced ER stress response. CHOP-GFP expression was evaluated after 16 hours of exposure to 6 μM of tunicamycin which was altered by 201 genes upon knockdown from which 74 could be confirmed. These potential regulators were further evaluated with other ER stress inducers and their role in induction of other UPR-related genes such as ATF4, XBP1 and Bip. To evaluate the relevance of 10 selected novel regulators for the human liver during ER stress, we evaluated the gene expression using TempO-seq transcriptomics technology in both HepG2 and PHHs after knockdown and subsequent exposure for 16 hours of tunicamycin. Three potential regulators were confirmed in PHH which showed upon knockdown perturbation of UPR activation after tunicamycin. Next, their role in DILI compound-induced ER stress was determined, where potential regulators could affect significantly the UPR activation and cell death induction during DILI compound exposure. Overall, our RNAi screen allowed the identification of novel regulators of the drug-induced ER stress response and will further shape our understanding and prediction of DILI liabilities. Supported by EU-ToxRisk project (grant agreement No 681002) and IMI-MIP-DILU project (grant agreement 115330).

**EGFR Activates the NRF2-KEAP1 Signaling Pathway in a Novel Mechanism Involving Cellular Localization Changes of FAM129B**

C. J. Schmidlin1, W. Tian1, and D. D. Zhang1,2. 1University of Arizona, Tucson, AZ; and 2University of Arizona Cancer Center, Tucson, AZ.

Resistance to chemotherapies and radiotherapies is an increasing issue among cancer patients. One mechanism by which these tumors can confer resistance to therapies is via an upregulation of redox regulating proteins as a result of induction of the nuclear factor (erythroid-derived 2)-like 2 (NRF2) signaling pathway. Canonical activation of NRF2 requires modification of key cysteine residues in its negative regulator, Kelch-like ECH-associated protein 1 (KEAP1), that results in NRF2 heterodimerizing with MAFG, binding to antioxidant response elements (AREs), and recruiting transcriptional machinery. It has been well demonstrated that the NRF2-KEAP1 signaling pathway is activated in response to reactive oxygen species (ROS); however, here we show a novel mechanism by which NRF2 is induced independently of ROS and cysteine oxidation. In these investigations we elucidate the mechanism by which family with sequence similarity 129, member B (FAM129B) induces NRF2 in cancer cells. We demonstrate that activation of epidermal growth factor receptor (EGFR) directly phosphorylates FAM129B, thus causing a shift in localization of the protein from the plasma membrane to the cytosol. Upon movement to the cytosol, FAM129B competitively binds to KEAP1 via its ETGE motif, thus resulting in translocation of NRF2 to the nucleus and activation of transcription. In this study, we show that mechanistically lead toxicity further upregulates NRF2 by activating EGFR, thus leading to the phosphorylation of FAM129B. Overall, we characterized a novel mechanism by which EGFR activation causes phosphorylation and thus changes in cellular localization of FAM129B, thus allowing binding to KEAP1 and induction of NRF2, which could be relevant to conferred resistance to cancer therapies.

**Digital Spatial Molecular Profiling of H&E or Antibody Stained FFPE: Measurement of Complex Gene Profiles within the Context of the Tissue Microenvironment**

E. Imler1, M. Marron1, R. Nagle2, P. Shepard1, J. Yeakley1, and B. Seligmann1. 1BioSpyder Technologies, Inc., Tucson, AZ; and 2University of Arizona, Tucson, AZ.

Measurement of complex gene expression molecular signatures from fixed tissue has been problematic, especially given the desire to correlate those measurements to existing histology techniques within the context of the tissue microenvironment. We report the use of the Digital Spatial Profiling (DSPM) assay, an in situ adaptation of the TempO-seq™ targeted gene expression analysis on FFPE or IHC stained slides from histologically defined regions of interest down to a spatial resolution of 20μm. FFPE sections were processed on an automated slide stainer (Bond RX/m) where they are infused with TempO-seq probes and stained. The antibody- or H&E-stained slides were then digitally imaged and TempO-seq probes automatically eluted from selected regions of interest using the CellSensus platform, followed by qPCR amplification, pooling of the samples, sequencing, and automated analysis using the TempO-seq™ software package. The H&E staining not only enabled identification of the areas of tissue histology to be profiled, but provided images that validated that the profiling data was tissue specific and not cross-contaminated. Using a pan-cancer assay of 5,207 genes that included the S1500 v2 surrogate assay, we profiled discrete focal areas of stroma, normal epithelium, cancer epithelium, and pre-cancerous high-grade PIN lesions from H&E stained archived prostate cancer patient resections. The data demonstrate not only that the different tissues within the FFPE section can be profiled without contamination by neighboring cell types, but demonstrate an unexpected level of biomarker specificity as a result of the spatial resolution of the assay. Many genes expressed by normal epithelium were not expressed in cancer or stroma, and many genes expressed in stroma were not expressed in cancer or normal. We hypothesize that spatial resolution provides biomarker specificity that is not seen in heterogeneous tissue assays, and speculate that there are factors in tissue which cause specificity, whether it is adjacent cells, the structural effects of tissue, or chemical factors segregated within the tissue, which are not present in cultured or isolated cells.

**Mechanism of Rapid Induction of Interleukin 22 in Dendritic Cells and Its Modulation by AhR Ligands**

Y. Ishihara1, S. Y. Kado1, T. Haarmann-Stemmann2, and C. F. Vogel1. 1University of California Davis, Davis, CA; and 2Leibniz Research Institute for Environmental Medicine, Duesseldorf, Germany.

The expression of interleukin 22 (IL-22) has been primarily associated with lymphoid cells including activated T cells and innate lymphoid cells (ILCs). Here we show that bone marrow-derived dendritic cells (BMDC) express and produce IL-22 after activation of the aryl hydrocarbon receptor (AhR) when cells are activated by agonists of the toll like receptor (TLR) family. The additional activation of AhR is necessary for a significant induction of IL-22 in TLR activated BMDC, while polyinosine-polyribonucleotide (P(LPS)-treated B6 mice. The results show that induction of IL-22 expression via AhR is independent from RORγt or IL-23. We identified four consensus dioxin responsive elements (DRE), one Reib/AhR (ReLB/AhRE) binding element and a consensus NF-κb site in the first 3500 bp upstream of the transcriptional start site of the mouse il22 gene. Deletion and mutation constructs of the IL-22 promoter revealed that the NF-κb consensus element and two DRE consensus elements upstream of the start site are necessary to mediate the synergistic effects of AhR and TLR ligands in BMDC. Inhibitor studies and BMDC derived from knockout mice confirmed that the induction of IL-22 by AhR and TLR ligands depend on the expression of AhR as well as Reib, but was not affected by the inhibition of RORγt or IL-23. In summary, these results show that simultaneous activation of AhR and TLR signaling rapidly induce IL-22 in BMDC and the synergistic induction of IL-22 in BMDC may differ from lymphoid T cells which require RORγt.

**Assessing the Role of Arsenite in Disrupting the EGFR Signaling Axis**

C. Kim and B. P. Ceresa. University of Louisville, Louisville, KY.

The epidermal growth factor receptor (EGFR) is a receptor tyrosine kinase localized on the cell surface. Overexpression of EGFR has been used as biomarkers for many different types of cancers, including lung cancer. Though there is a strong association between arsenic and lung cancer development,
the clear mechanism is unknown. We hypothesize that chronic arsenite exposure disrupts the EGFR endocytic trafficking, leading to increased receptor expression. The goal of this project is to study impact of chronic exposure to "a physiologically relevant" level of arsenite on the EGFR expression, distribution and trafficking. A non-malignant human bronchial epithelial cell line, Beas-2B cells were exposed to 100nM arsenite for 24 weeks. The chronic arsenite-treated cells showed decreased EGFR protein expression levels and activity, increased transcription levels of TGFα, and altered the distribution of the EGFR. In conclusion, the impact of chronic arsenite exposure on the EGFR signaling axis can explain arsenite-induced overexpression of the EGFR that is commonly characterized in lung cancer.

3013 TCDD-Inducible Poly-ADP-Ribose Polymerase (TIPARP) Catalytic Activity Protects against Dioxin-Induced Hepatotoxicity and Lethality

D. Hutin, V. S. Somisetti, S. K. Singh, P. Shao, G. Grimaldi, H. Soedling, C. Lucas, D. M. Grant, and J. Matthews. 1, University of Toronto, Toronto, ON, Canada; and 2University of Oslo, Oslo, Norway.

We have previously reported that whole body or hepatoocyte specific deletion of TCDD-inducible poly-ADP-ribose polymerase (TIPARP), an AhR target gene and mono-ADP-ribosyltransferase, increases the sensitivity of mice to dioxin-induced toxicities. Our in vitro data show that TIPARP functions as part of a negative feedback loop to repress AhR signaling in a mechanism that requires TIPARP's catalytic activity. We hypothesized that the loss of TIPARP catalytic activity would be sufficient to increase sensitivity to TCDD-induced toxicity in vivo. To test the hypothesis, we used CRISPR/Cas9 gene targeting to generate a histidine 532 to alanine A mutation in TIPARP, creating a catalytically deficient mouse (Tiparp<sup>H532A</sup>). Hepatocytes isolated from Tiparp<sup>H532A</sup> mice had increased AhR target gene expression compared with wild-type. Tiparp<sup>H532A</sup> mice given a single injection of 100 or 10 μg/kg dioxin did not survive beyond day 3 and 10, respectively. All wild-type mice survived the 30-day treatment. At day 6, dioxin (10 μg/kg) treated Tiparp<sup>H532A</sup> mice exhibited increased expression of AhR target genes, higher levels of several inflammatory cytokines and chemokines, increased body weight loss, reduced white adipose tissue, decreased hepatic and gut toxicity as indicated by increased alanine aminotransferase activity compared with wild-type mice. RNA-Sequencing identified 647 genes significantly different after dioxin treatment in wild-type mice compared with 4551 genes significantly different in similarly treated Tiparp<sup>H532A</sup> mice. These data illustrate that loss of TIPARP's catalytic activity is sufficient to increase AhR signaling and increase sensitivity to dioxin toxicity. Our findings support TIPARP and mono-ADP-ribosylation as important negative regulators of AhR signalling pathway.

3014 Characterization of the Aryl Hydrocarbon Receptor-Kruppel-Like Factor 6 Interaction

K. Pereira de Castro, University of Texas Medical Branch, Galveston, TX.

The aryl hydrocarbon receptor (AhR) is a transcription factor responsible to regulate toxic responses of chemical pollutants, including polycyclic aromatic hydrocarbons (PAHs) and 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). In the classical pathway, upon ligand binding, AhR translocate to the nucleus, dimersize with the Aryl Hydrocarbon Receptor Nuclear Translocator (ARNT) after releasing the chaperons Hsp90, Aip and Ara9. AhR/ARNT binds to DNA regions known as Xenobiotic Response Elements (XREs) facilitating the transcrip- tion of target genes. Our published results demonstrated that the AhR is also involved in a novel protein-DNA complex with the Kruppel Like Factor 6 (KLF6), a zinc-finger transcription factor related to SP1 that is involved in transcription of target genes. Our published results demonstrated that the AhR is also involved in a novel protein-DNA complex with the Kruppel Like Factor 6 (KLF6), a zinc-finger transcription factor related to SP1 that is involved in transcription of target genes. AhR and KLF6 complex is independent of XRE, targeting a non consensus XRE (AhR-KLF6 complex is independent of XRE, targeting a non consensus XRE). Further, a discrete sub-G1 population (18%) was unique to AhR<sup>-/-</sup> mice and returned CYP1A1 activity to control levels (p<0.05). 23C was also able to increase CYP1A1 to control levels, while 23A decreased the effects elicited by FICZ by 35% in Hepa1c1c7 cells (p<0.05). Importantly, all three compounds (5-20 μM) did not alter cell number following examination in a sulfurdihemate B assay. Thus, the change in CYP1A1 was not related to changes in cell number following treatment with the compounds. The results indicate that these marine-derived indoles may be able to reduce the toxicity caused by halogenated aromatic hydrocarbons. However, further direct aryl hydrocar- bon receptor binding studies are required to confirm these findings.

3015 Halogenated Indoles from Seaweed Act as Aryl Hydrocarbon Receptor Antagonists in Hepa1c1c7 Cells

J. A. King<sup>1</sup>, V. H. Woolner<sup>2</sup>, P. T. Northcote<sup>2</sup>, A. G. Bridge<sup>2</sup>, R. A. Keyser<sup>2</sup>, and R. J. Rosengren<sup>1</sup>. 1University of Otago, Dunedin, New Zealand; and 2Victoria University of Wellington, Wellington, New Zealand.

A range of polyhalogenated indoles have been isolated from Rhodophyllus membranacea collected in the Wellington harbor in New Zealand. The three most abundant indoles isolated were 4,7-dibrom-2,3-dichloroindole (23A), 7-bromo-2,3-dichloro-6-iodoindole (23B) and 6,7-dibrom-2,3-dichloro-2,3-dichloroindole (23C). These three compounds were then evaluated for their ability to induce CYP1A1 in Hepa1c1c7 cells and HepG2 cells. From ERD assays showed that only 23A (25-50 μM) induced CYP1A1 catalytic activity (3.5-fold) following 6-24 h exposure in Hepa1c1c7 cells and this effect was comparable to the EROD activity induced by 100 nM 5,11-dihydro-indolo[3,2-b] carbazole-6-carboxaldehyde (FICZ). In contrast, 23A, 23B and 23C (5-20 μM) were not able to significantly reduce CYP1A1 activity induced by 100 nM FICZ. Specifically, 23B (5 μM) + FICZ (100 nM) completely blocked FICZ induction and returned CYP1A1 activity to control levels (p<0.05). 23C was also able to decrease CYP1A1 to control levels, while 23A decreased the effects elicited by FICZ by 35% in Hepa1c1c7 cells (p<0.05). Importantly, all three compounds (5-20 μM) did not alter cell number following examination in a sulfurdihemate B assay. Thus, the change in CYP1A1 was not related to changes in cell number following treatment with the compounds. The results indicate that these marine-derived indoles may be able to reduce the toxicity caused by halogenated aromatic hydrocarbons. However, further direct aryl hydrocarbon receptor binding studies are required to confirm these findings.

3016 Distinct Roles for Xenopus laevis AhR Paralogs in Cell Cycle Regulation

The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor that mediates toxicity of dioxin-like compounds. AhR also plays roles in de- velopment and physiology in the absence of xenobiotics. These include pro motion of cell cycle progression through the G1/S checkpoint. Unlike humans and rodents, the frog Xenopus laevis has two AhR paralogs, AhRα and AhRβ, the result of a genome duplication ~34 mya. We recently generated mutant derivatives of the XLK-WG cell line, each lacking a functional version of either AhRα or AhRβ, and showed that the two receptors mediate distinct transcriptional responses to specific agonists. AhRα<sup>−/−</sup> mutants also require longer time to reach confluency. This study tests the hypothesis that each AhR plays a distinctive role in the regulation of cell cycle progression. To quantify differences in the proliferation of wild type and AhR knockout cell lines, we measured growth using the water-soluble formazan (WST-8) method. After 96 hours, XLK-WG and AhR<sup>−/−</sup> cells displayed nearly identical growth, whereas AhR<sup>α<sup>−/−</sup></sup> cultures contained approximately 30% fewer cells. We determined cell cycle distribution of each line by propidium iodide staining and flow cytometry. AhR<sup>β<sup>−/−</sup></sup> and wild type lines exhibited similar distributions of cells in the various phases (~ 5% in G0/G1, 50% in S, and 15% in G2. In contrast, only 16% of AhRα<sup>−/−</sup> cells were in S-phase, and only 7% in G2. Further, a discrete sub-G1 population (18%) was unique to AhRα<sup>−/−</sup> cells. These results are consistent with a distinctive role for AhRα in cell cycle regu- lation. However, AhRα<sup>−/−</sup> is approximately 3-fold more abundant than AhRβ<sup>−/−</sup> and its more severe knockout phenotype may stem from a greater overall reduction in cellular AhR content. Ongoing investigations seek to determine whether cell cycle regulation effects are caused by different expression lev- els of the AhR paralogs or truly distinct functions. Most vertebrates have multiple AhRs. This study contributes to understanding the differences between each receptor and how their expression affects interpretation of data from non-mammalian toxicological models.

2019 SOT Annual Meeting
3018 Hepatic Loss of Aryl Hydrocarbon Receptor (AhR), but Not AhR Nuclear Translocator, Mitigates High-Fat Dietary Challenge

N. Girer, I. Patrikeev, M. Motamed, and C. Efferink. University of Texas Medical Branch at Galveston, Galveston, TX.

The ligand-activated aryl hydrocarbon receptor (AhR) is a well characterized membrane receptor that responds to xenobiotic compounds, transforming proteins, and certain endogenous compounds. The AhR normally resides within a cytosolic protein complex that translocates to the nucleus upon AhR-agonist interaction. Following nuclear localization, the AhR dissociates from the complex to form a DNA-binding heterodimer with aryl hydrocarbon receptor nuclear translocator (ARNT). The AhR-ARNT dimer then binds to canonical and non-canonical xenobiotic response elements (XRE) to activate gene transcription. Our previous work has revealed that the AhR can also activate gene expression independent of ARNT, through interactions with Kruppel-type factor 6 (KLF6) at non-canonical XRE sites comprised of 5′-GGGA-3′ repeats. Here, we examined the effects of KLF6-specific AhR or ARNT loss in high-fat dietary (HFD) chow-induced, inducible conditional knockout mouse models that allows for the timed deletion of AhR or ARNT in adult mice. The data demonstrate that AhR loss significantly reduces HFD-driven weight gain by 59% compared to control mice, and significantly lowers fasting glucose by 28%. AhR deficiency additionally decreases hepatic lipid deposition and adiposity within perigonadal white adipose tissue (gWAT). Hepatocyte-targeted deletion of ARNT reduces hepatic lipid deposition, but does not alter HFD-driven weight gain or fasting glucose, and significantly increases qWAT adiposity 26%. Next-Generation Sequencing analyses reveal that only 3% of gene transcripts are down- or up-regulated in both HFD-fed AhR KO and ARNT KO mice. The data suggest that the protective effects of AhR loss against HFD challenge may be partly mediated via a loss of ARNT-independent signaling and highlight the need to further study this type of AhR activity. Current work is under way to identify specific gene pathways through which the AhR influences energy metabolism independent of ARNT. This work is supported by grants R01ES026874 and T32ES007254.

3019 Characterizing Compounds from the Tox21 10K Compound Library as Activators of the Human Constitutive Androstane Receptor

C. Lynch1, B. Mackowiak2, R. Huang3, L. Li4, S. Sakamuru1, H. Wang2, and M. Xia1. 1NIH/NCATS, Rockville, MD; and 2University of Maryland Baltimore, Baltimore, MD.

The constitutive androstane receptor (CAR; NR13) is a nuclear receptor which plays a significant role in all phases of drug metabolism and disposition. Recently it has also been implicated in modulating energy metabolism and different aspects of multiple cancer pathways. Therefore, identifying potential inducers of hCAR activation could allow for the prediction of potential therapeutic usage or drug-drug interactions. We screened the Tox21 10,000 compound collection to characterize potential hCAR activators. The screen revealed four compounds, rimacazole, dimepanid, phenothrin, and neticazole, as potential novel hCAR activators that also mediate CAR translocation from the cytoplasm to the nucleus of hepatocytes, which is the first step of CAR activation. One of these four compounds, rimacazole, demonstrated selectivity toward hCAR suggesting the need for further studies to establish the complete profile of this drug in the body. Categorized as hCAR activators, these compounds could be developed as potential therapeutic drugs, but are also at risk for drug-drug interactions.

3020 Aryl Hydrocarbon Receptor-Mediated Changes in Histone Mobility

E. Wright, A. Joshi, and C. Efferink. University of Texas Medical Branch, Galveston, TX.

The Aryl Hydrocarbon Receptor (AhR) is a ligand mediated transcription factor which regulates response to xenobiotics, including 2,3,7,8-tetrachlorodibeno- p-dioxin (TCDD). AhR signaling is mediated via xenobiotic response elements (XREs) found within the promoters of AhR target genes such as CYP1A1 and CYP1B1. Our laboratory has previously reported a distinct non-consensus xenobiotic response element (non-XRE) that also confers AhR-mediated target gene expression. AhR binding to NC-XRE sites in response to TCDD involves recruitment of both Kruppel-like Factor 6 (KLF6) and Carbamoyl Phosphate Synthase 1 (CPS1). CPS1 recruitment to the chromatin results in homocitrullination (H1K34hCIT), a novel epigenetic histone mark. The H1K34hCIT modification is agonist specific, occurring only in response to exogenous agonists such as TCDD, but not endogenous agonists such as cinnabarinic acid. We hypothesize the H1K34hCIT modification increases histone mobility in NC-XRE containing regulatory regions, to promote chromatin accessibility of the transcriptional initiation complex. Western blot analyses of nuclear extracts from TCDD-treated mouse liver demonstrate increased levels of H1K34hCIT. In vivo chromatin immunoprecipitation confirms the presence of the AhR, CPS1 and the H1K34hCIT modification at NC-XRE regulatory elements in known, non-canonical AhR target genes. Changes in nucleosome mobility and position in response to TCDD were evaluated genome-wide using Micrococcal Nuclease (Mnase)-seq. Here, we report that TCDD induces a significant increase in the amount of H1K34hCIT-risking Mnase fragments at the promoters of AhR target genes in response to TCDD. This work highlights the evolving intricacies of AhR biology and cross-talk with the epigenome. This work is supported by NIH grant R01ES026874.

3021 Triphenyl Phosphonate, an Environmental Contaminant, Is a Selective PPARy Ligand That May Not Be So Brite

S. Kim1, N. Rabhi2, S. Farmer1, and J. Schlezinger1. 1Boston University School of Public Health, Boston, MA; and 2Boston University School of Medicine, Boston, MA.

Metabolic homeostasis is regulated, in part, by a family of proteins called nuclear receptors through which lipophilic hormones and molecules regulate gene transcription. One such nuclear receptor is the peroxisome proliferator activated receptor y (PPARy). Its activation is essential for white, brite (brown in-white), beige and brown adipogenesis, mature adipocyte maintenance, and insulin sensitivity. Accumulation of white adipocytes significantly increases the risk of metabolic syndrome. On the other hand, brown and brite adipocytes potentially counteract metabolic disease-related symptoms. The white adipogenic, brite/brown adipogenic, and insulin sensitizing activities of PPARy are regulated separately through differential post-translational modifications and/or co-repressor recruitment, with ligands having distinct abilities to activate each of PPARy’s functions. In differentiated 3T3 L1 cells, triphenyl phosphonate (TPHP; a flax antibiotic, 20 μM) induces an adipocyte phenotype that is distinct from rosiglitazone (Rosi, a therapeutic PPARy ligand, 20 μM) and roscovitine (Rosco, a CDK5 inhibitor, 10 μM). While only TPHP and Rosi enhanced hormone-stimulated adipogenesis, as evidenced by the significant increase in lipid accumulation and gene expression of mature adipocyte markers (Ppard, Ppara, Cidea, Elov5). In addition, only Rosi and Rosco protected PPARy from phosphorylation at Ser-273. In mutated 3T3 L1 cells in which PPARy cannot be phosphorylated, TPHP is able to induce mRNA expression of Ucp1 and reduce Fabp4 expression. Moreover, short term (2 weeks) in vivo exposures to Rosi, TPHP, or Rosco in 8-week female C57BL/6J mice caused a significant increase in brite adipocyte gene expression (Elov5; Ucp1) in mature adipocytes from Rosi- and Rosco-treated mice and an increase in white adipocyte gene expression (Plin1, Retn) in mature adipocytes from TPHP-treated mice. These data support our hypothesis that environmental PPARy ligand, TPHP, skew...
adipocyte differentiation toward white adipogenesis at the expense of brite adipogenesis, potentially through modifying post-translational modifications of and/or co-regulator recruitment by PPARy.

**3022 The AhR Regulates Glycolysis to Promote SIRT1-Dependent Keratinocyte Differentiation**

Activation of the aryl hydrocarbon receptor (AhR) by the ligand, 2,3,7,8-tetrachlorodibenzodioxin (TCDD) increased AhR binding in the promoters of the glucose transporter, SLCA2A1, and the glycolytic enzyme, enolase 1 (ENO1). Chromatin binding of the AhR corresponded to decreases of SLCA2A1 and ENO1 mRNA, protein and activities. Measurements of the ENO1 promoter in reporter assays demonstrated that activation of the AhR decreased the transcription of ENO1. Glycolysis was lowered by activation of the AhR as measured by decreases in glucose uptake and the production of pyruvate and lactate. Down-regulation of glucose metabolism, either by activation of the AhR or inhibition of glycolysis, increased the level of SIRT1 protein in NIH3T3 cells. This increase of SIRT1 was inhibited by the addition of exogenous pyruvate. Moreover, keratinocyte differentiation in response to decreased glucose metabolism was dependent on SIRT1. These results indicate that keratinocyte differentiation is regulated by cellular metabolism and that ligand-mediated activation of the AhR decreases the expression of SLC2A1 and ENO1, thereby decreasing glycolytic flux and controlling the fate of keratinocytes.

**3023 Phenobarbital is an Agonist of Human but Not Mouse PXR**

L. Li1, Z. Li1, B. Mackowiak1, S. Heyward2, and H. Wang1. University of Maryland, Baltimore, MD; and BIOIVT, Baltimore, MD.

Phenobarbital (PB), a broadly used anti-seizure drug, was the first to be characterized as an inducer of hepatic cytochrome P450 (CYP) by the activation of the constitutive androstane receptor (CAR, NR1I3). While PB is recognized as a prototypical CAR activator through a well-documented indirect activation mechanism, conflicting results have been reported regarding whether PB can activate the orphan X receptor (PXRx, NR1I2), a sister receptor of CAR, across different species, and the underlying mechanisms are largely unknown. Here, we show that in the human CAR (hCAR)-knockout HepG2 cell line, both PB and rifampicin (a selective hPXRx activator)-mediated induction of CYP3A4 and CYP2B6 was intact while induction by CITCO (a selective hCAR activator) was significantly attenuated. In human primary hepatocytes and HepG2 cells, knockdown of PXRx by recombinant lentivirus or co-treatment with SPA70, a potent antagonist of hPXRx, inhibited CYP3A4 induction by PB and rifampicin. PB showed concentration-dependent activation of hPXRx but not mouse PXRx (mpXR) in HepG2 transactivation assays, while such activation was fully abolished by introducing a non-functional hPXRx mutant. Mechanistically, our surface plasmon resonance binding affinity assay showed that PB directly binds to the ligand binding domain (LBD) of hPXRx (KD (M) = 1.42E-05). PB also activates hPXRx but not mPXRx and provides an alternative pathway for PB-mediated CYP induction.

**3024 AhR2, but Not AhR1α or AhR1β, Is Required for Craniofacial and Fin Development and TCDD-Dependent Cardiotoxicity in Zebrafish**

J. P. Souder1 and D. A. Gorelick2. 1University of Alabama at Birmingham, Birmingham, AL; and 2Baylor College of Medicine, Houston, TX.

The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor that binds environmental toxins and regulates gene expression. AhR also regulates developmental processes, like craniofacial development and hematopoiesis, in the presence of environmental exposure. Zebrafish have three paralogues of AhR: AhR1α, AhR1β and AhR2. Adult zebrafish with mutations in AhR2 exhibited craniofacial and fin defects. However, the degree to which AhR1α and AhR1β influence AhR2 signaling and contribute to fin and craniofacial development are not known. We generated zebrafish with mutations in each AhR gene and compared morphology of adult AhR2 mutant and AhR1α/AhR1β single and double mutant zebrafish. We found that AhR1α/AhR1β single and double mutants were morphologically normal while AhR2 mutant zebrafish demonstrated fin and craniofacial malformations. At 5 days post fertilization, both AhR1α/AhR1β and AhR2 mutant larvae were normal, suggesting that adult phenotypes are due to defects in maturation or maintenance. AhR was shown to interact with estrogen receptor alpha, yet it is not known whether these interactions are constitutive or dependent on AhR1 genes. To determine whether estrogen receptors are constitutive co-factors for AhR signaling, we used genetic and pharmacologic techniques to analyze TCDD-dependent toxicity in estrogen receptor and AhR mutant embryos. We found that embryos with mutations in AhR1α/AhR1β or estrogen receptor genes are susceptible to TCDD toxicity while AhR2 mutant embryos are TCDD-resistant. Moreover, pharmacologic blockade of nuclear estrogen receptors failed to prevent TCDD toxicity. These findings suggest that AhR1 genes do not have overlapping functions with AhR2 in fin and craniofacial development or TCDD-dependent toxicity, and that estrogen receptors are not constitutive partners of AhR2.

**3025 AhR Signaling Regulation by ARNT Isoform Modification and Co-regulator Recruitment**

L. Bourner, I. Muro, A. Cooper, B. Choudhury, K. Gardella, G. Fang, K. Sarkar, and C. Wright. University of Texas Medical Branch, Galveston, TX.

The aryl hydrocarbon receptor (AhR) is a crucial transcription factor involved in remediating xenobiotic chemicals from within the human body, yet the mechanisms by which AhR is able to elicit different responses to exogenous and endogenous AhR ligands remains unclear. We hypothesize that the aryl hydrocarbon receptor nuclear translocator (ARNT), the DNA binding partner of AhR, performs a crucial role in the regulation of AhR ligand-specific gene expression. ARNT is expressed as two separate isoforms, ARNT isoform 1 and ARNT isoform 3, which differ by only 15 amino acids that make up exon 5 in ARNT isoform 1. This exon encodes a distinct phosphorylation site at serine 77 (S77), which can be induced upon exposure to the well-characterized AhR ligand and toxicant, 2,3,7,8-tetrachlorodibenzodioxin (TCDD). Upon mutation of S77 to alanine, RNA polymerase II is unable to be recruited to the CYP1A1 promoter, thus leading to a decrease in CYP1A1 transcription and leading to the importance of ARNT isoform 1 phosphorylation in AhR signaling. Differing functions of the ARNT isoforms have also been identified in AhR signaling through next generation sequencing, molecular techniques, and mass spectrometry in a human T cell lymphoma cell line. Uniquely recruited transcriptional co-regulators were found bound to ARNT isoform 1 or ARNT isoform 3 following mass spectrometry analysis with and without TCDD treatment, thus indicating another possible role the ARNT isoforms might perform in AhR signaling and suggesting that ARNT isoform 1 phosphorylation is required for the recruitment of unique co-regulators and activation of AhR target genes. Upon further validation of these co-regulator findings, we have continued exploration of the proteins interlink enhancer binding factor 3 (ILF3) and tripartite motif containing 28 (TRIM28) and the role they perform in AhR-ARNT signaling. These data indicate the critical roles of the ARNT isoforms in AhR signaling.

**3026 Regulation of ARNT Alternative Splicing**

A. Cooper, M. Kuyucu-Martinez, and C. Wright. University of Texas Medical Branch, Galveston, TX.

The aryl hydrocarbon receptor (AhR) is a cytosolic receptor that mediates the effects of environmental contaminants on the body. When activated, AhR translocates to the nucleus and dimerizes with the aryl hydrocarbon receptor nuclear translocator (ARNT) and together they bind to xenobiotic response elements of ARNT-related genes. During normal physiology this receptor plays a role in the differentiation of various pathways including hematopoiesis, B and T cells, and lymphoid systems. Toxic responses can occur when AhR is activated by exogenous ligands, like benzo-a-pyrene, and aberrant activation can occur. The aryl hydrocarbon receptor nuclear translocator (ARNT) is alternatively spliced to produce two isoforms, ARNT isoform 1 and 3. These isoforms differ in just 15 amino acids present in exon 5 that is included in the final mRNA transcript of ARNT isoform 1. Interestingly, normal lymphocytes have equal amounts of ARNT isoform 1 and 3, but lymphoid malignancies have ARNT isoform 3, which differ by only 15 amino acids that make up exon 5 in ARNT isoform 1. This exon encodes a distinct phosphorylation site at serine 77 (S77), which can be induced upon exposure to the well-characterized AhR ligand and toxicant, 2,3,7,8-tetrachlorodibenzodioxin (TCDD). Upon mutation of S77 to alanine, RNA polymerase II is unable to be recruited to the CYP1A1 promoter, thus leading to a decrease in CYP1A1 transcription and leading to the importance of ARNT isoform 1 phosphorylation in AhR signaling. Differing functions of the ARNT isoforms have also been identified in AhR signaling through next generation sequencing, molecular techniques, and mass spectrometry in a human T cell lymphoma cell line. Uniquely recruited transcriptional co-regulators were found bound to ARNT isoform 1 or ARNT isoform 3 following mass spectrometry analysis with and without TCDD treatment, thus indicating another possible role the ARNT isoforms might perform in AhR signaling and suggesting that ARNT isoform 1 phosphorylation is required for the recruitment of unique co-regulators and activation of AhR target genes. Upon further validation of these co-regulator findings, we have continued exploration of the proteins interlink enhancer binding factor 3 (ILF3) and tripartite motif containing 28 (TRIM28) and the role they perform in AhR-ARNT signaling. These data indicate the critical roles of the ARNT isoforms in AhR signaling.
**3027 Coffee as an Aryl Hydrocarbon Receptor (AhR) Agonist**

H. Park, U. Jin, L. A. Davidson, C. Alfred, A. Jayaraman, R. S. Chapkin, and S. Safe. Texas A&M University, College Station, TX.

Coffee is one of the most popular beverages worldwide, and several studies show a correlation between increased daily intake of coffee and decreased incidence of several conditions, including some cancers, liver and Parkinson’s disease and overall mortality. Extraction of coffee with boiling water and subsequent extraction of the water with chloroform showed that both the water and chloroform extracts induced the following aryl hydrocarbon receptor (AhR)-responsive genes CYP1A1, CYP1B1 and UGT1A1 in Caco2 colon cancer cells and in a young adult mouse colonocyte (YAMC) cell line. Compared to 10 mM 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) the water and chloroform coffee extracts induced ≥25% of the TCDD-induced CYP1A1 gene expression (maximal) whereas the coffee extracts maximally induced CYP1B1 and UGT1A1. In contrast, TCDD and the coffee extracts did not induce the detoxifying enzymes in AhR-knockout cells (Caco2-AhRKO and YAMC-AhRKO) demonstrating that coffee extracts contain AhR ligands and studies show that the AhR and AhR agonist are chemoprotective against some intestinal problems. Thin layer chromatography was used to separate the coffee extracts into 3 bands, namely top, middle (containing caffeine) and bottom and subsequent bioassays of these fractions showed that the AhR activity was concentrated in the top and bottom fractions and caffeine was inactive as an AhR ligand. Analysis of the total, top and bottom extracts by gas and chromatography-mass spectrometry showed that the coffee extract contained hundreds of compounds and several of these were screened in Caco2 and YAMC cells for their AhR-dependent activity. The alkaloid norharman was identified in the coffee extract and was a weak inducer of CYP1A1 gene expression in both YAMC and Caco2 cells and a more potent inducer of CYP1B1 and UGT1A1 thus resembling the differential gene induction pattern observed for the coffee extracts. Ongoing studies are focused on investigating other active constituents in coffee and their potential beneficial effects in the intestine and other target tissues.

**3028 Aryl Hydrocarbon Receptor Activation by Para-benzoquinones Are Substitution Dependent**

T. A. Thompson, D. A. MacKenzie, T. Borunda, G. Timmins, and T. Oprea. University of New Mexico Health Sciences Center, Albuquerque, NM.

The aryl hydrocarbon receptor (AhR) is expressed in many tissues and is extensively investigated due to its activation by environmental toxins. Benzoquinones are represented widely in nature and may act as mediators of toxicity. To investigate AhR activation by compounds containing benzoquinone structures, we developed an XRE/DRE-responsive GFP reporter system designated the Aryl Hydrocarbon Receptor Activation (AHRA) assay. How structural substitutions affect benzoquinone activation of the AhR is unclear. For example, it has been hypothesized that benzoquinone containing structures may activate the AhR through alkylation, though this has not been demonstrated definitively. In the current study, para-benzoquinone activation of the AhR was found to be modified extensively by substitutions present on the para-benzoquinone moiety. Unsubstituted para-benzoquinone had relatively potent activity, whereas substitution of all unsubstituted carbons with methyl groups (i.e., duroquinone, 2,3,5,6 tetramethyl para-benzoquinone) did not activate the AhR as measured using the AHRA assay. Addition of a single methyl substitution on the para-benzoquinone structure was a more potent AhR activator than para-benzoquinone. In contrast, substitution of the para-quinone structure with 3 methyl groups greatly reduced AhR activation. Similarly, either 2,6-dimethyl- or 2,5-dimethyl-benzoquinone substitutions had reduced activity compared to methyl para-benzoquinone. Interestingly, 2,3-dimethyl benzoquinone was a relatively potent activator of the AHRA assay. Tert-butyl para-benzoquinone was found to be the most potent activator of the AHRA assay among the para-benzoquinones investigated. Results from these studies support that alkylation of electrophilic carbons may contribute to benzoquinone activation of the AhR and substitutions on the quinone moiety strongly influence the potency of AhR activation by benzonquinones.

**3029 Microbiome-Derived Aryl Hydrocarbon Receptor Ligands Ameliorate Intestinal Inflammation in Mice**

P. Tu, L. Chi, and K. Lu. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Ligand activation of aryl hydrocarbon receptor (AhR) is an inviting therapeutic approach for inflammatory bowel disease (IBD), and dietary modulation of the gut microbiota received considerable attention. We investigated the role of microbiome-derived AhR ligands in intestinal inflammation via an integration of a mouse model of experimental colitis and a standardized black raspberry (BRB)-based dietary intervention. The results show that the BRB dietary intervention ameliorated the intestinal inflammation in mice in an AhR-dependent manner. With the dietary intervention, perturbations in the gut microbiota associated with colitis were partially restored. Furthermore, increased levels of AhR ligands in the diet-modulated gut microbiome resulted in enhanced AhR activation, which may contribute to the ameliorating effect on intestinal inflammatory status. Enriched bacterial genes and pathways in the biosynthesis of heme-related compounds that are known AhR ligands, in concert with strong correlations between specific bacterial species and these compounds suggested the involvement of gut bacterial activities in producing AhR ligands. Host metabolic profiling revealed restored metabolites that are relevant to inflammation and the gut microbiota. These findings provide insights regarding microbiome production of AhR ligands as an attractive therapeutic target of IBD via gut microbiome modulation.

**3030 PCB 126 Induces Macrophage Polarization and Inflammation through AhR and NfκB Pathways**

C. Wang, B. Hennig, and M. Petriello. University of Kentucky, Lexington, KY.

Polychlorinated biphenyls (PCBs) are persistent organic pollutants that contribute to inflammatory diseases such as atherosclerosis, and macrophages play a key role in the overall inflammatory response. Depending on specific environmental stimuli, macrophages can be polarized either to pro-inflammatory (e.g., M1) or anti-inflammatory (e.g., M2) phenotypes. We hypothesize that dioxin-like PCBs can contribute to macrophage polarization associated with inflammation. To test this hypothesis human monocytes (THP-1) were differentiated to macrophages and subsequently exposed to PCB 126. Exposure to PCB 126 significantly induced the expression of inflammatory cytokines, including TNFα, IL-1β and IL-6, suggesting induction of chemokines which regulate immune cell recruitment and infiltration of monocytes/macrophages into vascular tissues. In addition, oxidative stress sensitive markers including nuclear factor (erythroid-derived 2)-like 2 (NFE2L2) and down-stream genes, such as glutathione S-transferase (GST) and NAD(P)H quinone oxidoreductase 1 (NQO1), were induced following PCB 126 exposure. Since dioxin-like PCBs can elicit inflammatory cascades through multiple mechanisms, we then pretreated macrophages with both aryl hydrocarbon receptor (AhR) and NF-κB antagonists prior to PCB 126 treatment. The NF-κB antagonist BMS-345541 significantly decreased mRNA and protein levels of multiple cytokines by approximately 50% compared to PCB treatment alone, but the AhR antagonist CH-223191 was protective to a lesser degree. Our data demonstrate the involvement of PCB 126 in macrophage polarization and inflammation, indicating another important role of dioxin-like PCBs in the pathology of atherosclerosis. These data have translational implications, suggesting that environmental insults can influence the immune system and increase inflammation, creating an advantageous environment for cardiovascular disease progression.

**3031 Methylglyoxal-Derived Advanced Glycation End Products Mediate Matrix Metalloproteinases via Activation of ERK, JNK, NF-κB Signaling Pathways**

S. Jeong, H. Kim, and K. Lee. Korea University, Seoul, Korea, Republic of.

Advanced glycation end products (AGEs) is non-enzymatic reaction of reducing sugars and proteins. Accumulation of AGEs is associated with pathophysiological diseases, such as atherosclerosis, Alzheimer’s disease, cancer, and diabetic nephropathy. Receptor for AGEs (RAGE) mediates inflammatory signals leading to expression of inflammatory signals leading to tissue chronic cytokines. As the signal transduction RAGE is closely linked to diabetic nephropathy AGEs through its receptor RAGE have role in kidney cells inflammation proteolytic enzyme activation of Mitogen activated protein kinase (MAPK) signaling pathway. NF-κB activated range of signals including activation of MAPK path-
way process. MAPK pathway is responsible for initiating acute and chronic inflammatory in cells. In this study, we evaluated whether treatment of NRK-52E kidney cells with AGES influences the induction of matrix MMPs, which might be responsible for the development of kidney fibrotic dysfunction. The effect of methylglyoxal-derived AGES (AGE-4), among other AGES, on the induction of MMPs in NRK-52E cells was investigated. Enhanced MMP-2 and MMP-9 expression in methylglyoxal-induced NRK-52E cells was mediated by ERK, JNK, and NF-κB pathways. Therefore, our findings suggest that RAGE and AGE-4 contribute to the development of kidney fibrotic dysfunction. Effect of AGES on induction of inflammation in NRK-52E cells treated with AGES (100μg/ml). We suggest that AGES and RAGE interaction that plays an important role in MAPK pathway signals in inflammation-mediated cytokines in cells. This study indicates that AGE-4 increases MMP-2 and MMP-9 expression by RAGE expression in NRK-52E cells, and that RAGE-AGES is involved in the AGE-4 induced ERK, JNK, NF-κB signaling expression may be associated with the AGE-induced kidney dysfunction and elevated of T2DM patients via an increase in MMPs expression.

**3032 Novel Aerosol Treatment of Airway Hyper-Reactivity and Inflammation in a Murine Model of Asthma with an Inhibitor of Soluble Epoxide Hydrolase**

K. Tsuji1, J. Yang1, J. Singh1, J. Zhang1, S. M. Mack1, M. Takeuchi1, K. E. Pinkerton1, and B. D. Hammock1. 1University of California Davis, Davis, CA; and 2Kyoto Sangyo University, Kyoto, Japan.

Asthma affects more than 300,000,000 people in the world today, and the number of patients is increasing. Multiple methods of therapeutic intervention have been proposed, including steroid-based treatment modalities. Steroid-based treatments weaken overactive immune responses and control inflammation. However, they also carry some side effect risks to the immune system, including adverse effects on the liver, kidney dysfunction, and elevated of T2DM patients via an increase in MMPs expression. We discovered that NM treatment decreased MCP expression with specific small-molecule inhibitors. In previous studies, we and others found that skin inflammation effects induced by PGD2-G can be further augmented by inactivating CES1 activity. About 50% of its hydrolytic metabolism, and that PGD2-G could be stabilized by the inclusion of CES1 inhibitors. The inhibitor potency followed the rank order: CPO>WWL113>WWL229. THP1 macrophages co-treated with WWL113 and PGD2 prior to stimulation with lipopolysaccharide exhibited a more pronounced attenuation of pro-inflammatory cytokine levels (e.g. IL-6) than by PGD2 treatment alone. These results suggest that the anti-inflammatory effects induced by PGD2-G can be further augmented by inactivating CES1 activity with specific small-molecule inhibitors. Supported by R15GM12806-01.

**3033 Environmental Impact on Health through the Lens of Brain Microglia**

Inflammatory responses in the brain are thought to play a crucial role in the pathogenic process of a number of diseases. This inflammation may be induced by endogenous or exogenous stimuli, including neuronal death or environmental immune disruptors. The immune system plays a critical role in initiating a response to environmental stimuli, rendering the understanding of immune cell activation in the brain critical to understanding the environmental impact on the brain microglia. Microglia are resident immune cells of the brain that constantly survey their microenvironment and maintain homeostasis in the brain. This function of microglia suggests that these cells may be critical to understanding susceptibility to environmentally induced neurotoxicity and central nervous system disease pathogenesis. How the brain perceives the environment and whether it disseminates effects on the rest of the body when it is under attack has remained poorly understood. This study reveals a multi-organ immune response that is influenced by immune cell activation in the brain and results in dramatic events in peripheral tissues. Specifically, utilizing zebrafish larvae as an experimental model, we show that lipopolysaccharide (LPS)-induced neuroinflammation results in macrophage accumulation in the periphery in a tissue-specific and circulation-dependent manner. Additionally, we detect a systemic and tissue-specific upregulation of an acute-phase response gene, serum amyloid A (SAA), and a tissue-specific cytokine gene, metalloproteinase (MMP)-14 and inducible nitric oxide (iNOS) expression, suggesting a role for the p3023-stat3 signaling pathway in mediating a peripheral body response to brain inflammation. This study reveals dynamic functions of macrophages that may uncover how brain-specific perturbations might have widespread impacts on the rest of the body, and how changes to macrophage behaviors may provide a means to assess tissue-specific response to toxic stimuli.

**3034 Inactivation of Prostaglandin D2, Glycerol Ester Hydrolysis Using Carboxylesterase 1 Inhibitors Augments Its Anti-inflammatory Effects in Human THP1 Monocytic/Macrophage Cells**

H. Scheafer, S. Borazjani, B. Szafran, and M. K. Ross. Mississippi State University, Mississippi State, MS.

Human mononuclear cells in blood have important roles in host defense and express the enzyme carboxylesterase 1 (CES1). This metabolic serine hydrolase plays a critical role in the metabolism of many molecules, including prostaglandins called eicosanoids and oxygenated (PG) which are formed during cyclooxygenase-mediated oxygenation of the endocannabinoid-2-arachidonoylglycerol. Some PG-Gs have been shown to exhibit anti-inflammatory effects. However, they are unstable compounds and their hydrolytic breakdown generates pro-inflammatory prostaglandins. We hypothesized that by blocking the ability of CES1 in monocytes/macrophages to hydrolyze PGs, the beneficial effects of anti-inflammatory PGD2-G could be augmented. The goal of this study was to determine whether PGD2-G is catalyzed by CES1, than to evaluate the degree to which this metabolism is blocked by small-molecule inhibitors. A human monocytic cell line (THP1 cells) was pretreated with increasing concentrations of small-molecule inhibitors that block CES1 activity (chlorpyrifos oxon (CPO), WWL229, or WWL113), followed by incubation with PGD2-G (10 μM). Organic solvent extracts of the treated cells were prepared and analyzed by LC-MS/MS to assess levels of the hydrolysis product PGD2. Further, THP1 monocytes with normal CES1 expression (control cells) and knock-down CES1 expression (CES1KD cells) were employed to confirm CES1’s role in PGD2-G catalysis. We found that CES1 has a prominent role in PGD2-G hydrolysis in this cell line, accounting for about 50% of its hydrolytic metabolism, and that PGD2-G could be stabilized by the inclusion of CES1 inhibitors. The inhibitor potency followed the rank order: CPO>WWL113>WWL229. THP1 macrophages co-treated with WWL113 and PGD2 prior to stimulation with lipopolysaccharide exhibited a more pronounced attenuation of pro-inflammatory cytokine levels (e.g. IL-6) than by PGD2 treatment alone. These results suggest that the anti-inflammatory effects induced by PGD2-G can be further augmented by inactivating CES1 activity with specific small-molecule inhibitors. Supported by R15GM12806-01.

**3035 Skin Inflammation Following Exposure to Nitrogen Mustard Alters Levels Epigenetic Chromatin Modification Enzymes**

H. Kim1, L. B. Joseph2, G. M. Compstart-Wahler1, J. D. Laskin1, and D. E. Heck1. 1New York Medical College, Valhalla, NY; and 2Rutgers, The State University of New Jersey, Piscataway, NJ.

Inflammatory signaling networks are critical for oxidant defense and redox surveillance. However, many of the molecular events in cellular signaling following the exposure of skin to mustard agents remain poorly defined. Nitrogen mustard (bis-[2-chloroethyl]methylamine; NM) is a chemical threat agent that can cause inflammation, edema and ulcerative wounds in the skin. Currently there are no approved medical countermeasures to reverse the effects of NM. In previous studies we and others found that skin inflammation following exposure to NM is driven at least in part by oxidative stress. In the present studies, we tested the hypothesis that NM derived skin inflammation involves the modification of specific epigenetic pathways known to be modulated by cellular redox status. Using transcriptomics profiling and PCR gene array analysis, we visualized the effects of NM mouse keratinocyte PAM 212 cells and CD-1 mouse skin. We found that NM decreased DNA methyltransferase, histone methyltransferase and associated SET domain protein levels in PAM 212 cells. We hypothesized that these effects could regulate histone methyltransferase activity. We discovered that NM treatment decreased levels of Histone acetyltransferase 1 (K-specific demethylase, and Histone Acetyltransferase and Nuclear receptor coactivator 3 (Ncoa3) mRNA.
Interestingly, these alterations were associated with decreases in both histone phosphorylation and histone ubiquitination. Furthermore, we identified similar patterns of mRNA levels for histone methyltransferases, histone phosphorylation and histone ubiquitination modulating enzymes in NM-treated CD-1 mouse epidermis. Taken together, our transcriptomic profiles revealed markedly similar patterns of epigenetic chromatin modification enzymes in murine skin and keratinocyte cells. We speculate that these patterns play a critical role in regulation of inflammatory signaling in response to exposure to NM. Supported by NIH AR055073.

3036 Carbon Nanotubes Promotes Atherosclerosis Due to Enhancing Inflammatory Responses Triggered by Inflammasome Activation

1. Jichi Medical University, Shimotsuke, Japan; 2. Meic University, Tsu, Japan; and 3. Toyo University of Science, Noda, Japan.

Asbestos and silicon have been shown to activate the NLRP3 inflammasome. Inflammasome activation is triggered by reactive oxygen species, which are generated by a NADPH oxidase. Carbon nanotubes are a valuable industrial product but there is potential for human pulmonary exposure during production and their fibrous shape raises the possibility that they may cause inflammation and oxidative stress. We hypothesized that carbon nanotubes promote atherosclerosis due to enhancing inflammatory responses triggered by inflammasome activation. The present study investigated the roles of NLRP3 inflammasome in the atherosclerosis lesion induced by carbon nanotubes (DWCNTs) using apolipoprotein E-deficient (ApoE−/−) mice, a model of human atherosclerosis. Male ApoE−/− and age-matched wild type (WT) mice (n = 8 for each group) were treated with short or long DWCNTs (10 or 40 μg/mouse) once every other week for 8 weeks by pharyngeal aspiration.

After treatment, the aortic arch was stained with oil red-O solution to evaluate the extent of atheroma formation. ApoE−/− mice exposed to CNTs at the high dose showed increased plaque area in the aorta by oil red-O staining. RNA was extracted from the thoracic aorta and the expression of inflammasome activation was analyzed. The expression of NLRP3, which is a central constitutive factor of inflammasome, and the expression of inflammatory factors (VCAM-1, ICAM-1) and cytokine (MCP-1) were significantly increased in ApoE−/− mice treated with long DWCNTs at the high dose. Furthermore, in human umbilical vein endothelial cells (HUVECs) treated with the high dose of DWCNTs the level of cytokine (IL-1β) was significantly elevated. The results suggested that DWCNTs induced the formation of arteriosclerotic lesion due to enhancing inflammatory responses triggered by inflammasome activation.

3037 Effects of Deficiency of FXR and Lcn2 on Liver Injury in a High-Fat Diet-Induced Mouse NAFLD Model

J. Yang, L. E. Armstrong, B. Kong, and G. L. Guo, Rutgers, The State University of New Jersey, Piscataway, NJ.

Farnesoid X receptor (FXR), well-known for maintaining bile acid homeostasis, also critically regulates liver inflammation. FXR expression is downregulated with inflammation and in patients with non-alcoholic steatohepatitis (NASH). NASH is an aggressive form of non-alcoholic fatty liver disease (NAFLD) characterized by steatosis, lobular inflammation, hepatocyte ballooning, and even fibrosis. About 30% of adults in the U.S. have NAFLD, with 5-10% estimated to progress to NASH, potentially leading to irreversible cirrhosis and hepatocellular carcinoma. FXR has been shown to regulate innate immunity and one of the mechanisms is by inducing acute phase proteins (APPs) in hepatocytes. APPs are increased in response to acute phase response (APR), a systemic reaction to tissue injury or infection. Lipocalin 2 (Lcn2) is an APP that is responsive to cellular stress (cell injury or inflammation) and overexpressed in livers of NASH patients. This study aims to assess NAFLD development in mice deficient in both hepatic FXR and Lcn2. Wild type (WT), FXR−/−/Lcn2−/−, Lcn2−/−/FXR−/− (DKO) mice were fed a control (CD, 10% kcal) or high-fat diet (HFD, 60% kcal) for 1, 3, and 6 months. Genotypes were characterized for phenotypic differences based on serum markers, liver gene expression levels, and histology. DKO-HFD mice had worsened liver injury compared to all other genotypes by 6 months, with worsened steatosis and liver inflammation via H&E staining and elevated liver weight (9.7%). DKO-HFD mice had elevated serum ALT (290 U/L), total bile acid (TBA, 94 μmol/L), and cholesterol levels (297 mg/dL). Mcp-1 mRNA levels were significantly increased 10-fold by 3 months in DKO-HFD mice compared to all other genotypes, and this induction was sustained, while Lcn2−/−/FXR−/− mice achieved 10-fold induction by 6 months. Hepatic FXR mRNA was negatively correlated to TBA, ALT, Mcp-1, and Lcn2 levels, and hepatic Lcn2 mRNA was positively correlated to ALT and TBA levels. FXR and Lcn2 deletion worsened NASH phenotype; therefore, we propose that FXR, the APR, and Lcn2 play a significant role in preventing NASH progression.

3038 Voltage-Gated Kv1.3 Activation and Expression Are Increased in Neurotoxic Models of Parkinson’s Disease

E. Malovic1, S. Sarkar1, H. Nguyen1, M. Langley1, J. Luo4, N. Singh1, J. Jin4, V. Anantharam1, A. Kanthasamy1, H. Wulff2, and A. G. Kanthasamy3.

1. Iowa State University, Ames, IA; 2. Harvard Medical School, Boston, MA; 3. University of California Davis School of Medicine, Davis, CA; and 4. Mayo Clinic, Rochester, MN.

Chronic neuroinflammation sustained by persistent activation of the microglial cells is a primary contributor to the neurodegenerative processes of Parkinson’s disease (PD). Identification of key targets that regulate neuroinflammation will help in the development of novel therapeutic agents for the treatment of PD. Herein, we demonstrate that expression of the voltage-gated potassium channel Kv1.3 is significantly increased in microglia activated by misfolded aggregated α-synuclein (αSyNagg). The upregulated expression of Kv1.3 was also observed in various PD paradigms, including the neurotoxic MPTP model and the transgenic MitoPark model, and was further verified in postmortem PD patients. Notably, patch-clamping of Kv1.3 on microglia revealed that the increased expression levels were positively correlated with increased channel activity. The increase in expression and activity levels occurred concomitantly with the production of proinflammatory cytokines, suggesting that Kv1.3 regulates inflammatory inflammation. Indeed, pharmacological inhibition of Kv1.3 by PAP-1 significantly attenuated the production of proinflammatory cytokines in αSyNagg-stimulated microglia. Furthermore, oral administration of PAP-1 exhibited neuroprotection against MPTP-induced dopaminergic neurotoxicity and neuroinflammation. The Kv1.3 inhibitor also effectively reversed the motor deficits and the loss of striatal dopamine content in the chronic, progressively degenerative MitoPark mouse model of PD. Collectively, we demonstrate that Kv1.3 is vital for microglia-driven inflammation, contributes to dopaminergic neurotoxicity, and is a potential therapeutic for PD.

3039 Effects of Different Liquid Flow Rates on Cytotoxicity and IL-8 Secretion Level of Human Lung Macrophages

The human lung macrophages are the innate immunity, play a key role in the COPD’s progression. As its populations are mainly reside at the airspaces of the lung and localise in the interstitial space between the alveoli and blood vessels, macrophages are exposed to mechanical stress during the respiratory movement. Studies have shown that the mechanical stress generated by mechanical ventilation is the cause of further inflammatory damage in COPD patients. However, macrophages are typically cultured in a resting medium in vitro, which does not mimic the mechanical stress that macrophages undergo in vivo. The objective of this study was to use a drive-buffer-circulation system to generate a certain liquid flow rate to form mechanical stress to simulate the mechanical environment in which macrophages were exposed in vivo and to evaluate the effects of different flow rates on cytotoxicity and IL-8 secretion level of human lung macrophages. Human lung macrophages were cultured in the system (cell suspensions were distributed in buffer chamber (35 mL) and drive-circulation pipes (5 mL), respectively) and exposed to different liquid flow rates (0, 1, 5, 10 mL/min) for 3h. At 0, 0.5, 1, 2 and 3h time points, 0.8 mL cell suspensions in the system were separately removed for real-time detection or resting culture for 24 h before detection. CCK-8 proliferation assay was used to detect the cytotoxicity and ELISA test was used to detect IL-8 secretion levels. Compared with the 0 mL/min (0, 0.5, 1, 2 and 3h) groups, the results showed that the mechanical stress produced by the system decreased the survival rate of macrophages and promoted the secretion of IL-8 in a flow rate- and time-dependent manner, and the 1 mL/min (0, 0.5, 1, 2 and 3h) groups had no significant effect on survival rate of macrophages and IL-8 secretion levels. In addition, the resting culture 24h groups had lower cell viability and IL-8 secretion levels than the real-time test groups. These results suggest that in this system, mechanical stress which generated by liquid flow rates greater than 1 mL/min may induce macrophages cytotoxicity and inflammatory responses; and liquid flow rates less than 1 mL/min can be further used to study the mechanical environment in which macrophages are under in normal bodies.
A chronic disease condition of the gastrointestinal tract of humans, inflammatory bowel disease (IBD) is manifested as severe diarrhea, fatigue, and weight loss. Factors including genetic susceptibility, mucosal immune dysregulation, gut dysbiosis and exposure to toxic metabolites of drugs and chemicals play a role in the pathogenesis of IBD. Current treatment regime is predominantly symptomatic and provides limited relief. Due to inherent anti-inflammatory and immune modulatory effect, the use of cheese cultures could be a potential strategy against IBD. In this study investigated the anti-IBD effect of two cheese culture strains using a cell culture and mice model. Two cheese cultures Lactococcus lactis ssp lactis (MS8) and Streptococcus thermophilus (TA 61) were used in this study. These cultures were grown at 37 °C in deMan, Rogosa Sharpe broth for 24 h. Caco-2 cells were cultured in DMEM with 20% fetal bovine serum at 37°C for 16 - 20 days. Following differentiation, the monolayers were exposed to cheese cultures (~ 7 log CFU/mL) for 24 h. The cells were then treated with a cytokine cocktail (IL-1β, TNF-α, IFN-γ and LPS) for 24 h, to activate maximal inflammatory response. Inflammatory response was assayed by estimation of IL-8, pNF-κB and transcellular electrical resistance (TEER). The study was replicated thrice with duplicate samples, and the data were analyzed using Proc mixed procedure of SAS 9.4. In the mice study, IBD was induced with 2% dextran sodium sulphate administered orally on the fourth week following dietary supplementation of cheese cultures. Effects of the treatment were assessed by measuring the disease activity index (DAI), intestinal permeability and colonic inflammation. Exposure to probiotics prior to cytokine treatment significantly reduced the activation and nuclear translocation of NF-κB compared to cytokine control (P <0.05). Further, the reduction in pH in the stomach was associated with a significant reduction in pro-inflammatory cytokine production namely, IL-8 (P<0.05) and decreased intestinal permeability. The mice study validated the protective effect of cheese cultures in IBD by decreasing inflammation, reducing the DAI and improving barrier integrity. Results of our study indicate that the cheese starter cultures could be employed in the management of IBD.
The blood coagulation factor fibrinogen can modulate inflammation by altering leukocyte migration and activity. To date, analyses of fibrinogen-mediated pro-inflammatory activity have largely focused on leukocyte integrin binding activity revealed by conversion of fibrinogen to a fibrin polymer by blood coagulation enzymes. Entirely separate from clot formation, fibrinogen can serve as a substrate for tissue transglutaminase (TGM2), a widely-expressed enzyme involved in tissue injury. We tested the hypothesis that the pro-inflammatory activity of surface-adered fibrinogen is fundamentally altered through cross-linking by TGM2. Mouse bone marrow-derived macrophages (BMDMs) were cultured on tissue culture plates coated with fibrinogen or TGM2-cross-linked fibrinogen (10 μg/mL) and then stimulated with lipopolysaccharide (LPS, 1 ng/mL) or vehicle for various times. TGM2-mediated activity produced an atypical hybrid of fibrinogen Aα-g chain cross-linked products as determined by Western blot analyses. TGM2-cross-linked fibrinogen enhanced inflammatory gene induction (e.g., TNFα), but had no effect on expression of anti-inflammatory cytokine IL-10 relative to unmodified fibrinogen or stimulation with TGM2 alone. LPS treatment dramatically increased expression of TNFα and IL-10, and this was unaffected by unmodified fibrinogen. However, TGM2-cross-linked fibrinogen significantly reduced (>50%) LPS-mediated induction of IL-10 mRNA and IL-10 protein expression. The inhibition of IL-10 was rapid and selective, as LPS induction of TNFα was unaffected by TGM2-mediated cross-linking of fibrinogen. The results indicate that TGM2-driven cross-linking of fibrinogen selectively alters pro-inflammatory responses in macrophages and suggests a novel mechanism whereby fibrinogen may control IL-10 expression in conditions of tissue injury.
3049 Using the Aggregate Exposure and Adverse Outcome Pathways to Create a Taxonomy of Chemical Interactions Relevant to the Assessment of Human Health and Environmental Risks

P. S. Price¹ and J. Leonard². US EPA, Research Triangle Park, NC; and Oak Ridge Institute for Science and Education, Oak Ridge, TN.

