Background and Purpose: Cell Painting is a high-throughput phenotypic profiling assay that uses fluorescent cytochemistry to visualize a variety of organelles and high-content imaging to derive a large number of morphological features at the single-cell level. Most Cell Painting studies have used the U-2 OS cell line for chemical or functional genomics screening. The assay can be used with many human-derived cell types, given that it is based on the use of fluorophores that label organelles present in most human cells. Rather than assay fixed specimens, an alternative would be to employ a longitudinal study design that assays Cell Painting endpoints in living cells using a combination of organelle stains and endogenously expressed fluorescent protein(s) at prescribed intervals over a 72-hour period. Using non-toxic organelle labels alleviates the requirement for separate assay plates and reagents for each time point. This provides the opportunity to ascertain a more precise time to measure benchmark concentrations or tipping points in the cellular response to chemical exposure. **Methods:** U-2 OS cells were labeled using two live-cell labeling schemes. The first uses a multiplexed combination of NucleoLive (Saguaro) for the nucleus, Biotracker 405 (Sigma) for mitochondria, wheat germ agglutinin (WGA) 555 (Sigma) for the cell membrane, and LysoTracker 633 (Sigma) to label lysosomes. The second uses engineered U-2 OS cells containing endogenously tagged Blue Fluorescent Protein LaminB1 (Sigma) for the nuclear membrane, MitoTracker Green FM (Sigma) for mitochondria, WGA 555 and LysoTracker 633. For each assay, a stain mixture was combined with U-2 OS cells, which were plated in wells of a 384 well plate using a Certus Flex microdispenser. Following an 18-hour incubation for labeling and attachment, cells were rinsed twice with growth medium and imaged using a Revvity Opera Phenix Plus Imager. Immediately following the initial scan, chemical treatments were applied using an Echo 550 acoustic liquid handler (Beckman). Cells were returned to incubation and imaged at 6, 24, 30, 48 and 72 hours. After image acquisition, 1019 features were analyzed. Following feature extraction, data were normalized to vehicle controls using median and median absolute deviation (MAD). Cell-level data were aggregated to the well-level and used for concentration response modeling with the R package tcplfit2 (v.0.1.9). Normalized cell counts were calculated to evaluate any cytotoxic or cytostatic effects and used to exclude cytotoxic treatments from further analysis. Concentration response modeling was performed using Mahalanobis distance calculations of the well-level data. In addition, 34 separate 'Category-Level Mahalanobis' distance values, representing features categorized by channel, measurement type, and cellular compartment (e.g. DNA_Intensity_Nuclei) were also calculated. These distances were modeled in R to determine benchmark concentration (BMC) values for treatments where the bioactivity exceeded the benchmark response (BMR) of 1 standard deviation from the median of vehicle controls. A Phenotype Altering Concentration (PAC) was defined as the minimal of the global BMC and most-sensitive category-level BMC. **Results:** In this study, 17 chemicals were assayed. Cells were exposed to eight concentrations of Amperozide, Berberine Chloride, Ca-074-Me, Cucurbitacin I, Etoposide, Fenbendazole, Fluphenazine, Latrunculin B, Lys05, Metochlopramide, Oxibendazole, Rapamycin, Rotenone, Taxol, Tetrandine, Saccharin and one concentration of Staurosporine. For

all chemicals assayed, phenotypic profiles generated from the data largely agree with expected cellular effects. For example changes in mitochondria associated cellular features were evident at several time points following exposure to Berberine Chloride. Derived PAC values were compared to some of those found in previous Cell Painting time course studies (e.g Nyffeler et al, 2020) and found to be within expected ranges. **Conclusions:** The use of non-toxic fluorescent organelle labels in a longitudinal high-throughput phenotypic profiling assay is a potentially viable method for Tier 1 screening, and can provide time-course type data from a single exposure experiment. *This abstract does not represent US EPA policy.*

PS 3363 Evaluating an *in vitro* Human-Based Blood-Milk-Barrier Model for Drug Transport During Lactation

M. Garcia¹, C. Sullenberger¹, R. M. Geiger¹, S. M. Rahman¹, P. Hyland¹, K. Krutsch², E. Pfuma Fletcher¹, T. K. Feaster¹, and K. Blinova¹. ¹Food and Drug Administration, Silver Spring, MD; and ²Infant Risk Center - Texas Tech University Science Center, Amarillo, TX. Sponsor: K. Howard