Understanding the impacts of concurrent chemical exposures on human health and the environment requires information on chemical interactions (the ability of one chemical to influence the effects of a second chemical). Chemicals interact through a variety of mechanisms. Aggregate Exposure Pathways (AEPs) organize mechanistic data on fate and transport, exposure, and dosimetry, while Adverse Outcome Pathways (AOPs) organize mechanistic data on toxicological effects. Together they provide a framework for defining causal events over the entire source-exposure-response continuum for a receptor (a person, non-human organism, or population). A taxonomy of chemical interactions is proposed that is based on the location in the continuum where a chemical interaction occurs. The taxonomy consists of a set of hierarchal categories defined using the nodes and edges of the AEP-AOP framework. Four top-level and mutually-exclusive categories are defined as: 1) interactions that occur between the source and the external exposure surface (or boundary) of an organism; 2) interactions that occur between the surface and the target site exposure; 3) interactions that occur between the molecular initiating event (MIE) and the receptor's adverse outcome (AO); and 4) interactions that only occur for population level AOs (i.e. ecological endpoints). Categories 1 and 2 have subcategories for interactions involving: transport processes, transformation processes, and direct reactions between chemicals. Category 3 has subcategories for chemicals that interact through a common MIE, a common key event on an AEP or a common AO (but with separate AOPs). Category 4 has subcategories based on direct and indirect interactions that cause an AO in a population of organisms. The categories and subcategories provide insights potentially useful in assessing the impact of chemical interactions on non-cancer risks, developing standardized definitions for interaction terms, and designing assays to predict the potential for interactions between specific chemicals. The views expressed in this presentation are those of the authors and do not reflect the views or policies of the US EPA.

3050 Exposure to a Mixture of Suspected Thyroid Disrupting Chemicals Alters T Cell Differentiation in Xenopus laevis Tadpoles

C. McGuire, F. De Jesus Andino, F. Kim, and J. Robert. University of Rochester Medical Center, Rochester, NY. Sponsor: P. Lawrence

Thyroid hormones (TH) control postembryonic vertebrate development through thyroid receptor (TR) signaling. Deficiencies in TH production during development are known to contribute to immunodeficiency in humans and poorer outcomes in autoimmune disease models. To investigate whether endocrine disrupting chemicals that act on the TH pathway can alter the development of the immune system, we tested a mixture of chemicals used in unconventional oil and gas extraction that are suspected to be TR antagonists. TH synthesis inhibitors. This mixture consists of equimass concentrations of naphthalene, ethylene glycol, ethoxylated nonylphenol, and ethoxylated octylphenol. TR antagonist activity was verified by exposing pre-metamorphic Xenopus laevis tadpoles to 1.25 nM of the TR agonist triido-L-thryonine (T3) and T3 combined with 1 μg/L or 10 μg/L of the mixture or DMSO control for two weeks and evaluated changes in T cell subsets in the thymus and spleen, using monoclonal antibodies for CD8 and CD4 (a pan T cell marker) and two-color flow cytometry. Exposure to the 10 μg/L dose of the mixture significantly increased the frequency of CD8/CD5⁺ T cells, a cell population that is analogous to mammalian CD4⁺ T cells, in both the thymus and spleen. Exposure to the mixture also increased the frequency of CD8⁺/CD5⁻ T cells in the spleen but not the thymus. Notably, the ratio of CD8⁺ T cells to putative CD4⁺ T cells in the thymus was significantly reduced by exposure to the mixture. Taken together, these data suggest that thyroid hormone disruption induced by water pollutants during pre-metamorphic tadpole development unbalances differentiation of immature T cells toward the CD4 lineage rather than CD8 lineage. Future experiments will assess whether exposure to this mixture of TH-disrupting contaminants weakens antiviral T cell responses against viral pathogens in the short-term in tadpoles and the long-term in adult frogs after metamorphosis.

3051 Issues in Modeling Continuous Endpoints for Chemical Mixtures Risk Assessment

J. Swartout. US EPA, Cincinnati, OH.

Dose-response modeling of toxicological endpoints expressed as continuous measures for assessing the corresponding response of a mixture of chemicals can be challenging. The issues include: 1) differences in study control response, 2) differences in chemical response extrema (max or min), 3) differences in chemical dose-response curve shape, and 4) unknown capacity of the organism to accumulate damage. For 1), control responses theoretically should be the same for the same assay system (same species, strain, sex, etc.) but sometimes differ significantly across studies, which causes the mixture result to be dependent on the choice of the reference control; there appears to be no single optimal solution to this problem, but alternatives are suggested. For 2) is the problem of statistical agonism, which chemical components can elicit a response as extreme as a full agonist. In this case, when performing dose addition, the dose representing the partial agonist response is undefined beyond its extremum and the effective total mixture dose becomes ambiguous; solutions have been published, but have limited applicability or require subjective assumptions. For 3), relative chemical potencies will not be dependent on the response level, making the standard index chemical (IC), relative potency factor approach unsuitable, as the mixture result becomes dependent on the choice of IC. There are a few solutions that have been applied, with the “harmonic mean” method being in widespread use. However, all of these solutions have limitations, particularly with low-dosed extrapolation. Issue 4) applies to the use of effect summation when independence of action has been established for some mixture chemicals. Unrestricted addition of continuous measures will eventually exceed the biological capacity for damage accumulation, or will not be consistent with the inherent kinetics of damage accumulation, neither of which will probably be known. In this case, it may be prudent to limit effect summation to the lower end of the full response range and small levels of change in the effect. Examples for all 4 issues are shown, with potential “errors” in the order of magnitude, or less, range. The views expressed here are those of the author and do not necessarily reflect the views and policies of the US EPA.

3052 Virtual Cell Simulations to Probe the Effects of Complex Mixtures from Low to Higher Concentrations

L. D. Burgoon. US Army Engineer Research and Development Center, Apex, NC.

People and ecological receptors are exposed to chemicals as mixtures, not as single chemicals. However, there still exists a great deal of uncertainty with respect to how chemicals interact at low and higher environmental concentrations. The goal of this project is to use the estrogen receptor and gene expression response as a cell signaling model to explore how chemical mixtures respond both in vitro (i.e., the absence of endogenous estrogens) and in the likely in vivo situation (where endogenous estrogens are also present). The model uses known equations from biochemistry and affinity/dissociation constants for chemicals, and estrogen receptor binding to DNA, and gene expression kinetic models to integrate knowledge. We used an agent-based system, where chemicals, the estrogen receptors, and DNA, are all different agents, to simulate how the system as a whole interacts. This allowed us to ask questions about how different amounts and levels of chemicals in our mixture, which all have different dissociation constants, lead to differences in gene expression, and to address if concentration/dose addition or response addition explain the results we are seeing. In general, we found that due to low concentration of estrogen receptor, and due to the fact that binding is largely competitive and driven by affinity, that when there are large differences in the affinity of members of a complex mixture, that the chemicals with the most affinity tend to win out, with very little interaction between members of the mixture, meaning the potency tended to reflect those chemicals.
with the most affinity. We assumed for simplicity that efficacy was the same for all chemicals, which we know is not true, and were primarily interested in changes in potency due to the mixture. Future work will expand the model to also include efficacy estimates. The US Army Chief of Engineers has approved this paper for release. The views presented in this article do not necessarily reflect current or future opinion or policy of the US Army Corps of Engineers.

**3053** A Novel Risk Assessment Model for Incorporating Co-Exposures Provides Preliminary Guideline Values for Unregulated Chemicals

E. M. Tanner¹, C. Bornehag², and C. Gennings¹. ¹Mount Sinai School of Medicine, New York, NY; and ²Karlstad University, Karlstad, Sweden.

Traditional risk assessment provides guideline values based on single chemical evaluations, primarily using animal models. However, results do not account for multiple chemical exposures, may not adequately reflect human dose-response, and guideline values for internal concentrations are unavailable for many chemicals commonly detected in human biomonitoring. The Acceptable Concentration Range (ACR) model, a novel nonlinear dose-response model that incorporates co-exposures, previously found points of departure (POD) for 11 compounds below published Human Biomonitoring (HBM) or Biological Equivalent (BE) values when applied to epidemiologic data. Here, we extend the ACR model to provide PODs for 15 additional chemicals. We applied the ACR model to 26 prenatally measured compounds (µg/L) in relation to birthweight among the population-based Swedish SELMA pregnancy cohort of 1357 mother-child pairs to (1) estimate POD and asymmetric 90% CIs for these chemicals, and (2) assess how the ACR model scaled when analyzed for single compounds, chemical class groups, or a full mixture. Results: Consistent with prior analyses of 11 compounds, PODs were below published HBM/BE values for many chemicals (e.g. Bisphenol A POD =5.9 CI=2.9-16.1, vs. HBM=200). For chemicals without regulatory guideline values, PODs were generally less than the 95th% exposure level in the study population (e.g. Hexachlorobenzene POD=65.7 CI=39.2-79.4, vs. 90th%=68.9). On average, adding chemicals to the ACR model lowered estimated PODs by 24% and 34%, for the class grouping and full model, respectively, when compared to the single chemical model (e.g. Nonachlor single: POD=56.9, class grouping: POD=37.3, mixture: POD=29.3). When accounting for co-exposures in a sensitive human population, our results indicate that current regulatory guidelines may be too high. Where guideline values are unavailable, PODs can be estimated for multiple chemicals to provide empirical estimates for determining mixture assessment factors for single chemical guideline values. Future research will evaluate ACR model performance under varying assumptions and estimated POD generalizability to other study populations.

**3054** Multiple Environmental Stressors in Tropical Coastal Ecosystems Exert Biological Responses in Caenorhabditis elegans

M. Alcala-Orozco⁴, K. Caballero-Gallardo¹, M. Duran-Izquierdo¹, K. Fuentes-Lopez¹, J. Osorio-Martinez¹, J. De la Rosa¹, C. Corada-Fernandez², and J. Olivero-Verbel¹. ¹University of Cartagena, Cartagena, Colombia; ²University of Huelva, Huelva, Spain; and ³University of Cadiz, Cadiz, Spain.

Cartagena Bay (CB) is one of the coastal ecosystems more influenced by industrial and domestic activities in the Caribbean. The aim of this study was to evaluate contamination patterns by inorganic and organic pollutants in CB and Great Manabi (GMSM), a Ramsar site that is the largest estuarine system on the Caribbean coast of Colombia. Sediments were sampled during both dry and rainy seasons, at twelve and three locations, at CB and GMSM, respectively. Forty seven trace elements were analyzed using ICP-MS; Hg was measured using a direct mercury analyzer; PAHs and emerging pollutants, including UV filters, fragrances, organophosphate flame-retardants, pesticides, and PCBs were quantified by GC-MSM, respectively. Analysis of PAHs and emerging pollutants in sediments was evaluated using multivariate geospatial analysis. The number of available and new chemical substances call for the development of novel in vitro methods for the detection of synergistic or cumulative effects of mixtures, since it is highly desirable to reduce animal experiments. Here, we established multiplexed mass spectrometry and targeted metabonomics assays to profile toxicologically relevant proteins. After fragmentation of cell culture samples using tryptic one peptide derived from each protein of interest is enriched by TBP antibodies which recognize a very short C-terminal epitope. The peptides can be unambiguously assigned to the proteins by tandem mass spectrometry. The target proteins are indirectly quantified by referencing the endogenous peptides to spiked synthetic isotope-coded peptide standards. HepaRG cells were chosen as a model to investigate the effects of single pesticides and combinations thereof. Based on prior global mRNA profiling experiments, we selected a subset and analyzed the 24h effect of 30

**3055** Human-Relevant Potency-Threshold (HRPT) for ERα Agonism

C. J. Borgert¹,², J. C. Matthews¹, S. P. Baker¹, S. L. Levine³, and A. Bone⁴. ¹University of Florida, Gainesville, FL; ²Applied Pharmacology & Toxicology, Gainesville, FL; ³University of Mississippi School of Pharmacy, University, MS; and ⁴Bayer Crop Science, Chesterfield, MO.

The ability of chemicals to produce physiological effects depends on pharmacokinetics and potency via the modes of action (MoAs) underlying the effects. Besides pharmacokinetics, a chemical’s ability to produce a physiological effect via a particular MoA depends on its affinity for the functional components (receptors, enzymes, transporters, etc.) that comprise the MoA and the ability to alter their functional state (activity). We tested the hypothesis that dose-response, lowest effective mechanistic potency is required for chemicals to produce physiological effects by a particular MoA in humans by comparing their potencies for the ERα-agonist MoA to data from clinical trials of estrogenic effects. Systematic literature searches identified potency data for transcriptional activation of human ERα (ERTA) and for rodent uterotrophic activity (RUA) for chemicals with consistently observable, possible, and no physiologi- cal effects. Results: In a multiple regression analysis, potency data from ERTA (1E-04 CI=1E-06-1E-03), individual (17β-estradiol reference) in the form of best fit data which showed similar rank orders at 0.5 to 1E-01 the ERTA potency. Physiological estrogenic effects in clinical trials are clear for endogenous hormones and pharmaceuticals, absent for androgens, and were equivocally observed for botanical estrogens with relative ERα-agonist potencies in the range of 1.0E-03, but not lower. Based on this approach and analysis, we conservatively propose a human-relevant potency threshold (HRPT) for ERα agonism of 1E-04 relative to the potency of the endogenous estrogenic hormone 17β-estradiol or the pharmaceutical estrogen, 17α-ethinylestradiol. This approach provides a practical means for addressing hazard identification based on MoAs, for defining common assessment groups for mixtures risk assessment, and for determining candidate chemicals for AOPs. Preliminary analysis suggests future work could extend the approach to ecological species by de novo evaluations or possibly by species-extrapolation of potency data for conserved homologous molecular targets.
Development and Validation of a QuEChERS Based Gas Chromatography Tandem Mass Spectrometry Method for the Determination of Volatile Esters in Tobacco

The volatile constituents in tobacco are transferred directly from the tobacco into the mainstream of smoke without structural changes during smoking. The distinctive aroma of tobacco and specific notes in smoke are specifically related to some of these compounds. Esters usually have a sweet taste, a fruity aroma or a wine aroma, which is coordinated with the aroma of tobacco. To determine the aroma components that affect tobacco quality, 50 important esters were selected from the list of ingredients added to tobacco in the manufacture of cigarette products by major American tobacco companies, BAT and CNCTC. To satisfy the demand for monitoring esters in tobacco, a reliable and rapid gas chromatography tandem mass spectrometry (GC-MS/MS) multi-components method for the simultaneous analysis of 50 esters in tobacco was developed and validated using a QuEChERS based extraction procedure. Tobacco samples were soaked in acid solution to adjust to a pH of 3, extracted with acetonitrile and cleaned up by SinChERS-Nano purification column. Multiple reaction monitoring mode was applied for the quantification and confirmation of those compounds. The calibration curve of 50 esters presented good linearity. Average recoveries of all of the compounds in tobacco were in the range of 60-158% with relative standard deviations of 0.74-18.82% at three fortification levels. The limits of quantification (LOQs) of 38 compounds ranged from 0.002 to 0.087 μg/g at the signal-to-noise ratio (S/N) of 10, and the LOQs of the remaining 12 compounds is in the range of 0.10-0.46 μg/g. The results indicated that GC-MS/MS exhibits better performance in sensitivity and throughput comparing to GC-MS. The validated method was successfully applied to the analysis of real tobacco samples, Methyl hexadecanoate had the highest detected frequency, and this was followed by Methyl octadecanoate, ethyl palmitate and Methyl oleate. These results demonstrated that the method could be applied to the analysis of esters in tobacco samples.

An Organotin Mixture Inhibits Tributyltin's Adipogenic Differentiation in 3T3-L1 Cells

Y. Pu, J. V. Adomshick, and A. Vega-Lopez, Michigan State University, East Lansing, MI.

Organotin (OT) chemicals (butyltins and phenyltins) are used as stabilizers in pipes and foams. Tributyltin (TBT), and more recently dibutyltin (DBT), and triphenyltin (TPT) have been shown to stimulate adipogenic differentiation. Although these chemicals coexist in the environment, their effect in combination remains unknown. We investigated the adipogenic effect of eight OT chemicals upon either a single exposure or as a mixture using the preadipocyte 3T3-L1 cell line and hypothesized that OT mixtures would exacerbate the adipogenic effect of single OT exposures. TBT, added to adipogenic medium for 2 days followed by 8 days of growth medium plus insulin (1μg/ml). Cells were exposed to the vehicle (DMSO), dexamethasone (positive control), or a single OT (at 10 or 50 ng/ml; monobutyltin (MBT), DBT, TBT, tetrabutyltin (TebT), monophenyltin (MPT), diphenyltin (DPT), TPT, or tin chloride (SnCl2)). After 10 days, body lipid was used for lipid droplet identification as a marker of adipogenic differentiation and cells were harvested to measure mRNA expression of markers of late adipogenesis, such as FABP4. OTs that stimulated adipogenesis (DBT, TBT, and TPT) were used in dual or triple mixture combinations. Cell viability by MTT assay was only reduced in TBT50-DPT50-TPT50 (P<0.05). The strongest adipogenic differentiation occurred with TBT exposure (in a dose-dependent manner) followed by TPT and DBT (P<0.05). Adipogenic differentiation in a dual combination of TBT10 with DBT10 or TPT10 was similar to TBT10 single exposure but was reduced in dual exposure with DBT50 or TPT50 (P<0.05). TBT50-induced differentiation was also reduced in dual mixture with TPT10, TPT50, or DBT50 (P<0.05), but not DBT10. Both triple mixtures resulted in reversal of TBT’s adipogenic differentiation down to control levels (P<0.05). TBT-, DBT-, or TPT-treated cells (both 10 and 50 ng/ml doses) displayed a dose-dependent upregulation of FABP4 (P<0.05). All dual and triple combinations of TBT, DBT and/or TPT had upregulated expression of the control group (P<0.05). We demonstrated that DBT and TPT could counteract TBT’s adipogenic differentiation. These findings highlight the potential antagonistic effects among OTs at environmentally relevant doses and the need to understand the effects and mechanism of action of complex OT mixtures on adipogenic outcomes. Funding: NIEMS/NIMH Z2ES026208 to A.V.L.

Predicting the Activation of the Androgen Receptor by Mixtures of Ligands Using Generalized Concentration Addition

J. J. Schlezinger, W. Heiger-Barnays, and T. F. Webster, Boston University School of Public Health, Boston, MA.

Assessing the health effects of chemical mixtures is a crucial and difficult challenge. Concentration addition/dose addition (CA) is widely used for compounds that act by similar mechanisms. But CA cannot make predictions for mixtures that contain full and partial agonists for effect levels above that of the least efficacious component. As partial agonists are common, we developed Generalized Concentration Addition (GCA). Based on mechanistic information, we use pharmacologically-based Monte Carlo simulations to estimate the biological effect of mixtures; we test the predictions with empirical data. GCA has been successfully applied to systems where ligands compete for a single binding site: AhR ligands and PPARy ligands. Here, we develop a pharmacodynamic model for a system with two binding sites, the androgen receptor (AR). AR acts according to the classic homodimer activation model: each AR protein in the cytoplasm binds ligand, undergoes a conformational change that relieves inhibition of dimerization, and binds to DNA response elements as a dimer. The model meets the mathematical requirements for GCA.
iodine precursors that may enhance the formation of iodinated DBPs (I-DBPs). In the current study, source water containing one of the four ICM, iopamidol (IPAM), iohexol, iopromide, or diatrizoate, which are the ones detected most frequently in water, was chlorinated; non-chlorinated ICM-containing water samples served as controls. We quantified 21 regulated and non-regulated DBPs, 11 target I-DBPs, and performed a non-targeted, comprehensive, broad-screen identification of I-DBP formation. Mutagenicity of XAD-resin extracts of non-chlorinated and chlorinated ICM-containing water was examined in Salmonella strains with and without metabolic activation. ICM alone, i.e., without chlorination, did not result in DBP formation. However, the presence of IPAM increased chlorine demand and enhanced formation of bromoacetic acid, trichloroacetic acid, dichloroacetonitrile, dichloroacetonitrile, and trichloroacetaldehyde. IPAM also enhanced the formation of I-DBPs, notably dichlorodimethane, chlorodioxidemethane, iododioxetadie, iodooxetic acid, and chloriodoiodestic acid. Non-targeted, comprehensive, broad-screen analysis identified novel I-DBPs, including 1 new iodomethane, 3 new iodooxetic acids, and 2 new iododioxetanes. Mutagenicity of chlorinated source water was not increased by addition of any of the 4 tested ICM, regardless of metabolic activation status. In summary, DBP concentrations, including I-DBPs, were increased in extracts of chlorinated IPAM-containing source water, but Salmonella mutagenicity was not. This abstract does not reflect US EPA policy.

3063 Validation of a Screening Platform for Vascular Toxicities Utilizing Synthetic Substrates

S. Visuri, W. Richards, and C. Lebakken. Stem Pharm, Incorporated, Madison, WI. Sponsor: G. Kaushik

Angiogenesis is an essential developmental process that remains critical throughout the lifespan in response to conditions requiring increased oxygen supply, including physiological repair and exercise. The process is complex and tightly regulated through localized delivery of angiogenic factors, matrix remodeling, cellular migration and vessel maturation. The angiogenic process is also a critical component of several disease pathologies including cancer, neuropathies, critical limb ischemia, muscular degeneration and vascular malformations. For several decades, a primary in vitro assay to assess for vascular disrupters has relied on animal-derived biomaterials such as the Englebreth-Holm-Swarm mouse sarcoma-derived products marketed as Matrigel®, Gelnox® and Cultrex®. This material is complex, exhibits lot-to-lot variability and is challenging in an HTS workflow due to its temperature sensitivity. In collaboration with scientists at the University of Wisconsin, we have developed a synthetic vascular hydrogel that enables high throughput screening (HTS) for vascular disruptors utilizing human umbilical vein endothelial cells (HUVEC) or IPSC-derived endothelial cells. The hydrogel is optimized to promote a VEGF-dependent tubulogenic response which requires matrix remodeling and cellular migration. The assay detects appropriate inhibitors of these processes including Axitinib (AG013736) (IC_{50} 300 nM), Sunitinib (SU12148) (IC_{50} 6.3 µM), Nocodazole (IC_{50} 23 nM) and Pristomast HCl (AG3340 hydrochloride) (IC_{50}< 1 µM). The assay can be run in a 96 or 384 well plate format with Z' values of >0.5 and is insensitive to Suramin (Bayer 205), a compound which disrupts Matrigel and is a broadly referenced false positive in the Matrigel-based assay. Overall, the hydrogel platform is flexible for use in standard cell culture workflows and is suitable for co-culture and 3D organoid applications, facilitating their use for toxicity or efficacy screening applications. (1) Nguyen, E. H., W. T. Daly, N. T. N. Le, E. Farnooshian, D. G. Belair, M. P. Schwartz, C. S. Lebakken, G. E. Ananian, M. A. Saghir, T. R. Knudsen, N. Shelbain and W. L. Murphy. Versatile synthetic alternatives to Matrigel for vascular toxicity screening and stem cell expansion. Nat Biomed Eng 1, (2017).
tissue growth by day 4; 2) epithelial cell morphology similar to human colon; 3) a physiological TEER value of >300 Ω·cm² mimicking the colon microenvironment; and 4) expression of CK19 (epithelial cell marker), vimentin (fibroblast cell marker), and Alicant blue PAS staining (mucous producing goblet cell marker) on the villi-like structure. When mixed epithelial cells and fibroblasts are seeded on tissue culture inserts, there was a self-assembly pattern of differentiation with the fibroblasts occupying the base layer and the epithelial cells differentiating and stratifying on the apical layer. This new human cell-based colon tissue model will be a useful tool for pre-clinical assessment of microbiomes, mucosal inflammation, and screening of colorectal cancer products for their irritant potential. Such models will also reduce the use of animals for experimentation.

**3065 High-Throughput and Physiologically- Relevant Anisotropic hiPSC-Derived Cardiomyocyte Cultures Provide Better Resolution over Safety Profiles of Compounds with Known Cardiotoxic Mechanisms of Action**

Drug removal from the clinical market, as well as late-stage failures in clinical trials, are often linked to unforeseen cardiac toxicity. hiPSC-CMs are an integral component of a new paradigm, the Comprehensive in vitro Proarrhythmia Assay (CiPA) Initiative, through which panels of compounds with known mechanism of cardiotoxicity are being evaluated on hiPSC-CM platforms across independent test sites and through cutting-edge technologies. Key challenges under consideration for the hiPSC-CM system are sub-ideal cardiomyocyte geometry, sub-cellular structural organization, and electro-physiological maturity. Bioengineering approaches developed to enhance hiPSC-CM maturity have shown improvements in aspects of hiPSC-CM physiology, however those approaches have limited scalability and thus are not amenable to high throughput screening. hiPSC-CMs cultures plated on a high throughput platform which passively promote cardiomyocyte alignment have been shown to display physiologically-relevant features, including more physiologically cellular geometry, coherent unidirectional contraction, cardiac cell junction re-modeling, and improved calcium handling. To evaluate whether the changes induced by this platform translated into differential responses to cardio-active compounds, high throughput calcium flux assays were performed on hiPSC-CMs cultured in standard high throughput screening cell cultureware or anisotropic 384-well plates and subsequently interrogated with the 28 compounds included in the CiPA initiative. Interestingly, when combining high and intermediate risk compounds, differential responses were observed in 63% of the compounds tested. Specifically, all compounds in the high risk category showed a clearer dose-dependent progression in the severity of early afterdepolarizations (EADs). Six out of eleven compounds in the intermediate risk category, namely Pimozide, Droperidol, Cisapride, Astemizole, Domperidone and Terfanadine, showed a more sensitive response in anisotropy. No EADs were observed in either control or anisotropic conditions treated with low risk compounds. Altogether, anisotropic high throughput hiPSC-CM cultures formatted in the platform employed in this study showed better resolution over the progression and severity of pro-arrhythmic events.

**3066 Whole Transcriptome Extrapolation and Mechanism of Action Analysis Using GENIE Pipeline**

The Tox21 consortium is tasked to identify patterns of chemically-induced biological responses in order to characterize toxicity and disease pathways in a high-throughput manner and prioritize compounds for more extensive toxicological evaluations. The Tox21 is pursuing alternatives to cost prohibitive gene expression assessment techniques (Microarray or RNA-seq) that enable assessment of selected transcriptomic subsets in a high-throughput manner. Subsets measured using those techniques are not readily usable with standard differential pathway detection algorithms like Gene Set Enrichment Analysis (GSEA). This can yield limited gene-level differential expression results, necessitating the extrapolation of unmeasured portions of the transcriptome using inferences from measured portions. This can be achieved by modeling gene to gene interconnectedness of the transcriptome via large curated training samples with available whole transcriptome measurements. We present results of a transcriptome extrapolation comparing two popular large data extraction techniques: principal component regression (PCR) and Deep Learning (DL). For PCR, an eigenvalue ratio threshold of 0.1 was applied to identify significant PCs and perform prior standardization of inputs. For DL, a multi-task multi-layer feedforward neural network consisting of one input layer, 3 hidden layers (with 3,000 hidden units each), and one output layer was customized. RMA normalized signal for all unique (N=117,559) GPL570 microarray data files from NCBI Gene Expression Omnibus (GEO) were downloaded and computed. The probe-set signal values were averaged to compute gene-level signal over NCBI’s gene information database. The signal from 2,729 NCBI genes was used to extrapolate signal for 18,167 genes using each method. The extrapolation performance of each method was evaluated using 20-fold cross validation. Results indicate that PCR extrapolation outperforms DL extrapolation in terms of root mean square error (RMSE; PCR=0.39 vs. DL=0.51), median absolute error (MAE; PCR=0.20 vs. DL=0.26), and rank-biased overlap between the top 10% of true and extrapolated genes (RBO; PCR=66% vs. DL=58%). Additionally, PCR extrapolation is less computationally intensive, increasing its overall utility. These extrapolation efforts improve the scale and utility of transcriptomic data to fill in gaps between subsets of genes measured in individual studies and the ability to assess the entire transcriptome.

**3067 Improving Efficiency in Systematic Reviews by Automated Data Extraction: A Case Study Using NTP’s SRIE Challenge Dataset**

A. Varghese1, Y. Ahmad2, and A. Williams1. ICF, Durham, NC; and ICF, Fairfax, VA. Sponsor: J. Wignall.

Systematic reviews are labor-intensive exercises, especially the data extraction step in which subject matter experts must review full-text documents to extract specific data elements. While natural language processing-based information retrieval technologies are now widely used to increase the efficiency of the upstream literature screening and prioritization steps in systematic reviews, the use of information extraction algorithms in data extraction is still nascent, potentially owing to the lack of publicly available annotated datasets. In July 2018, the National Toxicology Program (NTP) conducted a public challenge, in which our group participated, to develop and apply information extraction algorithms to an annotated dataset of 100 articles related to toxicity. The articles were annotated with respect to commonly extracted data elements such as species, strain, dose, dose units, dose duration, endpoints, sample size, test article, and vehicle. In this research, we leverage NTP’s publicly accessible training dataset to test the accuracy and performance of various cutting edge information extraction algorithms. (The NTP’s test datasets were not publicly available at the time of performing this research, nor were the results of the challenge). Specifically, we split the NTP’s publicly available training dataset of 100 annotated articles randomly into a set of 80 articles used for model building (our training dataset) and a set of 20 articles used for validating results (our validation dataset). We fit a pipeline of information extraction algorithms including conditional random fields (CRF) models, long short-term model (LSTM) networks, and dictionary-based approaches to annotate the text in the validation dataset. We compared our predicted annotations with NTP’s gold standard annotations using NTP’s publicly available evaluation software that was custom developed for this challenge. For the various data elements predicted, we found extraction recall (sensitivity) rates ranging from 23% to 87%, with F1-scores ranging from 16% to 63%. We assess reasons for the differing levels of performance across various data elements, including challenges with the annotation framework and issues with the detection of phrases. We also compare the performance of the individual algorithms and their performance in sequence to assess their relative strengths. We estimate potential time savings from the use of this technology and, based on our empirical findings, propose a framework to minimize relevant data losses and maximize efficiency.

**3068 Using Liquid Chromatography Mass Spectrometry (LC-MS) to Assess the Effect of Age, Diet, and Rat Strain on the Global Metabolome**

The exposome encompasses the entire environmental exposures of an individual during a lifetime. These exposures include diet, lifestyle, environmental toxins, and workplace exposures. The interactions of combined exposures can lead to exacerbation of disease. The goal of this study was to use liquid chromatography mass spectrometry (LC-MS) to assess metabolic changes in three distinct animal strains based on two different diets. Sprague-Dawley (SD), Fischer 344 (F344), and Brown-Norway (BN) male rats were maintained on a high fat, Western (HF), or regular diet for 24 weeks. Serum was collected at 4, 12, and 24 weeks to assess metabolite changes. A cold methanol biopsy from the liver was then collected at 4, 12, and 24 weeks to assess metabolite changes. A cold methanol biopsy from the liver was then collected at 4, 12, and 24 weeks to assess metabolite changes.
3069 Physicochemical Characterization and In Vitro Toxicity of Emissions from a 3D Printer

Three dimensional (3D) printers are widely used for prototyping and building small physical objects in schools, home and businesses. Feedstock material used in 3D printing is polymer thermoplastic filament that may contain additives such as metals, ceramics, wood fiber, carbon fiber, graphene, or silica to impart aesthetic or functional properties. The use of 3D printers with polymer thermoplastics is of concern for workers and consumers because they emit a mixture of ultrafine particles and volatile organic compounds (VOCs) that are associated with respiratory and cardiovascular diseases. The scope of this study was to characterize aerosolized emissions from 3D printers and evaluate their toxic effects in human small airway epithelial cells (SAEC). Emissions were generated from a commercially available 3D printer while operating for 1.5 h with acrylonitrile butadiene styrene (ABS) or polyoxymethylene (PC) filaments. Both particles and VOCs were collected using an impinger sampler. Samples were characterized for their physicochemical properties, cellular cytotoxicity, oxidative stress response, apoptotic effects, and cytokine production. Results showed that printers with PC filaments generated two-fold more particles/ml than ABS. Mean sizes of PC and ABS-emitted particles in cell culture media were 201 ± 8 nm and 198 ± 10 nm, respectively. Bisphenol A and styrene were the predominant VOCs collected in the media for the PC and ABS emissions, respectively. At 24 h post exposure, both PC and ABS emissions elicited significantly increased cytotoxicity, with PC being more toxic than ABS. Moreover, PC induced higher production of reactive oxygen species, and decreased in total antioxidant capacity and glutathione peroxidase activity than ABS. Furthermore, both PC and ABS emissions induced apoptosis in SAEC with the PC emissions induced four-fold more apoptotic cells than the ABS emission. Cytokine and chemokine profiling showed that PC emissions induced higher production of seven proinflammatory cytokines and chemokines than ABS. Taken together, the results indicate that the emissions generated by PC and ABS filaments induce toxicity in SAEC, and the exposure to the PC emission induces more toxicity than that of the ABS emission.

3070 Capture Compound Mass Spectrometry: Elucidating Off-Target Binding to Deconvolute Drug Toxicity

Understanding both the on- and off-target protein binding interactions of small molecules is an essential part of the drug discovery process. A large proportion of toxicity findings in non-clinical or clinical studies are precipitated by the parent drug or a metabolite binding an off-target protein target, such as an enzyme or receptor, modifying its function resulting in cellular dysfunction and toxicity. Capture Compound Mass Spectrometry (CCMS) is an unbiased, proteome-wide approach for the identification of specific-binding protein targets for small molecules and peptides. The technology combines medicinal chemistry and in vitro pharmacology, coupled to high resolution proteomics mass spectrometry to isolate and identify target proteins that are responsible for an observed biological response. Thus, through in vitro investigation in target tissues of interest, the candidate proteins and pathways causing in vivo toxicity can be elucidated. An overview of CCMS technology and its application in identification of off-target compound activity is presented. The CCMS technology has been used to determine on- and off-target interactions at the 4-aminopyridine (APY) and tolcapone (COMT) inhibitor tolcapone in a human liver cancer cell line (HeP2). A comprehensive interaction profile was generated, revealing both on- and off-target binding proteins. Differential profiles of tolcapone which causes liver toxicity and entacapone that does not were elucidated and highlighted 3-hydroxyisobutyryl-CoA hydrolase (HIBCH) as a candidate target mediating toxicity. Medicinal chemistry was then initiated focusing on molecules without HIBCH activity resulting in ‘tolcapone-like’ molecules with reduced toxicity profiles that could lead the way to the development of improved COMT inhibitors.

3071 A Practical High-Throughput Co-Culture Plate to Screen Paracrine and Endocrine Interactions

B. P. Johnson, J. Jimenez-Torres, M. Morgan, and D. Beebe. "University of Wisconsin-Madison, Madison, WI; and "Onexio Biosystems LLC, Madison, WI.

Traditional HTS in microtiter plates is limited to one cell type, excluding important paracrine and endocrine cellcell interactions, while Transwell® inserts are too cumbersome with 30 wells and 15° well robotic HTS. We have developed a microtiter plate based co-culture system dubbed MICRO-MT as a solution to fulfill the HTS co-culture and multi-culture needs of the drug discovery and toxicity testing market. In the MICRO-MT, cells are monocultured in individual wells of a microtiter plate with standardized dimensions as usual, but by simply increasing fluid volume, the media from monocultures in adjacent wells are bridged through the integrated microchannels allowing co-culture through diffusion of metabolites between wells. Because the MICRO-MT operates by simple diffusion and in a traditional microtiter plate footprint, it doesn’t require additional equipment beyond that already in use and is compatible with existing HTS infrastructure. To illustrate the utility of this approach, we developed a conferred steroid metabolism assay using an estrogen receptor driven luminescent reporter cell line, MVLNs alone or in co-culture with HepG2 cells. HepG2 cells contain high levels of aromatase activity which converts testosterone to estrogen, while MVLN cells do not express aromatase. MVLN cells in monoculture treated with 17β-estradiol ranging 100pM to 10nM showed high luminescence activity, whereas testosterone treatment showed no luminescence activity as predicted. In contrast, co-culture of MVLN and HepG2 cells in the MICRO-MT showed dose-responsive increases in MVLN luminescence activity in response to testosterone treatment (EC50 = 4.1nM) indicating HepG2 cells converted testosterone to estrogen which then diffused in the reporter well containing MVLN cells activating the luminescent reporter. We have also found that this platform recapitulates a paracrine Sonic Hedgehog (SHH) signaling response, whereby SHH ligand produced from GMSM-K SHH transfected epithelium generates robust SHH pathway activation in cultured SHH reporter cells that combine for antagonists vismodegib and cyclopamine, but also secretory antagonists Ruskii-43 and U18666A. These studies show that the MICRO-MT plate is a viable solution to support paracrine and endocrine interactions in a technically simple format that is amenable to HTS.

3072 Evaluation of Transdermal Drug Delivery and Toxicity in a Microphysiological Body-on-a-Chip System

Body-on-a-chip (BoaC) in vitro systems are a promising technology for increasing the predictive power of drug efficacy and toxicity in humans compared to traditional animal models. These interconnected multi-organ systems can be improved by expanding drug delivery methodologies to include oral and transdermal applications. Towards that goal, we have developed a heart-lyer-"skin" BoaC system to assess the toxicity of topically administered drugs dosed acutely and chronically. To validate the topical delivery system, the moderate permeation drug diclofenac (1.5 and 3% solutions), and the low permeation compounds ketocanaol (0.11%), hydrocortisone (1%), and aspirin (1.5%) were applied to a synthetic skin surrogate (Strat-M). Understanding both the on- and off-target protein binding interactions of small molecules is an essential part of the drug discovery process. A large proportion of toxicity findings in non-clinical or clinical studies are precipitated by the parent drug or a metabolite binding an off-target protein target, such as an enzyme or receptor, modifying its function resulting in cellular dysfunction and toxicity. Capture Compound Mass Spectrometry (CCMS) is an unbiased, proteome-wide approach for the identification of specific-binding protein targets for small molecules and peptides. The technology combines medicinal chemistry and in vitro pharmacology, coupled to high resolution...
3075 Combining Trans-Epithelial Electrical Resistance (TEER) Measurements with a Microfluidic Gut-on-a-Chip System for Real-Time Assessment of Drug-Induced Barrier Disruption

Intestinal barrier disruption resulting from drug-induced toxicity can lead to life-threatening conditions and the cancellation of important therapeutic programs. Current in vitro 2D intestinal models lack the features of the in vivo settings like tubular structure or perfusion, and fail in clinical translation. Hence there is an urgent need for reliable epithelial barrier models and translatable, real-time readouts from these predictive in vitro systems. Here we present extracellular matrix-supported intestinal tubules in a perfused microfluidic platform, that are fully-compatible with trans-epithelial electrical resistance (TEER) measurements over the full duration of the experiment. These intestinal tubules exhibit tissue (polarization) markers ErbB1, ErBb2, Ezrin, Glut-2, MRFP and ZO-1, and crypt-like morphology. Further, these tissues exhibit relevant TEER values (~200 Ω/cm²) prior to compound exposure, while reaching maturation significantly faster than Transwell-based models (4 days vs. 21 days). Drug-induced toxicity was assessed by apical exposure of the intestinal barriers to model compounds, as well as to cytokines to mimic inflammatory, immune-mediated gut toxicity. A fully-automated TEER measurement platform was applied during the exposures, tracking barrier disruption in up to 96 gut tubules cultured in parallel and facilitating characterization of a dose- and exposure time-dependent response for predicting gut toxicity. The described techniques have been designed to be readily implemented in routine laboratories and high-throughput facilities, allowing for enhanced prediction of the clinical response to pharmacological stimuli in real-time.

3073 Comparing Tanimoto Coefficient Values Calculated by Toxmatch and OECD QSAR Toolbox

R. Galante, M. Zachary, and M. H. Whittaker, ToxServices LLC, Washington, DC.

The Tanimoto Coefficient is a measure of similarity between a query chemical and other chemical structures of interest. It is valuable tool to limit the number of analogue chemicals when performing read-across. As part of a Tanimoto Coefficient calculation, a chemical is broken down to structural or molecular fragments, which are based on pharmacologically known or predefined fingerprints. A “fingerprint” of a chemical is an ordered list of binary (1/0) bits, which records the presence (“1”) or absence (“0”) of the predefined fragment in the molecule. Fingerprints of two phthalate esters are compared for similarity using the Tanimoto Coefficient (T). The Tanimoto Coefficient varies from zero to one in value, with a coefficient closer to one indicating that the two chemicals share identical hits or fragments. Cutoffs of 0.6 have been proposed in the evaluation of structurally similar chemicals and the risk of teratogenicity, an endpoint that has poorly defined structural alerts. The Tanimoto Coefficient can be calculated using the Toxmatch program, an open-source software application that encodes several chemical similarity indices to facilitate the grouping of chemicals into categories and rank order for chemical similarity calculations. Similarly, OECD QSAR Toolbox, an open-source software that works by grouping chemicals into categories and then allowing the user to progress through the workflow by identifying relevant structural characteristics and/or potential mechanisms or modes of action of the target chemical, can be used to calculate the Tanimoto Coefficient. In a case study, Tanimoto Coefficients were calculated using both the Toxmatch and OECD QSAR Toolbox programs to compare the similarity between mono-(2-hydroxyethyl) terephthalate (CASRN 1137-99-1) and dimethyl terephthalate (CASRN 120-61-6). Toxmatch returned a value of 0.763, while OECD QSAR Toolbox returned a value of 0.45. As demonstrated through this comparison, calculation of Tanimoto Coefficients between molecules can vary, depending on the molecular features and atom specifications used to create the fingerprint. Toxmatch bases its fingerprinting on atom environments, while OECD QSAR Toolbox uses the default characteristics of atom centered fragments (molecular feature) and atom type, count H attached and hybridization (atom characteristics). This case example demonstrates differences between two software programs and underscores the importance of incorporating multiple software tools when employing read-across methods to identify and select chemical surrogates.
3077 Application of the Public Health Exposome Framework to Estimate Endo-Phenotypes of Resilience in a Model Ohio African-American Woman’s Cohort

P. Clfuentes, J. Reichard, W. Im, S. Smith, C. Colen, C. Giurescuz, K. Williams, S. Gillespie, P. Juarez, and D. Hood. 1Ohio State University, Columbus, OH; 2University of Cincinnati, Cincinnati, OH; and 3Meharry Medical College, Nashville, TN.

We report integration of the US EPA EJSSCREEN database with our Public Health Exposome dataset to interrogate 9,232 census blocks to model the complexity of relationships among environmental, and socio-demographic variables towards estimating adverse pregnancy outcomes (low birth weight, LBW and pre-term birth, PTB) in all Ohio counties. Using a hill-climbing algorithm in R software, we derived a Bayesian network that mapped all controlled associations among all variables available by applying a mapping algorithm. The results revealed 17-environmental, and socio-demographic variables that were represented by nodes containing 69-links accounting for a network with 32.85% density and average degree of 9.2 showing the most connected nodes in the center of the model. The model predicts that the socioeconomic variables low income, minority, and under age five populations are correlated and associated with environmental variables; particulate matter (PM10) level in air, proximity to risk management facilities, and proximity to direct discharges in water and are linked to PTB and LBW in the 88-Ohio counties. The methodology used to derive significant associations of chemical and non-chemical stressors linked to PTB and LBW from indices of geo-coded environmental neighborhood deprivation serves as a proxy for design of an African American women’s cohort to be recruited in Ohio from federally qualified community health centers within the 9,232 census blocks. The results have implications for the development of severity scores for endo-phenotypes of resilience based on associations and linkages for different chemical and non-chemical stressors that have been shown to moderate cardio-metabolic disease within a population health context.

3078 Dietary Influence on the Metabolism and Biological Effects of Arsenic Exposure: A Double-Blind, Placebo-Controlled Folate Supplementation Trial in Inner Mongolia, China

X. Chen, X. Guo, P. He, J. Nie, G. Mao, Z. Liu, D. Aga, H. Wu, and X. Ren. 1State University of New York at Buffalo, Buffalo, NY; 2Inner Mongolia Medical University, Hohhot, China; and 3Wenzhou Medical University, Wenzhou, China.

Chronic arsenic exposure via drinking water is a worldwide public health concern and is associated with increased morbidity and mortality from both non-cancerous and cancerous effects. Increasing evidence suggest that the intake of dietary nutrients has an impact on arsenic metabolism and DNA methylation, which could lead to differential susceptibility of individuals to the toxic and carcinogenic activity of arsenic. Folate, one of dietary methylation, which could lead to differential susceptibility of individuals to the toxic and carcinogenic activity of arsenic before and during the study periods. These participants were enrolled in a double-blind, placebo-controlled folate acid supplementation trial in Hetao Plain of Inner Mongolia, China. We got consent and enrolled three hundred adult participants who were exposed to arsenic before and during the study periods. These participants were enrolled and randomly divided into three groups and given folate acid at a dose of 400 or 800 µg/d, or placebo for 8 weeks. After the trial, in contrast to placebo group, subjects’ serum folate level and plasma homocysteine concentration significantly increased and decreased, respectively, in both folate acid supplementation groups; these individuals also showed a stronger arsenic metabolism capability, featured by the lower percentage of urinary iAs (inorganic arsenic) and MMA (monomethylarsonic acid) and higher percentage of urinary DMA (dimethylarsonic acid). Furthermore, a dose-dependent effect of folate was observed for folate between supplementation dosage and arsenic metabolism efficiency. In addition, folate supplementation was associated with an increased global DNA methylation level of peripheral blood. In conclusion, folate supplementation has a positive effect in facilitating arsenic biometabolism and maintaining global genome DNA methylation levels. The work was supported by NIEHS grant R21ES022329 and R01ES022629 to X.R.
AM blood concentrations from PM blood THC concentrations. Our weight of evidence analysis indicates current scientific data do not support prediction of AM blood concentrations from PM concentrations.

**3081** A Case-Control Study of Newborn Hearing Screen Outcomes and Neonatal Dried Blood Spot Metals

K. Carlson1, S. Park1, N. Basu2, and R. Neitzel1. 1University of Michigan, Ann Arbor, MI; and 2McGill University, Montreal, QC.

Toxicant metal exposures, such as lead (Pb) and mercury (Hg), have been associated with hearing loss in adults and youth. However, little is known about the role of prenatal exposures to Pb and Hg in hearing health during human fetal development. This case-control study explored the relationship between newborn newborn hearing screen pass/fail outcomes and newborn whole blood levels of two non-essential metals (Pb and Hg) along with six essential elements (calcium, copper, iron, potassium, selenium, and zinc). The Michigan Early Hearing Detection and Intervention Program provided data on 338 infants with an abnormal hearing screening result and 338 infants with a normal hearing screen result. All infants were born between 2003 and 2015. Cases and controls were matched by birth year, sex, and race by the Michigan Neonatal Biobank, which also provided the dried blood spots for each infant. Toxic and essential elemental levels in the newborn dried blood spots were determined by direct mercury analysis (DMA) for mercury and total reflection-X-ray fluorescence for metals. Blood metals were corrected for body weight and height. A novel statistical approach, principal component analysis (PCA), was used to perform a data-driven assessment of the relationship between metals and hearing screen outcomes. The findings suggest that neonatal blood calcium levels may be important determinants of hearing health, though further studies are warranted to understand the physiological mechanisms. These findings need to be interpreted with caution because this matched case-control study was unable to control for genetic causes of hearing loss, cytomegalovirus infection, or cranio-facial abnormalities, all which can cause hearing impairment. The present study contributes to the current knowledge that dried blood spots, while a novel metric, have merit for further use in determination of nutrient levels and environmental exposures.

**3082** Amniotic Fluid Exposomics Identifies Novel Prenatal Exposures and Metabolic Signatures in Relation to Preterm Birth: A Prospective Case-Control Study

Y. Lal. University of North Carolina at Chapel Hill, Chapel Hill, NC. Sponsor: K. Lu

Preterm birth (PTB, gestation age < 37 weeks) is a leading cause of neonatal mortality and long-term perinatal morbidity and is a top public health priority in the U.S. and worldwide. Despite advances in risk factor characterization, biomarkers for early diagnosis and effective prevention are lacking, so are the potential role of environmental exposures. Surprisingly, only a few classes of environmental agents have been studied to date, all in a targeted manner, as potential etiologic contributors to PTB, leaving the effects of ubiquitous yet complex prenatal exposures largely unexplored. Here, we conduct an untargeted exposomic investigation on PTB. Prospective amniotic fluid samples (n=21 cases; n=21 controls) were collected, extracted, and profiled by high-resolution accurate-mass (HRAM) mass spectrometry platform coupled to a state-of-the-art structural identification workflow. Differential case-control abundances were defined by Welch t-test (p < 0.05) and the association of abundance with gestation age was assessed via Pearson correlation. The study yielded a panel of compounds of which the abundance in amniotic fluid was negatively associated with gestational length. Of note, xenobiotic prenatals exposures embrace a large diversity by source, structure and health effects, ranging from microbial metabolites (e.g. 1,8-diazacyclotetradecane-2,9-dione), plant-derived alkaloids (e.g. N-methyllycine), to synthetic organic chemicals (e.g. diclofenac). Likewise, novel metabolic signatures were observed as well. Notable examples include cortisol (altered maternal stress levels), sphenamine (perturbed uterine contraction), hypoxanthine and uric acid (indicating hypoxia), and an array of lysophospholipids (lysOPC) (associated with PTB and fetal health). This exposomics study comprehensively characterizes prenatal exposures alongside metabolic features in relation to PTB, which may be valuable to inform strategies to develop new biomarkers and decrease prenatal exposures.

**3083** Diabetes and Persistent Organic Pollutants in the Anniston Community Health Survey Follow-Up

M. Pavuk1, T. Serio1, M. Cave2, and L. Birnbaum1. 1CDC/ATSDR, Atlanta, GA; 2University of Louisville School of Medicine, Louisville, KY; and 3NIEHS/ NTP, Research Triangle Park, NC.

In 2014, we conducted a follow-up study (ACHS II) of the Anniston Community Health Survey (ACHS in 2005-7) where residents’ polychlorinated biphenyls (PCBs) concentrations were about 3 times higher than in the general U.S. population. Results from ACHS showed significant associations between non-dioxin-like PCBs and diabetes. ACHS II included measurements of dioxins in addition to PCBs and pesticides. Toxicological studies have explored inflammatory response and insulin signaling disruption, glucose homeostasis and pancreas cell function, as well as the disruption of adipogenesis by which exposure to POPs may lead to the development of diabetes. Serum samples and covariate information were available for 338 participants. Diabetes status was defined as being on glycemic medication or having a glucose concentration greater than 125 mg/ml; 135 (39.9%) of ACHS-II participants were diabetic in 2014. The polychlorinated dibeno-p-dioxins (PCDD), dibenzofurans (PCDF), and non-ortho PCBs were measured using high-resolution gas chromatography/high-resolution mass spectrometry and expressed as total dioxin toxic equivalents (TEQs, pg/g lipid). Pesticides measure included pp'-DDE, hexachlorobenzene, β-HCH, oxychlordane, trans-nonachlor, and mirex. Odds ratios (OR) and 95% confidence intervals (CI) were estimated using unconditional logistic regression models. No consistent, significant relationships were observed for hearing screen failures for levels of Pb (OR = 1.04, 95% CI: 0.86-1.26) or Hg (OR = 1.09, 95% CI: 0.91-1.31). In infants with higher levels of blood spot calcium did show significantly decreased odds of hearing screen failure (OR = 0.49, 95% CI: 0.34-0.70). Other essential elements were not significantly associated with odds of hearing screen failure. These findings suggest that neonatal blood calcium levels may be important determinants of hearing health, though further studies are warranted to understand the physiological mechanisms. These findings need to be interpreted with caution because this matched case-control study was unable to control for genetic causes of hearing loss, cytomegalovirus infection, or cranio-facial abnormalities, all which can cause hearing impairment. The present study contributes to the current knowledge that dried blood spots, while a novel metric, have merit for further use in determination of nutrient levels and environmental exposures.

**3084** Urinary Metals and Pre-eclampsia in the LIFECODES Birth Cohort: A Single-Contaminant and Mixture-Based Approach

P. A. Bommarito1, S. S. Kim2, J. D. Meeker2, R. C. Fry3, D. E. Cantonwine4, T. F. McElrath5, and K. K. Ferguson1. 1University of North Carolina at Chapel Hill, Chapel Hill, NC; NIEHS, Research Triangle Park, NC; 2University of Michigan School of Public Health, Ann Arbor, MI; and 3Harvard Medical School, Boston, MA.

Pre-eclampsia (PE) is a major contributor to maternal mortality. Exposures to toxic metals and deficiencies in essential metals have previously been linked to increased risk of PE. However, the effect of exposure to combinations of toxic metals remains unknown. In this study we evaluated the relationship of individual trace metals, alone and in mixtures, and PE was investigated using 383 subjects from the LIFECODES prospective birth cohort, which included 28 women who experienced PE. Urine samples collected during pregnancy (median, 26 weeks gestation) were analyzed for 17 trace metals. We created Cox proportional hazard models to calculate hazard ratios (HR) of PE in association with the concentration of individual urinary trace metals. As a mixtures-based approach, we used principal components analysis (PCA) to identify components of trace urinary metals and their associations with PE. In addition, interactions between toxic and essential metals were investigated. In single-contaminant models, the HR (95% CI) associated with urinary chromium was 4.02 (1.10, 14.8). Although the overall relationship between urinary cadmium and PE was null, urinary cadmium was associated with an elevated risk of PE among women with low urinary selenium (HR: 2.52, 95% CI: 1.00, 6.32). In PCA, metals loaded onto 3 principal components, characterized by loading from Essential Metals (PC1: copper, selenium, and zinc), Toxic Metals (PC2: lead, manganese, and cadmium), and Seafood-Associated Metals (PC3: arsenic, mercury, and tin). Individually, these components were not associated with the risk of PE. However, among individuals with low Essential Metals (PC1), Toxic Metals (PC2) were associated with an increased risk of PE (HR: 2.22, 95% CI: 1.06, 4.64). Therefore, the relationship between prenatal toxic metal exposure and PE incidence may be modified by levels of essential metals.
Human Developmental Neurotoxicity of Chlorpyrifos: Quantitative Evaluation of Exposure

As part of a comprehensive risk assessment of chlorpyrifos, the California Department of Pesticide Regulation (DPR) examined the evidence for developmental neurotoxicity of this organophosphate insecticide in human epidemiological studies. Several ongoing prospective studies as well as some more recent observational studies have investigated the association between perinatal chlorpyrifos exposure and the potential for altered human growth and behavior later in life. The exposure-effect associations were evaluated using the following: 1) the choice of biomarker of exposure; 2) the timing of biological sampling in relation to the putative exposure and/or developmental effects; 3) variations in quantitative measurements within and across individuals; and, 4) the analytical methodologies utilized. The epidemiological studies were conducted in the United States as well as in the Philippines, China, and Mexico and measured either the parent compound in blood, hair, and meconium, or one or more metabolites such as 3,5,6-trichloro-2-pyridinol (TCPy) in blood and urine. There was considerable variation in the choice of biomarkers as well as the analytical methodologies and sensitivities of measurements across studies. Several of the most recent studies reported non-detection of chlorpyrifos in maternal and fetal samples. In some of the older studies that detected parent compound in biological samples, the standard curves terminated above the limit of detection/quantitation (LOD/LOQ) and occasionally the median biomarker values were below the LOD or LOQ. Findings from environmental epidemiology studies are becoming more frequently considered in human health risk assessment. However, doing so depends on the quality of the exposure analysis. Because of the limitations in the available data, DPR was unable to reliably discern an exposure-effect relationship or derive a regulatory target for chlorpyrifos based on human epidemiological data at this time.

Military Occupation as a Surrogate Measure of Potential Exposure to Fuels and Associated Long-Term Health Effects

T. D. Irons1, W. J. Culpepper1, F. Akhtar1, J. Escobar2, E. Ishii1, J. Leon2, and A. Schneiderman1. 1US Department of Veterans Affairs, Washington, DC; and 2United States Air Force School of Aerospace Medicine, Wright-Patterson AFB, OH.

The US Department of Veterans Affairs (VA) has received several inquiries regarding the potential health effects of exposure to fuels and their components during military service. Studies conducted by the US Department of Defense (DoD) have characterized the acute effects of fuels on service members; however, there is a need to better understand the potential long-term health consequences of chronic exposure. The purpose of this study was to determine the ability of investigating the long-term health effects of occupational fuel exposure in Veterans who served in the Air Force (AF). Occupation was used to define levels of exposure, and associations between occupational exposure to fuels and chronic health outcomes were assessed, including, but not limited to, potential effects on the auditory and visual function, other effects on the nervous system, hematological effects, respiratory effects, effects on immune function, and cancers. The health data from several VA and DoD databases were linked to ascertain these outcomes. Occupation proved to be an adequate surrogate for fuel exposure, as long-term health effects, such as chronic deficits in hearing, were identified in Veterans who had a high likelihood of exposure based on their duties. This feasibility study will serve as a "proof-of-concept" for a more comprehensive, DoD-VA, multidisciplinary investigation into the consequences of occupational exposure to fuels during military service.

Alterations in Profiles of Metabolome and Gut-Microbiome Due to Exposure of PCBs and p,p'-DDE in C-MACH Cohort

A. Eguchi1, K. Sakurai1, T. Kato2, Y. Nakanishi2, H. Tanabe3, Y. Sato4, M. Yamamoto5, M. Watanabe5, H. Ohno2,3, and C. Moei1. 1Chiba University, Chiba, Japan; 2RIKEN Center for Integrative Medical Sciences, Kanagawa, Japan; and 3Kanagawa Institute of Industrial Science and Technology, Kanagawa, Japan.

Exposure to environmental chemical, like persistent organic pollutants (POPs) has been associated with adverse human reproductive and fetal developmental outcomes. However, the biological mechanisms of adverse effects of these compounds in humans are not currently well established. In this study, we aimed to identify the altered biological pathways by exposure of PCBs and p,p'-DDE, in pregnant women using a metabolome profile in maternal serum and feces, and gut microbiota profiles. Pair of human serum and feces sample was corrected from 58 participants around 32 weeks of gestational age in “Chiba Study of Mother and Child Health (C-MACH)" consisted of three hospital-based cohorts. Data from participants were available for 51of the 58 maternal participants. Serum concentrations of PCBs, serum and feces metabolome, and gut microbiota were analyzed by GC-MS, LC-MS/MS, GC-MS/MS, and next-generation sequencing system, respectively. Dietary habits were corrected using a brief diet history questionnaire (BDHQ). We used the DIABLO (Data Integration Analysis for Biomarker discovery using a latent component method (OMICS studies)) models, and patients with the highest exposure levels of contaminants (first [Q1], second-third [Q2-3], and fourth quartile [Q4]) for pregnant women. The levels of PCBs (Mean: 450 pg g⁻¹ wet wt, Q1 < 280 pg g⁻¹ wet wt, Q2-Q3: 280-560 pg g⁻¹ wet wt, Q4: > 560 pg g⁻¹ wet wt) and p,p'-DDE (Mean: 440 pg g⁻¹ wet wt, Q1 < 290 pg g⁻¹ wet wt, Q2-Q3: 290-630 pg g⁻¹ wet wt, Q4: > 630 pg g⁻¹ wet wt) were lower than previous reports from the USA, EU, and Japan. In the classification DIABLO model for PCBs, p,p'-DDE for classification had > 0.72 AUC values. Interestingly, PCB and p,p'-DDE levels in maternal serum were strongly correlated; however, networks of related compounds were not well overlapped. Focus on candidate biomarkers and metabolite included in composited models for PCBs were related to microbiome, serum and feces metabolome profiles. On the other hand, p,p'-DDE was related to serum metabolome profiles.

Impact of the Opioid Epidemic and Fentanyl Related Overdose Cases in a Florida West Coast Medical Examiner District

Opioids are characterized by a high level of misuse and abuse with a high dependency and risk of overdose. Opioids can be divided into two classes, natural and synthetic, both classes acting on the mu opioid receptor. Fentanyl is a potent synthetic opioid that is roughly 50 to 100 times more potent than morphine. The United States is currently experiencing an opioid epidemic that does not show any signs of waning. The opioid epidemic’s impact has been so profound that evidence suggests it has caused a decrease in life expectancy for men. The current study evaluates trends in opioid use in overdose cases in the Florida District 6 Medical Examiner’s office and the role of fentanyl in overdose related mortality. Oxycodeone was present in 248 cases in 2011 in District 6. That number dropped to 108 cases in 2016. Cases with hydrocodone present demonstrated a similar profile, decreasing from 88 in 2011 to 28 in 2016. At the same time, in District 6 there was a 51.7% increase in deaths involving fentanyl or a fentanyl analog from the year 2011 to 2016. In 2011, 71% of the cases were men; 98% of those men were white. In 2011, the average age of fentanyl involved death was 44; in 2016, the average age was 38. The population most affected by the surge in fentanyl overdoses were men between the ages of 25-35 years old. The spike in fentanyl and fentanyl analog related deaths have caused difficulties from an analytical toxicology perspective. Fentanyl is an extremely potent drug, and thus very small amounts are required to cause accidental overdose compared to natural opioids such as morphine. The results suggest that fentanyl and fentanyl analogs are an emerging priority in opioid epidemic research.

Evaluating the Impact on IQ of Short-Term Increases in Blood Lead Levels

Significant research has been conducted on the relationship between blood lead levels in young children and IQ (e.g. Lanphear et al., 2005). Governmental agencies have relied on determinations of the blood lead – IQ association to set environmental exposure levels for lead. However, little has been done to protect young children from elevated blood lead levels. However, an unanswered question is the degree to which long-term average vs. short-term elevations in blood lead levels are more strongly associated with the observed IQ deficits. Available datasets are for children with long-term exposures to lead. However, children in these datasets who have peak blood lead levels substantially higher than their life-time average, consistent with short-term exposure, can be identified and analyzed separately. This analysis was conducted with the Lanphear et al. (2005) pooled blood lead - IQ dataset, with corrections described by Crump et al. (2013). The data were divided by establishing a threshold between two subsets defined by peak blood lead = 10.9 + 1.6 x concurrent blood lead, where approximately 10% of the data fall above the boundary. Analyses of the full datasets using the Lanphear log-linear model reproduced the coefficients and R²’s reported in Table 2 of Crump et al. The same model was run for the data subsets, regressing both peak blood lead
and concurrent blood lead against IQ. The chronic exposure data subset analyses have similar regression coefficients and R² values as reported in Crump et al. for the full dataset. Both regressions for this data subset are statistically significant. In contrast, the regressions of peak blood lead and concurrent blood lead vs. IQ for the acute exposure data subset are not statistically significant, and have positive rather than negative regression coefficients. This indicates that peak blood lead levels that are short-term are not correlated with IQ. However, concurrent blood lead levels for the acute exposure data subset are also not correlated with IQ. Several alternative analyses were also conducted, including with different blood lead metrics, different boundaries between data subsets, and with removing outliers. For all alternatives, regression results were similar. Possible explanations for the lack of correlation between blood lead and IQ for the acute exposure data subset will be presented. In conclusion, the results suggest that long-term chronic exposures to lead are more closely associated with IQ impacts than are short-term blood lead elevations.

3090 Environmental and Genetic Drivers of Telomere Length Variation in Ethnically Diverse Africans

M. McQuillan1, M. Hansen1, A. Ranciaro1, E. Mbuwe2, S. Fan1, W. Beggs1, A. Avi2, and S. A. Tishkoff1. 1University of Pennsylvania, Philadelphia, PA; and 2New Jersey Medical School, Newark, NJ. Sponsor: T. Penning

Telomeres are repetitive non-coding sequences at the ends of chromosomes that protect DNA from damage. Each time a cell divides, telomeres progressively shorten, until a critical length is reached and cell division stops. Thus, telomere length is closely associated with aging and lifespan. In addition, longer telomeres are associated with increased risk of many cancers, while shorter telomeres are associated with elevated cardiovascular disease risk. Finally, telomere length varies with environmental factors, including chronic stress and infection status. However, relatively little is known about the genetic architecture underlying telomere length, or the environmental factors that influence telomere loss. Here, we investigate the relationship between telomere length, genetics, and environmental factors in a set of ethnically diverse African people (n=1820) originating from populations in Botswana, Tanzania, Ethiopia, and Cameroon. We find significant variation in telomere length among populations after adjusting for age and sex, with the San hunter-gatherers from Botswana having the longest telomeres, and individuals from Cameroon having the shortest telomeres. Telomere length also varies with environmental factors, including chronic stress, in a way that is consistent across populations. Finally, when we analyze the relationship between telomere length and malaria endemicity, precipitation, and temperature variables. Finally, after accounting for genome-wide ancestry and relatedness among individuals, we find that a large proportion of inter-individual variation in telomere length (>40%) is explained by genetic factors. Ongoing work examines the relationship between telomere length and other phenotypes, including cardiovascular traits, as well as whether patterns of selection at genetic loci underlying telomere length vary with environmental factors across Africa. This research will help elucidate the evolutionary forces driving telomere length variation in humans, which will provide insight into the basis of telomere-related disease risk.

3091 Examination of the US FDA Adverse Event Reporting System to Assess the Halo Effect and Potential Reporting Bias

K. Towle1, D. Drechsel2, E. Fung3, D. Paustenbach4, and A. Monnot1. 1Cardno ChemRisk, San Francisco, CA; 2Cardno ChemRisk, Boulder, CO; 3Cardno ChemRisk, Aliso Viejo, CA; and 4Cardno ChemRisk, Jackson, WY.

The US Food and Drug Administration (US FDA) maintains an adverse event reporting system with data collected from users of various food, beverage, and cosmetic products. Recently, there have been concerns regarding alleged adverse health effects among users of WEN by Chaz Dean (WCD) hair cleansing conditioners, including hair loss, hair breakage, and skin sensitization and irritation. The objective of this analysis was to analyze the temporal trends in reported adverse event data specific to WCD cleansing conditioners before and after media coverage of alleged health effects in 2014. Publicly available data were extracted from the US FDA Center for Food Safety and Applied Nutrition (CFSAN) Adverse Event Reporting System (CAERS) from 2004 to 2018. Data were restricted to WCD-specific products, and were further limited to potential cleansing conditioner products. A total of 1,903 adverse events were reported among the products that fit the study inclusion criteria. The most prevalent reported adverse events were alopecia, pruritus, trichorrhexis, and rashes. Out of the total number of WCD-specific reported adverse events, 8.6% were reported to occur in or after 2014. Additionally, based on the available company sales records, a subset of adverse event data (2005 to 2015) was analyzed using negative binomial regression. The rate of adverse event reporting specific to WCD cleansing conditioners after 2014 was statistically significantly higher in comparison to the rate of adverse event reporting before 2014, adjusting for the number of hair cleansing conditioner units sold per year and the number of reported non-WCD-specific adverse events (to account for temporal trends in the adverse event reporting system). These findings suggest the potential for a halo effect, where negative news media may alter reporting behaviors due to societal shifts in product-specific risk perception.

3092 Increased Opioid-Related Overdose Deaths Are Associated with Increased Abuse of Illicit Fentanyl in the United States

S. Fang1, and F. Liu2. 1Winston Churchill High School, Potomac, MD; and 2US FDA/NCTR, Jefferson, AR.

Opioid-like substances are agonists binding the opioid receptors of neurons in the human central nervous system and serve as painkillers in clinical medicine. However, there has been a significant increase in the illegitimate abuse of fentanyl-like substances in recent years, which poses serious health risks to the general public. To better understand the use of illicit fentanyl-like substances, and its impact on public health including its correlation with opioid overdose deaths in the US, a systematic review from epidemiology databases was conducted and analyzed. The cohort datasets were collected from two major public health surveillance systems, including (1) The US’ Center for Disease Control and Prevention (CDC)’s Morbidity and Mortality Weekly Report (MMWR) during the years from 2010 to 2017 and (2) the data published by the National Forensic Laboratory Information System (NFLIS), which systematically collects results from laboratories nationwide that monitor the illicit use and exhibit of psychoactive substances. The CDC reported that 21,088 opioid overdose deaths in 2010 increased to 49,068 deaths in 2017, with a 13.08% average annual increase. The NFLIS reported 579 cases of illicit synthetic fentanyl use in 2010, increasing over 123-fold to 71,431 reported cases in 2017. The study results from both the CDC’s MMWR and NFLIS demonstrated a substantial increase in the occurrence of opioid-related overdose deaths and the use of illicit synthetic fentanyl in the US. In addition, there was a drastic increase in several synthetic fentanyl-like substances (i.e. acetyl fentanyl, acryl fentanyl, butyl fentanyl, furanyl fentanyl, etc.) with non-medical approval in the last four years. A correlation study shows that the increase in illegitimate use and exhibit is positively correlated with the increase in overdose death rates in the US. The analytic result is statistically significant. The results offer substantial evidence that the increased use of illicit fentanyl may positively contribute to the increased death rate due to opioid overdose. Based on this preliminary study, a further regulatory assessment or legal enactment may help reduce the risk to public health.

3093 The Risk of Lung Cancer Due to Occupational Exposure to Talc: A Meta-analysis of Miners and Millers

S. M. Benson1, A. Bowman2, K. A. Keeton3, R. C. Reid4, E. S. Fung5, and N. S. Egnott1. 1Cardno ChemRisk, Pittsburgh, PA; 2Cardno ChemRisk, Chicago, IL; and 3Cardno ChemRisk, Orange County, CA.

It has been suggested that occupational exposure to talc may be associated with lung cancer. However, none of the previous meta-analyses assessed the influence of smoking on this potential association. To address these concerns, an updated systematic review and meta-analysis of six miner and miller cohorts exposed to talc and their risk of lung cancer was conducted. The goal of this study was to evaluate whether a causal association exists between lung cancer and occupational exposures to talc from mining and milling processes. Specifically, four cohort studies (five occupational groups) were evaluated exposures to cosmetic talc and one cohort study evaluated industrial talc exposures. Without smoking adjustment, meta-analyses showed no increased risk of lung cancer for miners or millers separately. However, when the risk for miners and millers were pooled a statistically significant increased risk of lung cancer was observed (meta-RR = 1.438, 95% CI: 1.063, 1.943). Subsequently, indirect adjustment techniques were used to account for smoking behaviors among studies for which the initial lung cancer risks were not adjusted for smoking behavior. Adjustment for smoking lowered individual risk estimates for miners and millers and led to a reduction in lung cancer risk for the pooled miner and miller estimate such that the association was no longer statistically significant (meta-RR = 1.186, 95% CI: 0.844, 1.667). When assessing exposures to cosmetic talc alone, none of the meta-RRs showed a statistically significant increased risk of lung cancer, regardless of occupational designation. The results of this study demonstrate the importance of accounting for smoking behaviors when evaluating causal relationships between occupational expo-
sures and the development of lung cancer. In conclusion, this systematic re-
view and meta-analysis found no evidence to support a causal association be-
tween exposure to talc while employed as a miner or Miller and lung cancer.

3094 Five-Year Lung Cancer Mortality Risk Analysis and Topography in Xuan Wei: A Spatio-
temporal Correlation Analysis
J. Li,1,2, W. Guo,1, R. Tan,2, R. Tang2, H. Lin2, Y. Huang2, L. Tian1, and L. Chen1.
1New York University, New York, NY; 2University of Hong Kong, Hong Kong, 
Hong Kong; 3University of Oxford, Oxford, United Kingdom; 4Sun Yat-
sen University, Guangzhou, China; and 5Running Medical University, Kunning, 
China.

In Xuan Wei, China, the lung cancer mortality rate is rising significantly higher 
than the whole nation significantly. However, the improved diagnosis just 
can explain partially, other local risk factors might exist. This study inves-
tigates the spatial and temporal trends of lung cancer in Xuan Wei from 2011 
to 2015. Spatial autocorrelation was explored. Four sets of spatial analysis 
and spatial statistics were applied: 1) hotspot analysis and 3D-geographical 
visualization, 2) spatially weighted sum, 3) spatial interrelation between coal 
mines and lung cancer mortality; and, 4) a geographically weighted regres-
sion model. Females exhibited higher lung cancer mortality than males, with 
an increasing trend observed for both genders over time. The incidence rate 
in Laibin Town was the highest in Xuan Wei for each year. Higher mortality 
was found in the towns surrounded by the coal industries with smoky coal 
mines. The hotspot analysis showed the lung cancer mortality has been in-
creasingly concentrated at Laibin, Shuanglong and Longchang over the 5 
years. The 2D and 3D mapped health risks showed the geographical pattern 
of potential lung cancer health risks from the coal mine. The results of correla-
tion analysis illustrate that there was no significant correlation between lung 
cancer mortality as a whole and coal mine distribution for the five years span. 
However, the geographical weighted regression models revealed the stron-
ger correlation in the specific areas where smoky coal mines are concen-
trated. Lung cancer mortality has increased continuously since the third mor-
tality survey in Xuan Wei, especially for local females and the residents over 
35 year olds. Geographically, the locations for different kinds of mines have 
interrelation with the lung cancer mortality there. The specific areas within 
Xuan Wei demonstrated high correlations between lung cancer mortality and 
coal mines. Strategy for intervention and additional studies are warranted to 
systematically examine the local environmental health risks related to coal 
combustion indoor air pollution and eventually to conduct the early screen-
ing of lung cancer for local people who use the smoky coal in the high-risk 
spatial areas.

3095 Optimization of an In Vitro CYP450 Induction 
Assay Using Cryopreserved Cell Lines
A. Rizkallah, T. Lim, and B. Capacio. US Army Medical Research Institute of 
Chemical Defense, Aberdeen Proving Ground, MD. Sponsor: A. Ruff

Cytochrome P450 (CYP450) enzymes are responsible for the majority of Phase I metabolism. Induction occurs when a drug increases the rate of CYP450 enzyme production. As a result, the rates of metabolism of subsequent drugs increase, posing concerns for dosing and safety. To further expand the USAMRICD Absorption, Distribution, Metabolism, Excretion, and Toxicity 
Center of Excellence (ADMET CoE) profiling capabilities, a CYP450 induction assay is being developed using alternative cell lines to primary human he-
patocytes to measure changes in gene expression of CYP1A2 and CYP3A4 isoenzymes. Primary human hepatocytes are the gold standard for evaluating P450 induction in vitro; however, they have inherent limitations such as high 
costs, a fastidious nature, and significant lot-to-lot variability. Induction as-
sessments using cryopreserved hepatocytes and two immortalized cell lines, 
HepaRG and HepatoCells, are being conducted to determine a more robust, 
cost-effective alternative model. Each cell line was exposed to the standard 
inducers rifampicin and omeprazole to assess CYP3A4 and CYP1A2 activ-
ity, respectively. Following a 72-hour incubation period, RNA from the cell 
cultures was extracted and purified. Fold changes of gene expression were 
measured using real-time quantitative PCR (RT-qPCR). Hepatocytes displayed an average fold change of 92.7 for CYP3A4 and 49.6 for CYP1A2, whereas 
HepaRG displayed changes of 28.6 and 179.5, respectively. Average values for CYP3A4 and CYP1A2 for HepatoCells were 58.7 and 43.9. Based on the 
data, HepatoCells most closely mimicked cryopreserved hepatocytes in com-
parison to HepaRG cells. Additional data on assay parameters and technique 
optimization will be presented. Opinion disclaimer: The views expressed in this 
abstract are those of the authors and do not reflect the official policy of the US 
Department of the Army, US Department of Defense or the US Government. 
This project was generously supported in part by an appointment to the Postgraduate 
Research Participation Program at the US Army Medical Research Institute 
of Chemical Defense administered by the Oak Ridge Institute for Science and 
Education through an interagency agreement between the US Department of 
Energy and US Army Medical Research and Materiel Command. Support is also 
provided by the Defense Threat Reduction Agency - Science and Technology 
Office, Medical S&T Division.

3096 Comparison of Cytochrome P450-Related 
NADPH Oxidase Activity in Rat Liver 
Microsomes Expressing CYP2E1, CYP1A1/2, 
and CYP3A1/2
V. Mishin1, N. Tryon2, D. Heck3, D. Laskin4, and J. Laskin2. 1Emest 
School of Pharmacy, Piscataway, NJ; 2Rutgers, The State University of 
New Jersey School of Public Health, Piscataway, NJ; and 4New York Medical 
College, Valhalla, NY.

A characteristic of microsomal CYP enzymes is their ability to generate H2O2, 
either directly or indirectly via superoxide anion, a reaction referred to as 
"NADPH oxidase" activity. Excessive H2O2 production by CYPs can lead to 
the accumulation of additional cytotoxic reactive oxygen species and these 
can compromise cellular functioning and contribute to tissue injury. There 
is a widespread view that CYP2E1 is the major enzyme in microsomes generat-
ing H2O2 and that this activity is not related to its monooxygenase activity. 
Because of this property, CYP2E1 is thought to play a major role in oxida-
tive stress. Conversely, we found that CYP2E1-enriched isoniazide-induced 
rat liver microsomes produce approximately the same amounts of H2O2 (4-5 
nmol/min/mg of microsomal protein) as control microsomes (4-5 nmol/min/ 
mg protein) and CYP1A2 enriched β-naphthoflavone induced microsomes 
(3-4 nmol/min/mg protein), and much less than CYP3A1/2 enriched dexta-
methasone-induced microsomes (12-16 nmol/min/mg protein). To analyze the 
relative contribution of these CYPs to NADPH oxidase activities, we used 
form selective CYP inhibitors of monoxygenase activity including 4-methyl-
ypyrazole, α-naphthoflavone and ketoconazole for CYP2E1, CYP1A2, and 
CYP3A1/2, respectively. These inhibitors were found to block both mono-
oxigenase activities and H2O2 generation by recombinant CYP2E1, CYP1A1/2, 
and CYP3A1/2, respectively. In isoniazide-induced rat liver microsomes, 
while readily inhibiting p-nitrophenol hydroxylation, 4-methylpyrazole did 
not inhibit NADPH oxidase activity. In contrast, α-naphthoflavone and ke-
toconazole, while inhibiting ethoxyresorufin demethylation and alprazolam 
hydroxylation in β-naphthoflavone- and dexamethasone-induced rat liver 
microsomes, respectively, also inhibited the generation of H2O2 by these mi-
crosomes. These data demonstrate that CYP2E1 does not possess the great-
est NADPH oxidase activity. The fact that H2O2 production was inhibited 
by α-naphthoflavone in β-naphthoflavone induced microsomes and keto-
conazole in dexamethasone-induced microsomes, but not 4-methylpyrazole in 
isoniazide-induced microsomes suggests that CYP1A1/2 and CYP3A1/2 and 
possibly other CYPs, but not CYP2E1, are predominantly responsible for H2O2 
generation in microsomal membranes. Supported by NIH grants AR055073, 
NS108856, NS079249, ES004738 and ES050222.

3097 Comparative Analysis of 10 CYP2A6 from 
Different Sources by Assessing Nicotine 
C-Oxidation Activities
H. Wang, X. Li, L. Xu, K. Liu, H. Liu, and F. Xie. Zhengzhou Tobacco 
Research Institute of CNCTC, Zhengzhou, China. Sponsor: R. Meng

Nicotine is one of the major addictive components in tobacco. It is demon-
strated that the rate of elimination of nicotine can influence self-determined 
consumption in humans. The primary catalyst of nicotine metabolism in 
humans is CYP2A6, which is a member of the cytochrome P450 (P450) fam-
ily and one of the enzymes responsible for the metabolism of therapeutic 
drugs, such as nicotine, 4-(methylthio)anisole-1-(3-pyridyl)-1-butanone, and 
N-nitrosodimethylamine. CYP2A6 proteins showed significant individual 
differences in the metabolic effect of nicotine, which were associated with 
individual variation in smoking behavior, drug toxicities, and the risk of de-
veloping several cancers. In this study, our goals were to explore the relation-
ship between the expression levels and enzymatic activities of 10 CYP2A6 
proteins which were heterologously expressed in different sources, including 
recombinase, human cells and liver microsomes of humans, beagles, rhesus 
macques and mouse. The enzymatic activities were assessed on the basis of 
icotine C-oxidation by LC-MS/MS, and the CYP2A6 content were determined 
by western blot assay. The results showed that, among the 10 CYP2A6 from 
different sources, 25-donor mixed gender pooled human liver microsomes, 
human CYP2A6 expressed in Escherichia coli and liver microsome of male rhes-
sus macaques exhibited markedly reduced activity toward nicotine, whereas 
7 others exhibited no enzymatic activity. Meanwhile, there was a positive cor-
relation between the content of CYP2A6 and the activity of it approximately.
This study would significantly enrich our knowledge about the metabolism of nicotine enzyme by CYP2A6, and also provide useful insight into the toxicological evaluation of cigarette smoke in vitro.

The Role of Hepatic Cytochrome P450 in the Cytotoxicity of Dronedarone

Dronedarone is used to treat patients with cardiac arrhythmias and has been reported to be associated with liver injury. Our previous mechanistic work demonstrated that DNA damage-induced apoptosis contributes to the cytotoxicity of dronedarone. In this study, we examined further the underlying mechanisms and found that after a 24-h treatment of HepG2 cells, dronedarone caused cytotoxicity, G1-phase cell cycle arrest, suppression of topoisomerase II, and DNA damage in a concentration-dependent manner. We also investigated the role of cytochrome P450s (CYPs)-mediated metabolism in the dronedarone-induced toxicity using our previously established HepG2 cell lines expressing individually 14 human CYPs (1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, 3A5, and 3A7). We demonstrated that CYP3A4, 3A5, and 2D6 were the major enzymes that metabolize dronedarone, and that CYP3A7, 2E1, 2C19, 2C18, 1A1, and 2B6 also metabolize dronedarone, but to a lesser extent. Our data showed that the cytotoxicity of dronedarone was decreased in CYP3A4-, 3A5-, or 2D6-overexpressing cells compared to the control HepG2 cells, indicating that the parent dronedarone has higher potency than the metabolites to induce cytotoxicity in these cells. In contrast, cytotoxicity was increased in CYP1A1-overexpressing cells, demonstrating that CYP1A1 exerts an opposite effect in dronedarone’s toxicity, compared to CYP3A4, 3A5, or 2D6. We also studied the involvement of topoisomerase II in dronedarone-induced toxicity, and demonstrated that the overexpression of topoisomerase II caused an increase in cell viability and a decrease in H2AX induction, suggesting that suppression of topoisomerase II may be one of the mechanisms involved in dronedarone-induced liver toxicity.

Effect of the CYP2C8*3 Variant on Asthma Symptom Control and Montelukast Efficacy
M. Almestica, C. E. Deering-Rice, and C. A. Reilly. University of Utah, Salt Lake City, UT.

Asthma causes chronic inflammation of the airways and bronchial hyper-reactivity. Despite being treated with appropriate therapeutics, many asthmatics experience suboptimal control of their symptoms. This may be due in part to the effect of genetic variations in genes that dictate drug disposition and/or response. We previously found an association between CYP3A4*22 and CYP3A5*3 with improved asthma control among individuals being treated with fluticasone propionate (FP) and beclomethasone dipropionate (BDP), respectively. We hypothesized that additional genotype-phenotype correlations may exist for asthma drug metabolism pathways. Using TaqMan Open Array technology we assayed 170 different single nucleotide polymorphisms in approximately 1500 genomic DNA samples collected from children undergoing treatment for asthma. Multiple SNPs in the CYP3A gene family, as well as other cytochrome P450 enzymes, P450 reductase, the glucocorticoid receptor, and other asthma-related genes were assayed. We found a new association between variation in CYP2C8 and asthma control scores. For the CYP2C8*3 variant, which is defined by amino acid substitutions at Arg139(Lys) and Lys399(Arg), the mean asthma control scores were lower (i.e., better asthma symptom control) in patients expressing ≥1 copy of CYP2C8*3 allele, when compared to patients with the wild-type CYP2C8*1/*1 genotype (4.28 [n=845] vs. 3.32 [n=172]). Furthermore, when results were stratified by treatment with Montelukast, patients with ≥1 copy of CYP2C8*3 exhibited lower mean asthma control scores (3.56 [n=55] vs. 5.44 [n=214] [p=0.0017]), an effect that was not observed for several other asthma controller medications. Cytochrome P450 (CYP) 2C8 is the principal enzyme involved in the metabolism of Montelukast. Efforts are underway to study the role of CYP2C8 variation in Montelukast clearance and efficacy in human lung cells. These, and future findings should further our long-term goal of improving treatment of asthma through better understanding of the mechanisms associated with sub-optimal clinical responses to current therapies.

Effects of CYP1A on Benzo[a]pyrene and a Complex Polycyclic Aromatic Hydrocarbon (PAH) Mixture Exposure in Caenorhabditis elegans
J. B. Harris, J. H. Hartman, A. L. Luz, and J. N. Meyer. Duke University, Durham, NC.

Polycyclic aromatic hydrocarbons (PAHs) are environmental toxics produced during incomplete combustion; many are known carcinogens. The Elizabeth River in southeastern Virginia was declared a Superfund site due to coal tar creosote contamination that resulted in complex mixtures of high molecular PAHs accumulating within the water and sediment. PAHs are metabolized via cytochrome P450 enzymes (P450s, CYP for specific isoforms), mainly of the CYP1 family. CYP1A1 in human P450 metabolism, a carcinogenic metabolite can be created, which has the potential to damage cellular macromolecules such as DNA and proteins. Thus, P450s have the potential to eliminate PAHs and, paradoxically, create carcinogenic metabolites, so the question of whether CYP1A activity is beneficial or deleterious is unclear. We designed experiments aimed at answering this question using transgenic CYP1A-expressing Caenorhabditis elegans with a special focus on mitochondrial function. Mitochondria may be particularly sensitive to PAH exposure because the mitochondrial membrane attracts lipophilic molecules such as PAHs, and mitochondria lack the nucleotide excision repair pathway, which is primary repair pathway responsible for removing DNA adducts caused by PAH metabolites. In this study, we exposed wild-type and transgenic zebrafish CYP1A-expressing. C. elegans nematodes to a complex PAH mixture, the Elizabeth River Sediment Extract (ERSE), and a well-studied PAH found in the mixture, benzo[a]pyrene (BaP). The effect of CYP1A on BaP and ERSE exposure was tested through ATP, growth, reproduction, and DNA damage assays. CYP1A provided significant (p<0.05) protection against Benzo[a]pyrene-induced growth delay, DNA damage, reduction of offspring, and reduction of steady-state ATP levels. The protective effects of CYP1A on ERSE-dosed nematodes were less dramatic than those seen in BaP-dosed nematodes. CYP1A protected against ERSE-induced reduction of steady state ATP levels at all doses of ERSE studied, but only protected against growth delay and DNA damage at low ERSE exposures. There was no evidence of increased DNA damage due to the carcinogenic metabolite at high doses of ERSE. Thus, in this study, we found CYP1A activity to be mostly protective and hypothesize that another cytochrome P450 isoform such as CYP1B may be mainly responsible for producing the genotoxic metabolite.
Hypersensitivity to Cisplatin and Gentamycin Induced Nephrotoxicity in Mice with Decreased Expression of the NAPDHCytochrome P450 Reductase

L. Ding, Q. Zhang, and X. Ding. University of Arizona, Tucson, AZ.

Cytochrome P450 reductase (CPR or POR) is an obligatory redox partner for all microsomal P450 enzymes. A large, global decrease in POR expression, in a Cpr-low mouse model, was previously found to lead to altered sex steroid hormone homeostasis, female infertility, and decreased capacity for xenobiotic metabolism. The aim of this study was to further characterize the Cpr-low mouse model, in order to identify additional phenotypes that may reveal vulnerability in people with low POR expression. Here, we report differences between wild-type and Cpr-low mice in their sensitivities to drug-induced toxicity in the renal proximal tubules. We studied two drugs, the anticancer drug cisplatin and the antibiotic drug gentamycin, which are known as renal toxicants and do not P450 substrates. Toxicity was assessed by blood urea nitrogen (BUN) levels and histopathology of the kidney. At drug doses that do not cause renal toxicity in wild-type mice, cisplatin caused significant increases in BUN levels over vehicle control group in both male and female Cpr-low mice, whereas gentamycin caused significant increases in BUN levels over vehicle control group in male but not female Cpr-low mice. Corresponding histopathological changes, including appearance of extensive proximal tubule vacuolization, were found in the kidneys of drug-treated Cpr-low mice. These findings suggest that POR expression level could be a risk factor for drug-induced nephrotoxicity in patients.

Comparative Analysis of Epigenetic and Gene Expression Levels Using hGFP1A1 Transgenic Mice with Different Mouse Strains Exposed to 3-Methyloctanol

P. Maturu, W. Jiang, L. Wang, and M. Bhagavathula. Baylor College of Medicine, Houston, TX.

Lung cancer is the leading cause of death worldwide. It is known that the exposure of humans to polycyclic aromatic hydrocarbons (PAHs) via cigarette smoking or by consumption of charcoal broiled steaks is associated with an increased risk of lung cancer. In this study, we tested the hypothesis that the PAH, 3-methyloctanol (MC) elicits persistent human CYP1A1 induction in lungs and livers of transgenic hGFP1A1 mice in strain-specific manner, and CYP1A2 plays a mechanistic role in this phenomenon. WT, hGFP1A1, hGFP1A1/ Cyp1a1-l null or hGFP1A1/Cyp1a2-null on A/J or C57BL/6J background were divided into two groups. Group I was treated with vehicle corn oil (CO) (8 ml/kg) and group II was treated with four doses of MC (100 µmol/kg) once daily for 4 days in C57BL/6, or with single dose of MC (40 µmol/kg) by i.p in A/J mice due to differences in the susceptibility to develop tumors. Four animals in each group were sacrificed at 1, 8 and 15 days after MC withdrawal, lung and liver tissues were collected. The differences in gene expression of mouse and human mRNA, protein content and enzyme activities of CYP1A1 and 1A2, epigenetic markers and miRNA levels were determined at all time points. Though there was a similarity in mouse and human CYP1A1, and mCYP1A2 mRNA, protein levels and enzyme activities persisted up to 8 days and declined by 15 days, there were significant differences in the epigenetic markers and mRNA levels at various time points in a strain-dependent manner. These results suggested that the human CYP1A1 as well as host CYP1A1 and 1A2 enzymes contribute to the differential epigenetic and miRNA expression or vice versa in mice in relation to PAH-mediated carcinogenesis. The current comparative study may be useful to elucidate the role of genetic and epigenetic factors responsible for the differences in the susceptibilities to develop cancers in humans.

The Emerging Contaminant 3,3’-Dichlorobiphenyl (PCB-11) Impedes AhR Activation and Cyp1a Activity to Modify Embryotoxicity of AhR Ligands in the Zebrafish Embryo Model (Danio rerio)

M. A. Roy1, K. E. Sant2, O. L. Veneza1, and A. R. Timme-Laragy1. 1University of Massachusetts Amherst, Amherst, MA; and 2San Diego State University, San Diego, CA.

3,3’-dichlorobiphenyl (PCB-11) is a non-legacy lower-chlorinated PCB congeners that is a byproduct of pigment manufacturing. It is widely detected in environmental samples and has been detected in human serum, but its toxicity potential is poorly understood. We assessed its embryotoxicity and interactions with the aryl hydrocarbon receptor (AhR) pathway in developing zebrafish (Danio rerio). Zebrafish embryos were exposed to 0.2 µM, 2 µM, or 20 µM PCB-11 from 24-96 hours post fertilization (hpf), when they were assessed for gross morphology and Cyp1a activity using the in vivo EROD bioassay. AhR pathway interactions were probed by co-exposing the zebrafish to the AhR agonists PCB-126 or the model PAH beta-naphthoflavone (BNF). Liver development was assessed using the Tg(gut:GFP) zebrafish line. Zebrafish exposed to 20 µM PCB-11 for 4 days and 20 µM GFP-PCB or 20 µM BNF for 4 days were collected at 60 hpf for qRT-PCR and histology. Zebrafish exposure to PCB-11 alone mildly affected EROD activity but did not affect gross morphology. However, 20 µM PCB-11 alone altered the transcription of xenobiotic metabolism and liver development genes, impeded liver development, and increased vacuole formation. In co-exposures, 20 µM PCB-11 induced deformation caused by PCB-126 but exacerbated deformities in co-exposures with BNF. The 20 µM PCB-11 concentration tested in zebrafish can affect liver development, act as both a partial agonist/antagonist of the AhR pathway, and act as an antagonist of Cyp1a activity to modify the toxicity of compounds that interact with the AhR pathway.

Effects of Four Marine Toxins: Ciguatoxin, Maitotoxin, Brevetoxin, and Saxitoxin on Mouse Liver Detoxification Enzymes

S. González Santiago1, and B. Jiménez Vélez2. 1University of Puerto Rico, San Juan, PR; and 2University of Puerto Rico Medical Science Campus, San Juan, PR.

Dinoflagellates form a large group of flagellate organisms that are a predominant part of the plankton of aquatic systems. A number of illnesses have been traced to the ingestion of toxins produced by dinoflagellates. The transfer of these toxins through the food chain are eventually consumed by humans and are the cause for many fish poisoning diseases such as ciguatera, paralytic and neurotoxic shellfish poisonings. The metabolism of marine toxins are fairly understood, but that of others such as Ciguatoxin-1 (CTX-1), Maitotoxin-2, Brevetoxin-2 (PbTx-2) and Saxitoxin (STX) remain poorly understood despite being extensively studied with respect to their biological structure and activity. This study evaluated the effects of four purified marine toxins: Ciguatoxin (CTX-1), Maitotoxin (MTX-2), Saxitoxin (STX) and Brevetoxin (BTX-2) on murine (C57BL/6) and Webster mice liver detoxification enzymes. MTX-2 preferentially reduced the expression of hepatic cytochrome P4503A2 protein and mRNA levels. Histopathological analyses of the livers of control and experimental animals showed perivenous and midzonal necrosis in mice treated with MTX and CTX. Sublethal doses of MTX produces liver necrosis and affects the concentration of liver detoxification enzymes in particular cytochrome P4503A2. While MTX and CTX exerted similar effects on detoxification enzymes, BTX and STX were found to induce cytochrome P4501A2 and to a lesser extent cytochrome P4503A2 at the concentrations tested. To the best of our knowledge, these are the first known studies to evaluate the effects of these marine toxins on hepatic detoxification enzymes in mammals and the first to demonstrate their hepatotoxicity in mice.

Effect of Lambda-Cyhalothrin on the Transcription of the Genes Related to CYP Isomorphs and Inflammation, Oxidative Stress, and Apoptosis Responses in the Liver

Lambda-cyhalothrin, a type II pyrethroid insecticide, has been extensively used in the last two decades to control agricultural pests and insects of veterinary as well as human concern. Studies have reported links between insecticide exposure and adverse health effects including damage to the liver, endocrine disruption, fertility problems, neurological disorders and cancer. The aim of this work was to evaluate potential effects of lambda-cyhalothrin on the transcription of genes related to CYP isomorphs and inflammation, oxidative stress and apoptosis responses in the liver. All experimental procedures involving animals were conducted in accordance with the ethics requirements and authorized by the Institutional Animal Care and Use Committee of the Complutense University. Male Wistar rats received single daily oral administration of lambda-cyhalothrin at doses levels of 4 and 8 mg/kg bw, for 6 days. Animals were euthanized by decapitation after the last administration, livers excised, and portions of each liver tissue sample were individually stored at -80°C until gene expression analysis. Quantitative real-time PCR assays for rat CYP1A1/1A2, CYP2A1, CYP2B1/2B2, CYP2E1, CYP3A1/3A2, and CYP4A1 mRNA as well as for rat IL-1β, NFκB, Nrf2, p53, Casp-3, Bax and Bcl2 mRNA were performed to analyze mRNA gene expressions. The results included: (1) in both treatment groups, a significant increase of CYP isoform mRNA levels, mainly CYP2B1 (1463% and 961%) and CYP2B2 (604% and 501%); (2) IL-1β, Casp-3 and Bcl mRNA levels increased significantly in the group treated 4
mg/kg bw, 6 days. (19 %, 29 % and 46 %); (3) a significant induction of NfE8 and p53 mRNA was observed in both groups of treatment (37 %, 18 % and 55 %, 33 %, respectively); (4) NfE2 mRNA was induced (30 %) only at dose of 8 mg lambda-cyhalothrin/kg bw, for 6 days. These results suggest that an indiscriminate use of the pyrethroid lambda-cyhalothrin may lead to hepatic injuries in a time- and concentration-dependent manner. The potential of the pyrethroid lambda-cyhalothrin to induce hepatic aromatic-metabolizing enyzmes should be considered for the human risk assessment of this pyrethroid. 3108 Evolutionary Patterns in Expression of UDP-Glucuronosyltransferases in Vertebrates

P. van den Hurk, Clemson University, Clemson, SC.

UDP-glucuronosyltransferases are important detoxification enzymes in a wide variety of species. However, over the last decades, more and more examples have been discovered of perplexing differences in the expression of phase 2 detoxification enzymes in vertebrate species, not only in UDP-glucuronosyltransferases but also in glutathione S-transferases. These enzymes are involved in conjugating a hydrophilic group to a poorly water soluble substrate, thus reducing the biological activity or toxicity of the substrate, and facilitating the excretion of the conjugated complex. To further investigate species differences in marine fish taxa, a variety of species was evaluated for the activity of sulfation and glucuronidation enzymes, using the natural hormone 178-estradiol and the environmental toxicant 9-hydroxy-benz(a)pyrene as substrates. Primitive fish species like hagfish and lamprey appeared to have no glucuronidation activity towards these substrates, while activity in sharks and rays was lower than in teleost fishes. This would indicate that the earliest vertebrates had no glucuronidation capacity, and that the array of glucuronosyltransferases that is known in modern fish species and other vertebrates has evolved later. However, there are dramatic examples of other vertebrates that don’t have glucuronidation capability towards phe-nolic substrates. We performed experiments to demonstrate that a number of snake species have phenol-type glucuronidation activity, which is essential, like phenol-type glucuronosyltransferases in obligate carnivores and other reptilians like turtles and alligators had much lower activity than mammals. The lack of phenol-type glucuronidation enzymes, combined with the lack of N-acetylsulfotransferase, leads to an accumulation of highly toxic aminophenol in snakes when exposed to acetoaminophen, which phenomenon is used to control the invasive brown tree snake in Guam. In addition, it has been known that the felines lack phenol-type glucuronida-tion activity, which makes them extremely sensitive to compounds like acetaminophen. The explanation for this diverse expression of glucuronosyltransferases in different vertebrate taxa is probably a combination of phylogenetic origins and the degradation of genomic information in genes that are not essential, like phenol-type glucuronosyltransferases in obligate carnivores like cats, snakes and alligators.

3109 Absorption, Distribution, Metabolism, and Excretion of Didecyl Dimethyl Ammonium Chloride (DDAC) in Rats

B. L. Buruss, L. C. Fisher, and K. A. Hostetler, Toxicology Regulatory Services, A SafeBridge Consultants Company, Charlottesville, VA.

The absorption, distribution, metabolism, and excretion (ADME) profiles of DDAC were evaluated in Good Laboratory Practice and regulatory guideline compliant studies. In definitive experiments, ADME profiles of [14C]-DDAC were evaluated in Sprague-Dawley rats (5/sex/group) following a single low dose (10 mg/kg) or a single high dose (50 mg/kg) via oral gavage, after a single intravenous (i.v.) dose (10 mg/kg), or after repeated oral doses. In the repeated dose ADME experiment, rats were fed diets containing 100 ppm ADBAC for 14 days prior to a single oral gavage dose of 10 mg/kg [14C]- ADBAC. Following [14C]-ADBAC dosing, urine and feces were collected periodically and 7 days after dosing the rats were euthanized and selected tissues and organs harvested. Total radioactivity recovery for all groups ranged from 98.4-108% for males and 94.6-111% for females. In oral experiments, approximately 87-99% of the recovered radioactivity was found in the feces, 5-8% in the urine, and <1% in tissues. No significant differences in ADE patterns were noted between males and females of all orally dosed groups. Following acute i.v. administration of [14C]-ADBAC, approximately 45-55% of the administered dose was found in feces, 20-30% in urine, and 30-35% in tissues. The large fraction of [14C]-ADBAC present in the urine and feces following i.v. administra-tion indicates that ADBAC is excreted by the kidney and liver. Preliminary experiments with acute oral administration indicated little or no radioactivity as [14C]-CO2 was eliminated in the expired air and minimal radioactivity was systemically absorbed; however, detectable levels of radioactivity were pres-ent in the blood within 15 minutes. Appropriative extraction, chromatographic, and spectral techniques were used to identify major metabolites (>10%) of ADBAC in the feces following oral administration of [14C]-ADBAC at 5 mg/kg. Approximately 60-70% of the recovered radioactivity was ADBAC. Spectral analysis of the metabolites demonstrated that oxidation of the alkyl acid side chain and the terminal carbon to form hydroxyl ketone compounds also occurs, resulting in more polar and thus, more readily soluble metabolites for urinary elimination. There was no evidence of modification on the benzyl or N-methyl substituent.

3110 Absorption, Distribution, Metabolism, and Excretion of Alkyl Dimethyl Benzyl Ammonium Chloride (ADBAC) in Rats

L. C. Fisher, B. L. Buruss, and K. A. Hostetler, Toxicology Regulatory Services, A SafeBridge Consultants Company, Charlottesville, VA.

The absorption, distribution, metabolism, and excretion (ADME) profiles of ADBAC were evaluated in Good Laboratory Practice and regulatory guideline compliant studies. There was no evidence of modification on the benzyl or N-methyl substituent.

3111 Metabolite Profiling and Identification in Dog Plasma and Tissues of Edasalonexent (CAT-1004), a Conjugate of Docosahexaenoic Acid (DHA) and Salicylic Acid (SA) Using Smart Linker Technology

R. Dagher1, M. Fonsi2, C. Erratico2, H. Liu1, R. Forster2, and A. Nichols1.

1Catabasis Pharmaceuticals, Inc, Cambridge, MA; and 2Citiolab, Evreux, France.

Edasalonexent (CAT-1004) is an oral small molecule which inhibits NF-kB, a transcription factor that is activated in Duchenne Muscular Dystrophy (DMD) and drives inflammation, fibrosis, and muscle degeneration. Edasalonexent (CAT-1004), a Conjugate of Docosahexaenoic Acid (DHA) and Salicylic Acid (SA) Using Smart Linker Technology. This methodology allows the simultaneous intracellular delivery of two bioactives to elicit a pharmacological response that could not be elicited by administering the bioactives separately or in combination. Edasalonexent is currently in clinical development in 4- to 7-year-old boys with DMD regardless of mutation. The present study was conducted to identify edasalonexent metabolites formed in beagle dogs in vivo and to determine their levels in plasma and distribution in heart, liver and skeletal muscle using liquid chromatography-mass spectrometry (LC-MS). Beagle dogs were treated with 1,000 mg/Kg/day for 39 consecutive weeks. No treat-ment-related signs of toxicity were detected in this study. Edasalonexent was bio-transformed into thirteen and ten metabolites in male and female dogs, respectively; the biotransformation observed included phase I (oxidation and hydrolysis) and Phase II (mainly glucurono-conjugation) pathways with large overlaps between the two genders. Among the tissues analyzed (plasma,
heart, liver and skeletal muscle), liver showed the presence of the highest number and levels of edasalonexent metabolites. In heart, liver and skeletal muscle of both male and female dogs, DHA represented between 80 and 99% of the total drug related material detected (as relative LC/MS peak area intensity). In addition, consistent with the known metabolism of unsaturated fatty acids, oxidative metabolites (in the DHA moiety) were also identified. These results suggest that after extravasation of edasalonexent to beagle dogs DHA is preferentially retained by heart and skeletal muscle, two affected tissues in DMD disease, more than the parent compound and/or any other metabolite detected in the same tissues. DHA was also one of the major circulating metabolites observed in dogs.

2,4,6-Tribromophenol (TBP) is naturally-occurring bromanophenol that is widely used as a brominated flame retardant and wood antifungal. TBP is found in soil, dust, wild-caught seafood, and humans. TBP in vivo studies of oral and dermal disposition were conducted in rats and mice. Human dermal disposition was estimated based on studies of ex vivo split-thickness human and rat skin. Following intravenous administration, TBP was rapidly excreted in urine, with 89-94% recovered in urine, 5% in feces, and 1-2% in blood/tissues after 24h. TBP administered to female SD rats (0.1-1000 µmol/kg) by gavage was well absorbed, with ~88% eliminated via urine after 24h, 11% in bile, and 3% in feces. Male and female SD rats and B6C3F1/J mice had similar disposition profiles when administered a single oral dose of TBP (10 µmol/kg), with urine and fecal recoveries varying only slightly by sex or species. TBP kinetics were linear across a range of doses in short-term studies (0.5-10 µmol/kg, 4 h). Urine contained TBP, TBP-glucuronide, and TBP-sulfate. Bile contained TBP-glucuronide while fecal extracts contained only parent TBP. TBP did not appear to bioaccumulate after single or 5 repeated oral administrations. TBP was readily absorbed at all doses and routes tested. Oral bioavailability was 23-27%. TBP readily passed unchanged through both human and rat skin with 49% predicted to be dermally bioavailable in humans. We conclude from these data that humans are likely to have significant systemic exposure when TBP is encountered in the workplace, home, or outside environment. This research was supported in part by the Intramural Research Program of NIH/NCI [Project ZIA BC 011476]. This abstract does not necessarily represent US EPA policy.

Pharmacokinetics of TBP (CAS No. 118-79-6) was assessed in male Sprague-Dawley rats and compared to emtricitabine free macromolecular prodrug platform may have extraordinary potential for HIV and other anti-viral therapies. Funded by NCI Contract No. HHSN26120080001E, and supported by the National Cancer Institute of North Carolina at Chapel Hill Center for AIDS Research (CFAR), an NIH funded program P30 AI05410.

1,3-Dichloropropene (1,3-D) showed a statistically increased incidence of bronchoalveolar adenomas of in male B6C3F1 mice at 60 ppm during chronic inhalation testing. Saturation of metabolic clearance at this level would lack relevance for human health risk assessment. Therefore, the linearity of 1,3-D concentrations in mouse blood was investigated on Day 15 of repeated nose-only inhalation exposure to 0, 10, 20, 40, 60, and 120 ppm (6 h/d, 7/d/ wk). Additional groups were included at 20, 60 and 120 ppm for blood collection at 1.5-3 h of exposure to determine AUC and t½. As exposure increased from 10 to 120 ppm, mean steady-state blood concentrations ranged from 0.968 to 63.3, 7.19 to 283, and 8.16 to 346 ng/g blood for cis, trans and total (cis+trans) isomers of 1,3-D, respectively. The time-course showed steady-state blood concentrations at 1.5 and 3 h at 20 and 60 ppm, and by 6 h at 120 ppm. Blood concentrations declined rapidly after exposure (t½ = 5 to 12 min). AUC estimates for total 1,3-D were not dose-proportional, with values of 4.4, 30.2 and 89.7 min·µg/g, at the 20, 60 and 120 ppm, respectively. Statistical analysis for dose proportionality included a second-order regression model and a robust, piecewise linear (hockey-stick) model. Arithmetic comparisons for linearity were made at the 20, 60 and 120 ppm. Blood concentrations in blood were compared to the 10-fold (+) threshold of 60 ppm. These results support non-relevance of 1,3-D induced benign pulmonary tumorigenicity in mice for human health risk assessment.
3116 Comparison of Plasma Pharmacokinetics of Intravenous and Intramuscular Administration of Midazolam in Male Sprague-Dawley Rats

K. Walker1, M. Pennington1, S. Armstrong2, S. Litvin1, M. Stone1, C. Schultz1, S. O’Brien1, E. Kundiick1, B. Marrero-Rosado1, and L. Lumley1

1USAMRICD, Aberdeen Proving Ground, MD; and 2Dstl, Porton Down, Wiltshire, United Kingdom. Sponsor: J Younirk

Benzodiazepines are commonly used as first-line therapy to treat acute seizures and status epilepticus (SE), characterized by prolonged seizure activity, which if untreated leads to severe brain pathology. The benzodiazepine midazolam is a positive allosteric modulator of the GABA receptor and potentiates GABAergic inhibition. Midazolam has been sought to replace diazepam to treat seizures induced by chemical warfare nerve agents (CWA) for its rapid absorption and short duration of action. Although midazolam is often administered intravenously in the clinic, intramuscular administration would enable rapid treatment in the event of a high number of casualties. A New Drug Application for the use of intramuscular midazolam to treat SE was recently approved by the US FDA. In the present study, we compare the plasma pharmacokinetics of intravenous and intramuscular midazolam administration in rats to determine how route of administration affects the absorption rate of midazolam in rats, male rats pre-implanted with jugular catheters for repeated blood draws received midazolam (1 mg/kg) via intravenous or intramuscular injection and then had blood drawn at a range of time points (2-240 minutes) following injection. Sampling was randomized and each time point was sampled from up to six animals. Plasma was separated by centrifuging shortly after collection and frozen until biochemical assays were conducted. Samples were analyzed for peak plasma concentration using liquid chromatography and tandem mass spectrometry (LC-MS/MS). WinNonlin was used to analyze data using both non-compartmental analysis (NCA) and compartmental model fitting. Pharmacokinetic parameters were determined for intravenous (IV) and intramuscular (IM) administration including time to maximum concentration, maximum concentration, half-life of elimination, apparent volume of distribution, and area under the curve. Maximum plasma concentration (443±181 ng/mL) occurred within minutes following IM (6 minutes) and was eliminated twice as fast for IV than for IM, with the half-lives being 33 and 60 min, respectively. Bioavailability of midazolam by the IM route was approximately 50%. Volume of distribution was large being approximately 2 L/kg for IV and IM. A comparison of PK data between the two exposure routes will be presented. Funding was provided by the Defense Threat Reduction Agency.

3117 Cyfluthrin Toxicokinetics in Plasma and Nervous Tissues after Oral Administration in Rats

The intended uses of cyfluthrin, Type II pyrethroid insecticide, are to control flying and crawling insects, such as house flies, litter beetles as well as flies and red ants, cockroaches, ants and termites indoors. Cyfluthrin is acutely very toxic when administered orally in corn oil (LD₅₀ 250 mg/kg bw). Clinical signs were observed in all animals and indicated an effect on the CNS (tremor, rolling movements, disturbed motility and respiration). The aim of this work is to support new available pharmacokinetic data to be applied for cyfluthrin risk assessment. All experimental procedures involving animals were conducted in accordance with the ethics requirements and authorized by the Institutional Animal Care and Use Committee of the Complutense University of Madrid. Male Wistar rats received cyfluthrin (single oral dose 20 mg/kg bw). Serial blood and brain tissue samples were obtained and analyzed. Cyfluthrin concentrations in plasma and brain tissues (hypothalamus, striatum, hippocampus and frontal cortex) were quantified by LC/MS. Cyfluthrin disposition was best described by the use of a two-compartment open model. Plasma and nervous tissue kinetics showed an extensive oral absorption of cyfluthrin and a slow elimination. In plasma, the oral absorption half-life (T1/2a) and maximal concentration (Cmax) were 1.58 h and 0.385 µg/mL, and the elimination half-life (T1/2b) was 17.15 h. After oral administration, cyfluthrin was widely distributed to brain tissues. Cyfluthrin peak concentrations (Cmax, range 0.40 to 1.21 µg/g) were achieved in all brain regions at the similar time (Tmax, range 4.02 to 4.56 h). The primary target nervous tissue appears to be hypothalamus. Peak concentration of cyfluthrin in hypothalamus tissue (Cmax, 1.21 µg/g) was about 3.3 times higher than in plasma. Nervous tissue accumulation was also reflected by the area under the concentration-time curve ratios of tissue/plasma. The ratio AUC(0-24) tissue/AUC(0-24) plasma for cyfluthrin was 3.17 for hypothalamus. Because many toxicokinetic changes appear to have toxicokinetic basis, our results suggest that the indiscriminate use of this insecticide could induce neurological disorders after long-term. Project Ref. RITA2015-00010-C03-03 from Ministerio de Economía, Industria y Competitividad, Spain.

3118 Comparative Toxicokinetic Analysis of Available Inhalation and Oral Data on Cobalt and Its Salts

B. Hung1, N. Smith2, and S. Kabadi3. 1Joint Institute for Food Safety and Applied Nutrition, College Park, MD; and 2US FDA, College Park, MD. Sponsor: D. Bandele

Cobalt (Co) and its salts were reported to show carcinogenic incidences after inhalation exposure to animals and humans. However, no reports of oral carcinogenicity of Co and its salts are available. One approach for addressing this data gap is to use available inhalation data to assess the safety of Co and its salts via the oral route of exposure. However, the first step is to compare the toxicokinetics (TK) of oral and inhalation exposure for Co and its salts and determine if there are any exposure route-related differences in TK of Co and its salts. We reviewed available TK studies on Co and its salts and determined that TK profiles of different Co salts may differ due to variability in physicochemical properties of the test substances, such as solubility, salt size, particle size, etc. Overall, the oral bioavailability of soluble and insoluble Co salts is low. We located oral and intravenous rat studies on soluble Co (II) chloride and used noncompartmental TK modeling to estimate area under the curve (AUC) and determined its oral bioavailability in rats. Our analysis indicated that the oral bioavailability of Co (II) chloride in rats was low (2.41%). Furthermore, we identified sex-based differences in the TK of Co (II) chloride. Noncompartment TK analysis of published data on cyanocobalamin (i.e., vitamin B12) in human subjects demonstrated that its bioavailability was low (2.16%). We observed that Co naphthenate in rats demonstrated similar AUCs to Co (III) chloride, suggesting that its bioavailability would be low. We also reviewed TK data on cobalt (II, III) oxide and concluded that inhalation data could not be used for its safety assessment of oral exposure due to differences in reported TK parameters between the two routes. In conclusion, the oral bioavailability of evaluated Co salts is low. Furthermore, TK profiles of Co and its salts may markedly differ between the two exposure routes, possibly due to different effects of test substance-related physico-chemical properties, such as solubility. Therefore, the utilization of inhalation data to assess safety of Co and its salts after oral exposure should be performed on a case-by-case basis.

3119 Comparative Toxicokinetic Study of Three Bisphenols (BPA, BPS, and BPF) in a Sheep Pregnancy Model

J. Gingrich1, Y. Pu1, R. Ehhardt1, R. Karthikraj2, K. Kannan3, and A. Veiga-Lopez4. 1Michigan State University, East Lansing, MI; and 2Wadsworth Center, New York State Department of Health, Albany, NY.

Bisphenol A (BPA), S (BPS), and F (BPF) are the most abundant bisphenols detected in humans and can cross the placental barrier. We have recently shown that in vivo exposure to BPS, but not BPA, can reduce the endocrine function of the placenta. Gestational BPS exposure has been linked to longer gestation in humans and disruptions in mammary gland development. Although BPA, and recently BPS, toxicokinetics are known, those of BPF in pregnancy remain unknown. Women in the US are exposed to over 60 chemicals at any given time, and it has been demonstrated that BPA, BPS and BPF occur as a mixture in vivo. However, there has been no direct comparison among the three bisphenols, individually or in a mixture, which was the aim of our study. Given the structural and binding affinity differences among bisphenols, we hypothesized that BPF toxicokinetics will differ to that of BPS or BPA. Fetal catheterizations were conducted in pregnant sheep (n=6) at mid-pregnancy that were injected with either a single dose of BPS (n=3, 0.5 mg/kg, s.c.), or a combination of BPA, BPS, and BPF (n=3, 0.5 mg/kg for each chemical, s.c.). Maternal and fetal blood samples were collected to develop toxicokinetic profiles from 0 to 72 h. Maternal and fetal urine, and amniotic fluid were also collected. Bisphenols were assayed by HPLC/MS/MS and toxicokinetic parameters calculated via non-compartmental analysis. Half-lives varied among bisphenols in maternal circulation; BPF having the longest half-life and BPS having the shortest.
of the shortest (BPA: 5.3±0.4 h; BPS: 3.7±0.1; BPF: 7.7±2.2). On the contrary, in fetal circulation, BPS had the longest half-life and BPF had the shortest (BPA 52.0±20.3 h; BPS: 402.2±102.6; BPF: 14.2±1.8). All bisphenols reached basal levels at 48 h in maternal plasma but were still detectable in amniotic fluid and fetal urine at 72 h, highlighting the persistence of bisphenols in the fetus. This is the first study to simultaneously compare toxicokinetic profiles for BPA, BPS, and BPF during pregnancy. We demonstrated that BPS reaches in the highest relative concentration in maternal plasma and accumulates in the fetal compartment. These observations warrant further studies into progeny outcomes following gestational BPS exposure. Funded by NIHES K22ES026208 and R01ES027863 to AV-L.

3120 In Vitro ADMET and Pharmacokinetic Screening of Novel Epac1 Inhibitors for the Treatment of Rickettsiosis

Inhibition of exchange protein directly activated by cAMP 1 (Epac1) is a novel prophylactic and/or therapeutic approach for fatal rickettsiosis. The goal of this project is to design and evaluate Epac1-specific inhibitors (ESI) with favorable in vitro absorption, distribution, metabolism, excretion, and toxicity (ADMET) and pharmacokinetic (PK) properties using a systematic approach. To support the development of Epac1 inhibitors with promising in vitro and in vivo efficacy profiles, over 35 ESI have been screened for genotoxicity in vitro Ames mutagenicity and mouse lymphoma assays. Of these, ~30 compounds were selected for in vitro parallel artificial membrane permeability assay (PAMPA), metabolic stability in human, rat, dog, and mouse liver microsomes, and inhibition of specific human liver cytochrome P450 enzymes. The prototype of this series of substituted 2-(isoaxazol-3-yl)-2-oxo-N-phenyl-aceto-hydradonyl cyanides was ESI-09 from structure-activity studies, which displayed an apparent IC50 of 10.8 µM against Epac1. ESI-09 and 11 other analogs were selected for dose-range finding and PK studies in mice and rats, based on favorable in vitro results. PK studies with ESI-09 in female C57BL/6 mice after single dose ip (0 mg/kg) and oral (10, 50, and 100 mg/kg) administration indicated excellent bioavailability of ~95%, with plasma half-life (t1/2) of ~3 hr (ip) and ~3 to 6 hr (po). Apparent volume of distribution (V) of ESI-09 was ~95 ml/kg (ip) and ~230 to 310 ml/kg (po), suggesting minimal to low extra-vascular binding of ESI-09 in mice. ESI-09 also exhibited high bioavailability of ~100% after oral administration (1 and 10 mg/kg) in male and female rats, with plasma t1/2 of ~2 to 6 hr. Two other lead drug candidates NYO173 and NYO541 with IC50 values of 4.0 and 5.1 µM, respectively, were identified with promising efficacy and ADMET profiles. PK studies in female C57BL/6 mice resulted in t1/2 of 1 to 1.5 hr (NYO173) and 2 to 3 hr (NYO541). ESI-09, NYO173, and NYO541 are currently being investigated further in more detailed rat and dog PK and toxicology studies. Supported by NIH-NIAID under Grant Award R01AI111464.

3121 Comparisons of High-Dose Test Agent Levels in Plasma and Liver Over 28 Days of Dosing

J. Davis1, R. Council-Troche1, J. Hinckley1, S. Werre1, K. Boes1, B. Jortner1, M. Ehrich1, A. Leber2, R. Hontecillas2, and J. Bassaganya-Riera2

To determine potential for accumulation and safety of high dose multiple-day oral administration of a first-in-kind proposed therapeutic for inflammatory bowel disease (IBD), 1000 mg/kg/day doses suspended in Oraplus (Pennig) were given by gavage to adult male and female rats for 28 consecutive days. The product, known as BT-11, binds Lanthionine Synthetase C-Like 2 (LANCL2), which is a therapeutic target for treatment of IBD. In these experiments, blood samples were drawn at least twice from 3 rats per sex between 7 and 28 days after initiation of dosing. In addition, liver samples from 4 rats per sex were collected after dosing (day 29) and after a 2-week recovery (day 42). In female rats, plasma concentrations on day 7 averaged 20 ng/mL plasma and rose to over 70 ng/mL plasma on days 21 and 28. This increase was statistically significant. The difference between concentrations on days 21 and 28 was not significant. Plasma samples from male rats had lower concentrations of BT-11, and rose from 9.4 at 7 days to 28.0 ng/mL on day 21. Concentrations were 13.1 ng/mL at 28 days. However, these time-related concentration changes in male rats were not significant. BT-11 concentrations in liver samples were exceedingly variable but the average was higher in males than females at 28 days (429 vs 307 ng/g liver), with concentrations similar and much lower at 42 days (average 3.5 ng/g liver). No gross or pathological evidence of toxicity was seen after administration of these high doses in samples collected at 28 days. These results suggest that BT-11 is safe when high doses are given for multiple days, and that this potential therapeutic agent did not continuously accumulate in plasma over the 28-day dosing period or store in liver after cessation of dosing. Supported by VBHRC, the Virginia Biosciences Health Research Corporation.

3122 Development and Validation of an Analytical Method for Quantification of Alpha-Pinene Oxide in Rodent Blood and Mammary Tissue by GC/MS

T. Fennell1, S. Watson2, R. Fernando1, V. G. Robinson2, and S. Waidyanatha1

Alpha-pine (AP) is a potential metabolite of AP in rodents and humans. Given its potential reactivity in tissues, establishing the extent of its formation and concentration in blood and tissues is an important component of the evaluation of the toxicity of AP. The objective of this work was to validate a method to quantitate AP and in rat and mouse blood and mammary tissue, a potential target organ in vivo, in inhaled doses by gas chromatography and mass spectrometry. Standards were prepared by adding 5 µL of AP spiked solution to 100 µL rat blood followed by 300 µL ethyl acetate containing internal standard (IS, (+) limonene oxide). Sample was vortexed for 3 min and centrifuged for 3 min. The supernatant was analyzed by GC-MS in El mode. The ions monitored were m/z 109 (AP) and 94 (IS). The method was successfully validated in male and female rat plasma and rat mammary tissue. Precision and accuracy for rates were ≤±2% for all standards at all concentrations in both matrixes (r = 0.999). The relative standard deviations (%RSD) was ≤ ±5.3% and %RSD ≤ ±7.8%. The method was also evaluated in female B6C3F1 and rat mammary tissue. Approximately 50 mg mammary tissue was homogenized with a 950 µL of water. AP was added to give concentration in the range 25-500 ng/g mammary tissue. 100 µL of homogenate was extracted with ethyl acetate and analyzed as described above for blood. Mean %RE values were ≤ ±4.6% and %RSD ≤ ±8.1%. These results demonstrate that the method is suitable for the analysis of AP in rodent blood and mammary tissues generated from toxicokinetic and toxicology studies.

3123 Assessing Delivery Efficiency of Nanoparticles to Tumors in Tumor-Bearing Mice Using a Physiologically Based Pharmacokinetic Modeling and Simulation Approach

Y. Cheng, J. Riviere, N. Monteiro-Riviere, and Z. Lin

Unique physicochemical and biological properties of engineered nanoparticles (NPs) have led to key biomedical applications for diagnosis and targeting therapy of various diseases, including cancer. However, NPs translation into clinical applications are limited partly due to low delivery efficiency to the tumor and lack of knowledge on the quantitative effects of various physicochemical factors on NP tissue/tumor distribution. The goal of this study was to determine the main factors that affect tumor delivery efficiency of NPs and to identify the relative contributions of different factors using a physiologically based pharmacokinetic (PBPK) modeling approach. A PBPK model for gold NPs in healthy mice was developed first. Then the healthy mouse model was extrapolated to include a tumor compartment to simulate the biodistribution and tumor delivery of various types of NPs. A multiple linear regression model was employed to determine the potential effects of various physicochemical characteristics, including the type of administered NPs, targeting strategies, cancer types, and tumor models on tumor delivery efficiency. The healthy mouse PBPK model well predicted tissue distributions in plasma, lungs, liver, spleen, and kidneys in healthy mice after intravenous administration of 13-nm gold NPs (R² = 0.95). This PBPK model also adequately predicted most of the tumor delivery efficiencies of various types of inorganic and or-
clonidine is approved for therapy of attention-deficit hyperactivity disorder (ADHD) that is one of the most common neurobehavioral problems mainly afflicting the children and youth between 6 and 17 years of age with a high prevalence from 2% to 18% in USA. Three sustained release buccal formulations of clonidine were prepared by 3D printing technology. They showed different dissolution profiles in phosphate buffered solutions (pH 6.8). The purpose of this portion of the work was to use physiologically-based pharmacokinetic (PBPK) modeling to predict the pharmacokinetic profiles for these formulations to assist selection of an ideal formulation with a long-term sustained release for more than 72 hours. A PBPK model of clonidine was developed using Gastroplus™ (Simulations Plus, Inc.). Model parameters used in the PBPK model were collected from literature. The physicochemical parameters not available in literature were predicted using the ADMET Predictor™ module. The clinical data for clonidine was from clinical studies published in literature which included the BAC concentration–time data of both oral and intravenous (IV) administration. The Advanced Compartmental Absorption and Transit (ACAT™) and PBPKPlus™ were used for the simulation of clonidine after IV and oral administration. The simulated pharmacokinetic (PK) profiles of clonidine were compared with observed profiles for evaluation of the model performance. The model was then used to simulate PK profiles after dosing the sustained release formulations by incorporating the in vitro dissolution data into the model. The results indicated that initial high concentrations may be observed after administration of formulation 1 and 2, due to fast initial drug release, with Tmax observed around 4 hours and then fast decrease over 72 hours. Results indicated that more sustained plasma concentration could be achieved up to 72 hours after administration of formulation 3 which showed minimum initial drug release. The predicted pharmacokinetic profiles provide the evidence for formulation and preparation process screening of the sustained release buccal formulation of clonidine. This work demonstrated that PBPK modeling could be applied to optimize formulations to achieve desired pharmacokinetic profiles.

Optimization of Metabolic Parameters Using Physiologically Based Pharmacokinetic (PBPK) Modeling and Vapor Uptake Inhalation Chloroform (CHCl3) Data in F344 Rats

PBPK models are well established frameworks used to describe administration, distribution, metabolism, and excretion (ADME) of xenobiotics. To quantify metabolism, a PBPK model for a volatil compound can be calibrated with closed chamber (i.e., vapor uptake) inhalation data. Here, we graphically highlight a component of the optimization process to illustrate a strategy for metabolic parameter estimation when using vapor uptake data. Male F344 rats were exposed in vapor uptake chambers to initial concentrations of 100, 500, 1000, and 3000 ppm CHCl3. Inhalation time course data from these experiments, in combination with optimization using a chemical specific PBPK model, were used to estimate metabolism parameters Vmax and Km. Matlab® simulation software was used to integrate the mass balance equations and to perform the optimizations. The cost function used the logarithmic transformation of the in-chamber time course data and least squares to minimize the difference between data and simulation values. The final values for Vmax and Km were 4.9 mg/hr/kg

1

and 0.26 mg/L, respectively. Additionally, cost function and contour plots were used to analyze the dose dependent capacity to estimate Vmax and Km within the experimental range used. Based on the combined analysis, the best concentrations for determination of Vmax were 500 and 1000 ppm with 3000 ppm having a small contribution. Least square plots confirmed 500 ppm to be the best concentration to determine Vmax. Showing the smallest differences between experimental and simulated data. The contour plots showed narrow valleys where the optimization found the best values for Vmax at both 500 and 1000 ppm. The estimation of Km was more involved, needing data across the full range of experimental concentrations (100-3000 ppm). In summary, this work should help toxicologists interested in optimization techniques to understand the overall strategy employed when calibrating metabolic parameters in a PBPK model with inhalation data. Subjecting preliminary data to the analyses described here would guide selection of optimal exposure concentrations for more accurate estimation of Vmax and Km. This strategy could be explored for in vitro metabolism parameter optimization. This abstract does not reflect US EPA policy.

Developing Databases and Models to Integrate Toxicokinetic Data for Human Health Assessment

Toxicokinetic (TK) processes such as chemical absorption, distribution, bio-transformation and excretion (ADME) play a critical role in human and ecological hazard, exposure and risk assessment. Physiologically-based toxicokinetic (PBTK) model selection is dependent on the decision-making context and information requirements. We have developed a tiered framework of PBTK models for humans and rodents and novel TK databases and Quantitative Structure-Activity Relationship (QSAR) models to apply TK models in different contexts. The TK models are generally applicable for organic chemicals and progress from one-compartment (1-CoTK) models to more sophisticated and data intensive multi-compartment (M-CoTK) models. The M-CoTK model includes capacity for simulating the parent chemical and up to 5 metabolite products. While the 1-CoTK model does not explicitly consider metabolism, all other processes of chemical uptake and elimination are quantified and the 1-CoTK model is easier to parameterize and use. The 1-CoTK and M-CoTK models require input data that can be obtained from in vitro or in vivo
studies or predicted using in silico methods. We are addressing data gaps in biotransformation rates at multiple levels of biological organization through the development of critically evaluated in vitro and in vivo databases and the development of validated QSARs following OECD QSAR guidance. The new databases include: (i) in vitro biotransformation rates (S9, hepatocytes, microsomes) from human (n=8500 chemicals) and rodent (n=7000 chemicals) assays, and (iii) in vitro transport parameter studies (n=100 chemicals) and rodent (n=700 chemicals). We have developed five validated QSARs for predicting whole-body biotransformation half-lives. The first QSAR uses a fragment-based approach (R² = 0.89, R²-ext = 0.73, root mean square error = 0.75 log units). The other four QSARs use whole molecular descriptors (R² range = 0.77 - 0.80; R²-ext range = 0.75 - 0.79, root mean square error = 0.67 - 0.69 log units). A case example demonstrates the application of the 1-CoTK model and a biotransformation QSAR for human bioaccumulation assessment for approximately 20,000 data poor commercial chemicals highlighting the critical need for reliable biotransformation half-life data.

### 3128 Towards Harmonized Test Protocols for In Vitro Hepatic Clearance Studies

J. Louisse, M. Alevijn, A. Peijnenburg, and A. Punt. RIKILT Wageningen University and Research, Wageningen, Netherlands.

Non-animal methods for toxicokinetics, such as in vitro hepatic clearance studies, are expected to play a crucial role in next generation chemical risk evaluation. The development of harmonized test guidelines is essential for design and execution of in vitro hepatic clearance studies. As a consequence, divergent methods are used, hampering interpretation and exchange of data and regulatory acceptance. The aim of the present study was to obtain insight in the experimental conditions of in vitro hepatic clearance studies that influence obtained clearance values. To that end, in vitro hepatic clearance data and their methodological aspects (experimental setup) obtained with rat or human hepatocytes were collected from the literature. These data show that clearance values for the majority of chemicals differ more than one order of magnitude. We estimated the systematic effect of different experimental setups on the in vitro hepatic clearance data using a random forest regression analysis with several continuous and categorical experimental settings as input and (normalised) clearance data as output. The results show that several methodological aspects (e.g. 'hepatocyte concentration' and 'culture medium') have a relatively large impact on the clearance values obtained, indicating that harmonization of these methodological aspects is required to reduce variation. Indeed, the percent coefficient of variation decreased for the majority of chemicals when clearance data were only collected from studies in which methodological aspects were harmonized (e.g. only data obtained using '1.0 - 10^3 cells/mL' or only data obtained using 'WME medium'). These insights can subsequently be used as a starting point to develop a test guideline and/ or test guideline for in vitro hepatic clearance studies based on rat or human hepatocytes.

### 3129 Cell Model for Studying Nucleoside Transporters, a Key Component of the Blood-Testis Barrier

Sertoli cells in the testis represent the principle element of the Blood-Testis Barrier (BTB). Equilibrative nucleoside transporters (ENTs) are responsible for the transport of nucleosides across the BTB. These transporters are of particular interest in studying the disposition of nucleoside reverse transcriptase inhibitors (NRTIs) in the male genital tract because of their similarity in chemical structure to nucleosides. hENT1 is located on the basal membrane and hENT2 is located on the apicolateral membrane of Sertoli cells. This study characterized the transport of a specific nucleoside, uridine, in HeLa S3 cells to better understand the roles of two ENTs, ENT1 and ENT2, in nucleoside transmembrane transport. HeLa S3 cells were grown on 96 well plates and hENT1 mediated transport. HeLa S3 cells were grown on 96 well plates and cells were incubated with increasing concentrations of unlabeled uridine (0-300μM) and approximately 20nM [3H]Uridine. Two-minute kinetics of [3H]Uridine uptake showed no difference in Jmax (16.13 and 12.26 fmol cm-2 min-1) and a three-fold difference in Km (13.28 and 35.18 μM) for hENT1 and hENT2 mediated transport, respectively. This suggests that at low concentrations, hENT1 is primarily responsible for transporting uridine in these cells. Together, these data suggest that HeLa S3 cells are an adequate model for studying the characteristics of nucleoside transporters present in the BTB. Supported by R01GM123643.

### 3130 Interaction of Organophosphate Flame Retardants with the MDR1 Efflux Transporter

D. Viramontes1, S. M. Marco2, X. Wen3, J. R. Richardson3, B. B. Buckley2, and L. M. Aleksunes4. 1University of Nevada Reno, Reno, NV; 2Rutgers, The State University of New Jersey, Piscataway, NJ; and 4Florida International University, Miami, FL.

Organophosphate-containing chemicals have been used as pesticides, nerve agents, plasticizers and more recently, as flame retardants in clothing, plastics, building materials, electronics, and furniture. As the use of organophosphate flame retardants becomes more widespread, the exposure of humans also increases. Emerging data suggest organophosphate flame retardants are disruptive to the reproductive, endocrine, and nervous systems. One mechanism to reduce the toxicity of chemicals is active efflux that prevents accumulation in cells. The multidrug resistance protein 1 (MDR1) is one such efflux transporter that can remove substrates from cells using energy generated from the hydrolysis of ATP. We sought to determine whether the flame retardants tricresyl phosphate (TCP), tris(1,3-dichloroisopropyl) phosphate (TDCPP), and triphenyl phosphate (TPP) are substrates and/or inhibitors of MDR1. For this purpose, HEK293 cells expressing an empty vector or the human MDR1 gene were treated with TCP, TDCPP, and TPP for 72 h and cytotoxicity (LC50) assessed using the alamarBlue assay. The positive control MDR1 substrate doxorubicin exhibited a 4-fold increase in LC50 value in cells expressing MDR1 (LC50: 1115 nM) compared to control cells (LC50: 257 nM). By comparison, the cytotoxicity of TCP, TDCPP, and TPP were similar between control and MDR1-expressing cell lines. Likewise, neither TCP nor TPP were able to alter the efflux of the MDR1 substrate rhodamine, from MDR1-expressing cells following 0.5 h co-exposure. Taken together, these in vitro data suggest that MDR1 does not confer resistance to the cytotoxicity of organophosphate flame retardants nor do these chemicals inhibit MDR1 function. Determining whether the MDR1 transporter interacts with hazardous chemicals advances our understanding of potential mechanisms that can protect against toxicity. ### 3131 Pharmacological Inhibition of HDAC Enzymes Up-Regulates Hepatic Efflux Transporter Expression in Mice

Efflux transporters protect hepatocytes by exporting environmental toxicants, drugs, and xenobiotics into the circulation or bile. In the liver, efflux pumps include the multidrug resistance protein 1 (MDR1), breast cancer resistance protein (BCRP), and isogenous forms of the multidrug resistance-associated protein (Mrp) family. Recent research has demonstrated that histone deacetylase (HDAC) inhibitors that enhance histone acetylation can alter the expression and function of efflux transporters in cancer cells. Currently, the ability of epigenetic pathways to regulate the expression of hepatic efflux transporters is unknown. In our study, we sought to investigate whether the pharmacological inhibition of HDAC enzymes could alter efflux transporter mRNA and protein expression in mouse livers. For this purpose, adult male C57BL6 mice (N=5) were administered once daily intraperitoneal injections of vehicle or the HDAC inhibitor apicidin (5mg/kg). After 7 days, livers were collected for qPCR and western blotting. Compared to vehicle-treated control mice, treatment with apicidin reduced the hepatic mRNA expression of Mrp2 by 22% and induced Mdr1a, Mdrp3, and Mrp4 mRNAs by 25%, 64% and 131%, respectively. Likewise, the livers of mice treated with apicidin exhibited enhanced histone H3 acetylation (K9/K14) and up-regulation of Mdr1 (42%) and Mrp3 (72%) proteins. To identify candidate regulatory pathways responsible for altering transporter expression, target genes of prototypical transcription factors were quantified. Treatment with apicidin increased the hepatic expression of target genes of Car (Cyp2b10, 162%), Pxr (Cyp3a11, 113%), and Ppar alpha (Cyp4a14, 223%). Notably, no changes were observed for target genes of AhR (Cyp1a1) or Nr3f2 (Nrf1). Taken together, these data demonstrate that the pharmacologic inhibition of HDAC enzymes and increased acetylation of histone H3 proteins differentially alter the expression of hepatic efflux transporters. Supported by the Rutgers Summer Undergraduate Research Fellowship, Predoctoral Fellowship from Bristol-Myers Squibb, P30 ES005022 and ROI ES021800.
Enhanced Histone Acetylation and Renal Efflux Transporter Expression in Mice Treated with Histone Deacetylase Inhibitors

Multidrug Resistance Protein 1 (MDR1, ABCB1) and Breast Cancer Resistance Protein (BCRP, ABCG2) are key efflux transporters that regulate the disposition and toxicity of chemicals. In the kidneys, MDR1 and BCRP mediate the apical secretion of drugs and other xenobiotics from proximal tubules into urine. The purpose of the current study was to determine whether pharmacological inhibition of HDAC enzymes alters the renal expression of Mdr1 and Bcrp. Adult, male C57BL/6 mice were treated with vehicle or one of two HDAC inhibitors, suberoylanilide hydroxamic acid (SAHA) (15 mg/kg/d ip) or apicidin (5 mg/kg/d ip), daily for 7 days prior to collection of kidneys and analysis of Mdr1 and Bcrp expression by SDS-PAGE and western blotting. Treatment of mice with SAHA and apicidin increased renal acetylated histone H3 levels, confirming the pharmacological inhibition of HDAC enzymes. Compared to vehicle-treated controls, the kidneys of mice treated with either HDAC inhibitor had increased Mdr1 and Bcrp protein expression between 25 to 30%. In summary, pharmacological inhibition of HDAC enzymes increases histone acetylation and up-regulates Mdr1 and Bcrp expression which may enhance the renal secretion of drugs and xenobiotics. Supported by the Rutgers Summer Undergraduate Research Fellowship, a Predoctoral Fellowship from Bristol-Myers Squibb, P30ES050522, and R01ES021800.

Brain Region-Specific Histone Acetylation and Up-Regulation of Mdr1 and Bcrp Transporters in Mice

D. You1, H. Shin1, F. Mosad1, J. B. Richardson2, and L. M. Aleksunes1.

Rutgers, The State University of New Jersey, Piscataway, NJ; and Florida International University, Miami, FL.

The multidrug resistance protein 1 (Mdr1, Abcb1) and breast cancer resistance protein (Bcrp, Abcg2) regulate the passage of endo- and xenobiotics to protect various cells in the brain. We have previously demonstrated that histone deacetylase (HDAC) inhibitors, which are widely investigated as treatments for several brain disorders, can enhance histone H3 acetylation and regulate the expression of MDR1 and BCRP transporters in an in vitro model of the human BBB. In our present study, we sought to evaluate the ability of HDAC inhibitors to modulate these transporters in intact tissues. For this effort, adult male C57BL/6 mice were injected intraperitoneally with HDAC inhibitors (valproic acid, VPA, or apicidin) once daily for seven days and different regions of the brains were collected for analysis of mRNA and protein expression of Mdr1 and Bcrp by qPCR and western blot, respectively. Treatment with HDAC inhibitors had no significant effects on transporter mRNA expression at 7 days. On the other hand, VPA increased the protein expression of Mdr1 in striatum by 70% and Bcrp in midbrain by 30%. Apicidin also enhanced striatal Mdr1 protein by 30% and hippocampal Bcrp protein expression by 20%. Transporter up-regulation in these brain regions was associated with increased histone H3 (H3/K14) acetylation. In summary, our findings indicate that HDAC inhibitors significantly up-regulated the expression of Mdr1 and Bcrp proteins in specific regions of mouse brains. Pharmacological inhibition of HDACs may alter transport properties in the brain and consequently modulate brain levels of neuroactive drugs and neurotoxins. Supported by a Predoctoral Fellowship from Bristol-Myers Squibb, P30ES050522, and R01ES021800.

Area under Curve and Maximum Concentration Exposures and Time-Kill Response Relationships In Vitro Hollow Fiber Infection Model System

N. Garimella. US FDA, Silver Spring, MD.

Antibiotics by means of humanized pharmacokinetic schedules in interaction with infecting bacteria have the potential to predict antibiotic-resistances. Antibiotics including ampicillin (45 μg/ml concentration), fosfomycin (450 μg/ml concentration) and ciprofloxacin (0.72μg/ml concentration) and their dual combinations were in vitro applied pharmacokinetically against a clinical isolate, uropathogenic Escherichia coli strain CFT073 bacteria at 37°C. Approximately, 10^6 CFU/mL of bacteria in monolayers in plastic wells. Chemicals can distribute between the plastic, media, and the cells, but it is unknown for what fraction of the Tox21 chemical space and to what extent this differential partitioning between in vitro compartments occurs. These initial studies evaluate the in vitro distribution of chemicals over a period of 24 hours, the length of many of the Tox21/ToxCast experiments. This pilot study involves the use of MCF-7 cells exposed to a diverse set of ten chemicals. A Thermo Vanquish LC system is used in conjunction with a Thermo Q Exactive Plus mass spectrometer to determine the concentration of chemicals in the media, plastic, and cells. Results from this pilot show that at 24 hours the concentration of chemical in cells compared to the concentration in media can vary from 12-fold (atrazine) to 195-fold (triphenyl phosphate). This gives quantitative insight into the magnitude and directionality of the uncertainty in the assumption that media to cells and blood to tissue fosfomycin at AUCmax/MIC being 7.7 μg -hour/ml and C0-24/MIC being 1.6 μg/ml had inhibited the replication of resistant bacteria for first 5 to 7 hours. In dual combination experiments using same antibiotics, together they could inhibit the replication of resistance for 24 hours. The last doses in once daily experiments could significantly suppress bacteria to the range of 0 to 10^8 CFU/mL for the 48 hours and above. These findings suggest that, all antibiotics with respect to their exposure-response relationships could be relied to treat Escherichia coli of CFT073 causing uncomplicated urinary tract infection. From a pharmacodynamic viewpoint, these findings can be used to prescreen and minimize toxicities of antibiotics in treating infections.

Impact of Pegylation in Pharmacokinetic (PK) Assessment of Pegfilgrastim Using Alternate Assays

A. Shah, S. J. Schrieber, and K. E. Howard. US FDA, Silver Spring, MD.

Polyethylene glycol (PEG), a flexible, uncharged and highly hydrophilic polymer, is used to prolong the half-life and improve efficacy of therapeutic proteins and nanoparticles. Despite these key advantages of PEG conjugation, the biosimilars developed from their respective originator products may fail to meet requirements for approval. This could be broadly attributed to the presence of PEG, which can present challenges in the bioanalytical methods to assess serum concentrations of the PEGylated compound for PK studies. In addition, aggregate formation, steric hindrance, chemical properties of PEG (in size, length, conjugation density) and functionalization conditions could also attribute to the PK variability. As there are over a dozen PEGylated products currently marketed, there is an urgent need to understand the potential causes for variability in PK of PEGylated products. There has been intense development of pegfilgrastim biosimilar products, so we chose to use this product and its non-PEGylated counterpart as the initial products to evaluate. We evaluated three different ligand binding assays (LBA) that could be used by sponsors and followed US FDA’s Bioanalytical Method Validation guideline for initial validation. Parameters assessed included sample stability at different temperatures, effect of matrix, use of apigdard analyte, accuracy, recovery of recovery of mono- and di-PEG conjugates. Using the optimized and qualified assay methods, inter-conor variability in serum from 50 healthy donors were also evaluated for both pegfilgrastim and filgrastim. Two of three assays demonstrated performance within guideline recommendations for filgrastim and pegfilgrastim for both fresh and frozen samples. The third assay was not able to be validated for filgrastim, but not pegfilgrastim due to differences in both fresh and frozen sample results. The paired comparison between different LBA methods demonstrated key differences, which are critical for their applicability for PK assessment.

Where is the Chemical?: The In Vitro Disposition of Tox21 Chemicals

D. M. Crizer1, J. A. Harrill1, N. S. Sipes2, B. A. Wemore3, S. Waidyanatha1, A. M. Richard1, A. J. Williams1, S. S. Ferguson4, G. S. Honda5, J. E. Wambough5, B. S. Thomas5, K. Paul-Friedman5, and M. J. DeVito5. NIEHS/NTP, Research Triangle Park, NC; 1US EPA/NCTR, Research Triangle Park, NC; and 3US EPA/ORD, Research Triangle Park, NC.

Understanding the in vitro disposition of chemicals evaluated in alternative models would enable better translation of in vitro bioactivity to the human dose context. In an effort to extrapolate in vitro exposures to in vivo exposures, toxicokinetic models can be used to estimate human oral exposures that would result in blood concentrations equivalent to the nominal media concentrations. One assumption in these models is that the ratio of the chemical concentration in media to cells is equivalent to the ratio of blood to tissue. The other assumption is the static nature of the cell culture and exposure compared to the kinetic processes occurring in vivo. In contrast, human exposure is a dynamic process in which absorption, distribution, metabolism and elimination influence blood and tissue chemical concentrations. In the Tox21 project most of the assays employ immortalized cell lines cultured in monolayers in plastic wells. Chemicals can distribute between the plastic, media, and the cells, but it is unknown for what fraction of the Tox21 chemical space and to what extent this differential partitioning between in vitro compartments occurs. These initial studies evaluate the in vitro distribution of chemicals over a period of 24 hours, the length of many of the Tox21/ToxCast assays. This pilot study involves the use of MCF-7 cells exposed to a diverse set of ten chemicals. A Thermo Vanquish LC system is used in conjunction with a Thermo Q Exactive Plus mass spectrometer to determine the concentration of chemicals in the media, plastic, and cells. Results from this pilot show that at 24 hours the concentration of chemical in cells compared to the concentration in media can vary from 12-fold (atrazine) to 195-fold (triphenyl phosphate). This gives quantitative insight into the magnitude and directionality of the uncertainty in the assumption that media to cells and blood to tissue
Toxicokinetics can be used to extrapolate an oral equivalent dose from in vitro bioactivity data for comparison with potential external exposure rates, thereby providing an estimate of risk. More accurately predict the oral equivalent dose, it is desirable to estimate the oral bioavailability (F_int), which is the fraction of the oral dose that is actually available to the body. Caco-2 assays inform estimates for F_int by providing a measure of the in vitro apparent permeability (P_app \text{ cm/s}) across a membrane of human colon carcinoma cells. This permeability is highly correlated with the fraction of chemical absorbed (F_int) in the gut and the effective permeability rate (P_eff \text{ cm/s}) through the epithelium of the small intestine (Artursson, et al. 2001). Predicted P_eff may then be used with in vitro measured intrinsic hepatic clearance (Cl_int) to estimate the fraction of chemical surviving gut metabolism (F_g) (Yang, et al. 2007). Subsequently, F_bio can then be determined by combining F_g and F_int with the fraction of chemical surviving first pass hepatic clearance, with the result being Cl_int and in plasma. In this work, we developed a random forest QSAR model to predict P_app using recently measured values for environmental chemicals and literature values for pharmaceuticals. We then used the predicted P_app to estimate P_eff \text{ cm/s} and F_bio for comparison to literature values. Using a training set of 166 chemicals, the QSAR model provided reasonable prediction of the P_app for the validation dataset of 315 chemicals, yielding an RMSE of 0.60 for the log_{10} transformed values. Using the QSAR predicted P_app to predict P_eff gave an RMSE of 0.69 for the log_{10} transformed values. Predictions for F_g in humans made using the model reported by Darvich et al. (2010) had an RMSE of 0.26. Estimates for F_g in humans using the Q_m model (Yang et al. 2007) gave an RMSE of 0.26. Subsequent estimates of F_bio for human and rat had RMSE's of 0.32 and 0.47 respectively. With additional open-source models to predict Cl_int and F_g, it would be possible to make predictions for F_bio entirely using in silico methods. This abstract does not necessarily reflect US EPA policy. Artursson, et al. Adv. Drug Deliv. Rev. 2001, 46, 27-43. Yang, et al. Current Drug Metab. 2007, 8, 676-684.

### QSAR Modeling of Caco-2 Permeability for the Estimation of Oral Bioavailability

G. Honda, R. Sayre, C. Stock, D. Angus, R. Dinallo, R. Pearce, R. Thomas, and J. Wambaugh

Understanding saturation of absorption and elimination of parent chemical and biomarkers/metabolites in repeated dose toxicity studies provides insight into treated level selection for subsequent toxicity studies based on the kinetically-derived maximum dose (KMD). Knowledge of toxicokinetics (TK) and non-linearity of blood/urine concentrations of parent and metabolites aids in study interpretation and the relation between external exposure and internal systemic dose. Experience with integration of TK into toxicity studies (without use of extra animals) has provided information on the usefulness of TK for dose level setting, internal dose determination and study interpretation. A TK decision tree/framework was developed based on observations with agrochemicals over ~15 years of TK assessments with respect to variation in absorption, metabolism and elimination. Examples of chemicals that have simple and complicated metabolism pathways, low and high absorption, saturation of elimination pathways, enterohepatic recirculation and a perspective of when KMD has been successful or not for dose level setting and retrospective study interpretation will be presented. Examples include chemicals (poorly and extensively absorbed and metabolized) where biomarker/metabolites include parent (sulfoxaflor), parent and 1 metabolite (halofenoxymethyl and acid, flonyrauxfen-benzyl), parent and 1-2 metabolites (fenpicloram), and other chemical examples of parent with greater than 2 metabolites. The developed decision tree includes design of studies to select biomarkers of exposure, selection of biomarkers based on absorbed dose, timing of TK analysis relative to subsequent studies, interpretation of biomarker concentrations relative to routes of exposure and study endpoints and the use of TK for metabolism studies to investigate differences across species. In case studies presented, it is possible to analyze for blood concentrations of parent/metabolites and determine whether dose-proportionality is observed in repeated dose toxicity studies and use the KMD for dose level selection, study interpretation and internal dose measurement. There is high value in understanding the TK of a chemical and its metabolites in mammalian toxicology studies, the internal systemic exposure to the animal and the extrapolation of the internal dose to human exposure assessments.

### Integration of Toxicokinetics into Toxicity Studies: TK Decision Tree/Framework for Agrochemicals

### An Open-Source, Generalized Workflow for IVIVE Analysis

1. ILS, Research Triangle Park, NC;
2. Sciome LLC, Research Triangle Park, NC;
3. NIEHS, Research Triangle Park, NC;
4. NIEHS/NICEATM, Research Triangle Park, NC.

A critical challenge for implementing nonanimal approaches for chemical safety testing is to translate in vitro assay results to potential in vivo effects. To address this challenge, we have developed an open-source in vitro to in vivo extrapolation (IVIVE) workflow. The workflow incorporates in vitro data, quantitative structure-property relationships (QSPR) predictions, and one-compartment pharmacokinetic (PK) or multi-compartment physiologically based PK (PBPK) models to predict in vivo exposures that would result in blood concentrations equivalent to in vitro activity concentrations. We previously applied the IVIVE-PK workflow to evaluate estrogenic activity for environmental chemicals and observed good concordance between in vitro and in vivo dosimetry. However, for chemicals with poor oral bioavailability (e.g., bisphenol A, 17β-estradiol), the IVIVE-PK workflow tended to underestimate in vivo exposure levels, possibly due to a lack of extrahepatic metabolism in the one-compartment PK model. In this study, we developed a multi-compartment PBPK model that includes gastrointestinal glucuronidation to simulate a chemical’s plasma and tissue concentration after oral administration. We incorporated this PBPK model into the IVIVE workflow (IVIVE-PBPK) to estimate equivalent administered in vivo dose levels based on in vitro estrogenic activity concentrations for bisphenol A and 17β-estradiol, both of which are known to undergo glucuronidation, and achieved improved results. To apply this IVIVE-PBPK workflow to a larger chemical space, we also developed in silico models to predict kinetic constants for glucuronidation and other pharmacokinetic parameters. The IVIVE-PBPK workflow will be available via the NICEATM Integrated Chemical Environment (ICE) at https://ice.ntp.niehs.nih.gov, and a wide range of in vitro data within ICE, including CurtoX data, are available for workflow input. This optimized approach for using in vitro data to quantitatively predict in vivo effects is presented via an online tool that is accessible to a diverse stakeholder community and is designed to increase the utility of in vitro data in risk assessment applications. This project was funded with US federal funds from the NIEHS/NIH/HHS under Contract HHSN272201500010C.

### Ca2+-Dependent Gene Expression in Response to PCB95 and Triclosan Exposure

J. Alfaro, and E. Holland

California State University Long Beach, Downey, CA.

Health issues including neurodegenerative diseases and cardiac and skeletal muscle myopathies are strongly associated with cellular calcium signaling disruption (CSD). Two channels that contribute to Ca2+ signaling are the ryanodine receptor (RyR), a Ca2+ release channel imbedded in the sarco/endoplasmic reticulum, and L-type voltage-gated calcium channels (CaVι), on the plasma membrane that regulate Ca2+ entry upon cellular depolarization. Environmental pollutants such as non-coplanar polychlorinated biphenyls (nCPCBs) and triclosan (TCS) can alter RyR and CaVι function and may be related to altered cellular signaling. The project investigates whether CSD, caused by the nCPCB, PCB95, and TCS, may lead to altered transcription of genes regulated by the Ca2+-dependent transcriptional regulators DREAM (downstream regulator of the CaVι) and Distal C-terminal (dCT) of the CaVι channel. Using the GHR somatotrophic cell line, I measured time and concentration dependent impacts of chemical exposure on the expression of DREAM-regulated prolactin (PRL), neuronal PAS domain protein 4 (NPAS4), and brain-derived neurotrophic factor (BDNF), as well as dCT-regulated sodium-calcium exchanger (NCKΙ) and connexin (CΧ31.1). Here, cells were exposed to 0.1μM, 1μM, and 10μM concentrations of PCB95 or TCS for 3-, 6-, 12-, and 24-hr with subsequent qPCR. Preliminary results indicate upregulation of gene expression for CΧ31.1 after 6-hr exposure to 10μM TCS and NPAS4 after 3-, 6-, 12-, and 24-hr exposure to 10μM TCS. This work will help extend our knowledge of pollutant induced CSD by non-coplanar compounds and to determine whether CSD can contribute to altered transcriptional regulation with implications in endocrine, cognitive and striated muscle health in exposed organisms.
3141 Calcium Signaling Disruption Causes Changes in Gene Transcription as Mediated by DREAM

N. Schuko1, J. Alfarò1, J. Lepe2, and E. Holland3. 1California State University Long Beach, Downey, CA; and 2University of California Irvine, Irvine, CA.

Several environmental pollutants, including polychlorinated biphenyl (PCB) congeners and triclosan, are capable of causing Ca2+ signal disruption (CSD) by altering the activity of the ryanodine receptor (RyR) or the L-type voltage-gated Ca2+ channel (CaV1). These channels are important to neuronal and muscular physiology, but the extent to which CSD through these channels contributes to altered cellular pathways is currently unclear. We investigated whether CSD, caused by cellular exposure to PCB congeners and triclosan, alters transcription normally regulated by the Ca2+-sensitive transcriptional repressors DREAM (downstream regulatory element antagonistic modulator). When intracellular Ca2+ concentrations are decreased, DREAM remains bound to DNA and represses transcription, and at high intracellular Ca2+ concentrations, DREAM is released from DNA and activates transcription, representing a direct connection between CSD and transcription. We utilized GT1-7 hypothalamic neurons and ToT1 thyrotrrophs to measure whether CSD alters transcription of gonadotropin releasing hormone (GnRH), thyroid stimulating hormone (TSH), neuronal PAS domain protein 4 (NPAS4) and brain-derived neurotrophic factor (BDNF). Cells were exposed to varying concentrations of each pollutant for multiple time periods and GnRH, TSH, NPAS4, and BDNF levels assessed using qPCR. GT1-7 cells exposed to the potent RyR activator CB952 did not lead to changes in GnRH mRNA expression consistent with low basal RyR gene expression. Exposure of GT1-7 cells to triclosan, a CaV1 inhibitor, significantly decreased GnRH transcription in a dose and time dependent manner. Exposure of ToT1 cells to CB952 showed no significant changes in TSH, and beginning analysis of NPAS4 and BDNF transcription are trending upward. DREAM is important to proper functionality of the digestive system, central nervous system, and skeletal and cardiac muscle, and it has been tied to pain response and memory, and thyroid-gland health. This work will help address whether CSD is contributing to such alterations by altering DREAM-mediated transcription.

3142 Assessment of Avobenzene, Ensulizole, Homosalate, and Padimate-O in Endocrine Disruptor Screening Panel Studies

B. McIntyre1, L. Zorrilla2, S. Borroughoff1, and P. Foster2. 1NEHS/NTP, Research Triangle Park, NC; 2Bayer CropScience, Research Triangle Park, NC; and 3ToxStrategies Inc., Cary, NC.

Avobenzene (ABZ), Ensulizole (ESZ), homosalate (HMS) and padimate-O (PMO) are UV absorbing agents commonly used in sunscreens. The potential estrogen and androgen effects of these compounds were evaluated in vitro; estrogen receptor (ER) and androgen receptor (AR) binding and transcriptional activation and in vivo; rat uterotrophic and Hershberger bioassays, respectively. ABZ, ESZ, HMS, and PMO did not increase ERα-mediated luciferase activity in the HeLa-9903 system at any of the viable concentrations tested up to the limit of solubility. All four were classified as a “non-binders”. ABZ, ESZ, HMS did not demonstrate AR agonism, however there was an apparent estrogenic activity in the Hershberger assay. In the rat Hershberger bioassay, each pollutant for multiple time periods and GnRH, TSH, NPAS4, and BDNF levels assessed using qPCR. GT1-7 cells exposed to the potent RyR activator CB952 did not lead to changes in GnRH mRNA expression consistent with low basal RyR gene expression. Exposure of GT1-7 cells to triclosan, a CaV1 inhibitor, significantly decreased GnRH transcription in a dose and time dependent manner. Exposure of ToT1 cells to CB952 showed no significant changes in TSH, and beginning analysis of NPAS4 and BDNF transcription are trending upward. DREAM is important to proper functionality of the digestive system, central nervous system, and skeletal and cardiac muscle, and it has been tied to pain response and memory, and thyroid-gland health. This work will help address whether CSD is contributing to such alterations by altering DREAM-mediated transcription.

3143 Toxic Effects of UV Filter Chemicals (Benzophenones and Octocrylene) on Zebrafish Embryo-Larvae

K. Chang, Q. Meng, and K. Yeung. Chinese University of Hong Kong, Sha Tin, Hong Kong.

Ultraviolet (UV) filter chemicals found in sunscreen materials are common environmental contaminants that represent a growing health risk concern due to their presence in water, fish, and human systems. Benzoresorcinol (B1), oxazobenzene (B3), dihydrobenzoxazole (B8), and octocrylene (OC, CAS 6197-30-4) are four such chemicals that have been detected in environmental samples and linked to alterations in estrogen receptor signaling pathway and producing oxidative stress. Zebrafish is a well-established model to study molecular genetics, toxicology, and trans-generation effects of chemicals. We have previously used an in vitro model of ZFL liver cell-line to test the toxicities of these chemicals. In this study, zebrafish (AR strain) embryo-larvae was employed to investigate the potential risks of the benzophenones (BPs) and OC, and the molecular mechanism of their toxic effects. Chemical exposures (24-hour and 96-hour) were conducted on larvae to determine half lethal concentrations (LC50s) for each chemical and hatching rate on embryo at each 24 hours. Gene expression profiles on estrogen receptor (ER) pathway, aryl hydrocarbon receptor (AhR) pathway and gender differentiation have been detected by using quantitative real-time PCR (qRT-PCR). Preliminary data showed that OC has no obvious effect on the hatching rate of embryos, and did not cause larvae death even at high concentrations. However, it was found that OC strongly up-regulated the expression of ERs and other sex-determining genes by gene profiling using qRT-PCR. Based on this result, it was speculated that OC will cause serious interference to endocrine systems in vertebrates, and we are studying the chemical ingestion in the exposed embryo-larvae. On the contrary, BPs reduced the hatching rate of the embryos and caused larvae deformity with heart swelling. More importantly, the LC50 values of BPs on larvae is comparable to the concentrations detected in European countries. From our qRT-PCR data, all three BPs induced gene expression level of both ER pathway and AhR pathway. Research supported by a Direct Grant from Faculty of Science, Chinese University of Hong Kong.

3144 CLARITY-BPA Core Study: Analysis for Non-monotonic Dose-Responses

M. Badding1, L. Barraj1, A. Williams1, and R. Reiss1. 1Exponent, Alexandria, VA; and 2Exponent, Washington, DC.

A recently published study sponsored by the European Food Safety Authority (EFSA) described a methodology for evaluating non-monotonic dose responses (NMDR) by assessing study findings according to 6 checkpoints. The publication (Varret et al., 2018) suggests researchers consider a meta-analysis of available data when a finding fulfilled at least 5 of the 6 checkpoints. This methodology was applied to the recently released results of a large U.S. government-sponsored 2-year bisphenol A (BPA) rat study. The BPA study was a collaborative effort between the US FDA (FDA), the National Toxicology Program (NTP), and the National Institute for Environmental Health Sciences (NIUHS) and is called the Consortium Linking Academic and Regulatory Insights on Bisphenol A Toxicity (CLARITY-BPA) Core Study. It involved oral gavage treatment of rats to BPA at doses of 2.5, 25, 250, and 25,000 ug/kg/day and was designed to address some of the lingering toxicological issues associated with BPA, including its possible role in endocrine disruption and the potential to induce NMDR. The study was conducted according to guideline research standards and included two arms: in utero through perinatal exposure (stop-dose arm) and in utero through lifetime exposure (continuous-dose arm). The evaluation presented herein provides additional analyses of the data, beyond those of the study report, that focus on the statistically significant findings. Only 2 of the statistically significant findings met at least 5 of the 6 checkpoint requirements for NMDR according the EFSA-sponsored publication; these were for clinical chemistry changes in serum: an increase in percent basophils in stop-dose females and decreased total bile acids in stop-dose males. However, further evaluation showed these 2 findings to not be biologically significant. Overall, this analysis found little evidence for NMDR or biologically significant changes associated with BPA treatment in the CLARITY-BPA Core study.
3145 Influence of Bisphenol A on hCG Release, Differentiation and Proliferation of Human Trophoblast Cells
T. Hamad1, B. Bediako2, A. Elnabawi3, and A. Ishaque4. 1University of Maryland Eastern Shore, Salisbury, MD; and 2University of Maryland Eastern Shore, Princess Anne, MD.

BPA is an endocrine disrupter and is one of the most utilized industrial chemicals worldwide. Epidemiological and animal studies provide evidence that environmental BPA exposure can be harmful to humans. Several studies showed that exposure to low doses of BPA, particularly during prenatal development and early infancy, BPA can pass through the placenta and reach the fetus, as revealed by the concentrations in amniotic fluid, cord blood and placental and fetal tissues. BPA exposure to the developing fetus is of particular concern as the compound readily crosses the placental barrier and accumulates both in the placenta and in the fetus. Hormones, such as E2, progesterone and hCG are fundamental in pregnancy. Moreover, hCG has endocrine, paracrine and autocrine actions on a variety of cells and tissues. These actions are directed to promote trophoblast invasiveness and differentiation, placental growth, hormone production and fetal growth. Therefore, any interference with their action might be harmful in pregnancy and for fetal health. This study was aimed to examine the effect of BPA on estrogen and progesterone-induced cell proliferation and the release of hCG in the human placental trophoblast (BeWo) cells. Cells were treated with BPA, estrogen or progesterone at various concentrations alone or in combination. Cell proliferation, cell death and level of hCG were evaluated. Exposure to BPA for 24h significantly decreased cell viability in a concentration-dependent manner. BPA at low concentrations (0.01nM-10nM) significantly potentiates estrogen or progesterone-induced cell proliferation. The estrogen antagonist, ICI 182,780, and progesterone antagonist, mifepristone, blocked these effects, indicating the effect of BPA on steroid receptors involved in the control of cell proliferation and differentiation in the placenta. At low concentrations of BPA, hCG release was significantly reduced at 24h. The decreased hCG release indicates reduced trophoblast function. Our data suggest that maternal contamination with BPA could disrupt placental endocrine activity which, in turn, could lead to adverse effects on pregnancy outcome, the fetal development and possibly long-term effects in the adult life. Supported by Title III.

3146 In Vitro and In Vivo Evidence Suggest Estrigenic Potential of Cyanobacterial Microcystin-LR via Stimulating Steroidogenesis
L. Li1, J. Hou1, Y. Su1, W. Lin1, and D. Anderson2. 1Huazhong Agricultural University, Wuhan, China; 2Hubei Provincial Engineering Laboratory for Pond Aquaculture, Wuhan, China; and 3Woods Hole Oceanographic Institution, Woods Hole, MA.

Microcystins (MCs), produced by toxic cyanobacterial blooms that appeared world widely in eutrophic waters have the potential for disrupting endocrine homeostasis in aquatic animals. Thus far, the claim that MCs act as xenoeithogens remains uncertain. Using a combination of in vitro and in vivo assays, the present study investigated the endocrine disruption and estrogenic potential of the most toxic and common variant, microcystin-LR. Effects of microcystins (10, 100, 1000, 10000 μg/L) on steroidogenesis were assessed in in vitro H295R cells after 48 h. The contents of 17β-estradiol (E2) and testosterone (T) in the medium increased in a non-dose-dependent manner, which showed positive correlations with the expression of steroidogenic genes in H295R cells. In the in vivo assay, histopathological changes and hormone levels in the testis, gene expressions along the hypothalamic-pituitary-gonadal axis (HPG), especially the gonadal aromatase gene (cyp19a), were assessed. Meanwhile, spermatid percentage in the testis declined. In the liver, vitellogenin (vtg1) gene was significantly up-regulated while both the transcriptional and protein levels of ERα declined dramatically. The present results indicate that MC-LR induced non-dose-dependent estrogenic effects at environmental concentrations, which may result from steroidogenesis stimulation via a non-ER-mediated pathway. Our findings support a paradigm shift in the risk assessment of microcystin-LR from traditional toxicity to estrogenic risk, particularly at low concentrations, and emphasize the tremendous threat to the reproductive capacity of wildlife and even human beings in bloom areas.

3147 Estrogen Receptor Alpha-Coregulator Interactions and Transcriptomic Analysis of T47D Slightly Discriminate Diethylstilbestrol from 17β-Estradiol

Diethylstilbestrol (DES) is a synthetic estrogen and is a proven human teratogen and carcinogen. It has been reported that a functional estrogen receptor (α) is needed for DES-induced adverse effects. Since other estrogens that also activate the ERs, like 17β-estradiol (E2), do not show the adverse effects induced by DES in vivo, we hypothesized that DES’ interaction with the ERs differs from that of E2. Therefore, the current study aimed to investigate dose-specific differences in DES and E2 using in vitro assays related to ERα-mediated effects. To this end, the effects of DES and E2 on ERα-mediated reporter gene expression, ERα-mediated breast cancer cell (T47D cell) proliferation, ERα-coregulator interactions and transcriptomic analysis of T47D cells were studied. Results obtained indicate that DES activates ERα-mediated reporter gene transcription and T47D cell proliferation similar concentrations as E2. Furthermore, only minor differences between DES and E2 induced binding of the ERα to coregulator peptides and transcriptomic signatures obtained in the T47D breast cancer cell line were found. Although some of the minor differences observed may play a role in the differential in vivo effects of DES and E2, other modes of actions including possibly epigenetic mechanisms and/or differences in kinetics, may provide better explanations for the differences in in vivo effects of DES and E2.

3148 Towards Computational Modeling of Estrogen Receptor Alpha-Mediated Signaling in Endocrine Disruption
B. Dujindam1, T. van den Hoorn2, J. W. van der Laan3, and B. van de Water1. 1Leiden Academic Centre for Drug Research, Leiden, Netherlands; and 2Medicines Evaluation Board, Utrecht, Netherlands.

Estrogen receptor alpha (ERα) belongs to the nuclear hormone receptor family of ligand-inducible transcription factors, and regulates gene networks in biological processes such as cell growth and proliferation. Disruption of these networks, for instance in breast cancer cells in the presence of the non-endocrine carcinogenic 17β-estradiol (E2), can result in adverse outcomes such as unanticipated cell proliferation ultimately culminating in tumor formation. Since ER signaling is also involved in normal physiological responses, and not solely activated in adverse outcomes, it is essential to define quantitative relationships between different key events leading to a particular adverse outcome induced by non-physiological ER activation. To obtain quantitative information on these key events, a technique is favored which can provide single cell information on all these events. For this purpose, we established fluorescent protein reporter cell lines with bacterial artificial chromosome (BAC) green fluorescent protein (GFP) transgenomics of important players in the ERα signaling pathway. The human breast cancer cell line MCF7 was used as a model as its proliferation is dependent on ERα. In order to determine relevant target genes of ERα, we used transcriptional data of MCF7 cells exposed to either E2 or a combination of E2 and 4-hydroxytamoxifen, an ERα-antagonist. The candidate genes were validated by qPCR to determine the E2-dependence; siRNA knockdown of ESR1 showed ERα-dependent induction of these genes. Finally, siRNA knockdown of these target genes led to a reduced proliferation rate, identifying these genes as relevant ERα targets genes in the context of proliferation. Our fluorescent protein reporters enable to monitor the following key events: receptor activation, downstream transcriptional activation and cell cycle progression, driving ultimate enhanced overall proliferation. In combination with advanced live cell imaging, these reporters can monitor the spatial and temporal dynamics of these key events at a single cell level. This adverse outcome pathway-driven reporter platform will allow us to determine the quantitative relationships between the different key events and the precise cellular adverse outcome. These in vitro reporters can be used to screen e.g. drug candidates or other chemicals of concern for the potential of modulating ER activity and likely non-genotoxic mode of action.

3149 Development of a Computational Model to Identify Potential Aromatase Inhibitors

In the final step of estrogen biosynthesis, the cytochrome P-450 enzyme aromatase (CYP19A1) converts testosterone to estradiol. Inhibition of aromatase is one of the primary screening targets for potential endocrine disruption.
The goal of our work was to mine existing public data and develop an in silico model that predicts the likelihood that an unknown compound will or will not inhibit aromatase. We compiled a database of substances comprised of >2000 aromatase inhibitors and >1300 non-inhibitors from multiple sources (e.g., ToxCast, Tox21, published validation data) and using various aromatase assays. We developed a random-forest machine-learning prediction model that determines potential inhibitory relationships between 15526 compounds, 10 E2, and 10 vtg1 RNAs to identify steroid hormones, isoflavones and estrogens, isoflavones and estrogens, and protein-docking binding energies. Our prediction model was built by iteratively and randomly retraining it on 90% of the known active and inactive compounds. Our model showed very high sensitivity (96%) and balanced accuracy (94.2%), with a specificity of 92.4%. The positive and negative predictive values were 96.2% and 92.2%, respectively. The model was then applied to ~2000 aromatase inhibitors falling into several scaffold classes (e.g., steroids, isoflavones and azoles) and showed a distinct trend relative to controls for the predicted binding energies.

**3150 Quantitation of Steroid Hormones for Endocrine Disruptor Screening Using a Multiplex Immunoassay**

The US EPA offers guidelines for testing substances that have the potential to interact with the hormone system. This is referred to as the Endocrine Disruptor Screening Program (EDSP) and is intended to determine if pesticides create health or environmental risk humans or ecological systems. The steroidogenesis assay requires H295R cells, a steroid producing adrenocortical cell line, to identify adverse effects on the steroidogenic pathway by measuring production of testosterone and estradiol. Test chemicals forskolin and prochloraz, a model inducer and inhibitor, respectively, were added to the H295R cells at increasing concentrations. The US EPA EDSP guidelines were followed to plate H295R cells and expose the cell line to test chemicals. Induction with forskolin and inhibition with prochloraz were performed along with DMSO solvent controls. Cell supernatant were collected after 48 hours stimulation. The Milliplex Multi-Species Hormone Magnetic Bead Panel was used to measure the chemical influence on H295R cells and verified according to the US EPA criteria. Testosterone met the US EPA criteria for induction by demonstrating ≥2x concentration with 10 µM forskolin (4,863 pg/mL) compared to the solvent control (SC) (2,432 pg/mL). Testosterone also met the criteria for inhibition with the concentration decreasing ≤0.5x the SC (2,438 pg/mL SC vs. 73.2 pg/mL with 1 µM prochloroz). Estradiol levels following induction also met US EPA criteria increasing ≥7.5x SC (106.7 pg/mL SC vs. 1066.8 pg/mL with 10 µM forskolin). The criteria were also achieved with the addition of the inhibitor, reading ≤0.5x SC (102.2 pg/mL SC vs. 7.8 pg/mL with 1µM prochloroz). In addition, the data generated using the Milliplex Multi-Species Hormone Magnetic Bead Panel was evaluated by mass spectrometry. Measurement of testosterone levels by LC-MS/MS was based on a previously described workflow utilizing Currillant Testosterone Certified Reference Materials (CRMs). The data generated from our study demonstrates the utility of endocrine disruptor testing using the Milliplex MAP Multi-Species Hormone Magnetic Bead Panel.

**3151 In Vivo High-Throughput Screening System for Estrogenic Endocrine Disruptors Using a Fluorescently-Labeled Zebrafish Line**

A. Abdelmoneim, and M. Mukai. Cornell University, Ithaca, NY.

Evidence of exposure to estrogenic compounds has substantially increased over the past decade affecting reproductive health in humans, domestic animals and wildlife. There is a need for development of time- and cost-effect screening tools for biological reporting of endocrine disruptors in food and the environment, as well as for screening new compounds for estrogenic activity. This is referred to as the Endocrine Disruptor Screening Program (EDSP) and is intended to determine if pesticides create health or environmental risk humans or ecological systems. The steroidogenesis assay requires H295R cells, a steroid producing adrenocortical cell line, to identify adverse effects on the steroidogenic pathway by measuring production of testosterone and estradiol. Test chemicals forskolin and prochloraz, a model inducer and inhibitor, respectively, were added to the H295R cells at increasing concentrations. The US EPA EDSP guidelines were followed to plate H295R cells and expose the cell line to test chemicals. Induction with forskolin and inhibition with prochloraz were performed along with DMSO solvent controls. Cell supernatant were collected after 48 hours stimulation. The Milliplex Multi-Species Hormone Magnetic Bead Panel was used to measure the chemical influence on H295R cells and verified according to the US EPA criteria. Testosterone met the US EPA criteria for induction by demonstrating ≥2x concentration with 10 µM forskolin (4,863 pg/mL) compared to the solvent control (SC) (2,432 pg/mL). Testosterone also met the criteria for inhibition with the concentration decreasing ≤0.5x the SC (2,438 pg/mL SC vs. 73.2 pg/mL with 1 µM prochloroz). Estradiol levels following induction also met US EPA criteria increasing ≥7.5x SC (106.7 pg/mL SC vs. 1066.8 pg/mL with 10 µM forskolin). The criteria were also achieved with the addition of the inhibitor, reading ≤0.5x SC (102.2 pg/mL SC vs. 7.8 pg/mL with 1µM prochloroz). In addition, the data generated using the Milliplex Multi-Species Hormone Magnetic Bead Panel was evaluated by mass spectrometry. Measurement of testosterone levels by LC-MS/MS was based on a previously described workflow utilizing Currillant Testosterone Certified Reference Materials (CRMs). The data generated from our study demonstrates the utility of endocrine disruptor testing using the Milliplex MAP Multi-Species Hormone Magnetic Bead Panel.

**3152 Targeted Expression Profiling Identifies Potential ER Independent Mechanisms of Mammary Toxicants**

V. De La Rosa 1, M. Milanovic 2, E. Lehner 3, M. Jordanski 4, C. Vulpe 4, and R. Rudel 1. 1Silent Spring Institute, Newton, MA; 2Seven Bridges Genomics, Cambridge, MA; 3University of Belgrade, Belgrade, Serbia; and 4University of Florida, Gainesville, FL.

Over 200 chemicals have been associated with altered mammary gland development and breast cancer, yet the molecular mechanisms by which this diverse set of chemicals exert adverse effects on the mammary gland remain poorly understood. In this study we investigated gene expression profiles of 8 suspected mammary toxicants using the TempO-Seq platform and a targeted gene expression panel, Breast Carcinogen Screen (BCScreen). The BCscreen panel consists of 500 genes representing biological processes relevant to breast cancer and mammary gland development. We compared gene expression profiles from MCF-7 cells treated with four concentrations of PFOA, PFHXA, PFNA, genistein, genistein, 1,4 benzoquinone (BQ), BPA, butyl benzyl phthalate (BBP), or tamoxifen for 24hrs. The known ER agonists genistein, BPA, and BBP had highly similar gene expression profiles and were enriched for genes associated with cell cycle and DNA repair, particularly at high doses; and these profiles were also similar to the profile for cells treated with 10 nM estradiol. These weak estrogens activated a subset of cell cycle genes regulated by AhR and ERα1 transcription factors. In contrast, PFOA, tamoxifen, and BQ had higher gene expression changes at the lowest dose (1nM) compared with higher doses (10 nM to 10 micromolar) and were enriched for genes associated with cell cycle. PFOA and tamoxifen expression profiles were similarly enriched for several regulatory motifs including ERα1, E2F1 and E2F4, identifying a subset of cell cycle genes suppressed in response to these toxicants. PFOA has no known direct ER activity, yet we found these expression profiles were highly correlated with gene expression profiles from several known breast ER antagonists, suggesting indirect suppression of ER-regulated cell cycle genes that may modulate effects on mammary gland development and breast cancer risk. Genes upregulated by PFOA, BBP, and genistein were enriched among genes differentially expressed in breast cancer, whereas genes suppressed by tamoxifen, PFOA, and BQ were enriched in breast cancer. These findings highlight the potential for low doses of mammary toxicants to alter cell cycle pathways via ER-independent mechanisms that affect mammary gland development and breast cancer susceptibility.

**3153 Sex-Specific Associations of Prenatal Exposure to Persistent Organic Pollutants with Placental DNA Methylation of Thyroid Hormone Related Genes among Koreans**

S. Kim 1, Y. Cho 2, S. Won 3, J. Kuc 1, H. Moon 2, J. Park 3, G. Choi 1, S. Kim 1, and K. Choi 1. 1Seoul National University of Science & Technology, Seoul, Korea, Republic of; 2University of Montana, Missoula, MT; 3Seoul National University, Seoul, Korea, Republic of; 4Seoul National University College of Medicine, Seoul, Korea, Republic of; 5Hanyang University, Ansan, Korea, Republic of; 6Soochunhyung University, Asan, Korea, Republic of; and 7Soochunhyung University, Seoul, Korea, Republic of.

Exposure to persistent organic pollutants (POPs) during pregnancy is associated with disruption in thyroid hormone balance. The placenta not only regulates thyroid hormone supply to the fetus but is also a key tissue in understanding the mechanisms for the developmental origins of disease. This study was conducted to evaluate the relationship between maternal serum and placental DNA methylation of thyroid hormone related genes. We measured the promoter methylation of several genes in placental samples collected from 106 Korean mother-child pairs by bisulfite pyrosequencing.
The thyroid-stimulating hormone receptor (TSHR) is a G protein-coupled receptor that signals through adenylate cyclase to increase intracellular 3',5'-cyclic adenosine monophosphate (cAMP) and activate cAMP-dependent protein kinase, resulting in increased thyroid hormone (TH) production in thyroid follicular cells. Due to human health effects resulting from altered TH levels, it is important to evaluate whether environmental chemicals can disrupt thyroid function via TSHR-mediated signaling pathways. As part of the Tox21 collaboration, HER293-TSHR cells were used in a 1536-well assay format to demonstrate agonism or antagonism of the TSHR, using cAMP as a marker of TSHR activation. Homogeneous time-resolved fluorescence technology was used to quantify cAMP using a competitive immunoassay between native and dye-labeled cAMP. Out of the 7,872 tested chemicals, 6% agonist, 4% antagonist, and 0.6% agonist-antagonist hits were identified, for a total of ~10% putative active chemicals. Because receptor binding is highly specific, we hypothesized that many of the hits were false positives. Thus, we developed a novel prioritization scheme to select chemicals for screening in biologically-relevant follow-up assays. Chemicals (558/778 active chemicals) were clustered by structural similarity using ChemotypeToxPrint fingerprints. The priority score (within cluster and for non-clustered chemicals) was penalized for: i) activity in other ToxCast cAMP enzymatic assays, ii) promiscuity according to ToxCast total assay hit rate, iii) signal interference by autophosphorylation, and iv) cytotoxicity. Highly-ranked agonist clusters contain phenols, organochlorine insecticides, and retinoids. Cytotoxicity contributed significantly to the agonist priority rank, with as many as 68% of antagonists suspected to be cytotoxic in the active concentration ranges. The prioritization scheme has identified 69/778 [CJ1] [SA2] active chemicals that are structurally diverse for additional testing. Using this scheme, secondary screening of identified priority chemicals will be combined with structural prioritization to create an integrated predictive tool for TSHR activity. This abstract does not reflect US EPA policy.

**3157 Thyroid Disruption Screening Method Using Zebrafish Vertebrate Model**

Endocrine Disrupting compounds are being increasingly detected in the environment and may have a profound impact on the development and physiology of vertebrate organisms. Thyroid Disrupting (TD) compounds specifically alter the function of thyroid gland through the interference with the synthesis, transport and/or binding of the thyroid hormones. Several environmental contaminants such as polybrominated diphenyl ethers or halogenated organophosphates, used as plasticizers and flame retardants, are suspected to produce a TD effect. Given so, chemical manufacturing entities could benefit from cost-effective methodologies for the screening of TD substances in order to deselect candidates during the early phase of the development. The zebrafish vertebrate model is broadly used in both human and aquatic toxicity assessment due to their low cost, small size, rapid development, and homology with mammals. Besides, the existence of numerous transgenic strains enables to perform fluorescence-based screening assays with medium throughput. In this work, a screening method for TD substances assessment was developed using the Tg(tg:smcherry) transgenic zebrafish line. The fluorescence of the reporter gene allows monitoring in vivo the upregulation of the tyrosylbogulin gene expression as a compensatory reaction to thyroid gland disruption. In this assay, the exposure concentrations of test substances were selected according to the results of a preliminary acute toxicity assay to avoid any interference by non-specific toxicity. Afterwards, transgenic em...
bryos were exposed to the test substances from 48 to 120 hpf (hours post-fertilization) and subsequently imaged by fluorescence microscopy. A dose-dependent increase of the fluorescence was observed, and the intensity values were fitted to a concentration-response regression model to calculate TD predators, such as the Benchmark Concentration (BMC), Thyroid Disrupting Index (TDI), and Relative TD Potency (RTP). Finally, an rt-qPCR gene expression assay was developed over known markers of thyroid pathway (Tshβ, tgf, and tpo) to characterize the mechanism of action involved in the endocrine disrupting effect. The screening method presented in this work has been developed and validated using a set of 19 environmentally relevant TD substances. This screening methodology showed to be a sensitive and cost-effective assay to evaluate the potential thyroid disruptor activity of chemicals.

3158 Development of an In Vitro Human Thyroid Microtissue Model for Chemical Screening

C. Deisenroth1, V. Soldatow2, W. Stewart1, C. Brinkman1, E. LeCluyse2, and R. Thomas1.
1US EPA, Durham, NC; and 2LifeNet Health, Virginia Beach, VA.

Thyroid hormones (TH) are essential for regulating a number of diverse physiological processes required for normal growth, development, and metabolism. The US EPA Endocrine Disruptor Screening Program (EDSP) has identified several molecular thyroid targets relevant to hormone synthesis dynamics that include the TSH receptor (TSHR), Sodium/Iodide Symporter (NIS), Thyroperoxidase (TPO), Dual Oxidase (DUOX), Iodotyrosine Deiodinase (IYD), and Pendrin. High-throughput screening assays for TSHR, TPO, and NIS have been used to screen chemicals across the Toxicast/Tox21 chemical inventories to identify potential thyroid disrupting chemicals (TDCs). The uncertainty surrounding the specificity of hits identified in these screens, the relevance to human biology, and the quantitative potency relationship of molecular perturbation to decreased TH hormone synthesis, have led to relatively large data gaps in hazard identification for TDCs. The objective of this study was to develop a medium-throughput organotypic screening assay comprised of reconstructed human thyroid microtissues to quantitatively evaluate the disruptive effects of chemicals on TH production and secretion. Cells procured from qualified euthyroid donors were analyzed for retention of NIS by well plate image analysis to verify enrichment of follicular epithelial cells. A direct comparison of two-dimensional (2D) and three-dimensional (3D) 96-well culture formats was employed to evaluate TH production and secretion over the course of 20 days. The results of serial sampling in the 2D format revealed considerable loss of TH expression with no subsequent production of TH3 or TH4. In contrast, the 3D model continued to increase TH levels over time, with sustained output of TH3 and TH4. Inhibition of TH synthesis in an optimized 3D culture format was demonstrated with reference chemicals Methimazole, 6-Propyl-2-thiouracil, and Sodium Perchlorate. Overall, the 3D thyroid microtissue assay will prove to be a valuable resource for extending screening efforts currently underway in Toxicast/Tox21 and EDSP. This abstract does not necessarily reflect the policy of the US EPA.

3159 In Vitro Approaches to Risk Assess Chemical Mediated Changes in Thyroid Function

M. Principalle, L. Higgins, C. Haines, K. MacLeod, L. Chatham, and G. Clark. Concept Life Sciences, Dunbee, United Kingdom.

The hypothalamic-pituitary-thyroid axis (HPT axis) is conserved across vertebrate evolution. Perturbation of thyroid hormone homeostasis (THH) can lead to adverse effects in thyroid function affecting growth, metabolism and cognitive function. In vitro, appropriate thyroid hormone concentrations are absolutely required for normal nervous system development. Chemical disruption of THH can occur via a number of mechanisms, including increased hepatic thyroid hormone clearance, inhibition of iodide transport into the thyroid (sodium/iodide symporter), inhibition of iodide oxidation (thyroid peroxidase) and inhibition of thyroid hormone deiodination (deiodinases). To understand the effects of chemicals on these processes the following assays are utilised. 1. in vitro primary hepatic thyroid hormone metabolism (multiples species), 2. Thyroid peroxidase inhibition (multiple species), 3. Deiodinase inhibition (rat and human), 4. Sodium/iodide symporter inhibition (rat). Rat sodium iodide symporter inhibition and rat and human deiodinase 1,2 and 3 inhibition assays are currently being validated. Here we report the validation of in vitro rat, dog, pig and human TPO inhibition and in vitro primary hepatocyte metabolism of thyroxine (T4). In concurrence with the literature, TPO inhibition by 6-propyl-2-thiouracil (PTU) shows broad sensitivity across the species tested. In the dog (IC50 5.2 µM), the compound shows concentration-dependent inhibition of T4 metabolism in primary cultured dog hepatocytes showing a consistent dose response inhibition (approximately 2-fold over vehicle control) in response to item feature identification. These assays form part of an in vitro screen used to generate data to study chemical endocrine disruption hazard.

3160 Comparative In Vitro Investigation of Thyroxine Phase II Liver Enzyme Activities Using Rat and Human Hepatocytes to Address Species Differences in Thyroid Disruption

R. Bars1, L. Hinwell1, I. Damiani1, D. Guignard1, C. Parmentier1, M. Fonsi1, and L. Richard1.
1Boyer Sas, Sophia-Antipolis, France; 2Kaly-Cell, Ploutot, France; and 3Citotest, Evreux, France.

The in vivo induction of hepatic phase II enzymes via activation of nuclear receptors has been well described in the literature for several mammalian species following exposure to xenobiotics. This induction of phase II enzymes is an early key event in the AOPs leading to increased metabolism of thyroid hormones and further potential thyroid and neurodevelopmental adverse effects. However, comparative species assessment of the level of induction of these phase II enzymes has not been thoroughly studied, even though the magnitude of this early change may play an important role in the observed species differences in liver mediated thyroid toxicity (e.g. rat vs dog). The activity of liver enzymes involved in thyroxine (T4) conjugation was thus, compared using cryopreserved hepatocytes from rats (Wistar) and human donors following 72h of cell culture in the presence or absence of various concentrations of reference liver enzyme inducers: phenobarbital (PB), pregnenolone 16a-carbonitrile (PCN), 6-naphthoflavone (BNF), UGT-T4 (phenol and acyl) and SULT-T4 activities were measured by LC/MS/MS following incubation with 100µM T4 for 4h (showing kinetic linearity). Results indicate that the basal level of SULT-T4 was similar between the two species and was not increased by the enzyme inducers. Basal levels of phenol UGT-T4 were at least 10 times higher in rat compared to human hepatocytes. PB did not induce UGT-T4 activity in either rat or human cells, PCN showed a maximum 2-fold increase in phenol UGT-T4 in rat hepatocytes but no increase was observed in human cells. BNF induced a concentration-related increase in phenol UGT-T4 (up to 5-fold) in rat hepatocytes and a marginal increase in human hepatocytes. The results indicate that T4 glucuron-conjugation capacity and the response to inducers is greater in rat hepatocytes compared to human hepatocytes. Overall this work highlights a need to standardize and validate these in vitro assays if they are to be used in a weight of evidence approach to address species differences in liver mediated thyroid toxicity.

3161 In Vitro Screening Assays for Chemical Inhibition of Mammalian and Amphibian Iodotyrosine Deiodinase

J. Olker1, J. Korte1, J. Denny1, P. Hartig1, M. Cardon1, J. O’Flanagan1, P. Degoeij1, M. Hornung1, and S. Degitz2.
1US EPA/NHEERL, Duluth, MN; and 2US EPA/NHEERL, Research Triangle Park, NC.

Iodotyrosine deiodinase (IYD, dehalogenase) catalyzes the recycling of iodide from moniodotyrosine (MIT) and diiodotyrosine (DIT) and thus has an important role in retention of iodide for synthesis of thyroid hormone. In an effort to understand the susceptibility of IYD to chemical perturbation, 96-well plate in vitro assays were developed to screen chemicals for inhibition of mammalian and amphibian IYD enzyme activity. With recombinant human IYD enzyme and Xenopus laevis liver microsomal fractions, these assays were established using MIT as the substrate and 3-nitro-L-tyrosine (MNT) as the positive control, and tested against an initial set of ten chemicals (7 known/suspected IYD inhibitors and 3 non-inhibitors). There was strong cross-species agreement between human and Xenopus IYD in this initial test set of chemicals, with similar maximum inhibition and rank order potencies; however, a larger set of chemicals must be tested to complete this species comparison. Performance metrics support use of these assays for screening, with high Z’ factor (0.6 or greater) and low variability in the control chemicals (DMSO, NaOH, and MNT). The Toxicast phase 1, v2 chemical library was then screened with recombinant human IYD to identify chemicals that have the potential to disrupt the thyroid axis via this pathway. The majority of these chemicals did not inhibit IYD enzyme activity at a single, high concentration (target of 200 µM). Of the 293 unique Toxicast chemicals tested, 28 chemicals (9.6%) inhibited human IYD activity by 20% or greater, including 3 chemicals previously reported to inhibit IYD. Of these 28 chemicals, 7 produced inhibition of 50% or greater and were further tested in concentration-response mode to determine IC50s and rank order potency. These IYD inhibition assays can be used for future screening of large chemical libraries to expand the limited number of in vitro assays used to identify chemicals having potential to interfere with
thymus, thymic cortical lymphocytes, and thymic medullary lymphocytes. 

Toxicological effects of T-2 toxin include modifications to feeding behav-
ior, growth retardation, cardiovascular alterations, immunosuppression, and hemo-
stastic derangements. However, to date, effects on the central nervous system (CNS) have rarely been reported. In the present study, female Wistar rats were given a single dose of T-2 toxin at 2 mg/kg b.w. and were sacrificed at one, three, and seven days post-exposure. Histopathological analysis and transmission electron microscope (TEM) observations were used to investi-
gate injury to the brain and pituitary gland. Damage to the brain and pituitary 
at the molecular level was detected by real time-polymerase chain reaction 
(RT-PCR), western blot, and immunohistochemical assays. Liquid chromato-
graph-mass spectrometer/mass spectrometer (LC-MS/MS) was used to inves-
tigate T-2 toxin and metabolites in the brain. The results showed that perox-
ated phospholipid lesions were obvious in the brain at three days post-exposure; lesions in the pituitary were not observed until seven days post-exposure. Autothagy in the brain and apoptosis in the pituitary suggest that T-2 toxin may induce differ-
cent acute reactions in different tissues. Importantly, low concentrations of T-2 
toxin in the brain were observed in only one rat. Responsible for the above 
findings, T-2 toxin-induced acute lesions in the pituitary, skin, liver, and kidneys 
were divided randomly in three groups (n=6/each): Controls received corn 
oil; low dose DEHP group received 30 mg/kg/day DEHP (lowest observed ad-
verse effect level (LOAEL) for reproductive system) and high dose DEHP group 
received 60 mg/kg/day (LOAELx2) DEHP by oral gavage till the end of the 
adolescent period (37 days) starting at the 23rd day after birth. After eutha-
nasia, testis tissue homogenates were prepared in methanol:water mixture 
and centrifuged at 1500 rpm for 20 min at -8°C and supernatants were evap-
orated. The residues were derivatized and analyzed with GC-MS. The chro-
natograms were deconvoluted and aligned using AMDIS and SpectConnect 
software, respectively. Tests metabolic profiles of the study groups were 
compared by multivariate statistical techniques (PCA and PLS-DA). We found 
that metabolites "urea" and "erythrose 4-phosphate" were different among 
all study groups. Moreover, in high dose group, "urea" and "9,12,15-Z,Z,Z-
Z octadecatrienoic acid" levels were decreased and glucopyranose and panto-
thenic acid levels were increased vs. control. In low dose group, 1-hydroxy-
anthraquinone was increased and octadecanol, cholesterol and erythrose 
4-phosphate were decreased vs. control. The metabolic difference in high 
dose versus control was sharper than low dose group. When we compared 
low dose and high dose groups, L-alanine, hydroxyaspartic acid, octodeca-
enoic acid and L-norleucine levels were increased in high dose group. These 
findings show that DEHP may affect glucose, lipid and energy metabolism. 
It may also contribute the oxidative stress.

Perfluoroxyanoic acid (PFHxA) is a potential impurity and environmental 
degradation product of C6-based fluorotelomer products. Based on the con-
cern that perfluoroalkyl acids have endocrine activity, a hypothesis driven 
weight-of-evidence (WoE) analysis of PFHxA was conducted to evaluate endo-
crine disrupting properties as defined by World Health Organization (WHO). 
Following a comprehensive literature search within PubMed and Embase da-
tabase, five studies were selected: four were in vitro studies and one was a 
clinical study. A total of 21 in vitro and in vivo studies across species were identified for review. High Throughput Screening (HTS) assay data within the ToxCast/Tox21 da-
tabase were also included in this assessment. Studies identified consisted of 
Level 1 to 4 methods within the OECD Conceptual Framework for assessing 
endocrine disruptors (ED) were reviewed for reliability and endocrine end-
points extracted that represented lines of evidence for positive or negative 
activity across the estrogen (E), androgen (A), thyroid (T) and steroidogenesis 
(S) pathways. The endpoints extracted were ranked based on their specificity 
and sensitivity for identifying PFHxA activity across 8 endocrine hypotheses 
(e.g., E, A, or T agonist or antagonist or S inducer or inhibitor). Overall, PFHxA 
showed no endocrine effects in Japanese medaka, juvenile rainbow trout, 
chickens or reproductive parameters in northern bobwhite quail. In rodent 
studies, there was no significant activity associated with PFHxA exposure 
in endocrine endpoints identified in repeat-dose toxicity studies, a lifetime can-
cer study, or guideline and non-guideline reproductive and developmental 
studies. In vitro, there was weak or negative activity for T transport protein 
or activation of E, A, or T receptors. PFHxA was also negative for disrupting 
steroidogenesis in vivo and in vitro. Based on this WoE analysis across these 
disease pathways (e.g., E, A, T, and S), PFHxA exposure was found not to 
cause adverse effects associated with alterations in endocrine activity in any 
of the experimental models evaluated, as such would not be characterized as 
an ED according to the WHO definition.
Endocrine disrupting chemicals (EDC) are becoming increasingly prevalent in the environment and many are shown to accumulate within human tissues and interact with endogenous hormone receptors. One such EDC is organophosphate flame-retardants (OPFR). OPFR interact with multiple hormone receptors involved in homeostasis, including estrogen receptors (ER) and peroxisome proliferator activated receptor-γ (PPAR-γ). We have previously reported that adult exposure to a mixture of OPFR induces sex-dependent alterations of energy homeostasis and hypothalamic gene expression of anorectic and orexigenic neuropeptides on a standard chow diet. This dysregulation of energy homeostasis can cause an increase in susceptibility to metabolic disorders. In current studies, we repeated the previous adult sex exposure experiment with a common mixture of OPFR [tris(1,3-dichloro-2-propyl)phosphate, triphenyl phosphate, and tricresyl phosphate, 1 mg/kg/day each] for 4 weeks while adding a comparison between low-fat diet (LFD, 10% kcal fat) and a high-fat (HFD, 45% kcal fat) to generate a diet-induced obesity model. We recorded body weight, crude food intake, body composition, metabolic rate, locomotor activity, meal patterns, glucose and insulin tolerance, and plasma peptide hormone levels. Consistent with our previous results, OPFR exposure reduced body weight gain in LFD-fed males, but increased weight gain in HFD-fed males, while not altering female body weight. OPFR treatment also showed subtle sex-dependent effects on oxygen consumption, carbon dioxide production, energy expenditure, and activity. In males, OPFR exposure increased oxygen consumption and activity and reduced those parameters in females during the night (~0100-0400 h). Meal patterns in females fed a HFD were altered by OPFR treatment. OPFR treatment altered circulating levels of insulin and glucagon in females and ghrelin in males. No effect of OPFR exposure was found in glucose or insulin tolerance. We are currently processing hypothalamic samples to measure protein and gene expression of anorectic and orexigenic neuropeptides. In summary, our data indicates that adult OPFR exposure can induce, and perhaps exacerbate, the effects of diet-induced obesity in mice. Ingestions of plastic microbeads have been identified in different aquatic organisms globally. Potential acute toxicity of ingested microbeads could be characterized as physical effects including blockage of digestive system or biological effects linked to alterations in oogenesis process and detoxification processes. To identify the physical effects, behavioral changes and gene expression profiles of phase 1 detoxification enzyme gene (cytochrome P4501A, cyp1a) and oogenesis process related gene (vtg1) induced by plastic microbeads, different size ranges of polyethylene (PE) microbeads with colors (Cospheric Ltd, USA, polymer type verified by micro-Raman spectroscopy) were selected in this study because PE is the dominant microplastic found in Hong Kong coastal area and effluent samples. Adult zebrafish was used as model organisms because of its fully characterized genome and evolutionarily conserved behavioral responses. For the identification of upper and lower boundaries of microbeads ingestion, individual polyethylene microbeads with different sizes (10-22 µm, 45-53 µm, 90-106 µm, 212-250 µm and 500-600 µm) in 2 mg/L concentration were used for 96 hours exposure. For studying in behavioral changes or targeted gene expression profiles through real time PCR (qPCR), mixture of microbeads with different size (45-53 µm (blue), 90-106 µm (green) and 212-250 µm (white)) in effluent related concentration (11 particles/L), medium concentration (110 particles/L), high concentration (1,100 particles/L) were applied for 96 hours exposure. All concentrations used are relevant to the environmental concentrations found in local waters. Zebrafish behaviors were recorded by video and two observers (interrater reliability > 85%). Results implied that the upper boundary and lower size boundary for microbead ingestion were 500-600 µm and 10-22 µm respectively. In addition, 60 % and 30 % of fish ingested and retained with microbeads in intestine (medium and high concentration) and gills (high concentration). Microbeads could cause less void inside the intestine. The expression of cyp1a in intestine (medium concentration) and vtg1 in liver (medium and high concentration) were upregulated significantly in the zebrafish exposed to PE microbeads. Zebrafish with abnormal behaviors (i.e. seizure and tail bent downward) were observed (medium and high concentration). In summary, effects on aryl hydrocarbon receptor (AhR) pathway, disruption of oogenesis process and neurotoxicity in adult zebrafish could be caused by acute exposure to microbeads.
3170 Identification of microRNA Signatures following Multigenerational Exposure to Deoxynivalenol in Caenorhabditis elegans

L. Tang, P. Williams, and J. Wang. University of Georgia, Athens, GA.

Deoxynivalenol (DON) is one of the most widely distributed trichothecene mycotoxins commonly found in cereal grains and its ubiquitous contamination has become a big concern in the field of public health and food safety due to its potent acute and chronic toxicities to animals and humans. We previously demonstrated that DON produced significant toxic effects on growth, brood size and feeding behavior following multigenerational exposure to Caenorhabditis (C) elegans model. Because it has been well known that DON is not a genotoxic agent, we postulate that DON exposure may induce changes in the epigenome that can be used as potential molecular signatures of DON-induced toxicity. In this study, the total RNA in the worm groups treated with 200 μg/mL DON and control vehicle at different generation time (P0, F1, F2 and F3) were prepared, and the RNA sequencing was performed on Illumina NextSeq 500. The differentially expressed miRNAs were evaluated between the two treatment groups at different generation times. Compared to the control group, totals of 161 miRNAs (83 up- and 79 down-regulated), 177 miRNAs (110 up- and 67 down-regulated), 217 miRNAs (143 up- and 74 down-regulated), and 225 miRNAs (105 up- and 120 down-regulated) were differentially expressed following DON exposure at P0, F1, F2, and F3 generations, respectively. Further functional enrichment and bioinformatics analyses showed that the major alterations of these differentially expressed miRNAs were related to the protein synthesis, transcription, sex determination, balance of redox status, activity of kinases, and biotransformation. These data strongly suggest that alterations in miRNAs expression could serve as sensitive signatures for DON-induced multigenerational toxic effects, and may be potential biomarkers for DON-affected molecular pathways.

3171 Using Caenorhabditis elegans for Predictive Oral Toxicity Assessment of Mixtures

The effects of exposure to individual toxic elements have been well studied. Information on the effects of exposure to mixtures of toxic substances is urgently required, however. Alternative toxicity models have the potential to provide relevant data for human safety assessment of chemicals with rapid tumourigenicity and at greatly reduced cost relative to traditional methods. Caenorhabditis elegans is a small nematode with a 3-day lifecycle that can be easily maintained in axenic liquid media using standard laboratory techniques. The C. elegans digestive tract has several features that are analogous to the mammalian digestive system, making this simple model organism an attractive candidate for predictive oral toxicity testing. Many pathways involved in organo-siloxanate development and neurotransmission are conserved from worms to people. C. elegans have consistently shown concordance for developmental toxicity or altered motor activity when exposed to mammalian developmental toxins or neurotoxins. We have designed a novel worm Development and Activity Test (wDAT) that maps the timing of C. elegans developmental milestone acquisition as well as stage-specific motor activity levels. Arsenic, lead, and mercury are mammalian developmental neurotoxins that have been associated with hyperactivity in children. The wDAT detected both developmental delay and hyperactivity for soluble salts of these toxic elements, indicating that worms and humans are concordant for these endpoints. One concern in mixtures risk evaluation is the in vivo occurrence of synergistic effects not predicted by in vitro testing or in silico analyses. Binary mixtures of arsenic, lead, and mercury produced equivalent or additive effects on developmental delay and/or hyperactivity, however no synergistic effects were detected. Mixtures with mercury produced the most significant additive effects. The wDAT used a collection of more than 400 transgenic C. elegans strains, each a transgene coding for a fusion product between nuclear-localized LET-858 and the additional target organ. Furthermore, multigenerational studies in mammals and aquatic animals looking at the offspring of exposed parents have demonstrated changes in the F1 generation, including altered neurodevelopment, growth, and oxidative stress markers. In the alternative model Caenorhabditis elegans (C. elegans) MCs induce germline apoptosis and decrease brood size at P0, making it an ideal model to study the epigenetic impact of MCs several generations. A multi-tiered approach is used to evaluate the transgenerational impact of MCs. Epigenetic histone modifications, including H3S10p and H3K9me3, in the germline are evaluated using immunofluorescence, germline stress is monitored through desilencing via loss of repressive histone regulation, and germline and somatic cell toxicity is evaluated through apoptotic, growth, and behavioral endpoints. L4s are exposed to a range of environmentally relevant concentrations MC-LR or MC-LF (0.1-100 μgL/L) for 48 hours with food in liquid. The C. elegans strains N2 (wildtype) and NL2507, carrying an integrated low-complexity, highly repetitive array composed of a transgene coding for a fusion product between nuclear-localized LET-585 and GFP (pks15680Let585:GFP; rol-6(su1006)), are used. For NL2507, the gene is transgenic in somatic cells but it is epigenetically silenced in the germline via accumulation of the repressive marks H3K9me3 and H3K27me3. Prior exposure studies using bisphenol A (BPA) have established this method to evaluate transgenerational toxicity. Exposed P0 worms are recovered at early and each generation is evaluated for multi- (F1 and F2) and trans- (F3+) generational toxicity without further MC exposure. This study helps establish the transgenerational reproductive and somatic cell toxicity of MCs and the role of phosphorylation in the epigenetic repression of the germline.

3172 Effects of Polybrominated Diphenyl Ether-47 (BDE-47) on Sensory Avoidance Behaviors in Caenorhabditis elegans

K. Morrison, J. Sands, and C. Dodd. Fort Valley State University, Fort Valley, GA.

Manufacturing of PBDEs was phased out from 2008–2014, due to their potential health effects and ubiquitous presence in air, soil, and water. Concern for human exposure remains the highest for infants and toddlers as studies have shown a correlation between increased blood PBDE levels and delayed cognitive development. BDE-47 is one of the most commonly found PBDEs in humans, especially young children whose hand mouth behavior increases ingestion of contaminated house dust. While studies suggest that exposure to PBDEs may impact cognitive and motor development, the sensory system has not been thoroughly examined as a possible target. This current study examined the effects of polybrominated diphenyl ether-47 (BDE-47) on sensory behaviors in Caenorhabditis elegans (C. elegans). AFD and ASH are major sensory neurons in C. elegans involved in thermo-sensation (AFD, ASH) and chemosensation (ASH). Wall and brood sizes of worms treated at early developmental larval stage 1 with BDE-47 (5µM, 10µM, 20µM) will present atypical sensory osmotic- and thermo-avoidance behavior. Gravid adult worms were synchronized and embryos were stored in M9 buffer 18-21 hours until hatching. L1 worms were treated with BDE-47, and plated onto freshly seeded plates. Plates for the osmotic avoidance assay contained a 2 centimeter diameter ring of 4M fructose in 1% congo red. Five nematodes were placed in the center of the ring, and the number of worms leaving the ring, touching the ring, or staying in the ring was recorded at 5 and 10 minute intervals. Worms that leave the ring are considered to display abnormal avoidance behavior indicative of sensory deficits. Data revealed a dose dependent effect with the control worms having the lowest percentage of worms leaving the ring and BDE-47 (20µM) treated worms having the largest percentage of worms leaving the ring. The thermal avoidance response assay was done with an electronically heated metal tip pen that was held 1 mm from the animals’ head for 3-5 secs. Their response to the extreme temperature change was grouped into four classes. Class I was a normal rapid reflex with direction change, class II was rapid reflex with only little backing motion, class III was a slow backing, and class IV was no response. Results showed, control groups had high numbers of class I and II responses while, 10µM and 20µM BDE-47 induced higher numbers of worms in class III and IV. Together the data indicates that PBDEs can alter sensory neuron development in an animal model and therefore could potentially be an environmental contaminant that may be linked to atypical sensory deficit disorders.
The acute toxicity of 45 chemicals was assessed using TruLarv™ (Galleria mellonella wax moth larvae), a non-animal technology (NAT) model and the results compared with data published in the OECD 129 guidance for two cytotoxicity test methods (3T3 NRU and NHK NRU) and published rodent LD₅₀ values. Test compounds utilised in this study were selected directly from the OECD 129 guidance document with chemical classes represented for organic compounds including carboxylic acids, heterocyclic compounds, alcohols, amides, phenols and selected inorganic compounds. Treatment was performed by subcutaneous microinjection of 10 μL test chemical into the front pro-leg. All treated and untreated control larvae were incubated at 20 - 25°C and scored for morbidity at 24 hours, 48 hours and 72 hours post challenge and LD₅₀ (mg/kg) values calculated. TruLarv™ LD₅₀ values obtained in this study were categorised in terms of hazard class based on the Globally Harmonized System (GHS) for classification and labelling of chemicals. For chemicals tested in this study where published rodent acute oral LD₅₀ values were >2000 mg/kg (category 5/low toxicity), the results in TruLarv™ showed 100% concordance with chemicals being classified in this same hazard category. In comparison, concordance of cytotoxicity methods with rodent acute oral LD₅₀ values was <50% with chemicals including acetalaminophen, citric acid, dibutylyltartrate, sodium hyochlorite, trichloroacetic acid and dimethyldfoformamide being predicted as weakly toxic or very toxic (category 1 - 4), reflecting the general tendency for cell culture systems to over-estimate the toxicity of chemicals, especially those of low toxicity. In conclusion, the results obtained in this study showed the TruLarv™ model to be superior to current in vitro cytotoxicity methods for predicting low-toxicity chemicals thereby, potentially providing a more predictive starting point for in vivo toxicity testing. Addition of this model to ECHA guidance as a recommended element in in vitro approaches could lead to a reduction in numbers of animals used for toxicity testing and strengthen the options for registrants to justify the waiving of in vivo acute oral toxicity studies for chemicals predicted to be of low toxicity.

Atrazine, a triazine herbicide, is one of the widely used herbicides in the United States and many other countries. Several epidemiological studies have associated atrazine (herbicide) exposure with increased incidence of type 2 diabetes (T2D), which accounts for more than 90% diabetic cases. Therefore, we used Drosophila melanogaster, having conserved Insulin/Insulin growth factor-like signaling (IGS) as well as glucose homeostasis, to identify the diabetogenic potential of atrazine and to delineate the mechanisms underlaying atrazine mediated onset of diabetes. Flies reared on food containing atrazine (2 or 20 μg/mL) from egg to adult display insulin resistance with hyperglycemia, hyperinsulinemia and hyperlipidemia hallmarks of type 2 diabetes. In addition, we found elevated levels of advanced glycation end products (AGEs) and the receptor for AGE (RAGE) in flies from exposed group. Further, we found the levels of reactive oxygen species (ROS) and phosphorylation of c-Jun N-terminal kinases (JNK), were significantly increased suggesting oxidative stress-mediated activation of JNK signaling in response to atrazine exposure. Mitigation of oxidative stress through over-expression of sod2 in atrazine (20 μg/mL) exposed flies, revealed significantly decreased ROS levels and reduced phosphorylation of JNK. Moreover, glucose and Akt phosphorylation levels in sod2 overexpression flies exposed to atrazine were comparable to those of controls, suggesting restoration in insulin sensitivity. Also, these flies had AGE and RAGE levels comparable to those in controls. These findings suggest that oxidative stress and JNK signaling activation in response to atrazine exposure might lead to insulin resistance condition. Finally, this study not only provided experimental evidence to the epidemiological propositions on the diabetogenic potential of atrazine but also highlighted the potential of Drosophila as a model for deciphering the mechanisms underlying xenobiotic mediated onset of type 2 diabetes.

Developmental Exposure of Zebrafish (Danio rerio) Larvae to ∆9-Tetrahydrocannabinol and Cannabidiol Causes Significant Transcriptomic Changes

Z. Pandelides 1, Z. S. Miller 2, C. Thornton 1, D. R. Cartly 1, N. Aluru 1, and K. L. Willett 1.

1. University of Mississippi, Oxford, MS; and 2-Woods Hole Oceanographic Institution and Woods Hole Center for Oceans and Human Health, Woods Hole, MA.

Countries are relaxing laws regarding, and like Canada legalizing, the use of cannabinoids such as ∆9-tetrahydrocannabinol (THC) and cannabidiol (CBD). Recently, US FDA approved Epidiolex (> 99% CBD) for treatment of developmental and pediatric epilepsy in children as young as 2 years old. As a consequence of their increased use, understanding potential adverse outcomes following exposure to cannabinoids during critical developmental periods is important. The objective of this experiment was to assess transcriptomic effects following a developmentally relevant exposure to THC or CBD. Zebrafish were waterborne exposed from 5 hours post fertilization (hpf) through the larval stage (96 hpf) to 0.42 ± 0.13 mg/L THC or 0.031 ± 0.025 mg/L CBD. THC and CBD concentrations were selected to be below the lowest observed adverse effect concentrations for developmental toxicity. RNA sequencing (RNA-Seq) was conducted on zebrafish larval brain and revealed differential expression of 1026 and 90 genes for CBD and THC, respectively. Among them, 351 genes were common to both treatment groups. Analysis of THC and CBD differentially expressed genes by Ingenuity Pathway Analysis (IPA) revealed that molecular pathways including hepatic effects, lipid/fatty acid metabolism, cell survival/viability and immune response were significantly increased, while pathways relating to inflammation were significantly decreased. For the 351 overlapping genes, the top two significantly modulated canonical pathways were FXR/RXR and PXR/RXR. IPA upstream regulator analysis identified molecules including IL6 and HNF4-A as potentially responsible for observed gene expression changes. IPA predicted significant toxicological effects related to the liver, kidneys and heart. Collectively, these results indicate developmental exposure to THC or CBD alters metabolism, hepatic, and immune function gene expression that may be linked to latent adverse outcomes. Supported by the National Institute on Drug Abuse R21DA044473-01.

Oxidative Stress Mediated JNK Signaling Activation Causes Insulin Resistance in Atrazine-Exposed Drosophila

H. Gupta, and R. Kristipati. CSIR-Indian Institute of Toxicology Research, Lucknow, India.

Atrazine, a triazine herbicide, is one of the widely used herbicides in the United States and many other countries. Several epidemiological studies have associated atrazine (herbicide) exposure with increased incidence of type 2 diabetes (T2D), which accounts for more than 90% diabetic cases. Therefore, we used Drosophila melanogaster, having conserved Insulin/Insulin growth factor-like signaling (IGS) as well as glucose homeostasis, in addition to other MTJ factors, in muscle development and function of Drosophila. We therefore hypothesized that MeHg disrupts muscle development by targeting the myotendinous junction (MTJ). To address this hypothesis, we evaluated morphological and functional phenotypes following larval exposure to increasing concentrations of MeHg. In parallel, we assessed phenotypes of flies carrying RNAi knockdown constructs of genes involved in MTJ formation, including kon. Indirect flight muscle (IFM) morphology during pupal development was visualized using fluorescent reporter fly lines and immunostaining, while functional assays examined eclosion (emergence of adults) and flight behavior. MeHg treatment was seen to induce a dose-dependent increase in myosin heavy chains within developing dorsal longitudinal bundles of the IFMs, which paralleled a decrease in eclosion. Targeted RNAi knockdown of kon was seen to cause hyperactivity of the IFMs, while knockdown of kon and HNF4A as potentially responsible for observed gene expression changes. The top two significantly modulated canonical pathways were FXR/RXR and PXR/RXR.
Development of a Zebrafish S1500+ Sentinel Gene Set for High-Throughput Transcriptomics

Scimce LLC, Research Triangle Park, NC, and NHIES, Research Triangle Park, NC.

Sentinel gene sets have been developed with the purpose of maximizing the information from targeted transcriptomic platforms. We recently described the development of an S1500+ sentinel gene set which was built for the human transcriptome, utilizing a data and knowledge-driven hybrid approach to select a small subset of genes that optimally capture transcriptional diversity, correlation with other genes based on large-scale expression profiling, and known pathway annotation within the human genome. While this detailed bioinformatics approach for gene selection can in principle be applied to other species, the reliability of the resulting gene set depends on availability of a large body of transcriptomics data. For the model organism zebrasfish, we aimed to create a similar sentinel gene set for zebrafish (zS1500+ gene set), however, there is insufficient standardized expression data in the public domain to train the gene correlation model. Therefore, our strategy was to use human-zebrafish ortholog mapping of the human S1500+ genes and nominations from experts in the zebrafish scientific community. Knowledge from three ortholog databases was combined to determine human-zebrafish orthology. NCBi HomoloGene, Zebrafish Information Network (ZFNN), and Ensembl. 2,283 human S1500+ genes (84%) were found to have zebrafish orthologs. Prioritizing expert-nominated zebrafish genes (allowing multiple zebrafish orthologs for some human genes), 2,849 zebrafish orthologs of the human S1500+ genes were placed on the list. 206 additional expert-nominated genes were included for a total of 3,055 genes on zS1500+. Here we present the bioinformatics curation and refinement process to produce the final zS1500+ gene set, explore whole transcriptome extrapolation using this gene set and assess pathway-level inference. Leveraging the human-zebrafish ortholog mappings and a zebrafish > human > zebrafish extrapolation technique, we were able to approach 85% of the zebrafish whole transcriptome. This gene set will be immediately useful in performing targeted high-throughput transcriptomics in zebrafish for toxicogenomic screening and other research domains.

Leveraging Zebrafish to Identify Chemicals Disrupting Early Embryonic Development

S. M. Vlieet, S. Dasgupta, T. C. Ho, and D. C. Volf.

University of California, Riverside, Riverside, CA.

Alternatives to conventional toxicity testing are needed to support chemical screening and prioritization. Zebrafish embryos offer one of the most promising cost-effective vertebrate models to support toxicity testing. Therefore, the overall objective of this project was to leverage early, non-protected life stages of zebrafish embryos to identify compounds that disrupt the normal trajectory of early embryonic development. For the first aim, we carried out a high-content screen of the LOPAC2800 (Library of Pharmacologically Active Compounds) library - a commercially available library of 1,280 marketed drugs, failed development candidates, and well-characterized small molecules widely used for validation of high-throughput screening assays. Based on this screen, niclosamide - an anthelmintic drug used worldwide for the treatment of tapeworm infections - was one of the most potent development toxicants within zebrafish embryos during the first 25 h of development, with exposure to 10 μM niclosamide from 2-25 h post-fertilization (hpf) resulting in 100% embryo mortality. Therefore, the second aim of this study was to investigate the mechanism of toxicity of niclosamide during early stages of embryonic development. We found that niclosamide induced a concentration-dependent delay in epiboly progression during late-blastoula and early-gastrula stages that was dependent on exposure during the maternal-to-zygotic transition - a period characterized by zygotic genome activation and initiation of cell motility. Moreover, we found that niclosamide did not affect embryonic oxygen consumption, suggesting that oxidative phosphorylation - a well-established target for niclosamide within intestinal parasites - may explain a role in niclosamide-induced epiboly delay. However, mRNA-sequencing revealed that niclosamide exposure during late-blastoula and early-gastrula resulted in an increased abundance of maternal transcripts and decreased abundance of zygotic transcripts at 5 hpf relative to time-matched vehicle controls, suggesting that niclosamide may delay maternal transcript degradation and zygotic genome activation and may be preventing the progression of epiboly by disrupting the timing of the maternal-to-zygotic transition. Overall, our findings highlight the utility of embryonic zebrafish as a physiologically-intact, non-mammalian model for screening and prioritization of chemicals and environmental samples for further testing within rodents and human cell-based systems.

Coupled Host and Microbial Responses to Pthalate Exposure: Implications for Obesity

University of Florida, Gainesville, FL.

The prevalence of obesity has increased dramatically over the past 40 years at a rate no explained by poor diet and lack of exercise alone. Environmental chemical contaminants that are suspected to contribute to the obesity epidemic are called obesogens. Epidemiological evidence points to phthalates as a suspected class of obesogens to which humans are exposed daily due to their use as plasticizers in various products, including plastic packaging, medical devices, and toys. Mechanisms by which phthalates, such as diethylhexyl phthalate (DEHP), contribute to exacerbated obesity are largely unknown and focus on the host. However, the gastrointestinal microbiome may also undergo changes following phthalate exposure that contribute to the obese phenotype. This study addresses the contributions of host and microbial alterations to exacerbation of obesogenic mechanisms in zebrafish exposed to DEHP (Dano rio). Adult zebrafish were randomly assigned to one of three feeding regimes for 60 days: 1) Normal feeding (10mg/kg fish), 2) Overfeeding (20mg/kg fish), or 3) Overfeeding with DEHP exposure at 3 mg/kg food. Mass and body mass index (BMI) were measured throughout the duration of the experiment, and at 60 days zebrafish were euthanized and tissues and fecal matter excised for RNAseq, qPCR, and 16s microbial sequencing. Overfeeding and overfeeding with DEHP elevated BMI compared to normal feeding but differences in BMI at 60 days were not observed between these two groups. Significant alterations in both host and microbial processes were exacerbated in the DEHP treatments. In the host, processes related to lipid metabolism, immune system function and gut physiology were altered following DEHP exposure compared to overfeeding alone, and the emergence of peroxisome proliferator activated receptor alpha as a potential modulator of these processes is noted. The gastrointestinal microbiome experienced dysbiosis characterized by decreases in Bacteroidiae, traditional and in Fusobacteria taxa following only the DEHP exposure. Furthermore, DEHP treatment resulted in significant changes in bacterial carbohydrate, galactose, inositol, phosphorus, and taurine and hypertaurine metabolites. Finally, co-occurrence network analysis revealed decreases in cluster size and a fracturing of the network into unconnected communities following DEHP treatments. These findings suggest a role for DEHP in exacerbation of obesogenic mechanisms following overfeeding through both host gene expression alterations and microbial dysbiosis.
3182 The Results of a Pilot Study Applying Systematic Review Methods to Toxicological Test Method Assessment

S. A. Olmez1, R. Wright1, A. McCormack2, B. Marigliani3, K. Tsaloum1, S. Hoffmann4, and T. Hartung5. Johns Hopkins University, Baltimore, MD; 4Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3Mestre e Douradura em Biotechnologia (UNIFESP), Brasilia, Brazil; 5Johns Hopkins University, Paderborn, Germany; and 1Johns Hopkins University/CAAT, Baltimore, MD.

Systematic reviews (SR) involve a series of steps including framing the review question, defining inclusion and exclusion criteria, building a high-quality search strategy, assessing the risk of bias, extracting data, and analyzing and interpreting the results. SR play an important role in clinical medicine due to their transparency, objectivity, and structured methodology. Within toxicology, systematic reviews have not yet been applied to test method performance. In this study, conducted by a multi-stakeholder workgroup, a systematic review was performed to investigate the Zebrafish Embryological Toxicity Test (ZET) as a possible method for informing the assessment of developmental toxicity. The systematic review was designed to compare the outcomes of ZET and standard mammalian toxicity tests for the same set of substances. A two-stage literature search was conducted to (1) find ZET studies of well-defined substances and (2) find mammalian developmental toxicity studies that tested the same substances. The ZET search resulted in 5,074 studies. Of these, 50 were randomly selected for a preparatory study. After screening the titles and abstracts against predefined criteria, eight studies were included. After screening the full texts of these eight studies, one study was included in which seven substances were tested. We systematically searched the mammalian literature for these seven substances, which resulted in 1,442 studies. These were reduced to 263 studies after title and abstract screening and to 12 after full-text screening. These 12 studies contained data on two of the previously identified seven chemicals: thalidomide, tested in both rats and rabbits, and gambogic acid, tested only in rats. This preparatory study proved that translating systematic review methodology to a toxicological test method assessment is feasible, and we learned lessons along the way that helped us operationalize this process.

3183 Multi-omic Approach to Inform Quantitative Adverse Outcome Pathway Development for Acute Organophosphorus Poisoning

N. Vinas1, T. Ziv2, M. Arick3, E. Prats4, C. Gomez2, K. Conrow5, K. Watanabe6, A. Admon2, B. Pina4, and D. Raida4. 1US Army ERDC, Vicksburg, MS; 2Israel Institute of Technology, Haifa, Israel; 3Mississippi State University, Starkville, MS; 4CSIC, Barcelona, Spain; and 5Arizona State University, Phoenix, AZ.

Organophosphorus (OP) compounds constitute a class of acetylcholinesterase (ACHE) inhibitors used as not only pesticides but also chemical warfare nerve agents. Acute OP poisoning (OPP) can result from occupational (agriculture, industry, research), accidental, suicidal or homicidal causes and can be graded by severity as mild, moderate and severe. Epidemiological studies regarding OP pesticides estimate approximately 3 million cases of severe OPP and 300,000 deaths annually, most of them in developing countries of the Asia-Pacific region. Recently, we generated zebrafish models for mild, moderate and severe OPP. These were reduced to 263 studies after title and abstract screening and to 12 after full-text screening. These 12 studies contained data on two of the previously identified seven chemicals: thalidomide, tested in both rats and rabbits, and gambogic acid, tested only in rats. This preparatory study proved that translating systematic review methodology to a toxicological test method assessment is feasible, and we learned lessons along the way that helped us operationalize this process.

3184 Alterations of Expression of RNA Modification Regulators by Carcinogens in the Alternative Chicken Egg Model

T. Kobets1, J. Duan1, K. Brunnenmann1, D. Iacobas3, S. G. Vock1, G. Williams1, S. Iacobas4, J. Fuhlbreuck5, and S. Stegmüller1. 1New York Medical College, Valhalla, NY; 2Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany.

The abundance of cellular RNA structural modifications is well documented. Such epitranscriptome alterations ultimately regulate the expression of genes that control many biological processes. However, their role in various pathologic conditions, including cancer carcinogenesis in the developing organism, remains unclear. Similar to epigenetic alterations, epitranscriptome modifications are dynamic and may control enzymes, including methyltransferases, pseudoU synthetases and demethylases. The current study used microarray platform to investigate presence and expression of genes which encode for aforementioned enzymes in the Chicken Egg Model (CEM) after 3 daily injections of a wide array of established genotoxic and epigenetic carcinogens and their non-genotoxic comparators, including aromatic amines, dialkyltinotcarnosines, polycyclic aromatic hydrocarbons, aflatoxins, clofibric acid and phenobarbital. The CEM is an alternative to animal models that uses chicken fetal livers collected 3 hours after the last dosing on the incubation day 11, to evaluate various effects of chemicals, including their potential to produce DNA damage, alterations in gene expression and histologic changes. Chicken embryo-fetus is an intact, developing, metabolically active organism, which by definition is not yet subject to regulation for animals. Chemical-specific deregulation of 15 genes which encode for several RNA modification enzymes in other species including humans, in CEM could be expected by the presence of these enzymes in cell lines. Diallylthioleminosines produced most significant changes in the expression pattern of detected genes. Additionally, the majority of genotoxic carcinogens from the selected set of compounds altered the expression of several small nucleolar RNAs, including SNORD17, SNORAD2 and SNORA 18, which guide methylation and pseudouridylation of primarily RNA and tRNA. These findings lead to the hypothesis that chemicals are capable of producing chemical modifications of RNA, which in combination with established genotoxic and/ or epigenetic DNA damaging effects contribute to the process of chemical carcinogenesis. Based on our findings, CEM is an appropriate model to investigate this hypothesis.

3185 DNA Damage Produced by α- and β-Asarones in Alternative In Ovo Genotoxicity Models

G. Williams1, T. Kobets2, J. Duan1, K. Brunnenmann1, J. Fuhlbreuck5, S. Stegmüller1, and A. Cartus1. 1New York Medical College, Valhalla, NY; 2Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany.

The genotoxicity of several representatives of the food-borne alkenylbenzene (AB) class was previously reported in two in ovo genotoxicity models, the Turkey and Chicken Egg Genotoxicity Assays (TEGA and CEGA). In the current study, two additional ABS, α- and β-asarone, found in plants, e.g. Acorus and Asarum were investigated in both TEGA and CEGA for genotoxicity using comet and 8-<sup>P</sup>-postlabeling (NPL) assays. Additionally, fetal turkey liver samples were analyzed with ultra-high performance liquid chromatography (UHPLC)-electrospray ionization (ESI)-tandem mass spectrometry (MS/MS) method for confirmation, quantification and characterization of DNA adducts. DNA adducts detected with NPL assay. Fertilized turkey or chicken eggs were incubated under TEGA or CEGA protocol with vehicle, several dose levels of either α-asarone (5,10 mg/egg in TEGA; 2,4,8 mg/egg in CEGA) or β-asarone (2.5, 5 mg/egg in TEGA). Negative comet findings for β-asarone in CEGA could be explained by lower doses tested in chicken eggs, due to higher toxicity of the compound to chicken fetuses compared to that in turkeys. Both, α- and β-asarone also produced DNA adducts detected by NPL in chicken and turkey fetal livers. The chromatographic pattern of adducts formed by asarones was distinct for each compound while being similar between CEGA and TEGA. UHPLC-ESI-MS/MS analysis confirmed the presence and the nature of adducts after exposure to both ABS. In all samples the amount of dG adducts exceeded the amount of dA adducts. Thus, our findings, congruent with other data provide evidence of genotoxic potential for α- and β-asarones. Moreover, extensive analyses of DNA adducts formed in the in ovo models validated the sensitivity of NPL assay as a part of genotoxicity assessment in ovo. Overall, our results confirm that TEGA and CEGA can be used interchangeably.
Detection of Dose-Response Effects and No-Adverse-Effect-Levels of DNA Adduct Formation by Genotoxic Carcinogens in the Turkey Egg Genotoxicity Assay

C. Hickey1, T. Kobets1, J. D. Dong2, K. D. Brunemann2, G. M. Williams2, and B. Smith3.1Firmenich Inc, Plainboro, NJ;2New York Medical College, Valhalla, NY; and 3Agency for Science, Technology & Research (A*STAR), Singapore, Singapore.

Increased understanding of cellular defense mechanisms for DNA damage challenges the hazard based “as low as reasonably achievable” (ALARA) concept, and indicates that the existence of thresholds for genotoxic carcinogens is a valid assumption. Here we utilize the Turkey Egg Genotoxicity Assay (TEGA) to investigate and report on dose-response effects and the possibility of no-adverse-effect-levels (NOAELs) for the formation of DNA adducts of three known genotoxic carcinogens: 2-Acetylaminofluorene (AAF), Benzo[a] pyrene (BaP), and Quinoline (QUI). Medium white turkey eggs with 22- to 24-day old fetuses received 3 daily injections of a wide dose range for each compound: AAF (0.0005 - 0.05 mg/egg), BaP (0.05 - 0.3 mg/egg), and QUI (0.039 - 10 mg/egg), livers were harvested 3 hours after the final injection and the 32P-nucleotide postlabeling (NPL) assay was utilized to detect adducts in the fetal turkey livers. All materials produced DNA adducts in a dose-related manner. Even though very low doses were tested, a threshold level was not identified for AAF, the most potent hepatocarcinogen evaluated in these experiments. This finding highlights the sensitivity of the turkey liver to DNA damage produced by AAF as well as the sensitivity of the NPL method in general. NOAELs for DNA adducts were detected for BaP (0.15 mg/egg - 4 mg/kg bw) and QUI (0.08 mg/egg - 2 mg/kg bw), demonstrating that safe exposure levels to genotoxic compounds can exist and should be considered in the risk assessment of such compounds.

The Necessity of Uncertainty: Quantifying Uncertainty for Regulatory Application of New Approach Methodologies

E. Haugabrooks, PCRM, Washington, DC.

The face of regulatory toxicology is undergoing a makeover in the 21st century with the encouragement of new approach methodologies. However, is the way the scientific community accesses and understands uncertainty adapting to developing methodologies? Historically, toxicology testing for the assessment of human health has used animals, in which uncertainty factors were incorporated to address issues such as interspecies differences and species-specific mechanism of action. These uncertainties are in addition to the standard scientific uncertainties that exist with any experimental data. With the international push to accept alternative nonanimal testing in lieu of traditional in vivo testing, now is the time to understand acceptable uncertainty for developing methodologies. However, if uncertainty cannot be assessed and addressed in the same manner as the scientific community is comfortable with for in vivo data, what levels and expressions of uncertainty would be acceptable to make a regulatory decision with a new approach methodology for a specific regulatory context? This roundtable will discuss how uncertainty has historically been quantified, how it differs between methods (in vivo/in vitro/in silico), and how it has been addressed and should be addressed in order to facilitate development and implementation of new approach methodologies. We dare to broach the cultural barriers to accepting new approach methodologies in safety and risk assessment. We also intend to incite dialogue to address what types and subsequent levels of uncertainty are likely or tolerable in 21st-century toxicology.

Toxicology Education and Risk Assessment Training in Africa: Status, Challenges, and Role of SOT Special Interest Groups in Moving Forward

D. Hood, Ohio State University, Columbus, OH.

Reliable information about formal toxicology curricula and education-training in Africa is very scarce. Illustrative of that example is the fact that in the last 20 years there has been few publications (fewer than five) that have discussed toxicology education in South Africa and veterinary toxicology education in Africa. The continent of Africa is in a stage of rebirth after a long time in stagnation. Africa is now home to seven of the world’s 10 fastest growing economies. Africa is very rich in human capital, and today nearly 50% of Africans are under age 15. Africa has the fastest growth-rate in the world (due to dropping child mortality and high fertility), with the continent expected to have an estimated 2.8 billion people by 2060. Overall, the education in Africa is slowly improving. However, there is outstanding improvement in children’s primary education. The number of children enrolled in primary schools more than doubled, from 62 million to 149 million children, within 22 years (1990–2012). A systematic review indicates that university education continues to pose a significant challenge in Africa. In the continent’s 10 most-populous nations, there are 740 universities serving some 660 million Africans. This ratio in terms of the number of universities compared to the US represents a week 10%, with the US has some 5,300 universities and colleges serving a population of over 323 million people. Historically Africa hosts the two oldest universities in the world: the University of Al Qarawiyyin in Fez, Morocco, which opened in AD 859, and Al-Azhar University in Egypt, part of the larger complex of institutions associated with the Al-Masjid Mosque and Library. Today, African institutions enroll nearly 2 million students. This roundtable will provide an overview of the educational and training challenges within the toxicology diaspora and present research findings from studies that can inform the approach that SOT Special Interest Groups (SIGs) take to address the dilemma going forward. Desired outcome: is the majority of presenters have been involved in or are developing the toxigology and risk assessment training in various parts of Africa, the presenters will share this experience and explore innovative strategies to address the educational and training curricula in Africa despite the lack of meaningful investment in educational and research infrastructure by most African governments. A summary of the session presentations and recommendations will be shared with various organizations working in Africa.

Stepping Out of the Lab: Maximizing Access and Experience for Internships in Toxicology

N. Johnson, Texas A&M University, College Station, TX.

A major goal of the SOT Education Committee is to expand opportunities for students to engage in internships within industry, government, and nonprofit organizations. Immersion in internships provides students unique appreciation of the day-to-day activities of toxicologists and paths for success in these sectors. Such opportunities can help students establish their professional network, build confidence in career choices, and ultimately better prepare for transitioning into these sectors upon graduation. While numerous industries and governmental agencies have internship programs, or comparable opportunities, identifying these opportunities can be challenging. There are also barriers associated with funding, mentor buy-in, timing of the internship relative to the student’s graduate training, and feasibility for international student participation. The goal of this session is to bring together the various stakeholders—graduate students, faculty, and those hosting interns—to discuss best practices for developing internships, and strategies for increasing the number of available internships as well as improving awareness and access to available internships. The session will consist of five presentations followed by a group discussion on strategies that the SOT Graduate Education Subcommittee might develop to increase internship opportunities and overcome barriers for industry and government to host interns, and for graduate students to attain highly competitive internships. The formal talks will begin with a presentation by an individual who completed an internship as a graduate student discussing the benefits and logistical challenges they currently experience. Following this, representatives from various organizations working in Africa will share this experience and explore innovative strategies to address the educational and training curricula in Africa despite the lack of meaningful investment in educational and research infrastructure by most African governments. A summary of the session presentations and recommendations will be shared with various organizations working in Africa.

Consideration for Safety Assessment of Chemically Synthesized Therapeutic Peptides: A Drug Development Paradigm between the Large and Small

M. Mitra, Genentech, Inc., South San Francisco, CA.

Thousands of naturally occurring peptides act as key signaling molecules and thereby regulate crucial physiological pathways. Due to their high target selectivity and attractive intrinsic properties, novel chemically synthesized peptides continue to gain interest as an effective modality against drug-resistant targets. Currently, over 60 therapeutic peptides have gained worldwide approval and approximately 150 candidates are in clinical development. As with any other novel technology, development and safety assessment of chemically synthesized peptides present with an array of complex challenges. Additionally, there is a lack of specific regulatory guidance for peptide development. To address these challenges, this session will have presentations in preclinical (ICH M3(R2) and biologic (ICH S6(R1)) guidelines to develop therapeutic peptides. This symposium has been designed to provide a general scientific and strategic framework for safety assessment of therapeutic peptides. The session will begin with an introduction to peptides and give insights to their history,
Oxidative stress is an imbalance between oxidants and antioxidants in favor of the oxidants, leading to a disruption of redox signaling, which in turn leads to cellular injury. Damage mediated by reactive oxygen species (ROS) can arise from endogenous sources, such as mitochondria and peroxisomes, or by exogenous sources, such as pollution or tobacco smoke. ROS can cause DNA damage, lipid peroxidation, and protein oxidation, leading to cell death or cellular transformation.

In recent years, oxidative stress has been implicated in a variety of diseases, including diabetes, cardiovascular disease, and cancer. Oxidative stress is also associated with aging and neurodegeneration. Therefore, it is important to understand the mechanisms of oxidative stress and develop strategies to mitigate its effects.

The potential for oxidative stress in synthetic peptide drug development must be considered. Peptides may contain reactive groups or be modified to enhance membrane permeability, which can increase the risk of oxidative stress. Additionally, impurities in the synthetic peptide drug product may also contribute to oxidative stress. Therefore, it is important to assess the potential for oxidative stress in peptide drug development and to develop strategies to mitigate this risk.
ROS-Mediated Epigenetic Changes in Developing Lungs

L. K. Rogers, Research Institute at Nationwide Children's Hospital, Columbus, OH.

Reactive oxygen species (ROS) are essential to many physiological processes including reproduction. An imbalance of redox homeostasis can occur during pregnancy resulting in premature birth. Room air represents a “hyperoxic” environment to the preterm infant that developmentally should be in the low oxygen environment of the uterus. Furthermore, preterm infants are often treated with elevated oxygen tension to support gas exchange in underdeveloped lungs. The combination of increased oxidant stress from the cause of preterm birth and treatment with elevated oxygen tension, results in increases in ROS concentrations which can promote epigenetic modifications in the offspring. Increases in ROS concentrations are associated with increased activity of methyl transferases resulting in greater methylation of CpG islands and histone proteins. In human and mouse studies, we have identified increases in enzymes responsible for DNA methylation (DNMTs) and decreases in enzymes responsible for histone protein methylation (PRMTs) in immature hyperoxia-exposed murine lungs. Further, we have seen repression of histone methylation sites H3K9, H3K27, H4R3 which are responsible for transcriptional repression. This presentation will offer current data on changes in methylation and its role in altered lung development and new theories on treatments with demethylases as a novel therapeutic approach.

NRF2, Oxidative Stress, and Inflammatory Lung Injury

D. Zhang, University of Arizona, Tucson, AZ.

The transcription factor NRF2 is a critical regulator of cellular redox homeostasis whose target gene expression requires NRF2-SMAF dimers binding to antioxidant response elements (AREs) to initiate transcription. NRF2-ARE-dependent transcriptional repression is unreported, however, our group recently described a novel NRF2-mediated repression of the MYLK gene, which encodes the central cytoskeletal effector non-muscle myosin light chain kinase isoform (nmMLCK), via a 7 nucleotide NRF2-negative regulatory sequence (NNRS) adjacent to the ARE. We identified replication protein A1 (RPA1) as a novel binding partner of NRF2 that outcompetes NRF2-sMAF for ARE binding to reduce MYLK promoter activity. Furthermore, genome-wide silico and RNAseq analysis revealed that the NRF2-RPA1-ARE-NNRS complex also suppresses the expression of other genes involved in a diverse array of cellular processes, including tumor suppression (RASSF10 and FOCAD), cell growth and proliferation (FAM110B and NAV2), cell-cell adhesion (ITGA1 and TANC2), vesicle transport (SYT16), and the immune response (ADGRG5).

Finally, we investigated NRF2-mediated suppression of target genes by investigating MYLK repression in cellular processes, including tumor suppression (RASSF10 and FOCAD), cell differentiation, and inflammation. The symposium will also discuss new opportunities for translational research, which leads to the development of rational strategies (e.g., discovery of novel drugs in collaboration with pharmaceutical industry) for the prevention and/or treatment of human diseases by oxidative stress. Thus, this symposium would be of great interest to toxicologists who are focusing on the mechanisms of toxicity of a wide variety of chemicals that mediate toxicity by mechanisms entailing oxidative stress.

Mechanistic Role of Cytochrome P4501A and 1B1 Enzymes in the Metabolism of Reactive Oxygen Species (ROS)-Mediated Formation of Lipid Hydroperoxides: Implications for Hyperoxic Lung Injury and Human ARDS

B. Moorthy, Baylor College of Medicine, Houston, TX.

Hyperoxia is frequently used in the treatment of pulmonary insufficiency in preterm and term infants and in adults with acute respiratory disease (ARDS). In preterm infants, hyperoxia contributes to the development of broncho-pulmonary dysplasia (BPD). The molecular mechanisms of oxygen-mediated pulmonary injury are not understood, but reactive oxygen species (ROS) are the most likely candidates. Using in vivo approaches entailing Cyp1a1-null, new mechanism of NRF2 function, and highlight the potential importance of targeting NRF2-mediated suppression of target genes as a therapeutic approach for treating lung pathologies.
Cyp1a2-null and Cyp1b1-null mice, and in vitro approaches entailing purified human CYP1A1/1A2 and LC-MS/MS, we observed novel roles for cytochrome P450 (CYP1A) enzymes in the metabolism of F2-isoprostanes, which are generated by ROS-mediated mechanisms. Mice lacking the gene for CYP1A1 and the liver-specific CYP1A2 are more susceptible to hyperoxic lung injury, and these mice displayed augmented levels of pulmonary F2-isoprostanes and isoforms, suggesting that these molecules contribute to hyperoxic lung injury. On the other hand, mice lacking the Cyp1b1 gene show lesser injury than WT mice, suggesting a pro-oxidant role of CYP1B1. When mice lacking Cyp1a1/b1 double null and Cyp1a1/a2/b1 triple null mice were exposed to oxygen, the phenotype was similar to Cyp1b1-null mice, suggesting that CYP1B1 plays a key role in oxygen-mediated lung injury. We also found formation of bulky oxidative lesions (oxidative DNA adducts) in tracheal aspirates of premature infants and adults who received supplemental oxygen, suggesting that these adducts could serve as new biomarkers of BPD and ARDS. Future studies focusing on development of CYP1B1 inhibitors, in collaboration with pharmaceutical companies, could lead to prevention/treatment against hyperoxic lung injury in humans. Thus, the research described above offers novel opportunities for the development of rational strategies for the prevention/treatment of lung diseases in humans associated with hyperoxia.

3202 Understanding the Utility of In Vitro Developmental Toxicity Assays and Building Integrated Testing Strategies
J. Palmer, Stemina Biomarker Discovery, Inc., Madison, WI.

The performance of many alternative methods for developmental toxicity testing has been evaluated over the last 20 years; however, their application as new approach methods (NAMs) in a regulatory setting is still poorly defined. Several groups and regulatory agencies are working on ways to address this limitation through the development of strategic roadmaps and updating current testing requirements, including ICCVAM, US FDA, US EPA, ICH, ECVM, JACVAM, and the EU-ToxRisk consortium. Given the numerous complex processes involved in fetal development, it is unlikely that a single assay or adverse outcome pathway (AOP) concept will be sufficient for understanding and/or predicting the developmental toxicity potential of chemicals. Defining the applicability domain of each NAM, in terms of both chemical and biological space, establishing scientific confidence in their validity, and characterizing how they are best used in integrated testing strategies will be key for gaining regulatory acceptance of alternative methods. Evaluating well-defined groups of reference chemicals, such as the list proposed in the draft ICH Guideline SS(R3) on Detection of Toxicity to Reproduction for Human Pharmaceuticals or environmental chemicals identified by ICCVAM with robust animal data in multiple species, can help provide insight into the limitations of NAMs and how they can be combined. Systematic review techniques can integrate large sets of information from the scientific literature to identify high-quality studies and develop a weight of evidence approach for the application of NAMs. This session will highlight how the use of reference chemicals, systematic review, and evolving validation practices can be used to define the utility of NAMs, to develop integrated testing strategies, and will inform the discussion on how these approaches can help the field move toward regulatory acceptance. Experts from industry, academia, and government will present the results from a broad spectrum of reference chemicals (pharmacological, agrochemical, industrial, etc.) evaluated with different NAMs to demonstrate how these can be used to define the applicability domain of an assay.

3203 Evaluation of the Reference Chemicals Suggested in the Draft ICH SS(R3) Guideline with a Human Pluripotent Stem Cell-Based Developmental Toxicity Assay
J. A. Palmer, Stemina Biomarker Discovery, Inc., Madison, WI.

The International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) recently released the draft SS(R3) Guideline on Detection of Toxicity to Reproduction for Human Pharmaceuticals. The revised guideline would allow the use of in vitro, ex vivo, and non-mammalian embryo and developmental alternative assays to replace or eliminate in vivo studies in certain circumstances and provides a framework for qualifying alternative test systems for regulatory acceptance. The draft guidance includes a list of reference chemicals aimed at defining the applicability domain of an alternative assay. This list of chemicals has been evaluated with the DEVTOX quickPredict (devTOXqP) assay, which is an in vitro human pluripotent stem-cell based assay that predicts the developmental toxicity potential of chemicals based on changes in hPS cell metabolism. The results from this evaluation, as well as how devTOXqP can be used with other NAMs in an integrated testing strategy will be discussed.

3204 Retrospective Analysis: Can Existing Literature Be Used to Compare the Results from the Zebrafish to Mammalian Embryotoxicity Tests?
K. Tsaiou, Johns Hopkins University Center for Alternatives to Animal Testing (CAAT), Baltimore, MD.

A multi-stakeholder working group was assembled to conduct a systematic review (SR) comparing the performance of developmental toxicity test methods. In one, OECD Test Guideline 414 (Prenatal Developmental Toxicity) in rats and rabbits, which is currently mandated by various regulatory agencies for chemical registration is compared to a potential alternative, the Zebrafish Embryological Toxicity Test (ZET). ZET is being investigated as a possible replacement for the OECD TG 414 in total or replacement of one species (i.e., rabbit). We executed a wide literature search in 2016 and conducted a SR of all (7,778) published studies that used the ZET to screen 1,466 chemicals. These results, after assessment and comparison for methodological performance, are then being compared with the systematically reviewed results of OECD TG 414. The protocol, literature and database search strategies, and the results of the pilot study and lessons learned will be presented. The advantages of using text-mining and machine learning technologies in searching and reviewing the literature will be highlighted. We conclude that ZET is a valuable tool with which to assess the available literature on test method performance. Lessons learned and obstacles to doing literature-based assessments of test performance will be discussed.

3205 Mining and Modeling ToxCast/Tox21 Data for Developmental Toxicity
T. Knudsen, US EPA/ORD, Research Triangle Park, NC.

Synthetic reconstruction of embryonic development can provide in silico models that can be used to translate in vitro data from new alternative methods into critical phenomena for developmental toxicity. Computational methods are uniquely positioned to capture this connectivity and provide a mechanistic approach to AOP elucidation and toxico logical assessment with less reliance on animal testing. In ToxCast, for example, approximately 1 in 6 chemicals of 1065 tested give an exposure-based prediction of teratogenicity as a human stem-cell based assay. Mining these data for broader relationships to in vitro bioactivity profiles, together with model specific correlations to molecular pathways and cellular processes that drive human embryology and development, can be used in a defined approach to testing and assessment. This presentation will highlight some of the challenges for science and technology development in determining the applicability domain of high-throughput datasets ToxCast/Tox21 in support of developmental hazard identification and characterization. Progress in translating these large datasets into human-predictive models of developmental toxicity will be demonstrated utilizing case studies tying the in vitro data and in silico models to fundamental principles of teratogenesis. This work does not reflect US EPA policy.

3206 EU-ToxRisk DART Case Study Evaluating a Chemical Series across Multiple NAMs

Valproic acid (VPA) is a classical teratogen, and a set of nine VPA analogues with varying in vivo developmental toxicity potential were tested in the mouse embryonic stem-cell test, zebrafish embryotoxicity test, CALUX assays, and an iPSC-derived neuroepithelial cell model (UKN1). These NAMs, and a number of developed toxicokinetic models can be used with other structure-based information to apply read-across predictions within this chemical class and compared to reference in vivo data to understand their respective utility. This presentation will discuss combining results from multiple NAMs for predicting the teratogenic properties and potency of a series of structurally related chemicals and how this information can be used to establish a framework of testing for regulatory applications.
Under the US Strategic Roadmap for Modernizing Safety Testing, an ICCVAM working group was formed focusing on developmental and reproductive toxicity, with representatives from various federal agencies. The DART WG is developing a scoping document of regulatory needs and decision contexts, as well as opportunities for use of in vitro alternatives. An overview of the results of this effort, incorporating input from all US federal agencies that either require or consider safety testing data for developmental toxicity, will be presented. The working group scope and charge includes not only creating a catalog of existing technologies, but also mapping new and emerging technologies to known mechanisms of developmental toxicity and relevant adverse outcome pathways. Work to map the ToxCast/Tox21 assay targets to developmental toxicity mechanisms, and use in chemical prioritization, will be described. Further, the group plans to use study data from the National Toxicology Program and curated literature studies are being used to identify environmental chemicals with developmental toxicities in multiple species, ranging from overt malformations to subtle effects, that could serve as reference chemicals for evaluation of NAMs. This talk will include a discussion of the challenges and opportunities in data extraction and standardization, and the resulting database and candidate reference chemicals.

Active smoking and exposure to second hand smoke (SHS) increase the risk of vascular disease and is a major public health concern, but the mechanism(s) of action are complex and not fully understood. Disruption of endothelial functional homeostasis is considered as a key event in the development and progression of atherosclerosis. Endothelial homeostasis encompasses acute responses, such as adaption of flow to tissue’s demand, and more sustained responses to injury such as re-endothelialization and sprouting of endothelial cells and attraction of endothelial progenitor cells (EPCs) both supporting repair of damaged endothelium and maintenance of arterial integrity. The balance and the intensity of endothelial damage and repair might be reflected by inverse changes in circulating endothelial microparticles (EMP) and EPCs. Smoking appears to tip the balance by both inflicting endothelial injury while blunting regenerative responses leading to endothelial dysfunction and mal-adaptive arterial remodeling. One of the mechanisms may be an inhibition of nitric oxide (NO) production either through nitric oxide synthase in endothelial cells or EPCs. Previous studies indicate that even brief exposure to real-world levels of second hand smoke leads to vascular injury with release of EMPs, sustained endothelial dysfunction, and blunting of EPC function. While EPCs are mobilized into circulating blood, these cells are dysfunctional due to impaired nitric oxide production likely involving cotinine but also particulate matter. Dissecting the individual pathophysiologial roles of components of ambient air pollution is timely as the use of e-cigarettes is becoming increasingly popular and global urbanization is rapidly progressing.

Exposure to ambient air pollution is a leading cause of death worldwide. It has been linked globally to 7 million premature deaths and $5 trillion in costs per year. With continuing industrialization and urbanization, this disease burden is expected to increase even further. Interestingly, the majority of air pollution-associated deaths are due to cardiovascular disease (CVD). It has been estimated that in 2016, exposure to ambient and household air pollution combined was responsible for 3.5 million cardiovascular deaths. Because of this, air pollution exposure is now recognized as a modifiable risk factor that contributes to cardiovascular morbidity and mortality. Regardless of the strong evidence that air pollution exposure increases the risk for developing CVD, it remains unclear how the exposure to polluted air induces cardiovascular injury. Previous work has shown that chronic exposure to polluted air is associated with decreased endothelial function, suggesting that long-term inhalation of air pollution might result in endothelial injury and dysregulation of vascular homeostasis—effects that could accelerate CVD or trigger adverse cardiovascular events. Current research suggests that vascular homeostasis and endothelium health are maintained, at least in part, by endothelial progenitor cells (EPCs). These cells are a subpopulation of proangiogenic cells that reside in the bone marrow and circulate in the peripheral blood. Upon hypoxia or vascular injury, EPCs are mobilized from the bone marrow and home to the site of tissue damage where they contribute to vasculogenesis and/or angiogenesis either through terminal differentiation into mature endothelial cells or by paracrine stimulation of wound healing processes. Interestingly, recent studies show that EPCs are early and direct targets of air pollutant exposure. For instance, air pollution-induced impairments in EPC number and function have been found in humans exposed to particulate or volatile air pollution and in controlled exposure studies in rodents. These exposure studies demonstrated that inhalation of polluted air affects both circulating and bone marrow EPCs. This is important because chronically low circulating EPC levels and EPC dysfunction have been associated with vascular dysfunction in the risk and severity of CVD. Moreover, treatments that improve the number and function of EPCs (e.g., exercise, antihypertensive drugs) attenuate cardiovascular dysfunction. Because of the critical and non-redundant roles of EPCs in vascular health, air pollution exposure-induced EPC depletion and dysfunction could disturb vascular maintenance and repair, impairing vascular function, and consequently increase the risk for CVD. Hence, addressing how air pollution exposure induces EPC depletion and dysfunction is of high significance because it would help to discern the specific mechanism by which exposure to polluted air increases the risk for CVD. Understanding such mechanisms is important to develop effective prophylactic interventions and evidence-based regulations to mitigate against the major harmful health effects of air pollution. This session will highlight human studies and animal research that investigate the effects of air pollution exposure on EPCs. The specific presentations of the session will show that (1) inhalation of secondhand smoke modulates EPC number and function in healthy nonsmokers; (2) acute exposure to increased levels of ambient particulate matter (PM2.5) or other exposure to volatile organic components (benzene, acrolein) of polluted air are associated with changes in the number of these circulating proangiogenic cells; (3) the exposure to metal-rich particles impairs circulating EPC levels in humans and decreases number and function of bone marrow derived EPCs in mice; and (4) exposure to concentrated PM2.5 (CAP), by inducing oxidative stress, impairs circulating EPC levels and induces an anti-angiogenic dysfunctional EPC phenotype with a reduced ability to promote vascular tissue repair. Taken together, this session will provide a comprehensive overview that summarizes novel aspects of the mechanistic insights in understanding the adverse effects of air pollution exposure on cardiovascular health associated with changes in EPC number and function.

Exposure to airborne particulate matter (PM2.5) and volatile pollutants impacts the levels of circulating angiogenic cells in humans.

In response to vascular damage or hypoxic signals, a subset of adult progenitor cells, the circulating angiogenic cells (CACs), are mobilized from storage niches, home to sites of injury and participate in vascular regeneration through terminal differentiation or paracrine effects. Indeed, several animal studies have demonstrated the utility of CACs in restoring vascular perfusion and tissue repair. Levels of CACs are thus a useful indicator of vascular health and are inversely correlated with adverse outcomes. However, the availability of CACs is highly responsive to external cues and their levels are influenced by concurrent disease, lifestyle choices, and environmental exposures. In particular, we have shown that the levels of several CAC subtypes (most prominently those of the CD34+/CD31+/CD45+/CD133+ phenotype) are decreased in young healthy adults in response to acute exposure to fine airborne particulate matter (PM2.5). Consistent with this depletion of CACs and impairment of vascular perfusion, we also found that exposure of the same cohort led to a decrease of pro-angiogenic growth factors (VEGF, PDGF) and direct endothelial damage (increase in endothelial-derived microparticles). The sensitivity of CACs to environmental or demographic factors was further demonstrated in other human cohort studies where we show negative associations with exposure to the volatile organic compounds (benzene, acrolein) of polluted air or the exposure to volatile organic compounds. This work will further elaborate upon these findings and discuss how CACs are impacted quantitatively and qualitatively by multiple environmental influences.
The Role of Endothelial Progenitor Cells in Ambient Fine Particulate Matter (PM2.5)-Induced Atherosclerosis

1New York University School of Medicine, Tuxedo Park, NY; and 2Lanzhou University School of Public Health, Lanzhou, China.

Exposure to ambient fine particulate matter (PM2.5) increases risks for cardiovascular disorders (CVD). However, the mechanisms and components responsible for the effects are poorly understood. We have shown that nickel (Ni) found on or in PM has been associated with an increased risk of mortality in human population studies and significant increases in vascular inflammation, reactive oxygen species generation, altered vasomotor tone, and potentiated atherosclerosis in murine exposures. To test our hypothesis that exposures decrease endothelial progenitor cell (EPC) count and impairs EPC function, which may ultimately have significant effects on various CVD such as atherosclerosis, experiments involving inhaled Ni nanoparticle exposures were performed in order to quantify bone marrow-resident EPCs using flow cytometry in C57BL/6 mice. Plasma levels of SDF-1α and VEGF were assessed by ELISA and EPC function was assayed in vitro in cultured bone marrow EPCs. Exposure to Ni nanoparticles significantly reduced bone marrow EPCs and changed EPC tube formation and chemotaxis. Plasma VEGF and SDF-1α differences were not statistically significant. In addition, a translational pilot study was conducted in female residents of Jinchang and Zhangye, China. Daily ambient and personal exposures to PM2.5 and 35 elements were measured in the two cities. A total of 60 healthy nonsmoking adult women residents were recruited for measurements of inflammation biomarkers. In addition, circulating endothelial progenitor cells (CEPCs) were also measured in 20 subjects. The ambient levels of PM2.5 were comparable between Jinchang and Zhangye (47.4 and 54.5µg/m3, respectively). However, the levels of nickel, copper, arsenic, and selenium in Jinchang were 82, 26, 12, and 6 fold higher than Zhangye, respectively. The levels of C-reactive protein, interleukin-6, and VEGF were significantly higher in Jinchang. Furthermore, all phenotypes of CEPCs were significantly lower in subjects recruited from Jinchang than those from Zhangye. These results suggest that specific metals, particularly Ni, may be important components responsible for PM2.5-induced cardiovascular effects and that the reduced capacity of endothelial repair may play a critical role.

Pulmonary Oxidative Stress and Impaired Growth Factor Signaling: Potential Mechanisms of Air Pollution-Induced Changes in Endothelial Progenitor Cell Homeostasis and Function

P. Haberzettl. University of Louisville, Louisville, KY.

Exposure to air pollution is associated with an increase in the risk for cardiovascular disease (CVD) and cardiovascular mortality. A hallmark of air pollution-induced cardiovascular toxicity is endothelial dysfunction. However, the mechanisms by which air pollution exposure triggers endothelial dysfunction and increases the risk for CVD are still not known. We showed that in mice, inhalation of particulates (concentrated ambient fine particulate matter (PM2.5), CAP) and volatiles (e.g., acrolein released during combustion of endogenous progenitor cells (EPCs)) by impairing their VEGF-mediated mobilization from the bone marrow. Our recent study also shows that, in mice, exposure to CAP induces an anti-proliferative, anti-angiogenic EPC phenotype, impairs EPC function, and reduces the ability of EPCs to promote vascular tissue repair. Interestingly, early changes in EPC levels due to CAP (or acrolein) exposure were accompanied by impaired vascular sensitivity to VEGF and insulin, growth factors that are known to regulate EPC mobilization and function. In line with this idea we found that pharmacological agents that improve insulin sensitivity (metformin or rosiglitazone) not only prevented CAP-induced vascular insensitivity but also restored EPC trafficking in CAP-exposed mice. Treatment with metformin or rosiglitazone also prevented CAP-induced inflammation and oxidative stress indicating that PM2.5 exposure decreases circulating EPC levels by a pro-inflammatory oxidative stress dependent mechanism. This is supported by our findings that overexpression of extracellular superoxide dismutase (ecSOD) in the lungs that attenuates CAP-induced pulmonary stress, also protects against CAP-induced vascular inflammation, vascular resistance to insulin and VEGF, and EPC depletion and dysfunction. These findings, suggest that upon PM2.5 inhalation, pulmonary generation of superoxide induces vascular inflammation and impairs vascular signaling that compromises morphogenesis of EPCs. The CAP-induced decrease in the ability of EPCs to maintain a healthy endothelium and to promote angiogenesis could result in endothelial injury, which could heighten the CVD risk.

Complex CNS In Vitro Models for Safety Testing: The More Complex the Better?

S. Kustermann, F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Neurotoxicity is of complex nature and rarely predicted by the standard battery of in vitro safety tests applied in industry for early drug development. In addition, during the last years targets and therapeutic modalities got increasingly complex and sometimes for example large molecules drug candidates do not cross-react with any other species than human. This triggers a strong need for more complex cellular systems to be applied for safety testing. The central and peripheral nervous system is highly complex. Standard 2D systems do not necessarily enable the interplay of different cell types like neurons and glia cells crucial for physiological relevance of the model. Furthermore, as the accessibility of the CNS and PNS is limited due to implemented barrier systems the CNS and PNS are a challenge to model in vitro. The nervous system is a complex, dynamic organ. It is not only involved in the control of movement, the generation of thoughts, and feelings, but also has an important role in the control of the body's metabolic processes and its response to stress. It is therefore not surprising that the nervous system is one of the first systems to be affected by disorders such as stroke, Parkinson's disease, Alzheimer's disease, and multiple sclerosis. The nervous system is also one of the first systems to be affected by disorders such as stroke, Parkinson's disease, Alzheimer's disease, and multiple sclerosis. The nervous system is also one of the first systems to be affected by disorders such as stroke, Parkinson's disease, Alzheimer's disease, and multiple sclerosis. The nervous system is also one of the first systems to be affected by disorders such as stroke, Parkinson's disease, Alzheimer's disease, and multiple sclerosis.
tems as the blood-brain or blood-retina barriers, understanding compound disposition in those compartments is crucial for safety testing. These features cannot be recapitulated in a 2D system and 3D models or microphysiological systems would be of great value to mimic human physiology of the CNS or PNS to a very high degree. Are such systems already set up and ready for their use in drug development to test safety (and possibly efficacy) early on in a human relevant model? The need as well as the pros and cons of existing complex neural systems which are currently evaluated in-house for safety testing will be presented and the vision of their application will be addressed during the presentation. In addition, the existing and possible future requirements that will lead to a general use of these approaches for drug development will be discussed.

**3215 A Human BBB Microphysiological System for the Study of Neurotoxicity**

The human neurovascular unit (NVU) is a dynamic and highly organized structure that regulates biotransportation in the central nervous system (CNS). It consists of highly specialized endothelial cells (EC) that form the microvascular network, pericytes (PC) that wrap around the vessels, the basal lamina, and the end-feet of astrocytes extending to the vasculature. Together, they form a blood-brain barrier (BBB). While the BBB is exceptional at preventing foreign substances entering the CNS, there are compounds that can cross the barrier and cause neurotoxicity, including those with a high logP (low hydrophilicity that normally gives poor absorption and transportation) and those that are not cleared by P-glycoprotein and other efflux pumps. While many versions of a 2D BBB have been created, these fail to replicate the complex structure of the BBB and thus its unique capabilities. We have therefore developed an in vitro model of the human BBB with perfused vasculature, that allows for studies of BBB permeability and the pathological changes associated with inappropriate access of toxic drugs to the CNS. The platform is based on our human vascularized micro-organ (VMO) system where tissues are supported by nutrients delivered through perfused, living microvessels. Preliminary results demonstrate that the EC in the model display BBB characteristics, including expression of diagnostic transporters and junction molecules, and low overall permeability. We believe this model will prove to be an invaluable tool for testing the potential neurotoxicity of drugs in a human setting.

**3216 A Complex Human 3D Neural Cell System to Study Developmental Neurotoxicity**

H. T. Hogberg. Johns Hopkins University, Baltimore, MD.

Human in vitro models of brain neurophysiology are needed to investigate molecular and cellular mechanisms associated with neurological disorders and neurotoxicity. We have developed a reproducible iPSC-derived human 3D neural cell system, comprised of differentiated neurons (glutamatergic, dopaminergic and GABAergic neurons) and glial cells (astrocytes and oligodendrocytes). In this study we evaluated the developmental neurotoxicity effects of rotenone using high-content approaches, such as transcriptomics, metabolomics, immunohistochemistry and fluorescence assays. The data revealed that rotenone induced increased reactive oxygen species production (CellRos assay), and reduced mitochondrial dysfunction (MitoTracker assay). Furthermore, dopaminergic-neurons in the model seemed to be more sensitive to rotenone exposure than other neuronal cell types and glial cells (immunohistochemistry and gene expression data). Omics analysis showed changes in key pathways necessary for brain development, indicating rotenone as a developmental neurotoxicant and show a possible link between previously observed effects on neurite outgrowth and presently observed effects on Ca2+ reabsorption, synaptogenesis and PPAR pathway disruption. In addition, as our cell model reveals more than 40% overall myelination, something rarely seen in vitro so far, we evaluated the potential of chemicals to disturb myelination formation in our system. We selected four compounds shown to induce dys-myelination in animals (Cuprizone, BPA, Methylene, and TDCPP). Results showed that these chemicals also caused reductions in myelin formation in vitro at non-cytotoxic concentrations. This complex model has many advantages over simple monolayer cell cultures as it mimics better the in vivo situation. However, the throughput for toxicity testing is currently medium-low and the time it takes to differentiate the model is quite long and the costs are relatively high. Such a complex CNS model provides an excellent tool for future studies of neurological disorders such as multiple sclerosis, Parkinson’s disease as well as (developmental) neurotoxicity testing of drugs and chemicals.

**3217 Nerve-on-a-Chip Platform to Evaluate Peripheral Neuropathy with Clinically Relevant Metrics**

Electrophysiological and microstructural changes in peripheral and motor nerve tissue are arguably the most clinically relevant measures of pathology. These changes may manifest even before clinical symptoms arise, suggesting they may serve as more sensitive and physiologically-relevant metrics in an in vitro system. Our Nerve-on-a-Chip, an innovative preclinical model of both rat and human peripheral nerve tissue, enables electrophysiological and microstructural assessments in addition to cellular and molecular studies in a single, well-controlled preparation. This is the first in vitro model with the ability to perform nerve conduction tests and analyze histomorphometry, providing evaluation metrics of safety and efficacy that are analogous to those used clinically. We have successfully incorporated iPSC-derived sensory and motor neurons, astrocytes, and primary Schwann cells as well as primary rat dorsal root ganglion tissue to create a 3D in vitro Nerve-on-a-Chip which exhibits robust neurite outgrowth (up to 1 cm of growth) and myelination (up to 40% myelinated axons), and which has remained viable after two months, allowing us to perform more “chronic” and clinically relevant dosing regimens than a standard acute toxicity assay in vitro. Results on screening neurotoxic compounds using known chemotherapeutic and other agents with toxic mechanisms manifesting in changes to nerve conduction velocity, axon density, and degree of myelination have been able to predict clinical outcomes with historical compounds. We will present these results including dose responses to paclitaxel, bortezomib, vincristine, oxaliplatin, and others and compare to human clinical results. The ability to deliver high content, clinically-relevant data will enhance the field of preclinical neurotoxicology testing in efficiency, cost, and accuracy. In addition, I present a review of interaction with end users of MPS and organs-on-chips to provide insight on the relationship between model developer and biopharma. This discussion aims to better elucidate the place in which microphysiological systems fit within the drug development pipeline, both now and in the future, from the perspective of the MPS industry.

**3218 Retina-on-a-Chip: Merging Organoid and Organ-on-a-Chip Technology for Complex Multi-Layer Tissue Models**

P. Loskill. Fraunhofer Institute for Interfacial Engineering and Biotechnology, and Eberhard Karls University Tübingen, Tübingen, Germany. Sponsor: H. Hogberg

Retinal diseases such as age-related macular degeneration or retinitis pigmentosa are the leading cause of blindness. However, there is often no cure or treatment available, which is partly due to a lack of suitable model systems. Additionally, many substances induce retinal toxicity in the neuronal and/or the retina/blood-barrier component. To study retinal diseases and toxicities different model systems are available: i) in vivo animal-based models feature various similarities with the human retina but also significant differences e.g. not trichromatic or missing macula, ii) ex vivo models based on human retinal tissue extracted post mortem are problematic due to their limited availability and cultivability, iii) in vitro cell culture models mostly utilize cell lines and are not able to recapitulate the complex physiological structure and functionality of retinal tissue. Recent advances in stem cell biology and the possibility to generate 3D organ-like structures have opened up new possibilities for pharmaceutical and toxicological research. Yet, those so-called organoids are still limited by shortcomings such as proper functional maturation and the physiological interplay of retinal cells. The Organ-on-a-Chip (OoC) technology has the potential to address those limitations by creating physiological accurate in vitro models of human tissues in a microfluidic environment. However, it is extremely difficult to recreate the complex, stratified 3D architecture of the human retina featuring a large number of cell types within an OoC in its entirety. By merging OoC and organoid technologies, we have developed a microphysiological Retina-on-a-Chip, which successfully recreates the tissue structure and recapitulates physiological cell-cell interactions. The combination of the biological self-assembly mechanisms in organoids with the precise micro engineering of OoCs, enabled us to culture organoids containing the neuronal components of the retina and retinal pigmented epithelial cells in a vascularized environment and to observe a so-far unmatched functional interplay of the different cell types. The developed 3D retina chip is extremely versatile and applicable for drug development, toxicity screening and disease modeling.
Order from Chaos: Pattern Recognition in Challenging Human Health Datasets

J. Wambaugh. US EPA, Research Triangle Park, NC.

The science of complex systems has demonstrated that while some things about noisy, real-world data are unknowable, certain patterns and structures can emerge from the chaos. Given the increasing complexity of data related to assessing potential risk posed to human health by chemicals, this session is intended to incubate new methodologies for mining “Big Data” to inform functional human health outcomes. Driven by innovations in computational techniques, many problems that were once intractable can now be understood in terms of these recurring patterns. While the areas of research in this session are diverse, there is a surprising commonality about the challenges faced by researchers and the potential cross-domain applicability of the approaches used to solve the problems. The session begins with an exposomics-based approach to understanding the role that environmental chemical exposures may play in public health outcomes. The workshop continues by addressing metabolomics and novel, non-targeted analysis (NTA) of chemicals in environmental and biological media. NTA analysis generates thousands of chemical features per sample, and each sample contains information about the potential upstream chemical sources or pathways. Algorithms can identify unique feature signatures associated with sample groups, allowing understanding of sample content and history and development of source hypotheses. The session will then explore the world of in vitro testing where, among the hundreds of cell lines available, efforts are being made to identify a parsimonious few that explain as much phenotypic variability as possible. The final presenter is from a large, multi-national consulting firm. The presentation will examine prediction of human health outcomes using new analytics techniques to identify environmental toxin “Hot Spots” using Big Data. In all five presentations, identifying patterns in complex data to allow for more informed decision-making. Each presentation will consider: (1) What are the challenges of the system of study? (2) What aspects of that system are unknown or unknowable? (3) What patterns emerge from the complexity of the system? (4) What tools are available for identifying these patterns? (5) What are the human health implications for the patterns that can be recognized?

Informatics and Data Analytics to Support Exposome-Based Discovery for Public Health

J. Chung, and C. Patel. Harvard Medical School, Boston, MA. Sponsor: J. Wambaugh

Epidemiologic studies attempt to understand etiology through associations between environmental exposures and phenotype; from large genetics investigations, it is apparent that genetics explain a fraction of chronic diseases. Recent advances in measurement technologies create huge research opportunities to understand the true influence of environmental exposures in the exposomics era. However, the promise of high-throughput exposomics research is accompanied with increasing difficulty to decipher the subtle relationships due to complex data, including: dense correlational structure, low association sizes, mixture exposures, high dimensionality, missing values (especially an issue for chemical measurements), and high spatial, temporal, and individual variability. In addition, there are analytical challenges stemming from a lack of statistical power and reproducibility of findings. In contrast to the previous big data transparency workshop, here we focus on practical topics in exposomics-based research. Specifically, we will discuss analytical solutions to some of the data challenges, such as machine learning methods to understand patterns and structure in data, and emerging ways to systematically detect the associations between exposures and disease. We will also discuss briefly the need for setting up data standards and infrastructure for future exposomic studies.

Finding Patterns within Complex Metabolomics Datasets

B. van Ravenzwaay. BASF SE, Ludwigshafen, Germany.

The MetaMapTox data base contains the metabolome profiles of more than 800 compounds, obtained from rat blood samples in short-term studies. A prediction of toxicity of new chemicals is obtained by comparison with (1) > 100 sets of fixed metabolite regulations associated with a particular form of toxicity/mode of action, and (2) a ranking of the overall metabolome of the compound under investigation with all other available profiles. The high accuracy of prediction (> 80%) we have achieved is related to two features: the size of the data base, and the unique rigor of control of the experimental set-up. Recommendations from our 15 years of experience should be applicable to any of the ‘omics technologies. Control and understanding of variability, arising from the biological assay, sampling and storing procedures as well as from the measurement itself, is essential. At the start of a large-scale, multiple year-project extensive investigation in control variability is important. Using of reference (positive control) substances the signal/noise ratio should be determined. Once a satisfactory ratio has been obtained all procedures should be documented in standard operating procedures and followed meticulously during the rest of the project. It is strongly recommended to regularly perform exact controls and confirmatory controls to obtain information on the variability of positive responses. Control data should be regularly checked for any shifts and analyzed to obtain information concerning normality. Large sets of control data can also be used to obtain an historical-range for individual parameter variability. If possible, data should be analyzed by multiple procedures and conclusions should be drawn based on a combined assessment. We recommend to perform such final evaluations in a team of experts, not unlike peer review processes in histopathology.

Identifying Chemical Signatures of Manufacturing and Recycling in Household Products

This presentation will describe the challenges inherent in understanding high-resolution mass spectrometry (HRMS) data generated in non-targeted (NTA) analyses of the chemical constituents of household products. These approaches can help identify pathways that can be captured in the bands of molecular features (and thus chemicals) in a single analytical run without any a priori knowledge of the compounds present. These studies are being used by US EPA to screen consumer products articles of commerce for chemical content. These NTA screens generate large numbers of chemical features that are understood in part through comparison against large, newly compiled databases of chemical ingredients and weight fractions in household products. However, not all chemicals can be identified in these databases. Consumer product ingredient databases have therefore served as training sets for machine learning tools capable of predicting the functional use of chemicals in consumer products based upon structure alone. These tools prioritize chemicals for further study and identify novel compounds. Across many media samples of a given type, analysis of these features can uncover co-occurring groups of chemicals (“signatures”) that may be indicative of unique exposure sources. In consumer products, signatures could be associated with intentional (functional) addition, manufacturing process, or contamination. While unsupervised clustering and co-clustering methods are useful in elucidating local patterns, there are challenges in applying them to HRMS data. True variability in chemical content across samples, reproducibility in analytical results, and uncertainly in mapping of molecular features to chemicals all contribute to noise that imparts a large degree of complexity (and thus computational burden) to the problem. Where sample metadata are available, supervised or semi-supervised approaches can be used to further focus the analysis. Case studies of unsupervised and supervised approaches will be presented and challenges discussed. Development of standard methods and tools for identifying chemical signatures can improve identification, prioritization, and mitigation of chemicals in consumer products. This abstract does not necessarily reflect US EPA policy.

Parsimonious Selection of Cell Lines to Reproduce Phenotypic Variability

N. Sipes. NIEHS/NTP, Research Triangle Park, NC.

High-throughput transcriptomics can cost-effectively screen thousands of chemicals to identify changes in 3,000 to 20,000 transcripts in human cell lines. However, it is known that screening two cell lines over the same set of chemicals may give variable responses. If one cell type is decided, how can we efficiently pick the next cell type to screen where the responses will be complimentary and not entirely redundant? We hypothesize that a data-driven approach can choose a limited number of cell types that will reflect variability of chemicals may give variable responses. If one cell type is decided, how can we efficiently pick the next cell type to screen where the responses will be complimentary and not entirely redundant? We hypothesize that a data-driven approach can choose a limited number of cell types that will reflect a majority of the relevant biology for toxicity testing. Specifically, we have evaluated the genetic diversity in baseline gene expression data over >1000 human biological samples utilizing inter-cell differences in a “content maximization” approach. Maximizing phenotypic variability included choosing cell lines that displayed diversity in the most influential factor explaining the diversity, which was organ lineage. Surprisingly, organ lineage was identified as the most influential factor using either the baseline gene expression data, or a dataset of differential toxicity responses from 600 chemicals. This approach provides a data-driven way to examine cell line diversity to ensure adequate coverage of biological space, which will impact the way we choose cell lines for high-throughput approaches.
Identifying Environmental Toxin “Hot Spots” Using Health Care Data

M. Mardorff, Deloitte Consulting, Harrisburg, PA. Sponsor: J. Wambaugh

Deloitte is a multi-national professional services firm with more than 71,000 professionals in the US and more than 270,000 worldwide. At Deloitte there is interest in mining Big Data to be predictive of functional human health outcomes to support better and more timely responses by health and human services agencies. Vast amounts of data are characterized by Medicaid claims/encounters, All Pay Claims databases, and most recently statewide Health Information Exchanges (HIE). The data have the potential to be used to identify, and potentially address, “Hot Spots” (these could be geographic, demographic, etc.) due to adverse effects induced by environmental toxins. Data sets that are available to states via HIE is especially interesting: with the correct machine learning model and process we could support the scanning of data flowing through an HIE and identification of hotspots in near real time. In a different but related context, we have recently used this approach and these same data sets to identify opioid abuse hotspots along with enabling prescribers.

Risk Assessment of Consumer Products and Articles: Critical Considerations and Case Studies for Characterizing and Quantifying Consumer-Relevant Exposures to Chemicals and Nanomaterials

S. Felter, Procter & Gamble Company, Mason, OH.

Increasingly, toxicologists are challenged to do risk assessments for consumer products for which the determination of relevant exposure is not straightforward. Quantification of potential exposure from many types of existing and emerging consumer products (e.g., textiles, diaper, diaper printed products) is still an emerging science and the application of nanomaterials introduces even further challenges. Quantifying exposure that mimics actual and foreseeable consumer use associated with a range of consumer products can require advanced sampling approaches and analytical capability. This raises the question of how we should define what is “reasonably conservative” versus “not relevant” when developing methods. Given the limitations/absence of these capabilities and/or accepted methods, overly conservative methods and assumptions are often used that are not relevant to consumer exposures or represent extreme worst-case use scenarios. The session will provide examples of frameworks and sampling and analytical methods that have been developed to determine exposures from products and articles that are relevant for actual consumer use scenarios. Case studies include the estimation of chemical migration and relevant consumer exposure estimates to engineered nanomaterials along the product value chain, release of silver from nanotechnology-based children’s products, and the potential for migration of any constituents above a TTC-based threshold from a disposable diaper. Factors that are important to consider when developing extraction methods for mimicking consumer use scenarios, including relevant solvents, will be discussed. These data can then be used in robust risk assessments leading to informed decisions on safety decisions that in such products under normal usage conditions and improve product safety and risk communication to the public. This session will also consider what exposure data are needed by regulators associated with the new Frank R. Lautenberg Chemical Safety for the 21st Century Act and how end uses of a chemical are considered when estimating the potential for consumer exposure.

Introduction: Relevance of Exposure Data for Toxicological Research and Risk Assessment of Chemicals and Emerging (Nano) Materials in Consumer Products

T. A. Thomas, Consumer Product Safety Commission, Rockville, MD.

Assessing potential health risks from chemicals and emerging materials incorporated into consumer products/articles (e.g., clothes, toys, furniture, hygiene products) requires robust data from a number of disciplines including toxicology, exposure science and risk assessment. The releases of chemicals of interest from products and subsequent are influenced by a number of factors including product use patterns and exposure science plays an important role in developing methods to adequately characterize and quantify consumer exposures. The toxicology community must produce data that is relevant for these real-world consumer exposures. Risk assessors must also engage with these communities to ensure the development of exposure and toxicity data and that this information is appropriately incorporated in risk assessments and the results communicated to stakeholders. As emerging materials, such as nanomaterials continue to be commercialized, their potential health impacts will be assessed along with other chemicals. In 2018, the Society of Toxicology took an important step forward in embracing exposure science by developing an exposure assessment specialty section. This workshop will explore the relationship between exposure assessment and the relevance of exposure data for toxicity research and risk assessment for traditional and emerging chemicals and materials, and how information for these various classes of compounds can be utilized to develop more robust risk assessments for a range of chemicals in consumer products. Case studies will be presented that highlight these concepts.

Understanding the Changing Exposure and Toxicity Profile of Engineered Nanomaterials from Production to Application

A. Erdely, NIOSH, Morgantown, WV.

Engineered nanomaterials, because of their electrical, chemical, and thermal properties, are being incorporated into existing, everyday products, with broad applications to medicine, electronics, composites, and construction. From smart phones, to water purification, to cosmetics, to thermoplastics (e.g., toys, containers), human exposure to engineered nanomaterials and their applications is inevitable. It is critical that interpretations of potential toxicity along the product value chain be exposure-informed as TSCA requires a risk evaluation at all points along the life cycle of a chemical. Properly understanding and developing risk profiles for workers and end-users are necessary to prevent unintended health consequences. Engineered nanomaterial research initially focused on as-produced (pristine) material with little attention to downstream applications. Given the broad applications of nanomaterials into existing and emerging technologies, a more expansive characterization of exposure was needed to understand potential health risks. To accomplish this goal, a multidisciplinary team with private sector partners was needed. This work will describe a comprehensive case study evaluating carbon nanotubes, which represent a highly visible engineered nanomaterial due to the significant toxicity observed following in vivo evaluations. The work evaluates the changing toxicity and exposure characteristics along the product value chain from the production of the as-produced material, to post-production modification, to matrix (or product) incorporation. The results clearly indicate that exposure and toxicity, and thus potential risks to workers and end users can be quite different from product to product. Understanding the changing exposure profile of engineered nanomaterials along the product value chain is critical for determining potential human health risks and overcoming risk-driven concerns that are potential barriers to increased commercialization. The case study also provides a framework and recommendations for evaluating other materials and scenarios, develops reproducible methods, and highlights new, or alterations to existing, methodology to characterize exposure and toxicity at different points along the product value chain. The comprehensive approach of combining toxicity and exposure assessment is necessary to provide direct inference to potential consumer risks.

Estimating the Release of, and Exposure to, Silver from Nanotechnology-Based Consumer Products for Children

M. E. Vance. University of Colorado Boulder, Boulder, CO. Sponsor: S. Felter

Silver nanoparticles (nanosilver) are gaining significant attention in the academic and regulatory communities, not only because of their antimicrobial effects and subsequent product applications, but also because of their potential health and environmental impacts. Although some human health effects of silver and silver nanoparticles have been reported, realistic exposure levels from the use of consumer products must be estimated to inform toxicity studies. The objective of this work was to characterize the release and potential exposure to silver and silver-containing particles during the normal use of silver nanotechnology consumer products for children. We developed a framework to assess (1) whether products contained silver, (2) whether silver in products was in nanoparticulate form, (3) whether products might release silver under realistic usage scenarios, and (4) in what form and concentration silver releases are most likely to take place. To put this framework to use, we compiled an inventory of 82 children’s consumer products that claim to contain nanosilver and selected 13 products for presence of silver and its release into liquid media, into air, and onto skin. All products contained some form of silver, but silver-containing particles were observed in only four products, with sizes ranging from nanoscale up to 10 µm in size. Silver leached preferentially into synthetic biological media with higher chloride concentrations, such as sweat and urine. We determined that levels of silver to which children would be exposed during normal use of these products are likely to be low, and bioavailable silver is expected to be in ionic rather than particulate form. This framework may be used to assess exposure from other increasingly popular nanotechnology-enabled consumer products.
Modern disposable diapers are composed of large polymeric materials that are not bioavailable. In some cases, there might be other aspects of a diaper such as a lotion applied to the topsheet, which are intended to transfer to the skin to provide skin health benefits. But what about the diaper itself? Will smaller molecular weight constituents (eg, fiber finishes) transfer to the skin? What about constituents present in the core or other part of the diaper that is not in direct skin contact? While diapers are associated with a long-history of safe use, how should this be substantiated prior to marketing? One approach is to conduct paper-based safety assessments based on supplier disclosures of starting materials used in making diaper components and applying conservative assumptions about how much might actually come into contact with the infant. While this is generally considered to be quite conservative, it does not accurately portray what an infant will be exposed to during normal diaper wear. In many cases, the actual exposure to substances used in the making of a diaper will be negligible. However, it is also recognized that analytes might be detected that were not in the supplier disclosures. To develop a more rigorous approach to the safety evaluation of diapers, we developed methods that involve subjecting a diaper to conditions reflective of consumer use, including use of physiologically-relevant amounts of solvent (surrogate for urine), and applying an amount of pressure to the diaper relevant to that of an infant sitting. This is followed by analytical analysis of the small amount of liquid (“rewet”) that can be collected, which would include any low-level constituents in the diaper that could be solubilized by urine and brought back to the surface in contact with the infant. This is in contrast to targeted analyses focused on predetermined substances of interest. The Threshold of Toxicological Concern (TTC) is used to establish a level above which a compound would need to be identified and below which safety is not a concern. The final safety assessment is conducted on all constituents detected above TTC. This talk will present a case study, demonstrating the quantitative safety assessment of diaper components using methodology based on physiologically relevant exposure conditions.

On June 22, 2016, the Frank R. Lautenberg Chemical Safety for the 21st Century Act was signed into law thereby amending the Toxic Substances Control Act (TSCA). This new legislation is the first update to TSCA in 40 years. Consumer products and articles are significant sources of indoor chemical exposures. Exposure estimates can be developed using measured exposure data, modeling approaches, or a combination of both. The US EPA’s Office of Pollution Prevention and Toxics evaluates exposures to new and existing chemicals, including nanomaterials, and has augmented their suite of exposure estimation tools with updates to the Consumer Exposure Model (CEM), the Indoor Environmental Concentrations in Buildings with Conditioned and Unconditioned zones (IECCU) model, and the development of indoor exposure testing protocols to experimentally determine exposure parameters. The experimental results can be used on their own, or in combination with exposure models to quantify consumer exposures. Updates to CEM include improved use, and functional use category definitions through the OECD can be used to inform development of consumer exposure scenarios. This presentation will provide an overview of the interrelatedness of consumer exposure models, available empirical data, indoor exposure testing protocols, and use descriptors in estimating consumer exposures. The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

Millions of Americans use e-cigarettes, even as rates of smoking combustible cigarettes continue to decrease among young adults. Recent survey data show that e-cigarette use is greater in youth (under age 18) compared with adults (age 18 and older); among adults, e-cigarette use is generally greater among young adults and decreases with increasing age. In May 2016, the US Food and Drug Administration (US FDA) issued a rule which extends its regulatory authority to all products that meet the “substance use disorder” definition of tobacco product, including e-cigarettes. To gain insight into the risks and benefits of e-cigarettes, the US FDA’s Center for Tobacco Products, by congressional mandate, requested the National Academies of Sciences, Engineering and Medicine (NASEM) to convene a committee of experts to conduct a review of the evidence about the public health consequences of e-cigarette use. This discussion led by Dr. Vorhees and Dr. Talpos on the evidence for increased vulnerability in adolescents compared with adults and the extent to which proposed neurocircuit targets and biological markers are unique to teenage vulnerability for dependence. They will also evaluate whether approaches are generalizable to toxicity testing to screen for effects of chemical and drugs that may increase susceptibility of teenagers to substance use disorders (SUD). Participants will discuss implications of unique patterns of behavioral, neurochemical, and other biomarker changes in adolescents for public health. Ms. Kwan, a graduate student in Public Policy and Public Administration at George Washington University, who has been involved with research on age of initiation of nicotine on public health outcomes, will briefly introduce the topic and frame the overarching questions for the session. Dr. Eaton will set the stage by presenting recently published (2018) results from one of the most comprehensive studies by the National Academies that he chaired on human health effects of e-cigarettes, including youth initiation. Dr. Levin will begin with a brief introduction on neurochemical and anatomical pathways of addiction followed by presentation of ongoing research on behavioral, anatomic, and signaling pathway markers of nicotine dependence in adolescent and adult rats. Dr. Dow-Edwards will compare and contrast the effects of delta-9-tetrahydrocannabinol (d9THC), the chemical responsible for most of marijuana’s psychological effects, on adolescent brain-behavior relationships with emphasis on male-female differences in alterations of neural circuits mediating these relationships. Dr. Andersen will present a state-of-the-art translational approach showing how a dopamine receptor mediated “switch” underlies age-related periods of drug-induced “protection” or drug-induced vulnerability associated with addiction with the ultimate goal of developing targets that can be used in teenagers to reduce addiction. The workshop will end in a 40-minute panel discussion led by Dr. Vorhees and Dr. Talpos on the evidence for increased susceptibility and identification of data gaps that will encourage cross-fertilization of ideas for development of novel screens for the potential of chemicals and drugs to increase susceptibility of teenagers to SUD. This session introduces an important new scientific area to SOT; namely, the vulnerability of the adolescent brain to chemical/drug exposure. It will be of interest to a broad audience, including those interested in neurotoxicology, public health, clinical and translational toxicology, drug discovery toxicology, and social implications of this science.

Human variability is an important consideration in toxicology and risk assessment. Significant advances have been made to address differences between the adult and fetus/children or the elderly. In contrast, adolescent teenagers are generally considered to be smaller adults when considering the toxic effects of drugs and chemicals. With the recent legalization of recreational marijuana in California, it is generally considered to be quite conservative, it does not accurately portray what an infant will be exposed to during normal diaper wear. In many cases, the actual exposure to substances used in the making of a diaper will be negligible. However, it is also recognized that analytes might be detected that were not in the supplier disclosures. To develop a more rigorous approach to the safety evaluation of diapers, we developed methods that involve subjecting a diaper to conditions reflective of consumer use, including use of physiologically-relevant amounts of solvent (surrogate for urine), and applying an amount of pressure to the diaper relevant to that of an infant sitting. It will be of interest to a broad audience, including those interested in neurotoxicology, public health, clinical and translational toxicology, drug discovery toxicology, and social implications of this science.
Drug addiction is a particularly nefarious form of neurotoxicity, inasmuch as one of the principal neurotoxic effects is to cause those exposed to dose themselves with more of the toxic chemical. Adolescence is an especially vulnerable time for the initiation of drug addiction. Neural systems involved with addiction are still developing during that period. Nicotine is the principal neuroactive chemical in tobacco and is central to the addictiveness of tobacco. The great majority of people who become addicted to tobacco start during adolescence, when the brain is still undergoing important phases of development. Does adolescent onset potentiate addiction? This is difficult to determine in humans since there are a number of different causative factors underlying the substantial adolescent onset drug use problem. The same genetic/environmental conditions that predispose individuals to tenacious addiction also could induce them to start using early; drug use during adolescence could shape brain development around the addictive behavioral pattern; or the increased plasticity of adolescence could be a more fertile ground for the growth of addiction. With animal models we can determine the causative nature of adolescent vs. adult-onset nicotine self-administration with random assignment to drug-taking groups that is not possible in humans. We have found in a series of studies that male and female rats that are given access to nicotine self-administration during adolescence self-administer significantly more nicotine than rats first given access in adulthood. Male adolescent rats have higher rates of nicotine self-administration than female adolescent rats; female rats that start nicotine self-administration in adolescence have a more persistent elevation of self-administration as they mature into adulthood. Adolescent-onset nicotine self-administration also causes long-term impairment in regulation of nicotine intake. In other studies, we have shown long-term adverse behavioral effects of gestational nicotine. Like many chemicals nicotine has differential neurobehavioral toxicity depending not only on dose but also age.

**Sex-Dependent Effects of Delta-9-Tetrahydrocannabinol on Adolescent Brain-Behavior Relationships**

D. Dow-Edwards. SUNY Downstate Medical Center, Brooklyn, NY. Sponsor: A. Li

With increasing legalization of marijuana, the public hears little about the toxic effects of the drug. Marijuana can interfere with experience-dependent plasticity, the foundation of cortical neural circuitry development during adolescence which is largely completed by adulthood. During adolescence, delta-9-tetrahydrocannabinol (THC) administration alters brain-behavior relationships differently within circuits subserving affect, reward and cognition. These alterations exhibit period-specific and sex-specific vulnerabilities. For example, THC administration during the prepubescent period produces significantly greater effects on affective behavior than later exposure and since males and females undergo puberty at different ages, the age of maximal effect is different in males and females. We also have data showing that males and females respond differently to early stress such that during mid-adolescence, females show alterations in cannabinoid receptors in a specific constellation of brain regions while males show a different constellation of effects. Also, studies have demonstrated that adolescent exposure to THC produces permanent and even transgenerational effects on reward circuits by increasing the consumption of drugs of abuse while similar exposures to the adult do not. Emphasis will be placed on marijuana toxicities determined in relevant animal models in comparison with available human data in this relatively understudied population. The dose-response nature of the relationship between marijuana and neurotoxicity will be highlighted to emphasize the message that consuming less marijuana, less frequently and beginning at an older age will reduce the overall impact of smoking marijuana during adolescence on adult brain function.

**Panel Discussion with Drs. Charles Vorhees (Cincinnati Children’s Hospital) and John Talpos (US FDA/NCTR)**

C. V. Vorhees1, and J. C. Talpos2. 1Cincinnati Children’s Hospital Medical Center, Cincinnati, OH; and 2US FDA/NCTR, Jefferson, AR.

Two discussants will preview the presentations prior to the meeting so that there will be vigorous productive discussion on the evidence for increased susceptibility and identification of data gaps. This abstract highlights some of the questions that break down some of the issues that need to be discussed in order to address the overarching question of whether there are biological markers unique to adolescent vulnerability to dependence toxicity. There are human data indicating that drug initiation during adolescence poses a greater risk for addiction and long-term effects than when drug use starts later in life. To what extent do the human data allow distinction between whether the increased risk is due to biological immaturity, underlying biological susceptibility to dependence, or psychosocial and environmental factors? There are numerous studies testing the effects of drugs on adolescent rodents but every lab seems to define the adolescent period differently. What is the definition of adolescence in rodents and humans, how is it differentiated from puberty, and is it the same in males vs. females? Dopamine and dopamine receptors play key roles in addiction and dopamine projections undergo synaptic pruning during adolescence: what is the role of these processes in the vulnerability of the adolescent brain? What evidence indicates that adolescent exposure is unique and qualitatively or and quantitatively different from the same exposure to adults? To what extent does this evidence support specific behavioral, neurochemical or other endpoints as unique biomarkers of adolescent vulnerability to dependence toxicity. Does the evidence suggest that these biomarkers depend on the specific drug or are there consistent patterns of change across different classes of drugs? What, if anything, can science practically contribute as recommendations for clinical practice or drug development toxicity evaluations to reduce or prevent addiction/drug abuse in teenagers? Dr. Vorhees studies the developmental effect of chemicals using neurobehavioral and genetic animal models of CNS disorders. Dr. Talpos worked in a drug-discovery setting developing pro-cognitive treatments for psychiatric and neurodegenerative disorders prior to joining US FDA where he runs the nonhuman primate translational cognitive program.
Influenza A viruses (IAV) cause severe disease in humans and are a significant public health problem. Contemporary epidemiology studies show that dioxin and PCB levels are associated with increased incidence and severity of respiratory tract infections and poorer vaccine responses in infants and children. These compounds bind the aryl hydrocarbon receptor (AhR), an environment sensing transcriptional regulator. In addition to dioxins and PCBs, humans are exposed to other AhR ligands regularly, further emphasizing the need to elucidate how AhR signaling alters host immune responses during viral infection. The mechanisms by which AhR signaling modifies antiviral immune responses are poorly understood. One cell type critical in mediating antiviral host responses is the dendritic cell (DC). DCs are highly specialized antigen presenting cells and bridge innate and adaptive immune responses. DC function is perturbed following exposure to AhR ligands, and this is directly tied to poorer outcomes following in vivo IAV infection. Using a combination of FACS and RNA-Seq, we show that AhR activation during IAV causes significant changes to the DC transcriptome, including genes associated with viral uptake and processing. A major virulence factor of IAV, the non-structural protein 1 (NS1), plays a role in influencing DC gene expression and function. Utilizing state-of-the-art fluorescence expressing IAV, we show that AhR activation increases IAV levels within infected DCs, suggesting that AhR signaling may affect viral responses within DCs. IAV lacking NS1 protein (∆NS1) is replication defective. Infection of mice with ∆NS1 IAV combined with AhR activation did not alter morbidity or mortality; however, serum anti-IAV antibody levels were significantly reduced. These data suggest that AhR activation may alter the ability of DCs to stymie IAV NS1 function. Thus, AhR activation modulates intracellular antiviral defense systems in DCs, providing new mechanistic insight to explain why exposure to environmental AhR ligands is associated with greater morbidity and decreased adaptive immune responses upon primary viral infection.

**Mechanism(s) of Th2 Polarization in Mouse CD4+ T Cells Exposed to the Food Preservative, tBHQ**

Michigan State University, East Lansing, MI.

The United States has seen a dramatic increase in food allergy prevalence over recent decades. Though the etiology of this disorder is multifactorial, environmental factors, including certain food additives, have been implicated. tert-Butylhydroquinone (tBHQ) is a food preservative known to activate the nuclear factor erythroid 2-like 2 (Nrf2) transcription factor to induce antioxidant gene expression. Data from our lab suggest a previously unknown immunomodulatory role of Nrf2, where tBHQ activation induced Nrf2-dependent skewing of CD4+ T cells towards a Th2 (allergic) phenotype. Polarization resulted in increased production of Th2 cytokines (IL-4, IL-5, and IL-13) and DNA binding of the master regulator of Th2 differentiation, GATA3. To date, the molecular mechanism(s) responsible for increased GATA3 activity and subsequent Th2 cytokine protein production are unknown and elucidation of this mechanism(s) is the goal of this study. Primary mouse CD4+ T cells (WT and Nrf2-null) were treated with tBHQ and GATA3 activity was analyzed. Additionally, Nrf2 binding to putative AREs identified within an intron and the promoter of GATA3 was demonstrated in D10 cells. The results of these experiments suggest that GATA3 is regulated at the transcriptional level by Nrf2. First, GATA3 gene expression and protein production increased after tBHQ treatment in WT, but not Nrf2-null, mice. Second, Nrf2 binding to putative AREs within an intron and the promoter of GATA3 was demonstrated in D10 cells. Finally, the functionality of these putative AREs was established by luciferase assay. These data demonstrate Nrf2-dependent upregulation of GATA3 in Th2 polarization of CD4+ T cells, which could have potential implications in Th2 mediated disorders such as food allergy. This study was supported by NIH grants ES024966 and ES725530.

**Anti-Metallothionein Management of Chronic Inflammatory Disease**

M. A. Lynes, S. Bhandari, V. Robinson, C. Melchiorre, and J. Messina.
University of Connecticut, Storrs, CT.

Metallothionein (MT) is upregulated as a consequence of cell and tissue encounters with a variety of stressful conditions. Basal MT levels are responsible for management of essential divalent heavy metal cations and redox metabolism, with the exception of Cu and Zn, which are primarily maintained in healthy individuals and serve as a target for reactive oxygen species. In light of these essential housekeeping roles, research has largely focused on the intracellular pool of MT and how stress can disturb these housekeeping roles. In that context, we have found that MT manages intracellular free Zn in a range that can modify intracellular signal transduction in CD4+ T cells. Although it lacks a signal peptide for export, a less recognized extracellular pool of MT can be found in cases of stressor exposure. Its release is not blocked by Brefeldin A or monensin. Unlike some heat shock proteins, MT does not appear to be released via the exosome pathway of unconventional protein secretion. This extracellular pool influences the progression of humoral responses to T-dependent antigen challenge. As a consequence of its sequence similarities to closely linked chemokine genes, we have explored the ability of extracellular MT to act both as a chemotactic factor itself, and to interfere with the cellular responses to other chemokines. MT is able to initiate chemotaxis of a variety of cell types, including monocytes, macrophages, T lymphocytes, spleenocytes, and cloned mammary tumor cells. This movement can be blocked with either cholera toxin or pertussis toxin, suggesting that MT initiates chemotaxis via interaction(s) with G protein-coupled receptors (GPCR). Inhibitors of signaling elements (e.g. Arp 2/3 and PLC) downstream of GPCRs can block MT-mediated chemotaxis. Pre-incubation of Jurkat T cells with MT blocks the subsequent response to CXCL12 (SDF-1α), a known ligand for CXCR4 and SDF-1α can block MT-mediated chemotaxis. Moreover, AMD3100, a known antagonist of SDF-1α binding to CXCR4 can also block MT-mediated chemotaxis. A monoclonal antibody to MT, clone UC1MT, has been shown to interfere with MT-mediated chemotaxis, suggesting that UC1MT might be able to diminish inflammation in vivo when stress-induced MT is released from cells to establish a pro-inflammatory positive feedback loop leading to inflammatory disease. Treatment in several mouse models of inflammatory bowel disease (IBD) with UC1MT, including an adoptive T cell transfer model, has been found to significantly diminish the progression of that disease.
Gastrointestinal disorders are highly prevalent among veterans who suffer from Gulf War Illness (GWI), a series of pathological events that plague the veterans of the first Gulf War (1990-1991). Most of the associated pathologies have been ascribed to chemical exposures like Pyridostigmine Bromide (PB) and insecticide Permethrin, diethyltoluamide (DEET) and organophosphates. Symptoms include fatigue, pain constipation, and diarrhea similar to inflammatory bowel disease (IBS). Our previous studies have linked some of these symptoms to an altered gut microbiome which results in inflammation in the gut. The present study uses a mouse model of GWI and investigates the role of a unique virome and phageome signature in influencing the microbiome. The results showed that the alpha diversity that depicts virome abundance decreased significantly in GW-chimical treatment while antibiotic treatment restored their diversity. Further, our study for the first time has successfully tracked a phageome signature in a GWI rodent model. The results showed that Bacteriophages of family Siphoviridae, known to attack probiotic bacteria increased by 40% compared to the control groups, while family Podoviridae was reduced significantly. The results associated strongly with alteration in the microbiome with a loss in Bacteroidetes and increase in Firmicutes phyla, that has been reported in other bowel disorders such as IBS and IBD. Furthermore, mice treated with war theatre chemicals (PB+PER) that had decreased viral diversity and suppressed Siphoviridae phage showed an increase in claudin-2 expression and a reduction in occludin tight junction protein. The above group also had an increase in mRNA expression of inflammatory markers CD68 and IL-1β. Antibacterials restored viral diversity while treatment with antiviral drugs caused a marked increase in inflammatory markers compared to antibiotic-treated mice. Taken together, these results indicate that bacteriophages might greatly influence the health of the gastrointestinal tract via regulating the microbiome and paves way for a possible therapeutic strategy.

Inorganic arsenic (iAs) is a potent carcinogen and immunotoxicant, which poses a risk to millions of people worldwide through the consumption of contaminated water and food. iAs exposure in adults and children has been correlated with increased gastrointestinal and respiratory tract infections, including tuberculosis (TB) and influenza, often in a sex-dependent manner. Environmental exposures are thought to contribute to the persistent global burden of vaccine preventable infectious diseases. However, it is unclear what role the sex-specific mechanisms have played in these phenomena. Studies in animal models and human populations suggest the aryl hydrocarbon receptor (AhR) provides a link between environmental exposures and immune responses later in life, but little is known about the cellular and molecular mechanisms driving these durable changes. Recently, we showed that developmental AhR activation, by maternal exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD, the prototype AhR agonist), impairs CD4+ T cell responses to influenza A virus (IAV) infection in adult offspring. Moreover, the damped CD4+ T cell response to IAV can be transferred to mice that were not exposed during development. This suggests that these changes are laid down during development, are long lasting, and implicates altered epigenetic regulation as a potential mechanism. Since DNA methylation is an epigenetic system that influences CD4+ T cell proliferation and differentiation, we hypothesize that developmental AhR activation alters immune responses via changes to DNA methylation. We utilized whole genome bisulfite sequencing to map how developmental exposure impacts DNA methylation in CD4+ T cells before and after infection. Developmental exposure results in differential methylation and an enrichment of gene ontology categories related to differentiation and immune response. Differentially methylated regions reflect a combination of hyper- and hypo-methylated regions, and span all genomic features. To determine whether altered DNA methylation is responsible for impaired CD4+ T cell responses, we treated developmentally exposed mice with S-adenosylmethionine (SAM) or zebularine to enhance or decrease DNA methylation, respectively. Following infection, SAM restored the expansion of CD4+ T cells in TCDD exposed offspring. It also reversed the dampened Th1 cell response. Zebularine rescued the diminished frequency of Th1 and Thb, but it did not alleviate suppression of CD4+ T cell expansion. Taken together, these results indicate that altered DNA methylation is a mechanism by which developmental exposures cause durable changes in antiviral immunity, and that hyper- and hypo-methylation regulate distinct aspects of CD4+ T cell responses to infection.

The transcription factor nuclear factor erythroid-derived 2 like-2 (Nrf2) is activated by a number of cellular stressors, such as reactive oxygen species and electrophilic compounds including tert-butylhydroquinone (tBHQ), a widely used food preservative. Upon activation, Nrf2 upregulates many cytoprotective genes, including genes involved in antioxidants defense, detoxification, and phase II metabolism. Nrf2 plays a role in the regulation of immune responses, with an established role in the regulation of inflammation in animal models. Studies have also indicated cell-type specific roles for Nrf2 in immune cells such as dendritic cells, macrophages, and T cells, among others. In murine helper (CD4) T cells, Nrf2 activation skews CD4 T cell differentiation towards a Th2 (allergy-like) phenotype and has differential effects on activation. However, the role of Nrf2 in human CD4 T cells remains unclear. Previous studies demonstrated that the Nrf2 activator tBHQ inhibits events of primary human CD4 T cell activation, but the role of Nrf2 in these effects was not determined. To address this gap, primary human CD4 T cells were transfected with siRNA targeting Nrf2 to generate Nrf2-deficient primary human CD4 T cells. These cells, along with the corresponding scrambled control siRNA -transfected cells, were used to determine the role of Nrf2 in tBHQ-mediated effects on early T cell activation. tBHQ treatment followed by T cell activation with antiCD3 antiCD28 inhibited induction of the cytokines IL-2, IFNγ, GM-CSF, and TNFα, and the cell surface proteins CD25 and CD69 in both scrambled control and Nrf2-targeted siRNA transfected cells, suggesting these effects are Nrf2 independent. RNA-seq analysis identified differentially expressed genes between the scrambled control and Nrf2-deficient cells, suggesting there are genotype differences in early T cell activation. In addition, the RNA-seq analysis showed Nrf2+ independent and Nrf2-dependent effects of tBHQ at the RNA level. This indicates a potential role for Nrf2 in aspects of primary human T cell activation and differentiation. This work is funded by NIH grants ES018885, ES023755 and ES024966.
3245 Lipopolysaccharides Increased the Expressions of Interleukin-8 and Interleukin 1-Beta in the Macrophages Differentiated from ML-1 Monocytes and Upregulation of Cellular Antioxidants Reduced Lipopolysaccharides–Induced Inflammation

Sepsis is a condition known to damage bodily tissues and organs caused by a dysregulated response to infection by the body. It causes millions of deaths annually throughout the world and is the primary cause of death in hospitalized patients. However, the precise mechanisms underlying this illness remain to be defined. Macrophages have been suggested to play an essential role in the initiating the cascade of inflammatory cytokines and the pathophysiology of septic shock. In the current study, we used phorbol-12-myristate-13-acetate (PMA) to differentiate the ML-1 monocytes into macrophages as demonstrated by an increase in the expression of Cluster of Differentiation 206 (CD206, a macrophage differentiation marker), and further investigated if macrophage antioxidants would modulate LPS-induced inflammation. Cellular reduced glutathione (GSH) and NAD(P)H:quinone oxidoreductase 1 (NQO1) are two important cellular defenses against oxidative and inflammatory stress. Triterpenoid 2-cyano-3,12-dioxoolean-1,9-diene-28-imidazolide (CDDO-im) was used to upregulate expression of GSH and NQO1. Our data demonstrated treatment with LPS at 100 ng/mL dramatically increased the levels of inflammatory gene expression such as interleukin-1 beta (IL-1beta) and interleukin-8 (IL-8) in the macrophages differentiated from ML-1 monocytes. Interestingly, induction of GSH and NQO1 by CDDO-im afforded protection against the LPS-induced expression of IL-1beta and IL-8 suggesting that GSH and NQO1 may play an important role in the LPS-mediated inflammatory response. Together our data demonstrated that upregulation of endogenous cellular antioxidants could attenuate LPS-induced inflammation. This study may contribute to advancing our understanding of sepsis, a life-threatening illness.

3246 Identification and Characterization of a Sensitive Immunologic Target of TCDD: CDS+ Innate-Like B Cells

L. Blevins, J. Zhou, N. Wawee, R. Crawford, S. Bhattacharya, and N. Kaminski. Michigan State University, East Lansing, MI.

Xenobiotic-mediated activation of the aryl hydrocarbon receptor (AhR) is immunotoxic in a number of immune cell types, with the B cell being a well-established sensitive target. Recent advances in immunology have provided evidence that the B cell repertoire is a heterogeneous population, with subpopulations exhibiting vastly different cellular and functional phenotypes. Recent work from our laboratory identified the T cell specific kinase lck as being differentially regulated by 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), which is a potent activator of AhR. While lck is primarily expressed in T cells, a broad class of B lymphocytes termed innate-like B cells (ILBs) which are critical mediators of innate immunity through constitutive secretion of polyvalent natural immunoglobulin M (IgM). We hypothesized that CDS+ ILBs may be sensitive to AhR-mediated immunotoxicity. Indeed, when CDS+ B cells were isolated from the TCDD-treated pool and treated with TCDD, they showed increased expression of CDS, CD5, and interleukin-8 (IL-8) in response compared to CDS+ B cells. Further, characterization of the CDS+ population indicated increased basal expression of AhR and cytochrome p450 family 1 member a1 (Cyp1a1). Indeed, the levels of AhR-mediated suppression of the IgM response from individual donors strongly correlated with the percentage of the B cell pool that were CDS+, suggesting that CDS+ B cells are more sensitive to AhR-mediated immunotoxicity. Together these data highlight the sensitive nature of CDS+ ILBs to AhR activation and provide insight into mechanisms associated with AhR activation in human B cells.

3247 The Synthetic Food Additive TBHQ Impairs Host-Defense to Influenza Infection

In the 2017/18 flu season, the United States had 80,000 deaths attributed to influenza virus infection. Despite enhanced vaccination efforts, influenza infection rates and related deaths have not improved, suggesting a disconnect between clinical efforts and patient outcomes. Therefore, it is important to consider other factors that may contribute to worsened influenza burden and poor vaccine efficacy. We previously showed that the widely-used food additive butylhydroxyanisole (BHA), impairs post-infection cytokine secretion in T cells and T1 cell polarization (important in anti-viral defense) through activation of NFκB, a stress-activated transcription factor. Accordingly, we hypothesized that TBHQ consumption would impair host-defense against influenza virus infection. To test this hypothesis, we fed C57BL/6J mice control or TBHQ-containing diets prior to infection with influenza A/PB/1934 (H1N1). TBHQ consumption reduced cytotoxic T cell infiltration in the lung, CD4/CD8 T cell activation and effector function, influenza-specific T cell numbers, and viral clearance. Additionally, TBHQ substantially increased expression of the inhibitory receptor, CTLA-4, providing a novel mechanism by which TBHQ can suppress T cell activation. Upon primary exposure to influenza, weight loss was unaffected by TBHQ consumption. However, the diminished T cell response by TBHQ led to exaggerated weight loss and prolonged recovery in a secondary infection model, suggesting that TBHQ impaired the memory response to influenza infection. It should be noted that the NOAEL used to establish the allowable daily intake (ADI) of TBHQ is 72 mg/kg/day, and the current study’s dose was between 1-3 mg/kg/day, suggesting a need to re-evaluate the current ADI. Moreover, the doses used in our studies are easily achievable with a western diet. Overall, our studies show that consumption of a physiologically-relevant dose of TBHQ impairs the primary immune response to influenza virus infection leading to worsened outcome during secondary infection, which would be expected to result in poor vaccine efficacy.

3248 A Multi-Stakeholder Dialogue on Using Proprietary Modeling Platforms to Support Risk Assessment and Regulatory Decisions

A. Hofstra. Syngenta Canada Inc., Guelph, ON, Canada.

Powerful modeling platforms embedded with large databases allow researchers to more efficiently generate robust predictions to evaluate a specific endpoint (e.g., potential toxicity of a compound) even when little data are available. For example, several proprietary physiologically based pharmacokinetic (PBPK) modeling platforms contain extensive demographic, physiologic, and biochemical databases, and simulate internal dosimetry of a compound to assist in extrapolations necessary to estimating human health risks from exposures to environmental chemicals, or evaluating safety and efficacy of drug compounds. Being able to predict human relevance is of keen interest to diverse groups including regulatory agencies that use PBPK models to determine safety of chemicals, drugs, and consumer products; regulators; and the general public. Proprietary models have been used extensively in certain regulatory arenas, such as drug development, and are new to others, such as pesticide registration. The primary concern that prevents a regulatory agency from incorporating predictions generated from proprietary modeling platforms into their decision-making processes is the lack of open access to the platforms and underlying models and databases. In this case, regulators, academics, or members of the general public may not be able to replicate the model predictions, or to evaluate the predictive capability of the model within a desired chemical space. This roundtable assembles model developers, model users (e.g., chemical registrants and academics), risk assessors within regulatory agencies, and external stakeholders to share their experience and perspectives on both scientific and nonscientific challenges that limit the use of proprietary modeling platforms in regulatory assessment. While this session will focus the discussions on PBPK modeling platforms, the perspectives are applicable to other modeling platforms. The session will start with brief presentations of different perspectives on the utility of proprietary modeling platforms in both development and safety assessment of chemicals, drugs, or consumer products; processes involved in validating/evaluating model assumptions and predictions; and considerations for protecting intellectual property. Following the presentations, there will be a 50-minute moderated discussion among presenters and audience addressing questions such as, “Is evaluation of a model by the platform developer sufficient to provide confidence in the outputs of a model?” and, “Is access to all modeling platforms and databases used to generate model outputs required to verify the output?” This roundtable gathers parties involved in the use of proprietary models to explore strategies that...
Nerve Agent and Pesticide Poisoning: Best Practice Methodologies for Assessing Long-Term Health Effects

L. Roszell, Army Public Health Center, Aberdeen Proving Ground, MD.

Exposure to nerve agents, such as chemical warfare agents and organophosphorous pesticides, is a highly topical subject in toxicology, unfortunately because of their recent use in civilian and military conflict. Nerve agent poisoning after acute high doses is often fatal; however, if life-threatening symptoms can be controlled through medical intervention, many people can survive the acute lethal toxicity. There is an existing body of literature that strongly suggests that nonlethal adverse health effects occur in survivors of acute nerve agent exposure. These "long-term" health effects include neurochemical, neuropathological, and behavioral deficits that occur within days, weeks, or even many years after the exposure. The acute lethal effects of organophosphorous (OP) nerve agents and pesticides have been well described, and data exist for the assessment of hazard and risk. However, understanding and assessing the risk of long-term sequelae is less clear due to the heterogeneity and rigor of human and animal studies. Data on the long-term effects are also important for developing effective medical interventions, since some of the studies describe persistent effects that can significantly reduce quality of life. Often risk assessments are largely retrospective, relying on qualitative data by estimating signs and symptoms at the time of exposure and how long it took for them to develop. The session will present examples of methods for assessing long-term effects in humans and animals following acute exposures to OP nerve agents and pesticides. The session will begin with an overview of the issue, including examples of significant incidents and efforts to retrospectively link exposures to outcomes. The next presenter will describe an NIH/NTP Systematic Review of long-term neurological effects of sarin. This will be followed by a presentation describing a toxidrome-based, subject-matter expert (SME)-informed approach for assessing the risk of long-term health effects following acute exposures to OP nerve agents and pesticides, and the fourth presentation will discuss preclinical models for assessing the neuro-pathological changes induced by acute intoxication with OPs, and the short- and long-term functional deficits associated with the acute exposures. The session will conclude with a panel discussion.

Overview: Why Do We Need to Understand Long-Term Adverse Health Outcomes following Acute Exposures to Nerve Agents?

L. E. Roszell, Army Public Health Center, Aberdeen Proving Ground, MD.

The issue of long-term health effects caused by acute chemical exposures is relevant to both military and civilian populations. From a military perspective, understanding such risks would assist planners in better assessing the overall health risk of a mission and assist medical personnel in the long-term care of soldiers. Similarly, from a civilian perspective, understanding would improve health risk assessment capabilities associated with accidental or intentional exposures as well as assist medical personnel in the long-term care of civilians. Acute exposures may be the result of an intentional or unintentional chemical release. For example, twelve people were killed and many more injured when sarin was released on the Tokyo Metro in 1995. More recently, both civilians and soldiers were exposed to the organophosphorus (OP) nerve agent sarin when it was used as a weapon in the Syrian conflict. There are also numerous reports of agricultural workers acutely poisoned with OP pesticides. A major question is whether there are long-term adverse health effects subsequent to surviving sublethal acute exposures to OP chemicals. Because most studies to date have been retrospective it is difficult to definitively link illness to exposure. Current efforts to address this issue include systematic literature reviews and laboratory studies. If adverse effects are believed to be a result of OP exposure, a critical follow-on question relates to the severity of the long-term effect; more severe effects might require greater resources to manage and treat. Filling these data gaps will provide information that can be used by military planners to assess overall risk to US forces, and by civilian planners to inform long term risk and medical care.

A Systematic Approach for Assessing Long-Term Effects of Sarin

D. A. Jett, R. Blain, C. Sibrizzi, P. Hartman, and A. Rooney, NIH-Countermeasures Against Chemical Threats (CounterACT) Research Program, Bethesda, MD; ICF International, Fairfax, VA; ICF International, Durham, NC; and NIH/NIEHS, Research Triangle Park, NC.

Several literature reviews of the long-term neurological effects following exposure to sarin have been published. However, a systematic review of the evidence has not been performed in which selection criteria were clearly stated and consistently applied; where a broad hierarchy of evidence is considered including uncontrolled studies and case-reports or case series; and in which individual studies were assessed for internal validity or risk of bias. A review of data on long-term effects of acute exposure has also never been done where the search was narrowed to eliminate confounding elements such as the possibility of multiple chronic exposures to the agent and exposure to other agents, and where the focus is on a specific set of outcome measures (neurological). The National Institutes of Health (NIH) is conducting a systematic review that focuses on the neurological sequelae following acute exposure to sarin nerve agent. This review is conducted in partnership with several NIH Institutes, including the National Institute of Neurological Disorders and Stroke (NINDS), which leads the NIH CounterACT program, and the National Institute of Environmental Health Sciences (NIEHS), National Toxicology Program, Office of Health Assessment and Translation (OHAT), which is providing expertise in the conduct of systematic reviews for environmental hazards. The specific literature search is led by informatics specialists from the NIH Library who also have substantial experience in the conduct of systematic reviews. Early results confirm the heterogeneity of the data among different studies, and difficulty in finding common data elements among human, animal, and mechanistic data streams. Despite these and other caveats, the results suggest there are long-term neurological effects of acute sarin exposure in humans and animal studies, but there are uncertainties in the existing data, and several data gaps yet to be filled. This systematic review will help understand better the potential long-term effects of organophosphorous nerve agent and pesticides.

A Novel SME-Informed Approach to Assess the Likelihood of Long-Term Injury following Acute Exposures

K. Wegman, Battelle Memorial Institute, Columbus, OH. Sponsor: L. Roszell

The acute effects of many chemicals are well described with supporting data through traditional toxicology studies. In contrast, long-term health effects resulting from a single acute exposure are sparsely supported by anecdotal data. Assessing the risk of long-term sequelae depends entirely on qualitative data or limited data sets with severe limitations. To overcome these un-
certainities and limitations, a novel toxidrome-based, subject matter expert (SME)-informed approach was developed to derive long-term health effect estimates for the cholinergic toxidrome based on the currently available data. Using the Delphi Method, ten SME estimates were obtained for the likelihood of long-term mild, moderate or severe health effects following an acute mild, moderate, severe, or life-threatening health effect from an acute exposure. Responses from all SMEs were combined into a representative consensus and reviewed by all SMEs for approval. The consensus SME input was then linked with chemical-specific, acute dose-response data for chemicals from the cholinergic toxidrome to yield chemical-specific, long-term health effect curves. This toxidrome-based approach allows for applicability across a range of chemicals by applying the toxidrome level results to individual chemicals with similar acute clinical signs and symptoms. The results of this approach provide risk assessors and planners with a method to estimate long-term health effects following acute chemical exposures until more robust data are available.

### Preclinical Models to Assess Long-Term Neurological Sequelae of Acute Intoxication with Organophosphate Nerve Agents

P. J. Lein, University of California Davis, Davis, CA.

Preclinical models are critical for corroborating clinical and epidemiological data and for identifying mechanisms and biomarkers of disease. Given the challenges in studying in vivo health effects of acute, sublethal exposures to chemical warfare agents, the development of relevant preclinical models has been an active area of research. This talk will: (1) provide an overview of the various models that have been developed to assess the long-term neurological sequelae of acute intoxication with OP nerve agents and OP pesticides, including in vitro and in vivo models; (2) describe the short- and long-term functional deficits that have been described in these models following acute OP intoxication, which range from molecular effects (calcium dysregulation) to neuropathology (neurodegeneration and neuroinflammation) to behavioral deficits, including recurrent seizures; and (3) discuss the relevance, and limitations, of these models to the human condition, including how data from animal models may be useful in identifying critical gaps in the human literature.

### New Mechanistic Insights into Causes and Outcomes of Epigenetic Dysregulation by Carcinogenic Metals

C. Jin, New York University School of Medicine, New York, NY.

Metal contamination impacts hundreds of millions of people in the world. Metal exposure can cause human diseases including cancer. Carcinogenic metals are in general considered to be weak mutagens, suggesting that mechanisms other than genetic changes play major roles in metal-induced carcinogenesis. Epigenetic mechanisms have recently emerged as important players in response to metal exposure. Epigenetic regulations include DNA methylation, histone modifications, microRNA expression, incorporation of histone variants, and nucleosome positioning and chromatin accessibility. Most studies of metal-induced epigenetic dysregulation have focused on changes in epigenetic profiles in terms of DNA methylation, global histone modifications, and microRNA expression. However, mechanisms that control these changes and consequences of these changes are not well examined. Moreover, little is known about genome-wide changes in chromatin accessibility and assembly of variant histones following metal exposures. While high-throughput sequencing technologies such as RNA-seq, CHIP-seq, and Methyl-seq have recently been applied for studies of metal-induced epigenetic regulation, newer technologies such as ATAC (Assay for Transposase-Accessible Chromatin) have not been as widely used in studies involving metal toxicity. This symposium aims to highlight recent advances in environmental epigenetics, focusing on new molecular insights into epigenetic dysregulation by metal exposure and on the use of cutting-edge new technologies in studies of environmental epigenetics. The first speaker identifies a set of differentially methylated genes in exfoliated urothelial cells (EUCs) in a cohort study. Promoter analysis shows that the arsenic-associated genes are enriched for the binding sites of canonical histone transcription factors known to play roles in carcinogenesis. The second speaker demonstrates hsa-miR-186 induction by arsenic exposure and how overexpression of hsa-miR-186 induces chromosomal instability in keratinocytes, providing a mechanism for induction of aneuploidy by arsenic exposure. In the third presentation, the speaker presents the changes in the levels of histone variants during arsenic-induced epithelial to mesenchymal transition (EMT) as well as a possible mechanism that causes differential methylation at specific genomic loci in arsenic-transformed cells. The fourth speaker uses cutting-edge new technologies such as DANPOS (Dynamic Analysis of Nucleosome Positioning and Occupancy by Sequencing) and ATAC (Assay for Transposase-Accessible Chromatin) to show how nucleosome positioning and chromatin accessibility are changed by chromium exposure. The fifth speaker uses an animal model to demonstrate polyadenylation of canonical histone mRNAs following nickel and arsenic exposures. In vitro studies further reveal that increase in polyadenylated canonical histone mRNAs disrupts nucleosome assembly of histone variants at active promoters. In summary, this symposium will provide attendees mechanistic and new aspects of epigenetic dysregulation by metal exposure and their implications in metal-induced carcinogenesis, as well as better understanding of new approaches for studying chromatin landscape following environmental exposures. Potential use of these epigenetic changes in cancer risk assessment will be discussed.

### Links between Arsenic-Associated DNA Methylation and Bladder Cancer

J. Rager, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Human population studies support that chronic exposure to inorganic arsenic (iAs) is associated with cancer of the bladder. This health effect, like many related to iAs, may be tied to epigenetic modification. In a cohort in Chihuahua, Mexico, we examined DNA methylation patterns associated with iAs and its metabolites in exfoliated urothelial cells (EUCs) that originate primarily from the urinary bladder, one of the targets of arsenic-induced carcinogenesis. A genome-wide, gene-specific strategy was used to assess promoter DNA methylation levels in EUCs from study subjects. The relationship between promoter methylation profiles and the intracellular concentrations of total arsenic and arsenic species was examined. A set of 49 differentially methylated genes (DMGs) was identified with increased promoter methylation associated with EUC tAs, iAs, and/or monomethylated As (MMAs) enriched for their roles in metabolic disease and cancer. Further analysis showed that a subset of the 49 arsenic-associated genes are also differentially methylated in bladder cancer tissue using The Cancer Genome Atlas (TCGA) repository. Both the arsenic- and cancer-associated genes are enriched for the binding sites of common transcription factors known to play roles in carcinogenesis, demonstrating a novel potential mechanistic link between iAs exposure, the DNA methylome and bladder cancer.

### hsa-miR-186 Overexpression Induces Aneuploidy in Human Keratinocytes

J. States, University of Louisville, Louisville, KY.

Arsenic exposure is known to induce aneuploidy and aneuploidy can play a major role in carcinogenesis. miRNAs can act as oncogenes or tumor suppressors and thus dysregulated expression can play a role in carcinogenesis. Linkage between dysregulated miRNA expression and aneuploidy is unknown. We have observed that hsa-miR-186 is overexpressed in squamous cell carcinoma samples from patients chronically exposed to arsenic in drinking water. The effect of hsa-miR-186 overexpression in keratinocytes on chromosomal stability was investigated in human keratinocytes. Ectopic expression induced an increase in fraction of cells with supernumerary chromosomes and also increased chromosomal structural abnormalities. Overexpression of hsa-miR-186 combined with incubation with 100 nM sodium arsenite increased the frequency of double minutes which are associated with gene amplification. hsa-miR-186 is an intronic miRNA embedded within the ZRANB2 gene. Further investigation on mechanism of hsa-miR-186 induction suggests that arsenite disruption of zinc fingers in ZRANB2 may result in increased transcription of the parent gene in which hsa-miR-186 is embedded. These results are consistent with and may provide a mechanism for induction of aneuploidy by chronic arsenic exposure.

### Chromatin Structural Changes and Function in Inorganic Arsenic-Mediated Cellular Transformation

Y. Fondue-Mittendorf, University of Kentucky, Lexington, KY. Sponsor: C. Jin

Inorganic arsenic (iAs) is a ubiquitous environmental toxicant implicated in carcinogenesis. Epigenetic regulation is a potential mechanism by which iAs causes cancer. To decipher this mechanism, we carried out high resolution profiling of the epigenetic changes as cells go through iAs-mediated cellular transformation or epithelial to mesenchymal transition (EMT). Two high-resolution methods were used to profile these epigenetic changes: top-down mass spectrometry to quantify the changes in the levels of H2B variants; and Methyl-seq to identify DNA methylation changes. iAs exposure induces car-
Human exposure to well-established carcinogenic metals nickel and arsenic is associated with increased incidences of various cancers including lung cancer. Although these metals have long been known to induce toxicity and carcinogenicity via epigenetic mechanisms, alteration in histone gene expression is scarcely studied. Canonical histone mRNAs are unique in that they are the only mRNAs in multicellular organisms that do not contain poly(A) tail in their 3′ ends and thus are unstable. Instead, they contain a conserved 26-nucleotide sequence in their 3′ ends, which is the binding site for the Stem-loop binding protein (SLBP). SLBP is essential for processing of the canonical histone pre-mRNA and the loss of SLBP has been shown to induce aberrant polyadenylation of canonical histone mRNAs. Previously we demonstrated that arsenic exposure induces polyadenylation of H3.1 mRNA (a canonical histone H3) in cells due to the loss of SLBP, which appeared to be attributable to arsenic-induced degradation of SLBP and an increase in poly(A)-containing H3.1 mRNA. Intriguingly, increase in polyadenylated H3.1 mRNA compromises assembly of H3.3 (a variant histone H3) nucleosomes at promoters of 2,000 most active genes. In addition, we found that transcription of histone H3.1 with a poly(A) tail causes a G2/M block in the cell cycle, chromosome instability, and DNA damage. To further distinguish between G2 and M arrest, we determined the cellular level of histone H3S10 phosphorylation, a mitotic phase specific modification, by flow cytometry assay. The phosphorylation of H3S10 was increased from 4.6% to 11% upon transcription of H3.1 poly(A) as compared with the control. We further found that transcription of H3.1 with a poly(A)-coding sequence induces a high incidence of cell transformation and these transformed cells form tumors in athymic nude mice. Furthermore, arsenic exposure of mice by inhalation results in the loss of SLBP and gain of polyadenylated H3.1 mRNA in lung tissues. These results suggest that the polyadenylation of canonical histone mRNAs is disruptive to chromatin structure and genomic integrity and may contribute to both arsenic- and nickel-induced carcinogenesis.
3263 Testicular Toxicants as Modifiers of Sperm Epigenetic States: Ethylene Glycol Monomethyl Ether as a Case Study

A. Stermer. Brown University, Providence, RI.

Many male reproductive toxicants adversely affect fertility through mechanistic targets in one or more distinct cell types in the testis. Regardless of the primary cell targeted by a testicular toxicant, the common thread among these compounds is impairment of spermatogenesis and/or sperm quality. Ethylene glycol monomethyl ether (EGME) targets a specific germ cell subset, the primary spermatocytes, and leads to germ cell apoptosis at high levels of exposure. We hypothesize that the sperm that develop from EGME-exposed germ cells, and their epigenetic contents delivered to an oocyte upon fertilization, may be compromised. We used 0, 50, 60 and 75 mg/kg EGME for 5 days as a case study, measuring small RNAs in sperm by next-generation sequencing 5 weeks after exposure. Our data illustrate dose-dependent changes in the small RNA populations after EGME exposure with significant increases in mRNA fragments and micro-RNA populations. Many of the individual mRNA fragments are decreased, specifically in the RNA population cellular survival and spermatogenesis pathways. However, there was a dose-dependent increase in number of unique mRNA fragments after EGME exposure. Many Piwi-associated RNAs (piRNAs) were differentially expressed with treatment, and there was a significant increase with EGME exposure in the number of these piRNAs that aligned to transposable elements. The small RNA endpoints have lower BMD values compared to histopathology or sperm motility endpoints. This study provides a mechanistic basis to link preconception exposure to EGME on offspring development and health through sperm quality.

3264 Male Preconception Phthalates on Sperm Epigenetics and Early-Life Development

J. Pilsner. University of Massachusetts Amherst, Amherst, MA. Sponsor: A. Timme-Laragy

Compelling data demonstrate that preconception environmental exposures can be embodied within the developing male germ cell through epigenetic marks. In turn, these epigenetic marks may impart information at fertilization to affect the trajectory of offspring health and development. Phthalates, a class of endocrine disrupting compounds (EDCs) used in plastics and personal care products, are ubiquitous environmental contaminants resulting in widespread human exposure. Phthalate exposures have been reported to cause a host of behavioral and reproductive health issues. In particular, phthalate exposure in males is associated with poor sperm quality, and more recently, with longer time to pregnancy, which suggests a sperm-derived effect. The proposed oral presentation at SOT 2019 will focus on our results from two ongoing studies; 1) our human cohort, Sperm Environmental Epigenetics and Development Study (SEEDS), and 2) our mouse model system, which utilizes divergent genetic backgrounds of parental mice that allows for allele-specific examination of DNA methylation in F1 offspring. Utilizing genome-wide DNA methylation approaches, we will present our findings on the effect of preconception phthalate exposure on sperm methylation and early-life development. Our findings in SEEDS show that male preconception anti-androgenic phthalates are associated with sperm DMRs and subsequent blastocyst quality. Additionally, our mouse data support our human findings, such that di(2-ethylhexyl) phthalate (DEHP) exposure results in altered DNA methylation in sperm and gene expression in F1 hybrid embryos. These results suggest that paternal adult environmental conditions may influence epigenetic reprogramming during spermatogenesis, and in turn, influence early-life development.

3265 Maternal Preconception Exposure to PFOS Affects Nutrient Content of Oocytes and Later-Life Pancreas Development

K. Sant. San Diego State University, San Diego, CA.

Before the placenta becomes fully functional late in the first trimester, the human embryo’s primary source of nutrients is the yolk—a cache of maternally-deposited lipids and proteins. The yolk quantity and composition deposited in oocytes can be disrupted by maternal exposures to environmental toxicants, with potentially profound impacts on the developing embryo and later-life health. In this study we used zebrafish (D. rerio), the nematode worm (C. elegans) and the fruitfly (D. melanogaster) to identify evolutionarily conserved changes in egg nutrient composition and later-life health following maternal exposure to the legacy toxicant perfluorooctanesulfonic acid (PFOS). We have shown that maternal perfluorooctane sulfonate exposure in the zebrafish altered nutrients loaded in to the oocytes resulting in lower amounts of protein and cholesterol. These exposures also impaired pancreatic organogenesis during the embryonic stage of the fish. In the fly we found that exposure of female adults to PFOS resulted in reduced egg numbers per female, a response reflective of inadequate nutrition in the egg chamber, and also a reduced expression of megalin, a gene that encodes for an important transporter of nutrients into the oocyte. In the worm, we also found that preconception exposure results in later-life elevation of triglycerides in the gonad, suggesting potential metabolic dysfunction. Overall, these data indicate that maternal preconception exposures can reduce oocyte quality and impair metabolic function at later-life stages.

3266 Does Exposure to Mitochondrial Toxicants during Germ Cell Development Result in Lifelong Alterations in Mitochondrial Function Mediated by Epigenetic Changes?

J. Meyer. Duke University, Durham, NC.

Growing evidence suggests that the toxic effects of certain chemicals on mitochondrial function can be highly persistent. This is critical because mitochondrial function influences organismal phenotypes related to chronic diseases such as metabolic diseases, cancers, neurodegenerative diseases, and reproductive disorders. The likelihood of persistent effects may be especially great for exposures of germ cells and gametes, because mitochondria undergo biogenesis and major functional changes during germine proliferation and gamete production. Furthermore, epigenetic patterns that can have long-term effects on cellular function are reprogrammed in the same timeframe. Using the model organism Caenorhabditis elegans, we are testing the hypothesis that pollutant exposures targeting mitochondria in germ cells result in persistent changes to histone modification that escape embryonic reprogramming and alter regulation of pathways governing mitochondrial metabolism in offspring. To date, we have found that developmental exposures to rotenone (a complex I inhibitor) and arsenic (which inhibits the function of multiple mitochondrial as well as non-mitochondrial proteins) can result in lifelong alterations in mitochondrial function (in particular, oxygen consumption) and organismal fitness. Metabolomic and genetic analysis of alterations resulting from arsenic-induced exposure suggest that this is a result of persistent alterations in insulin and mitochondrial oxidative stress pathways. In the case of rotenone, preliminary data (two replicates) demonstrated that F1 offspring of exposed (preconception) parents had 50—75% decreases in ATP-linked oxygen consumption, as well as decreases in basal and maximal, but not non-mitochondrial, oxygen consumption. This was true at all exposure levels, including levels that had no effect on growth.

3267 Potential Alternatives to Systematic Reviews: Evidence Maps and Scoping Reviews

B. Beverly. NIEHS, Research Triangle Park, NC.

Systematic reviews, with their comprehensive, transparent, and repeatable protocols, are rapidly becoming the gold standard. However, there is literature to assess environmental health questions. However, there are instances when a full systematic review may not be feasible or necessary to address particular questions or to make decisions (e.g., for funding, future research, or regulation). Interestingly, there are a variety of methods that can be used to answer questions in environmental health data that do not require (or are premature for) an exhaustive systematic review. Scoping reviews and evidence maps are systematic, transparent assessments that may be better suited for some research questions. These intermediate alternative products can be performed more quickly and are often used to inform systematic reviews (usually in the initial steps of problem formulation and development), and can also serve as publishable stand-alone products. Two major challenges of conducting systematic review for decision-making are the time and resources needed to complete the review. On average, systematic reviews can take more than 1,000 hours to complete and can cost over $100,000. Further, adult stage, suggestive of metabolic dysfunction. Overall, these data indicate that maternal preconception exposures can reduce oocyte quality and impair metabolic function at later-life stages.
3268 Brief Overview and Introduction to Systematic Review and Related Products

B. Beverly, NIEHS/NTP, Research Triangle Park, NC.

Systematic review is rapidly becoming the gold standard for addressing environmental health questions. The systematic review process involves the objective and transparent method of collecting and synthesizing data for reaching hazard conclusions on specific research questions. This overview will provide a brief review of systematic review methodology and the relatively recent uptake of systematic review practices from different environmental health groups. This overview will highlight the strengths and challenges of conducting systematic review in addition to briefly introducing the intermediate products (systematic maps and scoping studies) that can be used for decision-making for environmental health questions that will be discussed in subsequent presentations.

3269 Rigor and Resources for Systematic Reviews in Toxicology: Case Study Applications in Food Safety, Consumer Product Safety, and Environmental Health Risk Assessment

D. Wikoff, ToxStrategies, Inc., Asheville, NC.

Systematic review is a type of rigorous, evidence-based analysis for answering a specific research question. This methodology is rapidly being implemented globally in the field of toxicology, though is often met with resistance due to the resources required to conduct a high quality review. The objective of this presentation is to provide a demonstration of the rigor and resources required to conduct full systematic reviews in toxicology with the aim of helping practitioners to determine when such a review is needed. A systematic review of caffeine safety in healthy adults, pregnant women, adolescents, and children will be used as a case study to demonstrate key elements of conducting a systematic review according to standards from the Institute of Medicine. Broad in scope, this systematic review addresses five PECO questions and integrates >380 papers to develop conclusions. This case study will highlight the role of problem formulation in determining if and when a systematic review is needed, as well as the protocol development and topic-specific refinements needed for the application of systematic review methodologies originally developed for clinical medicine. The case study on caffeine will also address the utility of multidisciplinary teams, implementation of a priori methods, and application of systematic review to a very large evidence base. It will also highlight the need for refined guidance and frameworks unique to the conduct of systematic review (e.g., multi-endpoint reviews) in the fields of toxicology and risk assessment. Using other case studies, additional elements of systematic review which are commonly underappreciated will be addressed, including appraisal and integration of study validity via risk of bias, evaluation and integration of multi-stream evidence bases ([including mechanistic data], and application of such concepts in qualitative vs. quantitative assessments). Collectively, the case studies will characterize the rigor and resources required for the conduct of high quality systematic reviews—practical information needed for toxicologists and risk assessors to understand the benefits and challenges of conducting meaningful systematic reviews in the fields of toxicology and risk assessment.

3270 Systematic Mapping as a Tool for Regulatory Risk Assessment in Environmental Health: Tetrabromobisphenol A (TBBPA) as a Proof of Concept

T. Harrison. Lancaster University, Lancaster, United Kingdom. Sponsor: B. Beverly

Tetrabromobisphenol A (TBBPA) is the highest production volume brominated flame retardant on the market, finding extensive application in printed circuit boards and polymers. Regulatory interest in TBBPA can be found in its listing as a Toxic Substances Control Act (TSCA) work plan chemical in the United States, and in its selection as a Community Rolling Action Plan (CoRAP) Chemical in the European Union, making it an ideal candidate for exploration of the potential and practicalities of systematic mapping for regulatory decision-making. Key lessons learned from the construction of a proof-of-concept systematic map on the human health risks posed by TBBPA and the long-term implications for the conduct of chemical risk assessment are presented. These include how the production of a context-neutral evidence map necessitates development and implementation of new database techniques not previously used in systematic reviews or systematic maps, but long familiar in computer science. In particular, the value of graph databases—the technology underpinning ultra-connected platforms such as Google, Twitter and Facebook—for capturing and enabling the querying of complex relationships in large toxicological datasets will be discussed. Storing data in network-like graph structures has significant implications for enabling AI augmented probabilistic chemical risk assessment. Very large datasets will allow AI to describe the statistical “shape” in evidence space of toxicity concepts such as carcinogenicity, and then compare this to the “shape” of individual substances in that space. Resulting in a probabilistic description of the extent to which a substance can be said to be known as carcinogenic.

3271 Illustrating Fit for Purpose in Systematic Evidence Maps: Case Study Mapping of the Evidence of Transgenerational Health Effects

V. Walker. NIEHS/NTP, Research Triangle Park, NC. Sponsor: B. Beverly

Evidence maps are a new method in environmental health science used to categorize literature and rapidly map key concepts, types of evidence, and gaps in research related to a defined topic. Mapping displays the extent of literature with varying degrees of detail depending on topic and goals. A detailed scoping review of the frequently debated issue of transgenerational inheritance exemplifies the fit for purpose approach for evidence mapping and illustrates the range of complexities that can be mapped. While an increasing number of reports suggest early life exposures result in adverse effects in offspring who were never directly exposed (or “transgenerational inheritance”), attempts to synthesize findings across studies are complicated by the lack of consistent terminology and diverse evidence base. A simple evidence map for transgenerational inheritance by health effects, exposures, and evidence streams demonstrates the utility of a low detail, rapid mapping for identifying data gaps and more robust pockets of evidence. With in-depth mapping, consideration of study quality and reporting factors is layered onto the existing map as an example of more complex categorization. We illustrate systematic mapping as a flexible tool to assist problem formulation, more efficiently focus resources and facilitate evidence synthesis in regulatory decision-making.

3272 Using Scoping Reviews to Guide Systematic Reviews and Future Research

C. Kwiatkowski. The Endocrine Disruption Exchange, Eckert, CO. Sponsor: J. Rochester

Many of the challenges of conducting systematic reviews in environmental health and toxicology can be addressed by the use of systematic scoping techniques. Scoping provides data to plan the protocol and frame the research question. It identifies specific endpoints and exposures that have sufficient evidence for systematic review. Scoping is also useful for identifying research gaps that can be addressed in the design of future studies. TEDX recently published several scoping reviews that demonstrate the role of the scoping process. They included many features of systematic review, such as a planned protocol with a PECO statement, rapid scoping, a context-neutral evidence map for transgenerational inheritance by health effects, exposures, and evidence streams, consideration of study quality and reporting factors. TEDX recently published several scoping reviews that demonstrate the role of the scoping process. They included many features of systematic review, such as a planned protocol with a PECO statement, rapid scoping, a context-neutral evidence map for transgenerational inheritance by health effects, exposures, and evidence streams, consideration of study quality and reporting factors. Data extraction included the number and age of subjects, the models used (e.g. human, rodent, fish), exposure routes and duration, doses/concentrations measured, and outcomes assessed. Unlike systematic reviews, they did not assess individual studies for quality
Inhalation is a major route of human exposure to airborne substances. This may cause portal-of-entry effects in the respiratory tract and can also lead to systemic uptake and subsequent effects. Several adverse outcomes in the airways are known, including acute lethal effects and chronic diseases. Adverse outcome pathways (AOPs) can be used to describe the mechanism through which a substance causes toxicity and inform the selection of in silico and in vitro methods to include in integrated approaches to testing and assessment (IATAs). In this session, speakers from government, industry, academia, and NGO will discuss how mechanistic risk assessments reflecting inhalation exposure, including lung inflammation and irritation, and the in silico and in vitro methods that can be used to assess key events. Case study examples showing how AOPs have been used to design testing approaches that inform risk assessment decisions will be highlighted. The presentations will discuss the implementation of IATAs that combine the use of existing data with dosimetry considerations, physicochemical property information, in vitro, and computational approaches to fulfill current data needs. Specifically, the first presentation will set the stage for the remaining talks by highlighting the importance of and providing an example of material characterization and dosimetry considerations that must be addressed. The second talk will describe a computational and in vitro approach based on an AOP for squamous metaplasia that has been submitted to the US EPA for the registration of a fungicide. The third talk will discuss an integrated approach for testing reactive gases using an AOP for ILC-2-mediated respiratory remodeling to inform alternative interpretations of study results. The fourth presentation will detail the use of precision-cut lung slices to query key events in an AOP for chronic obstructive pulmonary disease. The final talk will present a regulatory perspective on processes in place to accept alternative approaches for inhalation toxicity testing, the use of mechanistic and exposure information to facilitate regulatory acceptance, and remaining hurdles.

**W 3274 Methods for the Dispersion Preparation and Characterization of Nanomaterials in Physiologically-Relevant Media: Linking Particle Kinetics, Dosimetry, and Bioactivity**

P. Demokritou, Harvard T. H. Chan School of Public Health, Boston, MA.
Sponsor: A. Clippinger

An understanding of cellular dosimetry is essential in the design of studies to assess the toxicity of inhaled substances. As a case study, this presentation will focus on the effects of particle dispersion and characterization of engineered nanomaterials (ENMs) on dosimetry and bioactivity of various classes of ENMs including metal and metal oxides and anisotropic materials.

The engineering of nanomaterials and control of their morphological properties are an essential step in the development of ENMs. There has been a rise in the rise due to their versatile nature and applicability in many industrial fields. Their intrinsic properties depend on the raw material and their manufacturing approach. A thorough physicochemical and morphological characterization of ENMs at the pristine level as well as their dissolution kinetics and transformation in biological and environmental media will be displayed. The regulatory and toxicological implications of these changes are critical for the meaningful assessment of their biological properties. Unfortunately, the description of interactions between carbon-based, anisotropic ENMs and biological and environmental media presents a technical challenge. As a result, there is a lack of standardized methodologies across the dispersion, preparation, and characterization of these materials which can be implemented in cellular studies of their toxicological profile. The objective of this presentation is to present standardized methods for the dispersion preparation and characterization of ENMs, including anisotropic ones, in physiologically relevant media. Specifically, we present methods for the reproducible dispersion and characterization of these materials in water, phosphate buffered saline, and cell culture media. The dispersibility of such ENMs was assessed using light scattering and absorption as well as electron microscopy techniques. The objective was to identify any medium-specific transformations of their interfacial properties and how they might impact their biological properties. Finally, the delivered mass and surface area of anisotropic ENMs to an in vitro cellular system as a function of time was also assessed providing important information in terms of particle kinetics and dosimetry. Such well-defined and standardized methodologies could ensure the safe and sustainable use of emerging ENMs, enable the cross-comparison of toxicological data across laboratories, and represent a key first step in the development of human-relevant integrated testing approaches.
extend the AOP into a network that includes contribution from activation of
TRP channels will also be briefly described. The views expressed in this abstract
are those of the author and do not necessarily represent the views or policies of
the US Environmental Protection Agency.

3277 Ex Vivo Precision-Cut Lung Slices: Highlighting Key Chronic Obstructive
Pulmonary Disease (COPD) Events for Adverse Outcome Pathways
H. Behrsing. Institute for In Vitro Sciences, Inc., Gaithersburg, MD.

Many available in vitro models for human airway exist and can provide var-
ious levels of relevant biological complexity to allow toxicological pathway
assessment. Arguably the most physiologically-relevant non-animal model of
the lower lung (with reasonable throughput), precision-cut lung slices (PCLS)
offer native lung architecture, including small airways and respiratory
parenchyma. These more physiologically-relevant, 3-dimensional tissues that
contain immune-competent cell types such as macrophages and dendritic
cells are often considered essential to the establishment of relevant expos-
sure-induced changes. Tissue conditions such as chronic inflammation are be-
lieved to drive key events involved in diseases leading to chronic obstructive
pulmonary disease (COPD). This presentation will highlight various endpoints
PCLS have exhibited that are also known to be involved in COPD disease pro-
gression. Markers of irritation, inflammation, fibrosis, etc. will be reviewed in
the context of their representation of key events involved in adverse outcome
pathways of lung disease. With an ever-growing scope of inhalable materials
requiring safety testing, robust and relevant non-animal models are essential
to making reliable assessments about risk to human health.

3278 Opportunities to Use Alternative Approaches for Inhalation Risk Assessment of Pesticides

The US Environmental Protection Agency’s (US EPA) Office of Pesticide
Programs (OPP) regulates the use of all pesticide chemicals. To evaluate poten-
cial risks to humans, the OPP evaluates exposures from multiple routes, includ-
ing inhalation, as part of the human health risk assessment. Typically, in
vitro studies are required and/or used to evaluate inhalation exposures: how-
ever, the regulatory statutes provide the US EPA with the flexibility to
modify the actual data and studies required on an individual basis. Therefore,
the Agency may use data from alternative methods and strategies to satisfy
data requirements. The organizing framework for the US EPA’s strategy to
reduce vertebrate animal testing relies heavily on what have been termed
new approach methodologies (NAMs). NAMs have been adopted as a broadly
descriptive reference to any non-animal technology, methodology, approach,
or combination thereof that can be used to provide information on chemi-
cal hazard and risk assessment. There are currently a variety of approaches for
integrating NAMs for regulatory decision making, including defined ap-
proaches, adverse outcome pathways (AOP), and integrated approaches to
testing and assessment (IATA). Furthermore, OPP has developed guidance on
waivers for in vivo subchronic inhalation studies. The waiver guidance uses a
weight of evidence approach that incorporates exposure patterns, physico-
chemical properties, toxicological characterizations, mode of action information
and read across. This presentation will highlight the adoption of waivers and in
vitro mechanistic approaches to inhalation risk assessments and provide
case studies on how understanding the pathways and magnitude of exposure
informs the need for such studies while also discussing the successes and
challenges with replacing in vivo inhalation studies.

3279 Assessment of Cardiovascular Effects following E-vapor and Conventional
Cigarette Smoke Exposure in the ApoE-/- Mouse Model
E. Wong1, J. Szostak2, F. Paneni3, T. Lee1, C. Teng1, K. Lee4, J. Zhang5, P. Leroyp, B. Phillips1, W. McKinney2, M. Peitsch3, P. Vanscheewijk2, and J. Hoeng1, 1PMI R&D, Singapore, Singapore; 2PMI R&D, Neuchatel, Switzerland; 3Center for Molecular Cardiology, Zurich, Switzerland; and 4Altria Client Services LLC, Richmond, VA.

Chronic exposure to cigarette smoke (CS) is a risk factor for the develop-
ment and progression of cardiovascular disease. Considerable attention has
been given to the potential reduced harm of e-vapor products. ApoE-/- mice were
used to evaluate atherosclerosis development, cardiac function, and
aortic stiffness upon exposure to fresh air (Sham), CS from a 3R4F reference
cigarette, or e-vapor aerosols generated using capillary aerosol generators from
various e-vapors ("CARRIER" containing humectants [propylene glycol, glycercin], "BASE" containing humectants and nicotine, and "TEST" contain-
ing humectants, nicotine, and flavors). ApoE-/- mice were exposed for three
hours per day for six months via whole-body inhalation. Measurement of li-
ipoprotein cholesterol concentration, quantification of atherosclerotic plaque
formed, and ultrasound scans of the hearts and aortas were performed. Total serum and very low-density lipoprotein cholesterol were increased in the
3R4F group at Months 3 and 6 but were reduced in the BASE and TEST
groups compared with the Sham or CARRIER groups at Month 6. In contrast
to CS, exposure to any of e-vapor groups did not increase aortic plaque for-
mation when compared with the Sham group. CS exposure was associated
with an impairment of both systolic and diastolic cardiac function, as assessed
by ejection fraction, fractional shortening, isovolumic relaxation time, and
E/A ratio. A subtle impairment of systolic-diastolic performance, as assessed by
myocardial performance index, was observed in BASE and TEST groups when
compared with the Sham or CARRIER groups. All groups containing nicotine
(ICS, BASE, and TEST) displayed increased stiffness of abdominal aorta and
carotid artery, with the effect being most prominent in the CS group. In con-
clusion, chronic CS exposure aggravated atherosclerosis, which was not ob-
erved in the e-vapor aerosol-exposed groups. Increased aortic stiffness was
more pronounced in the CS-exposed group as compared with nicotine-con-
taining e-vapor aerosol-exposed groups.

3280 The Role of the TRPA1 Channel and Beta-
Adrenergic Receptors in the Arrhythmogenic
and Autonomic Effects of E-cigarette Aerosols
S. E. Bush, D. H. Wilson, D. J. Conklin, and A. P. Carl, University of
Louisville School of Medicine, Louisville, KY.

Electronic cigarette (e-cig) use has increased in prevalence, especially among
youth. E-cigs heat liquid media - dominated by propylene glycol (PG) and
vegetable glycerin (VG) - to generate potentially toxic constituents. Exposures
to e-cig aerosols and their individual constituents have been linked to adverse
cardiopulmonary effects, but the extent of harm and underlying mechanisms
are unknown. The transient receptor potential A1 (TRPA1) channel in airways
is triggered by irritants to activate sensory neurons and may destabilize auto-
nomic regulation to increase cardiac risk. We sought to elucidate the role of
TRPA1 and β-adrenergic receptors (βARs) in the cardiac effects of e-cig aero-
sols. Electrocardiograms (ECGs) were collected by radiotelemetry in TRPA1
knockout (KO, n=4) and wild type (WT, n=4) mice and analyzed for heart
rate variability (HRV) and repolarization (QT, and J amplitude). After sham
exposure (Air, 90-min), mice were acutely exposed on a separate day to e-cig
aerosols (three 9-min exposures) from equal-ratio PG and VG (PG:VG) and
were subsequently pretreated with a β-blocker (propranolol) and exposed to
PG:VG again. During exposure, PG:VG markedly decreased heart rate (HR) and
increased time-domain HRV parameters in WT while decreasing J amplitude
(all P<0.05 vs. Air) and inducing frequent bradyarrhythmias. These effects
were abolished by TRPA1KO and attenuated by βAR-inhibition, indicating
TRPA1 as primary and βAR as partial mediators of PG:VG’s immediate cardiac
effects. After exposure, PG:VG increased HR, decreased HRV, and prolonged
QT interval in WT (P<0.05 vs. Air). KO did not significantly alter the post-ex-
posure effects on QT; however, post-exposure effects on HR and HRV were
attenuated by TRPA1KO, and declines in HRV were further inhibited by βAR
blockade, with equivalent impacts of β-inhibition between genotypes. Thus,
e-cig aerosols induce bradycardia during exposure and sympathetic domi-
nance after exposure in mice, and concomitantly impede cardiac repolariza-
tion. E-cig solvent aerosols may increase cardiac risk by inducing autonomic
immunology and arrhythmia via both TRPA1 and βARs in independent but com-
plementary pathways. Additional studies in both animals and humans are
needed to assess the role of these pathways in the effects of chronic exposure
and determine which e-cig aerosol constituents mediate these effects. Our
findings suggest health agencies may reduce harm by regulating e-cig char-
acteristics to diminish byproducts known to stimulate TRPA1.
Acetaldehyde (AA) is an agent that causes an inflammatory reaction; however, the mechanism behind the immune activation by AA is not well understood. Physiologically, it has been shown that 1,4-dihydropyridine-type malondialdehyde (MDA)-AA-lysine (M2AA) adducts are formed by a reaction between AA and the aldehydes of MDA and lysine. We successfully conjugated purified M2AA (pm2AA) to bovine serum albumin (BSA), and we found that pm2AA-BSA is immunogenic in mice. Using our pm2AA-BSA ELISA assay, we detected natural antibodies against M2AA in the blood of mice, and their titers are elevated in atherosclerosis-prone ApoE ko mice. As one of the components of M2AA, MDA is not only one of the most abundant carbonyl compounds caused by lipid peroxidation, but it also possesses unique reactive properties. In addition to its dialdehyde structure, the central carbon of MDA reacts with carbonyl moieties; therefore, MDA can produce various complex lysine adducts with AA. As such, we hypothesized that the combination of AA, MDA, and lysine could lead to the formation of additional immunogenic adducts other than M2AA. In the present study, the reaction product of AA, MDA, and 6-aminoacapric acid (6-ACA, a lysine analog) was fractionated by HPLC. All of the fractions were conjugated with BSA, and each fraction-BSA conjugate was utilized for an ELISA assay to detect antibodies against each fraction product. The immunogenicity of the immunoreactive fractions specific to 1,4-dihydropyridine-type adducts showed a positive response to the fraction containing M2AA, but not to other fractions. Interestingly, when we ran blood samples from wild-type and ApoE ko mice on the ELISA, we found that the titers of antibodies against all of the fractionated products were increased in the blood of ApoE ko mice, indicating the existence of multiple immunogenic epitopes in the reactant of MDA, FA, and 6ACA. Further, we identified that the most significant increase in antibody titer in the blood of ApoE ko mice was not the fraction containing the M2AA adduct. From this, we believe that evaluating serum titers of natural antibodies against various complex MDA-AA-lysine adducts could be used as a biomarker for metabolic syndromes. Our next step is to apply this ELISA assay to human samples obtained from individuals with different LDL levels.

Tyrosine kinase inhibitors (TKI) have greatly improved the treatment and prognosis for a wide range of cancers. Unfortunately, numerous TKIs produce cardiotoxic effects, which were not well predicted during preclinical studies. We developed an in vitro assay, Cardio quickPredict, for predicting cardio-vascular activity based on changes in human iPSC-derived cardiomyocytes (iPSC-CM) metabolism and cell viability, which identifies both functional and structural cardiotoxicants. The assay’s prediction model (PM) is based on the response of three metabolite ratios (viability (VIA)/lactate (LAC), thymidine (THY)/arachidonic acid (ARA), and N-acetylsapartate (NAA)/2-deoxyctydine (2DC)) and predicts the concentration a compound exhibits cardiotoxicity potential. The PM classified 78 compounds with known cardiotoxicity outcomes (49 cardiotoxic, 29 non-cardiotoxic) with 87% accuracy, 90% sensitivity, and 83% specificity. The current study evaluated the utility of this assay for evaluating the cardiotoxicity potential of TKIs. We tested 10 TKIs that induce a variety of cardiotoxic effects, including eight compounds clinically associated with cardiotoxicity (crizotinib, dasatinib, imatinib, lapatinib, nilotinib, sorafenib, sunitinib, and vandetanib) and two compounds considered to be relatively cardiac-safe (axitinib and erlotinib) to compare changes in metabolism of the PM ratios. Human iPSC-CMs were exposed to eight concentrations of each compound for 72 hours and cell viability and metabolites in the spent media were analyzed. Every compound except axitinib altered at least one metabolite independent of a change in cell viability. Crizotinib, dasatinib, erlotinib, imatinib, sorafenib, sunitinib, and vandetanib elicited a response in all three ratios; however, a difference was observed in which ratio was impacted at the lowest concentration. For example, crizotinib altered VIA/LAC at significantly lower concentrations (2-fold) than where a response was observed in NAA/2DC and THY/ARA. In contrast, sorafenib elicited a response in all three ratios at similar concentrations. These results suggest that the Cardio quickPredict assay can be used to screen for cardiotoxicity potential of TKIs and can identify TKIs that cause a range of functional and structural cardiotoxic effects. The metabolic readout of this assay can be combined with other assays, such as the CIPA myocyte assay, to provide a more comprehensive evaluation of a compound’s cardiovascular liability.

The use of microelectrode array technology (MEA) has proven to be a very powerful tool for prediction of proarrhythmic liabilities in iPSC derived cardiomyocytes. This work has focused primarily on the prominent cardiac ion channels with an emphasis on hERG. To this end, the Comprehensive In Vivo Proarrhythmia assay (CIPA) initiative was established and has been tasked with prediction of proarrhythmic compounds in an in vitro setting with acute short term dosing. Although most of the focus on the early work has been on arrhythmias driven primarily by hERG block, the real power of iPSC-derived cardiomyocytes on an MEA platform is predicting unexpected liabilities and long term chronic effects in vitro. These type of studies are currently performed in telemerized dogs at great expense. Here we show examples of compounds whose liabilities were identified with chronic dosing of compounds in an MEA assay. Due to the ability to measure and maintain cells over long periods of time, this platform is ideal for evaluating short and long term exposures early in drug development. Examples of hERG trafficking effects are demonstrated at 24 and 48 hours utilizing Pentamidine. The FPD is significantly lengthened while the amplitude of the repolarization peak is reduced. The hepatitis C drug BMS-986094, which failed in clinical trials, is shown to progressively deteriorate cardiomyocyte health as compared to safe hepatitis C drugs such as sofosbuvir in 14-day studies. The results show a complete loss of beating at 400mV and above while showing significant effects on the electrophysiology as low as 80mV. We also tested compounds that have other unexpected responses such as delayed onset arrhythmias and Na amplitude effects that are not observed acutely and cannot be predicted by channel screening. These compounds confirmed results found in animal studies. These results demonstrate that iPSC derived cardiomyocytes on an MEA platform are an effective tool for screening compounds to identify unexpected long term liabilities before expensive preclinical animal experiments are performed, thus improving the chances of moving forward with a safe compound.

Effect of TSN3015 on the Development of Pulmonary Arterial Hypertension in Male Sprague-Dawley Rats

K. R. Doherty, P. B. Senese, D. Bullough, V. Carreira, and M. R. Gralinski. ConDynamics Inc., Chicago, IL; Thesan Pharmaceuticals, Inc., Carlbad, CA; and VeT Path Services, Inc., Mason, OH.

TSN3015 (β-naphthoflavone), an AhR agonist with seborepressive activity, was used as an anti-acne medication. In toxicology studies in rats, microscopic changes suggestive of pulmonary arterial hypertension (PAH) were observed in the lungs and hearts of some TSN3015-treated animals. This study was undertaken to determine the effect of TSN3015 on pulmonary artery pressure (PAP). Conscious pulmonary artery-telemeterized male Sprague-Dawley rats were subcutaneously administered either vehicle or TSN3015 at 3 mg/kg for 28 consecutive days, followed by a 55-day recovery period. Clinical observations, telemetry data and blood samples were collected at defined time points throughout the study. The heart and lungs were collected at necropsy for weights and histological examination. No adverse clinical observations were noted over the 84-day study though 2 animals died during the recovery period. A 3 mg/kg dose of TSN3015 elicited an increase in systolic PAP that remained elevated for up to 49 days after the last dose was administered (36.2±8.3 mmHg on Day 84 vs 31.5±2.6 mmHg on Day -1), with the peak increase occurring on Day 49 (range: +34.3% to +117.8%).

TSN3015 did not notably affect the diastolic PAP or heart rate. Necropsy findings showed an increase in right heart weight and Fulton Index (FI) in animals given TSN3015, while histological examinations showed microscopic changes in the lungs and hearts of some TSN3015-treated animals. Microscopic findings in the lung consisted of minimal hypertrophy/hyperplasia of the tunica media of medium- and small-size arteries and minimal foamy alveolar macrophages; the heart findings presented as microscopic alterations predominately in the right ventricle. TSN3015-treated animals with lung pathology had a statistically significant elevation in sPAP and FI when compared to either vehicle-treated animals (p<.001 for both parameters) or TSN3015-treated animals without lung pathology (p<.001 for sPAP; p=.004 for FI). Overall, 9 of the 12 animals treated with TSN3015 developed right heart hypertrophy as indicated by an increased FI (0.373±0.016 TSN-treated animals vs 0.318±0.015 for vehicle-treated animals, p<.05), and these elevated FI values correlated with histologic findings in the heart and lungs. Thus, under the confines of this study, TSN3015 appears to create characteristics consistent with PAH in male rats.

The ability to generate a reliable VM lead from the 3 input leads in NHP and produced expected changes in QTc and JTp each of the drug combinations.

Effect of TSN3015 on the Development of Pulmonary Arterial Hypertension in Male Sprague-Dawley Rats

S. Authier, E. Boulay, S. Dubois, M. Pugsley, and R. Forster. CitiToxLAB, Laval, QC, Canada; and CitiToxLAB, Evreux, France.

Qtc was identified as a central proarrhythmic risk biomarker in ICH S7A but recent clinical data have revealed limitations when using QTC mostly related to false positives. Drugs with balanced multi-ion channel inhibition were shown to prolong QTC without increased proarrhythmic risks. Research led by the ICH FDA has identified JTPc as a reliable ECG biomarker that evaluates drug-induced proarrhythmic risk in clinical trials and HESI showed similar effects in canines and non-human primates. In humans or non-clinical species, proarrhythmic drugs are associated with an increase in QT but also JTPc. The current study evaluated the effects of common ECG confounders on QTc, JTpca and Tpeca. Beagle dogs were anesthetized with isoflurane and subjected to progressive hyperthermia (42°C), hypothermia (33°C) (n=4) or epinephrine IV injections (0.03 mg/kg) (n=10).

Dofetilide, verapamil and ranolazine were used as positive control drugs. All ECG parameters (QTc, JTpca and Tpeca) were subjected to individual rate correction. QTc (slope -9.2 mseg/degree Celsius) and JTpca (-6.7 mseg/degree Celsius) durations were negatively correlated with core body temperature but Tpeca was minimally affected. Epinephrine was associated with QTc and JTpca shortening which could be related to under-correction in the presence of tachycardia but minimal effects on Tpeca.

Dofetilide was associated with significant increase in JTpca while verapamil and ranolazine tended to prolong Tpeca. Multi-lead derived ECGs showed improved morphology for T-peak detection. The above results highlight the importance of potential confounders on the traditional ECG biomarker QTc but also on JTpca and Tpeca. These potential confounding effects need to be considered in the interpretation of ECG biomarkers during proarrhythmic risk assessment in non-clinical drug development.

Discrimination of the Effects of Multi-Channel Ion Blockade Using ECG Biomarkers in St. Kitts Green Monkeys

S. Liddie, B. Brockway, D. Maddrell, X. Morton, T. Delahanty, R. Hamlin, and M. Lawrence. 1 RoGen, New Haven, CT; VivaQuant, St. Paul, MN; TSE Systems, Bad Hamburg, Germany; and QTest, Columbus, OH. Sponsor: PLA.

FDA and the HESI JTP working group have laid the groundwork for use of J to T-pea (JTP) interval to differentiate drugs that exhibit multichannel block in clinical and preclinical studies. Clinical studies typically include 12-lead electrocardiography (ECG) monitoring with JTP assessed from a vector magnitude (VM) lead while preclinical assessment is often based on a single ECG vector such as Lead II (L2). In this study we usedStellar multichannel ECG, blood pressure, temperature, and activity telemetry implants (TSE Systems) to assess changes in corrected QT interval (QTc) and JTPc intervals for human ether-a-go-go related gene (hERG) potassium channel blockers (Dofetilide; Dof) in conjunction with calcium (Verapamil; Ver) or sodium (Mexiletine; Mex) ion channel blockers using both VM and L2. St. Kitts green monkeys (n=4) were instrumented with subcutaneous electrodes to record limb leads I, II, and III. ECGs were analyzed with the Rhythm Express software (VivaQuant) to remove noise, assess arrhythmias, and derive interval measurements from L2 and VM leads. This study was undertaken to determine the importance of potential confounders on the traditional ECG biomarker QTc but also on JTPca and Tpeca. These potential confounding effects need to be considered in the interpretation of ECG biomarkers during proarrhythmic risk assessment in non-clinical drug development.

An Integrative Lipidomic and Proteomic Approach to Understanding the Nanoparticle-Biocorona

L. Kobos, and J. Shannahane. Purdue University, West Lafayette, IN.

When nanoparticles (NPs) enter a physiological environment, a biocorona (BC) forms on the surface, impacting both NP properties and cellular interactions, leading to pharmacological and toxicological consequences. The majority of NP-BC research has focused on the protein components of the BC, while other components such as lipids lack sufficient evaluation. Our current evaluation utilized an integrated -omics approach (lipidomics and proteomics) to examine the identities and quantities of lipids as well as proteins that adsorb to the NP surface. We hypothesized that gold nanoparticles (AuNPs) would form BCs with distinct protein and lipid content based on physicochemical properties of NPs (size and coating) and disease states (healthy or obese). AuNPs with two different coatings (PVP or citrate) and diameters (20 nm or 100 nm) were incubated individually in either pooled healthy or obese human serum to form a BC. Lipids were extracted from the resultant BC via the Bligh-Dyer method, while peptides were isolated by digestion of proteins and subsequent column separation. AuNP size and zeta potential were found to be differentially altered following incubation in serum samples. Analysis of both proteins and lipids demonstrated that the biomolecular profiles of AuNP-BCs incubated in normal serum tend to be more unique than those incubated in obese serum, and that citrate-coated AuNPs form more similar BCs between serum conditions than PVP-coated AuNPs. Additionally, in normal serum, BC composition is influenced primarily by AuNP coating as opposed to size. Conversely, in obese serum size is the primary property determining AuNP-BC formation. Lipid classes were found to differentially adsorb to the NP surface. Specifically, the most abundant class of lipids in the BC was glycerolipids, with 300 unique species identified in each NP-BC. The least abundant classes were sulfatides and glycosylinositolphosphoryl ceramides, with less than three of each unique species identified in each NP-BC. The most abundant class of lipids in the BC was glycerolipids, with over 300 unique species identified in each NP-BC. The least abundant classes were sulfatides and glycosylinositolphosphoryl ceramides, with less than three of each unique species identified in each NP-BC. The most abundant class of lipids in the BC was glycerolipids, with over 300 unique species identified in each NP-BC. The least abundant classes were sulfatides and glycosylinositolphosphoryl ceramides, with less than three of each unique species identified in each NP-BC.
The liver and the mononuclear phagocyte system are a frequent target for engineered nanomaterials, either as a result of particle uptake and spread from primary exposure sites or systemic administration of therapeutic and imaging nanoparticles. In this study, we performed a comparative analysis of the toxicological impact of 29 metal oxide nanoparticles (NPs), some commonly used in consumer products, in transformed or primary Kupffer cells (KCs) and hepatocytes. We not only observed differences between KCs and hepatocytes, but also differences in the toxicological profiles of transition-metal oxides (TMOs, e.g., Co3O4) versus rare-earth oxide (REO) NPs (e.g., Gd2O3). While pro-oxidative TMOs induced the activation of caspases 3 and 7, resulting in apoptotic cell death in both cell types, REOs induced lysosomal damage, NLRP3 inflammasome activation, caspase 1 activation, and pyroptosis in KCs. Pyroptosis was accompanied by cell swelling, membrane blebbing, IL-1β release, and increased membrane permeability, which could be reversed by knockdown of the pore forming protein, gasdermin D. Though similar features were not seen in hepatocytes, the investigation of the cytotoxic effects of REO NPs could also be seen to affect macrophage cell lines such as J774A.1 and RAW 264.7 cells as well as bone marrow-derived macrophages. These phagocytic cell types also demonstrated features of pyroptosis and increased IL-1β production. Collectively, these findings demonstrate important mechanistic considerations that can be used for safety evaluation of metal oxides, including commercial products that are developed from these materials.

### 3290 Transcriptional Signatures in Human LP9 Mesothelial Cells after Treatment with Differentially Purified and Surface Functionalized Multiwalled Carbon Nanotubes

C. Ziemen1, S. Ream-on Bruet1, D. Lison2, S. van den Brül2, J. C. Bonner3, and O. Creuzen1.1 Fraunhofer Institute for Toxicology and Experimental Medicine ITEM, Hannover, Germany; 2Université Catholique de Louvain, Louvain, Belgium; and 3North Carolina State University, Raleigh, NC.

Exposure to certain long and straight multiwalled carbon nanotubes (MWCNT) has been implicated in adverse biological effects, including induction of malignant mesothelioma. Besides morphology, functionalization seems to affect the toxic potential of MWCNT. The ERA-ETN SiINN project ICONS (“International Collaboration On Nanotube Safety”) therefore aimed at mechanistically evaluating and ranking the pro-fibrotic and genotoxic potential of seven differentially purified (chemically or thermally) and functionalized (TMOs, e.g., Co3O4) versus rare-earth oxide (REO) NPs, made from one batch of industrially relevant Nanocyl NC7000 (tangled morphology). As a prerequisite, initial tests indicated sterility and lack of relevant endotoxin contamination of the materials. In a subproject performed by Fraunhofer ITEM, human peritoneal mesothelial LP9 cells (target cells for mesothelioma development) were incubated for 24 h with 5 μg/cm2 of the diverse MWCNT, followed by microarray analysis to evaluate material-specific transcriptional signatures. In subsequent bioinformatic analyses, significant number of differentially-regulated genes (DEGs) was noted for all eight MWCNT (range: 555 to 2524 genes), with the amount of differentially-regulated genes and the observed fold-change values being strongly dependent on the MWCNT type. Interestingly, number of DEGs was about two- to five-fold higher for the surface-modified samples than for pristine/unmodified ENPs.

### 3291 Induction of Oxidative DNA Damage and Promotion of Epithelial Mesenchymal Transitions through Emitted Engineered Nanoparticle Exposure in Human Primary Small Airway Epithelial Cells

C. Wright, K. Pearce, R. Faisthalab, and I. Okon. Georgia State University, Atlanta, GA.

Engineered metal nanoparticles (ENPs) are frequently incorporated into aero- solized consumer products, known as nano-enabled products (NEPs). There is a growing concern regarding consumer pulmonary exposures as certain NEPs produce high concentrations of emitted ENPs that are chemically modified by constituent chemicals. While understanding the potential health effects of pristine/unmodified ENPs has gained importance, a significant knowledge gap still exists surrounding emitted ENP biological activity and potential respiratory effects. Our research evaluated emitted ENP induced oxidative stress and 8-oxoguanine, a prominent base lesion, repaired by DNA glycosylase OGG1 in the Base Excision Repair (BER) pathway and how these outcomes can contribute to mesothelial mesenchymal transition (EMT) - a precursor to airway remodeling. Our main hypothesis is chemically modified ENPs emitted from NEPs increase oxidative stress levels, resulting in oxidative DNA damage and EMT through OGG1-BER pathways. In this study, we utilized an automated NEP generation system to monitor and gravimetrically collect aerosols from two aerosolized NEP cosmetic lines to conduct physico-chemical, colloidal, and toxicological assessments. Scanning electron microscopy (SEM-EDX) and dynamic light scattering (DLS) were used for colloidal characterization. The toxicological profiles of pristine and emitted nanoparticles were compared using human primary small airway epithelial cells to assess ROS and oxidative stress by a recently developed assay. Single stranded DNA damage and 8-oxoguanine were detected using the CometChip® assay after 24-hour exposure. EMT was assessed via Western blot analysis on lysates from 21-day exposures to evaluate modulation of E-cadherin and Vimentin. SEM-EDX analysis revealed that emitted particles were spherical and primarily titanium dioxide or iron oxide. DLS assessments indicated that certain emitted ENPs were more negatively charged than pristine ENPs. Toxicity results indicated higher oxidative stress at 24-hour exposure due to emitted nanoparticles in comparison to pristine ENPs along with increased levels of single-stranded DNA damage and 8-oxoguanine. Western blot analysis revealed Vimentin induction after 21-day exposure indicative of EMT. This work elucidates the role oxidative DNA damage plays in potential pulmonary health risks due to NEP exposures and thus the importance of regulation and consumer product safety.
of pleural mesothelioma replicating the pathogenesis of human disease and highlighting commonality in the hazard mechanism of long pathogenic fibers at the molecular level with epigenetic changes preceding malignant transformation of inflammatory lesions. Crucially, our findings reinforce concerns that long straight CNT may pose an asbesto-like hazard, leading to mesothelioma.

### 3293 An In Vitro Approach to Assess the Pulmonary Fibrosis of Nanomaterials

M. Sharma1, B. Rothen-Rutishauser2, H. Barosova1, S. Chortare3, F. Zerimarian1, M. Cliff1, V. Stone1, P. Hayden2, A. Maione1, and A. Clippinger1.

Pulmonary fibrosis is one of the main adverse health effects that may be linked to the inhalation of multi-walled carbon nanotubes (MWCNTs). Several jurisdictions require a 90-day rodent test to assess the inhalation toxicity of substances of concern. Ethical, scientific, and financial concerns related to in vivo testing have led to an increase in the use of animal-free approaches. Presented here is an approach informed by a mechanistic understanding of fibrosis, which uses a primary human cell-based system (EpiAlveolarTM) exposed to MWCNTs at realistic exposure concentrations. EpiAlveolarTM (MatTek Corp.) - a reconstructed primary human alveolar tissue model comprised of alveolar epithelial cells, pulmonary endothelial cells, and fibroblasts, with or without macrophages (THP-1 cells) - was characterized to assess cell morphology, barrier properties, cytotoxicity, and ability to predict fibrosis in response to a positive control chemical (transforming growth factor-beta (TGF-β)). EpiAlveolarTM was then exposed to MWCNTs at the air-liquid interface (using the VITROCELL® Cloud system) for up to 21 days to assess their fibrotic potential using immunostaining, transepithelial electrical resistance (TEER), and collagen 1A1 and fibronectin release. MWCNTs (Mitsui 7 or Nanocyl) were characterized using a combination of qualitative and quantitative methods to assess the nanomaterial form and concentration that reaches the cell layer, including ultraviolet-visible-near infrared spectroscopy, bright field and enhanced dark field microscopy, and quartz crystal microbalance. The goal of this work is to develop an in vitro testing strategy using human-relevant methods to predict pulmonary toxicity and to enable effective risk assessment of substances including MWCNTs.

### 3294 A Novel Method of Measuring ENM Induced Lipid Disruption in Macrophages and Model Membranes Systems

The expanded use of nanotechnology has led to increased production and use of engineered nanomaterials (ENM), resulting in an increased risk of human exposure. Many ENM are taken up by cells where the ENM accumulate in phagolysosomes. Some ENM have been shown to cause a leakage of phagolysosomes, resulting in phagolysosomal membrane permeability (LMP). LMP leads to the release of proteolytic enzymes into the cytosol, leading to release of inflammatory cytokines and cytotoxicity. This suggests that ENM may interact directly with the lipid membrane, disrupting the normal state. Time-resolved fluorescence anisotropy measurements, using suitable lipid probes, can measure changes in membrane characteristics, such as lipid order (Lo) and disorder (Ld). These changes are quantified as a cone angle, the free movement of the probe in the membrane. Additionally, THP-1 cells stably expressing a YFP-ASC protein can be used to determine inflammasome formation, an immediate downstream event of LMP. In this work, THP-1 cells and 100 nm liposomes made of POPC (1-palmitoyl-2-oleoyl-glycerol-3-phosphocholine) and DOPS (1,2-dioleoyl-sn-glycero-3-phospho-L-serine) were used as model systems for interaction with ENM. Both models were exposed to 12.5 to 100 µg/ml titanium dioxide (TiO2) at 210 nm ZnO nanoparticles. Fluorescence membrane probe DI-4-ANEPPDHQ and a time-resolved fluorometer were used to determine the changes in lipid Lo/Ld of the liposomes. Inflammasome formation (specks) were quantified using a laser scanning cytometer. 2.5-3.5% of control THP-1 cells at both 24 and 4 h speck formation, indicating that some cells had spontaneous speck formation. THP-1 cells exposed to 100 µg/ml TiO2 for 4 h had a significant increase in speck formation. 11.4% after 24 h the 50 µg/ml TiO2 increased to nearly the same level as the 4 hr 100 µg/ml. There was no significant increase in speck formation at 100 µg/ml TiO2 between 4 and 24 h. ZnO exposed THP-1 had a significant increase in speck formation at 50 µg/ml after 4 h (14%) and at 25 and 50 µg/ml after 24 h, 25% and 45%, respectively. POPC (neutral charge) liposomes exposed to 100 µg/ml TiO2 had a decrease in cone angle from 38° to 29°, with no significant change in DOPS (negative charge) liposomes. ZnO exposure (100 µg/ml) saw a decrease from 36° to 26°, with no change in POPC. This indicates that while both materials may be disrupting lipid membranes, the target lipids are different. ### 3295 Developing an Animal Model of Drug-Induced Respiratory Depression to Assess Co-Administration of an Opioid with Other Sedative Psychotropic Drugs

Opioids and benzodiazepines are frequently co-prescribed to patients with both pain and psychiatric or neurological disorders. Co-prescription of these drugs increases the risk for severe respiratory depression and death. In 2016, the US Food and Drug Administration required the addition of boxed warnings describing this risk to labeling for all prescription opioids and benzo- diazepines. Other sedating psychotropic drugs (SPDs) with differing mechanisms of action (e.g., antipsychotics, antidepressants, non-benzodiazepine sedative-hypnotics, etc.) may be increasingly prescribed in place of benzodiazepines. Despite being marketed for years, many SPDs have neither human nor animal data to quantify or qualify the potential for causing respiratory depression, either alone or in combination with an opioid. In this work, an animal model was established to address this question and generate data to inform regulatory decision-making. Arterial partial pressure of oxygen (pO2) and carbon dioxide (pCO2) were selected as practical and sensitive measures of respiratory depression. An oral exposure route was selected for all drugs to allow for clinical use. Diazepam was selected as a benzodiazepine positive control to demonstrate that the model was sufficiently sensitive to detect an additive or synergistic effect on respiratory depression with the opioid, oxycodone. Pharmacokinetic studies were conducted at three dosing concentrations with oxycodone (opioid; 6.25, 65, 150 mg/kg) and diazepam (benzodiazepine; 2, 20, 200 mg/kg) to determine whether oxycodone and diazepam caused similar pO2 and pCO2 changes at different combinations (200 mg/kg). Based on area under the curve assessment, oxycodone 150 mg/kg and diazepam 20 mg/kg were approximate clinical single dose exposures in humans. Diazepam was administered 30 minutes after oxycodone to deliver peak serum concentrations of both drugs at near the same time. Decreases in pO2 and increases in pCO2 consistent with additional respiratory depression were observed in rats co-administered oxycodone and diazepam compared to oxycodone alone. These findings support the utility of this animal model for assessing opioid-induced respiratory depression and its potential exacerbation by other SPDs.

### 3296 Thalidomide Inhibits Human iPSC Mesendoderm Differentiation by Modulating Cereblon-Dependent Degradation of SALL4

D. G. Belair1, L. E. Waller2, J. A. Gustafsrn; N. D. Collins3, and K. L. Kolaja3.

1 Celgene Corporation, Summit, NJ; and 2 Millipore Sigma, St. Louis, MO.

Thalidomide exposure during a narrow time window of fetal development produces phocomelia in humans. Several teratogenicity mechanisms for thalidomide have been proposed, but recent evidence suggests thalidomide exerts teratogenicity through binding to and modifying the substrate-binding specificity of cereblon, a component of the ubiquitin ligase complex with DDB1 and CUL4A. Thalidomide enhances cereblon-dependent degradation of the transcription factor SALL4, mutations in which are known to produce developmental defects in humans and mice that phenocopy thalidomide-induced limb defects in humans. We interrogated thalidomide-induced degradation of SALL4 as a possible mechanism for limb teratogenicity using human induced pluripotent stem cells (hiPSCs). Thalidomide inhibited hiPSC definitive endoderm differentiation to a SOX17+ phenotype (IC50 = 8 µM), resistant to thalidomide-mediated interference of endoderm differentiation, suggesting the effect of thalidomide on differentiation was dependent on cereblon binding and SALL4 degradation. We further sought to explore the influence of thalidomide on hiPSC differentiation to lateral plate mesoderm, which is the developmental origin of the ENM tested. Mesendodermal differentiation was up-regulated by thalidomide. Cereblon (CBL) and SALL4 expression was decreased in thalidomide-treated EpiAlveolar (T) expression and after 48 h induced GATA4, FOXF1, and PITX1 expression and reduced NANG and POU5F1 expression in hiPSCs consistent with
Impact of Monoclonal Antibody (MoAb), Payload and Linker Structure in Antibody Drug Conjugates (ADCs) on Primitive Myeloid Progenitors (CFU-GM), or Mature Neutrophil Cytotoxicity

P. Ryan1, E. Clarke2, G. dos Santos1, T. Kell3, Y. Huang4, J. Borrok5, V. Balakumaran3, S. Gregson1, P. Ryan1, P. Howard1, and R. Dixit1. MedImmune LLC, Gaithersburg, MD; 2ReachBio Research Labs, Seattle, WA; and 3Spirugen Ltd, London, United Kingdom.

ADC design involves a tumor antigen-specific antibody, a linker and a cytotoxic drug. In some clinical trials, ADCs caused neutropenia in patients despite having targets that are not present on hematopoietic stem cells (HSC) or neutrophils. The CFU-GM assay, predictive of clinical neutropenia and validated by Pessina et al. (2003), evaluated compound effects on primitive myeloid precursors, whereas the platform described by Zhao et al. (2017) suggested the extracellular cleavage of the ADC linker was responsible for cytotoxicity to differentiating mature neutrophils. We tested 2 naked antibodies, 1 cytotoxic drug and multiple ADCs with different cleavable linker sites (valine-alanine, valine-citriulline and maleimidomethyl cyclohexane-1-carboxylylate) on both platforms to compare their utility to identify potential off-target bone marrow (or hematologic) effects of ADCs. For the CFU-GM assay, compounds were added to cells in a liquid medium for 72 hours, then the treated cells were transferred to a methylcellulose-based medium for 14 days. To assess neutrophil toxicity using the Zhao platform, CD34+ cells were cultured for 3 days initially to expand the HSC followed by 4 days in a differentiation media and then another 4 days with various cytokines. The various MAbPs, payload and ADCs were added to the culture for the final 6 days (G-CSF only) and assessed for CD15. The naked antibodies, IC1-Maia and trastuzumab, had no effect on CFU-GM or neutrophil numbers. The payload (drug plus linker) demonstrated significant toxicity to the CFU-GM (IC50 of 0.0060 nM), but much less potency to mature neutrophils (IC50 > 0.3 nM). Kadcyla (FDA approved trastuzumab-based ADC) was 3 times more inhibitory to the CFU-GM assay compared to mature neutrophils, whereas trastuzumab-vc-MMAE ADC was 5 times more inhibitory to mature neutrophils compared to primitive progenitors. There was more than a 10-fold difference in the IC50 values of the ADCs R347-Maia-SG3294, CS1-Maia-SG3294 and 1C1-Maia-SG3249 between assays, with more toxicity towards the CFU-GM than the differentiating neutrophils. With many ADCs in clinical trials, these assay platforms may be useful for predicting preclinical development to identify potential off-target effects of antibodies and payloads or susceptibility for single or dual cleavage sites to release the cytotoxic drug.

Bilateral Distal Femoral Epiphyseal Defect Models for Safety Testing: A 5-Week Rat Bone Healing Study

L. Negro Silva1, J. Haruna1, P. Malhi1, S. Authier1, Y. Trudel2, R. Kubaszky2, V. Badalone3, and M. Assadi1. 1CTXoxLAB, Laval, QC, Canada; and 2AccelLAB, Boisbriand, QC, Canada. Sponsor: P. Singh

Low trauma fractures represent clinical complications from our aging society. Most fractional injuries are known to occur in long bones with inevitable low trauma fractures representing 30% of all fractures. Per-op and terminal digital radiography was performed on male Sprague-Dawley rats. Following an IACUC-approved protocol from an AAALAC-accredited institution, nine (9) female Sprague-Dawley rats were used to evaluate if 2-mm critical-size defects in distal femoral condyles were adequate for toxicology evaluation of drugs with potential impact on bone remodeling. Under anesthesia, both hindlimbs were prepped and draped in sterile fashion. Then, bilateral cylindrical defects of 2x5mm (DxL) were created in distal femoral condyles. Per-op and terminal digital radiography was performed on all femurs. Then, at 5 weeks post-op, all femoral defect sites were harvested, decalcified, and embedded in paraffin. Central longitudinal histological sections were then taken from the bone defect site and prepared for microscopic examination following H&E and Goldner’s Trichrome staining. Histopathology scoring was performed on the quality of new bone formation, while the extent of new bone formation was quantified by histomorphometry (Table 1). Regardless of treatment, all defect sections demonstrated significant bone remodeling as characterized by the ratio of the cortical bone to the cellular bone (x3). Results indicate that creating a 2-mm long-bone defect enables evaluation of potential drug effects on bone healing in toxicology. In contrast, a 2-mm femoral epiphyseal defect will not be considered a critical-size defect in the femoral condyle (x1), but lacks representative improvement in healing observed from the cortical bone to the cellular bone (x3) for this purpose. When this is met, this rodent femoral defect model may then represent a promising one to evaluate the superiority of new bone substitutes with osteoconductivity and osteoinductivity properties.

Determining Mechanisms of Mitochondrial Toxicity Using Agilent Seahorse XF Technology

Mitochondrial dysfunction is increasingly implicated in the etiology of drug induced toxicities and is a major reason for safety-related compound attrition and post-market drug withdrawals. Most assays currently used for mitochondrial toxicity studies are not direct, not specific and provide limited mechanistic information. Here, a standard workflow is presented to enable a comprehensive characterization of the mechanism of action of mitotoxic compounds. A library of commercially available small-molecule compounds was screened in npsG2 in dose- and time-response studies using the Agilent Seahorse XF analyzers. Performing the XF-Real time ATP Rate Assay that simultaneously measure the mitochondrial and glycolytic activity in intact cells we identified several compounds with mitotoxic activity before observing significant changes in cell viability after either acute (1 hr) treatment or long exposure (18 hr) treatment. Interestingly, we found that acute treatment, the fatty acid amide hydrolase (FAAH) inhibitor PF-3845 induced a transient decrease of mitochondrial ATP production that is almost fully compensated with an increase in glycolytic activity without significant impact in cellular bioenergetics inside the dose range analyzed. Using the XF Mito Stress Test we were able to confirm the inhibition of mitochondrial function under both basal and stressed conditions. Additionally, using the permeabilizing agent XF Plasma Membrane Permeabilizer we were able to identify the mechanism of action of the mitotoxic compound at the molecular level. Treatment of cells for 1 hr with the FAAH inhibitor induced a dose-dependent decrease of complex I activity when respiring on various substrates but did not affect complex II-dependent or complex IV-dependent respiration. The proposed workflow provides a specific and sensitive assay to study mitochondrial function that can be used for deeper evaluation of safety of lead compounds, to discard presence of off-target effects or to characterize the mechanism of mitotoxicity observed in pre-clinical studies.

Occurrence of Spontaneous Arrhythmias in Freely Moving Non-Treated Healthy Telemetered Sprague-Dawley Rats

S. Authier1, P. Juliana Brizuela de Seadi Pereira1, M. Pouliot1, A. Easter2, C. Harper1, A. Prefontaine1, L. Miraucourt2, W. Tan3, W. Wallis4, and R. Kubaszky1. 1CTXoxLAB, Laval, QC, Canada; 2Biogen, Cambridge, MA; 3Avrobio (Formerly at Biogen), Cambridge, MA; and 4Safety Pharmacology Consultant, Royal Tunbridge Wells, United Kingdom. Sponsor: P. Singh

The aim of this analysis was to characterize the occurrence of arrhythmias in freely moving non-treated healthy Sprague-Dawley rats. Male (n=55) and female (n=40) Sprague-Dawley rats (297-654g) were implanted with a telemetry transmitter (Data Science International, model HD-511-F2) with ECG in DII. Arrhythmias were assessed from continuous ECG monitoring over a 48-hour period, and data analyzed using an automated platform (Data Insights™ for the Ponemah™ software v6.3). A total of 1825 ventricular ectopic arrhythmias were identified on freely moving Sprague-Dawley rats. Male (n=55) and female (n=40) Sprague-Dawley rats (297-654g) were implanted with a telemetry transmitter (Data Science International, model HD-511-F2) with ECG in DII. Arrhythmias were assessed from continuous ECG monitoring over a 48-hour period, and data analyzed using an automated platform (Data Insights™ for the Ponemah™ software v6.3). A total of 1825 ventricular ectopic arrhythmias were identified on freely moving Sprague-Dawley rats. The occurrence of arrhythmias in Sprague-Dawley rats was observed in pre-clinical studies. This study represents a promising one to evaluate the superiority of new bone substitutes with osteoconductivity and osteoinductivity properties.

Arrhythmias were assessed from continuous ECG monitoring over a 48-hour period, and data analyzed using an automated platform (Data Insights™ for the Ponemah™ software v6.3). A total of 1825 ventricular ectopic arrhythmias were identified on freely moving Sprague-Dawley rats. Male (n=55) and female (n=40) Sprague-Dawley rats (297-654g) were implanted with a telemetry transmitter (Data Science International, model HD-511-F2) with ECG in DII. Arrhythmias were assessed from continuous ECG monitoring over a 48-hour period, and data analyzed using an automated platform (Data Insights™ for the Ponemah™ software v6.3). A total of 1825 ventricular ectopic arrhythmias were identified on freely moving Sprague-Dawley rats. Male (n=55) and female (n=40) Sprague-Dawley rats (297-654g) were implanted with a telemetry transmitter (Data Science International, model HD-511-F2) with ECG in DII. Arrhythmias were assessed from continuous ECG monitoring over a 48-hour period, and data analyzed using an automated platform (Data Insights™ for the Ponemah™ software v6.3). it was noted that individual animals tended to have a predominant ventricular depolarization pattern (i.e., high repetition of a specific ventricular depolarization scheme) possibly originating from a ventricular ori. Premature junctional complexes were more frequent during the dark period and were more frequent in males than females. As expected, 2nd degree atroventricular (AV) blocks, sinus pauses and junctional escape complexes were noted with increased incidence during daytime (i.e., when rats slept). Most AV blocks (57%) were Mobitz type I while 2nd degree AV block Mobitz type II represented 43%. This work may be considered to support interpretation of arrhythmias in rat telemetry studies, by providing a thorough baseline and a better understanding of gender- and time-dependent effects. The prevalence of commonly observed arrhythmias in rats highlights the importance to thoroughly evaluate each animal prior to study initiation.

3301 Application of In Vitro Multi-Parametric Analysis for Early De-Risking Cardiac and Mitochondrial Toxicity of Ciluprevir: A HCV NS5A/4A Serine Protease Inhibitor

Ciluprevir (BILN 2061), an investigational drug inhibiting HCV NS5A/4A serine protease, induced myocardial vacuolization corresponding to mitochondrial swelling and diminished left ventricular cardiac ejection fraction in a 28-day micro dosing mechanistic study. Detection of cytochrome c release was also noted, possibly due to mitochondrial swelling and/or mitochondrial dysfunction due to cardiotoxicity. Hereby, we retrospectively evaluated a multi-parametric assay (MPA) approach to assess cardiac and mitochondrial function in vitro, as tools for identifying risk for ciluprevir toxicity. Ciluprevir showed minor/no effect on cardiac ion channels (hERG, hIKs, or hNav1.5). When studied in human induced pluripotent stem cell-derived cardiomyocyte (hiPSC-CMs), ciluprevir increased both Ca2+ transient and impedance beat duration, and slowed the beating rate concentration-dependently starting at 11μM. It had no effect on Ca2+ transient amplitude, but associated to major, transient (+21%) increases in impedance amplitude. Ciluprevir 7-day treatment assays showed mitochondrial respiration at 100 μM and high-content imaging assay revealed that it affected mitochondrial intensity and texture, cytoplasmic and nuclear features at IC50s (50-65.4 μM) in hiPSC-CMs. While ciluprevir tested negative using HepG2 glucose/galactose medium switch assay, it acutely induced proton leak and showed an uncoupler-like profile (60 and 100 μM) while had no effect on electron transport chain activity up to 100 μM. The increased glycolysis is likely related to the metabolic adaptation to mitochondrial inhibition. In conclusion, MPA approach supports cardiac and mitochondrial disruption caused by ciluprevir. Uncoupler-like property corroborates with mitochondrial swelling observed in rhesus monkey heart tissues. Furthermore, this retrospective case study demonstrated the unique value of combining acute and long-term in vitro MPA approach as a tool for early de-risking cardiac and mitochondrial safety liability of new therapeutic drug candidates and facilitating preclinical candidate selection.

3302 Characterization of EEG Morphologies during Drug-Induced Seizures and Peri-Ictal Changes in Nonclinical Species

Drug effects on hemostasis may represent intended pharmacology or can be an observed adverse effect. Bleeding time tests (BTT) are used for diagnosis in patients, but also to assess platelet function in non-clinical drug safety assessments. The goal of the study was to assess and compare anatomical sites for BTT in species commonly used for non-clinical drug development. Beagle dogs, cynomolgus monkeys, New Zealand White rabbits and Sprague-Dawley rats were used to assess BTTs at several anatomical regions (i.e., gums, cranium, upper lip, pinna, inner cheek). A single use Surgicutt® bleeding time device for consistency in incision length and depth (1 mm depth by 5mm length) was employed. Craniun presented low inter-occasion variability in all species, most likely due to cutaneous attachment to the cranial structures which enables stable application of Surgicutt® devices. Gums and pinna (evaluated in dogs, monkeys and rabbits only) presented intermediate variability. Lips showed greater variability, possibly due to differences in tissue immobilization and/or saliva levels. Between species, monkey lips (lower lip 10.9 min. and upper lip 7.5 min.) presented the highest inter-occasion variability, but cranium (5.4 min.), pinna (5.4 min.) and inner cheek (4.7 min.) showed values within expected ranges. These results support the use of BTT assessments in duplicate or triplicate at each time point to increase sensitivity of this assay in the context of toxicology assessments.

3303 Safety Risks Due to Low Seizure Detection Specificity: Applications and Limitations of Automated EEG Algorithms in Preclinical Studies

C. L. Douglas,1 and M. Meteaz.2 Covance Laboratories Inc, Madison, WI; and2 Preclinical Electrophysiology Consulting, LLC, Mattapoisett, MA.

The preclinical seizure liability of investigational compounds frequently involves EEG assessments including the presence of compound-induced electrographic seizures and preictal epileptiform morphologies indicative of focal events (e.g., sharp waves). The EEG is a clinically-translatable signal and remains the gold standard for sensitive assessment of a drug’s seizure liability. With the widespread use of affordable video-telemetry EEG, it is presently possible to collect vast amounts of data spanning from 24 hours to many weeks, thus shifting the challenges from data collection to quality data analysis. Most preclinical EEG visualization platforms offer tools intended to automate the search for salient features of the signal related to seizure risk, based usually on a variation of amplitude and frequency or spike train detection. Similar tools are used in the clinic supporting the neurologist-driven EEG interpretation, which remains the only acceptable diagnostic methodology due to the complexity and variability of the signal. Here we present case studies using EEG from rodents, dogs and monkeys, illustrating a consistent lack of specificity of automated algorithms resulting in false negative and false positive findings. Recommendations are made for a tiered approach to preclinical EEG data analysis, including expert-driven and computerized tool-box aided approaches, that provides a sensitive and systematic analysis that reduces the risk of incorrect interpretation and omissions and increases the value of this information-rich functional measure.

3304 Evaluation of Primary Hemostasis Using Bleeding Time Tests: Anatomical Sites and Species Comparison

When studied using human induced pluripotent stem cell-derived cardiomyocyte (hiPSC-CMs), ciluprevir increased both Ca2+ transient and impedance beat duration, and slowed the beating rate concentration-dependently starting at 11μM. It had no effect on Ca2+ transient amplitude, but associated to major, transient (+21%) increases in impedance amplitude. Ciluprevir 7-day treatment assays showed mitochondrial respiration at 100 μM and high-content imaging assay revealed that it affected mitochondrial intensity and texture, cytoplasmic and nuclear features at IC50s (50-65.4 μM) in hiPSC-CMs. While ciluprevir tested negative using HepG2 glucose/galactose medium switch assay, it acutely induced proton leak and showed an uncoupler-like profile (60 and 100 μM) while had no effect on electron transport chain activity up to 100 μM. The increased glycolysis is likely related to the metabolic adaptation to mitochondrial inhibition. In conclusion, MPA approach supports cardiac and mitochondrial disruption caused by ciluprevir. Uncoupler-like property corroborates with mitochondrial swelling observed in rhesus monkey heart tissues. Furthermore, this retrospective case study demonstrated the unique value of combining acute and long-term in vitro MPA approach as a tool for early de-risking cardiac and mitochondrial safety liability of new therapeutic drug candidates and facilitating preclinical candidate selection.
organ toxicity data exist.

**3306 Prediction of Tyrosine Kinase Inhibitor Contractility Risk with Adult Human Primary Cardiomyocytes**

Tyrosine kinase inhibitors (TKIs) provide effective cancer treatments by blocking kinases involved in tumour growth and angiogenesis, but they are often associated with cardiotoxicity ranging from heart failure, left ventricular systolic dysfunction and hypertension to arrhythmias. In order to enable the development of a new generation of safer TKIs, it is therefore critical to establish novel strategies that can help rank the cardiotoxicity of molecules in early drug discovery. Here, we have employed adult human primary cardiomyocytes from donor hearts and have shown that these cells exhibit the expected physiological properties and can be used for in vitro safety studies. In the present work, we have employed adult human primary cardiomyocytes to assess the cardiotoxicity of 7 US FDA-approved TKIs and one experimental TKI. Using clinical reference data, we have investigated the ability of non-invasive measurement of cardiomyocyte contractility to predict the cardiac safety risk associated with each one of the drugs. Both negative and positive controls were selected, including 4 known cardiotoxic drugs (AZD7762, Imitinib, Sorafenib, Vandetanib) as well as 4 non-cardiotoxic (Afatinib, Dasatinib, Erlotinib, Gefitinib). Our data demonstrate that isolated adult human primary cardiomyocytes are differentially affected by safe and cardiotoxic TKIs. For example, while Afatinib, Dasatinib, Erlotinib and Gefitinib had no effects on contractility up to concentrations equivalent to 30-fold the Cmax at therapeutic dose, AZD7762, Imitinib, Sorafenib and Vandetanib inhibited contractility with IC50 values of 0.8μM, 44μM, 1.2μM and 4.6μM, respectively, which closely match the therapeutic plasma concentrations. Thus, adult human primary cardiomyocytes can provide a useful strategy for the early assessment of cardiac risk associated with anticancer TKIs. Furthermore, this study resulted in the unexpected finding that human cardiomyocyte contractility can be affected by toxic TKIs, irrespective of the effects on the vasculature and chronic cardiac remodelling.

**3307 Trial to Detect Significant Metric Parameters and to Find Novel Methodologies for Drug-Induced Seizure Liability Using Microelectrode Arrays Data Analysis and Primary Rodent Neurons**

N. Miyamoto1,2, A. Ojima1,2,3, S. Inaba1,2, T. Kitamura4, T. Osada5, I. Suzuki2, A. Odawara6, N. Matsuda6, and T. Yoshinaga1,2,3. Eisai Co., Ltd., Tsukuba, Japan; 1,2,3Consortium for Safety Assessment using iPS Cells (CSAHi), Kawasaki, Japan; 4TechnoPro R&D Company, Tsuchiura, Japan; 5LSI Medience Corporation, Kamisu, Japan; 6LSI Medience Corporation, Chiyoda, Japan; and 7Tohoku Institute of Technology, Sendai, Japan. Sponsor: H. Suganuma

Drug-induced seizures are a key reason for clinical failure and drug withdrawal from the market. Despite the huge safety problem, detecting seizure liability preclinically remains challenging and there is not yet a reliable, non-clinical, in vitro model to predict seizure liability of drug candidates. To address this, the study was designed to test effects of known compounds with defined seizure liability profiles on neuronal activity on the MEA, with the goal to identify activity signatures that associate with specific liability profiles. If yes, those profiles could be used to screen unknown compounds for seizure liability. Primary cortical neurons were prepared from fetal Wistar rats, 18 days post-coitum, and then seeded on 48-well Classic MEA plates and 24-well MED-Q2430M plates for extracellular recording using Maestro and Maestro Pro or using ME604-Presto respectively. Twelve compounds (pentyletetrazole, picrotoxin, 4-aminoypyridine, linopryridine, amoxapine, pilocarpine, amoxapine, chloromazone, oxinoklon, phentolamine and acetaminophen) were added to the cells (n = 6) at 5 concentrations for each compound to see phenotypic changes on spontaneous electrical activity in neural networks, after 19 days of culture. We identified consistent profiles of neuronal activity changes induced by compounds with similar modes of action. The structure of synchronized burst firing showed characteristic changes in neuronal activity patterns that were consistent with the effects found on significant metric parameter analysis. A deep learning algorithm could also successfully classify drugs by mode of action and accurately predicted synchronized burst response patterns in all drug types. MEA technology has the potential to predict the seizure liability of drugs using Analysis of Metric Parameters, Synchronized Burst Firing Structure, and Deep Learning Methodology.

**3308 Evaluation of a High-Content Cytometry Methodology for Drug-Induced Seizure Liability Using Microelectrode Arrays Data Analysis and Primary Rodent Neurons**

A. A. Bieberich1, V. Shankey2, B. Rajwa2, R. Fatig1, M. Kuhl1, and T. Johnson3. 1AsedaSciences AG, West Lafayette, IN; 2Purdue University, West Lafayette, IN; and 3Merck Research Laboratories, West Point, PA.

Predicting in vivo toxicity liability with in vitro screens during early drug discovery could improve selection of lead series/single candidate pharmaceuticals while reducing animal usage, cost and time of chemical synthesis scale up. Therefore, high content, high throughput (HTS) assays using cultured cells, multiple toxicity markers, and machine learning methods have been used to correlate in vitro results with human and/or animal toxicity. Merck and AsedaSciences collaborated to use an HCS acute cellular stress assay, employing automated flow cytometry, to evaluate 115 compounds from discontinued Merck programs where in vivo organ toxicity data exist from short-term rat studies used for candidate selection. HLC60 cells were plated in 384-well plates at 10,000/well and incubated with duplicate 10-step dilution series of each compound for 4hrs, 5μM to 100μM. Unlike the traditional method of determining EC50 values for each of the 12 phenotypic parameters, an automated computational algorithm produces a set of distance values between controls and test compound concentrations for all 12 parameters. A supervised learning classifier then scores each compound relative to a training set of ~300 annotated failed and on-market pharmaceuticals and environmental toxicants. Results of the in vitro screen were compared to the in vivo rat outcome, i.e. organ toxicity assessed by gene transcriptional markers and/ or histopathology. In the in vivo studies compounds that were well tolerated, lacked organ toxicity, and achieved rat plasma Cmax exposures of ~50μM or higher were considered negative. Relative to the in vivo studies, the in vitro cellular stress screen exhibited 24% sensitivity and a high specificity (94%, only 5 false positives), desirable for an early drug discovery screen. In addition, there was high replicability for in vitro phenotypic parameters and scores in independent runs. Factors expected to limit HLC60 sensitivity include metabolism, transporters and ion channels, organ systems, and species differences (human vs rat). Overall, the results of this in vitro assay are promising for identifying intrinsic chemical potential of parent compounds to disrupt highly conserved cellular organelles. Predictive power will increase with growth of the training set and deployment of a parallel test strategy.
There is a strong focus on the development of new in vitro toxicity assays that are predictive of adverse events linked to drug attrition. These assays are often validated using only those drugs that have reached the clinical or market and for which adverse event profiles are known. For example, new hepatotoxicity assays are often validated using drugs contained within the Liver Toxicity Knowledge Base (LTKB). Whilst these ‘global’ validation datasets are critical towards understanding the human relevance of new assays, one of their limitations is that they are largely compiled of structurally-dissimilar compounds that have large variations in ADME profiles and pharmacological potency. These datasets are not reflective of the situation in early drug discovery where new in vitro assays must also be able to differentiate the toxicological profiles of compounds that may have similar structural and pharmacological profiles. For example, sunitinib, an anti-cancer multi-targeted kinase inhibitor, is classified as most-DILI concern, yet is associated with multiple organ injuries and is active in many in vitro assays. In contrast, aspirin, a compound of less-DILI concern is relatively pharmacologically inactive. An assay that can differentiate the hepatotoxicity profiles of these two compounds is clearly beneficial, yet it is possible that the assay is differentiating non-specific pharmacological potency as opposed to actual mechanistic, hepatotoxic potential. Therefore, in addition to a global validation, we conducted local analyses based on target class, mode-of-action and chemotype-similarity for new in vitro assays: 1) a human 3D liver microtissue model, 2) a proximal tubule cell model and 3) a human hematopoietic stem cell derived myeloid model. The importance of a local validation is clear, both the liver and myeloid model could distinguish internal compounds within same pharmacology and chemotype. For example, a drug candidate associated with bone-marrow toxicity had an IC$_50$ value of 0.11 μM in the myeloid model, whereas a non-toxic analogue of just two carbon difference was safer at 58 μM. This extra validation step is essential to ensure that activity observed in new in vitro assays is a result of toxicologically-relevant mechanisms and not the result of mechanistically-irrelevant pharmacological potency or physicochemical properties. In addition, local validation provides the evidence that assays can be used confidently to de-prioritize risky compounds at the design stage, thereby enabling a Safety-By-Design strategy.

Antibacterials and Nucleoside reverse transcriptase inhibitors (NRTIs) are known for their potential to induce mitochondrial dysfunction through depletion of mitochondrial coded proteins. The depletion of mitochondrial coded proteins can be achieved through effects on mitochondrial transcription or translation so direct evaluation of the protein expression is necessary to evaluate effects on both of these mechanisms. Existing high throughput methods utilize qPCR or inCell ELISAs to measure these effects. qPCR fails to determine effects on translation. InCell ELISA methods directly measure protein expression of one mitochondrial and nuclear coded protein in the cell culture well but it does not have the ability to quantify cell count and therefore could be misleading if the test article causes significant cell cycle arrest or cytotoxicity. Here we show development of a high content imaging assay which uses immunofluorescence to directly and simultaneously measure expression of the mitochondrial coded protein, COX-1, and the nuclear coded mitochondrial protein, SDH-A, on a per cell basis. Because of this, we are able to identify compounds that inhibit mitobiogenesis even when the cell count is reduced. Cell count can also be reported with the use of Hoechst in the nuclear channel. We evaluate the effects of 8 NRTIs and 8 antibacterials in 8-point dose response curves in a 384 well plate for 5 days. We show that we correctly identify the antivirals ddC and 4’ Azidocytidine (R-1479) as well as the antibiotics chloramphenicol and linezolid at their expected concentrations. For the positive compounds, we show a reduction in the COX-1 expression while we observe no loss in expression of the nuclear coded SDH-A. We also show that by generating a ratio of these two mitochondrial proteins, we can also create a much tighter curve as compared to the COX-1 alone. In conclusion, this assay is quantitative and reproducible, with the added advantage that cell count is determined simultaneously and results can be directly verified by analysis of the cellular images.
Drug-related mitochondrial toxicities are common off-target effects resulting in myriad of organ toxicities. High energy-demanding organs and tissues such as the liver are notably susceptible to the toxicities. Accordingly, hazards of mitochondrial toxicity are associated with drug-induced liver injury (DILI) in humans. To detect compound-related mitochondrial effects during lead optimization through candidate selection, companies employ in vitro assays including glucose/galactose switching assay (GGA), mitochondrial membrane potential/swelling, mitochondrial DNA and oxygen consumption rate measurements. Cell-based respiration studies that measure changes in OCR (OCR assay) are becoming a common tool and have potential to be more sensitive to identify mitochondrial toxicities than GGA. However, a thorough qualification of OCR assays has not been done yet in the context of DILI to date. Here, we evaluated a set of approximately 170 drugs with/without DILI in HepG2 cells using the Seahorse Extracellular Flux Analyzer. Compounds were preincubated at 1, 10 and 25 µM for 2h, followed by a standard protocol with minor modifications. Forty-five out of 173 compounds caused significant reduction in basal and maximal respiration (BR, MR) as compared to vehicle controls. Interestingly prospective uncouplers prevented reduction of OCR at certain doses after oligomycin injection, suggesting identification of dose-dependent uncoupling effects. For risk classification, we defined compounds causing >50% reduction in BR and/or MR as High Risk, <50% reduction as Low Risk, but as Medium Risk in case of obvious dose-dependent reduction in OCR observed. Results were compared to clinical DILI classification. OCR assay showed increased sensitivity (37%) and specificity (84%) as compared to GGA (21% and 80%). For comparison of each assay to identify mitochondrial toxicants from those that are not associated with clinical DILI, we calculated the positive/negative likelihood ratio (PLR/NLR) based on the sensitivity and specificity estimates. Higher PLR/lower NLR values were observed in OCR assay (2.22/0.76) in relation to GGA (1.01/1.00), supporting enhanced predictive value of OCR assay to correctly identify clinical DILI. When addressing only high dose drug (e.g. plasma Cmax > 1 µM), the predictivity of these assays increased with PLR/NLR values in OCR assay and GGA of 4.67/0.67 and 3.50/0.81, respectively. Taken together, the cell-based respiration assay outperformed GGA assay and appears a promising tool for prediction of DILI.

**3313 Evaluating the Utility of Microbrains Using Microelectrode Array, Calcium Oscillation and Calcium Imaging Technologies for Compound-Induced Seizure Risk Assessment**

Drug-induced seizure is the leading liability underlying the central nervous system toxicity attrition in drug discovery and development. To improve emerging in vitro methods to support compound-induced seizure risk assessment, we evaluated the utilities of human induced pluripotent stem (iPS) cellderived neural models (2D and 3D microBrains) using microelectrode array (MEA), calcium oscillation, and calcium imaging technologies. First, we characterized the microBrains, which were found to be evenly comprised of cortical neurons (GABAergic and glutamatergic) and astrocytes. Functionally, the 2D microBrains showed spontaneous firing on the low-throughput MEA platform. The 3D microBrain showed spontaneous synchronized calcium transient oscillations on the high-throughput Fluorescent Imaging Plate Reader (FLIPR) platform. Secondly, we selected rodent nonclinical seizure models using seizurogenic reference compounds, including but not limited to kainate, 4-aminopyridine, pentylenetetrazole, and bicuculline, to evaluate related genomic/proteomic biomarkers including expression level changes in markers of neuronal (e.g. UCHL1) and astrocyte toxicities (e.g. GFAP). Lastly, we examined whether the changes in MEA, FLIPR and/or biomarkers could be used to systematically detect seizure risk of proprietary compounds. Taken together, the 2D and 3D microBrains and associated biomarker changes showed promise as tools to reveal translational mechanisms of compound-induced seizure risk.

</table>

The above table is a snapshot of the author index from the 2019 SOT Annual Meeting document. It lists authors and their abstract numbers, with asterisks indicating presenters. The table includes authors from various fields, with a variety of abstract numbers ranging from 1194* to 2250. The document also includes metadata at the top, indicating the starting page (1782) and the last page (2820), and a footer at the bottom indicating the meeting's date and location (2019 SOT Annual Meeting in Philadelphia, PA).
The numerals following the author names refer to the abstract numbers.
The asterisk after the abstract number indicates the author is the presenter.
The numerals following the author names refer to the abstract numbers. The asterisk after the abstract number indicates the author is the presenter.