Background and Purpose: Breastfeeding provides well-established maternal, infant, and economic benefits, yet the use of medications during lactation remains a major barrier due to limited data on drug transfer into human milk. Because lactating women have historically been excluded from clinical drug studies, significant knowledge gaps persist, complicating treatment decisions for breastfeeding mothers. Existing approaches, such as targeted clinical studies, animal models, and traditional 2D cell cultures, offer useful insights but are limited by slow enrollment, ethical constraints, and reduced ability to recapitulate complex 3D human breast tissue structure and function. These challenges highlight the need for new approach methodologies (NAMs) to study drug transport across the blood-milk barrier. In this study we evaluate a microphysiological system (MPS) that models the human blood-milk barrier *in vitro* as a tool to predict drug transfer into breast milk. **Methods:** Here, we utilize a blood-milk barrier MPS composed of primary human mammary epithelial and endothelial cells. The MPS is designed to recreate key features of the human mammary epithelium and its microenvironment *in vitro*. Primary mammary epithelial cells were exposed to lactogenic media and characterized by qPCR for milk-associated and transporter gene expression, as well as by immunostaining of tight-junction markers pre- and post-differentiation. Nonspecific drug binding was assessed through an LC-MS/MS-based adsorption study to quantify nonspecific interactions within the MPS. Evaluation of drug transfer using a panel of medications with diverse physicochemical properties is planned and will be incorporated as the next phase of the study. **Results:** Characterization of the blood-milk barrier MPS confirmed formation of a continuous epithelial monolayer expressing tight junction markers, indicating functional barrier integrity. qPCR analysis demonstrated induction of milk-related proteins following exposure to lactogenic media, supporting the physiological relevance of the model. Preliminary assessments of nonspecific drug binding enabled differentiation between compound loss and true permeability. A panel of medications with diverse LogP values and passive permeability characteristics is currently being evaluated to determine drug transfer across the barrier. Drug-transfer metrics generated by the MPS will be compared with existing human lactation data to assess concordance and the predictive performance of the model. **Conclusions:** Critical physiological features and performance criteria of the MPS have been demonstrated, and validation of this platform for predicting drug transfer into human milk is ongoing. This tool has the potential to advance toxicology assessment and regulatory science by addressing data gaps and improving the safety assessment of medications used during breastfeeding. Ultimately, this approach may inform on the use of medications in breastfeeding mothers and enhance maternal-infant health. **Disclaimer:** This abstract reflects the views of the authors and should not be construed to represent FDA's views or policies.

PS 3364 CAMERA: A Centralized Public Resource for Validated Alternative Methods to Support Regulatory Decision-Making

A. R. Cole¹, K. Needham¹, P. Osei-Akyeampong¹, T. Abioye¹, E. N. Reinke², B. Reisfield², B. Chambers², J. Hamm², R. Tieghi¹, T. Saddler¹, J. Mensah¹, C. DeGroot¹, W. Casey³, N. C. Kleinstueber⁴, and H. T. Hogberg⁵. ¹Dynanet Corporation, Elkridge, MD; ²Inotiv, Research Triangle Park, NC; ³DTT, NIEHS, NIH, Research Triangle Park, NC; ⁴DPCCPSI, NIH, Bethesda, MD; and ⁵NICEATM, DTT, NIEHS, NIH, Research Triangle Park, NC.

Background and Purpose: The Collection of Alternative Methods for Regulatory Application (CAMERA) is a publicly accessible online resource that provides streamlined access to validated and qualified new approach methodologies (NAMs) for chemical and biological safety assessment. Agencies within the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) identified a critical need for a unified platform that compiles validated alternative test methods to support the transition toward reduced animal use, consistent with the recent initiatives of the National Institute of Health (NIH) and the US Food and Drug Administration (FDA). The CAMERA initiative aims to integrate alternative methods into a cohesive workflow to better support and inform regulatory decision-making. **Methods:** Validated NAMs for human relevant endpoints, including skin sensitization, skin irritation, eye irritation, and corrosion, were identified from OECD-accepted test

guidelines. Validation reports for these methods were reviewed to extract and curate key information such as test method type, endpoint, test system, mode of action, applicability domain, validating organization, reference chemicals, and performance metrics. In addition, relevant supporting documents, regulatory guidance/guideline and literature were identified. **Results:** CAMERA illustrates the effective consolidation of validated NAMs into a single, accessible platform, improving the accessibility of methods and their underlying validation data that was previously scattered across multiple agencies and organizational websites. The platform's architecture enables user-driven, filtered searches by method type, endpoint, and regulatory agency. The platform also allows side-by-side comparisons of method information, including a Venn-diagram that visualizes reference chemicals across methods, with downloadable tables detailing chemical properties and performance results. Chemicals can be further explored for their characteristics and toxicity information through the Integrated Chemicals Environment. CAMERA integrates supporting materials such as standardized method descriptions, performance metrics, links to validation study reports, protocols, curated datasets, regulatory acceptance documents, adverse outcome pathways, and access to publications via PubMed query. User testing indicated strong support for CAMERA's ability to streamline the identification of regulatory-accepted NAMs, enable comparison of method applicability, validation status, and performance. Initial feedback emphasized its value in meeting agency needs for transparency, harmonization, and improved access to NAMs that advance the principles of the 3Rs in replacing, reducing and refining animal tests. **Conclusions:** CAMERA provides an efficient, user-friendly platform that significantly enhances access to validated and qualified NAMs, supporting broader federal goals to reduce animal use and modernize toxicology. By integrating study reports, protocols, performance data, and regulatory guidance into a unified interface, CAMERA enhances transparency and facilitates consistent application of NAMs in chemical safety evaluation. Ongoing development will expand method domains, strengthen interoperability with ICE, integrate new tools for enhanced interactive capabilities, and continue to integrate user feedback to strengthen CAMERA's utility. This research was supported by the Intramural Research Program (ES# 103386) of the National Institute of Environmental Health Sciences, National Institutes of Health under contract HHSN273201500010C. Information technology service associated with this project was provided under contract 75N93025F00252. The findings and conclusions presented in this abstract are those of the authors and do not necessarily reflect the views of the National Institutes of Health or the US Department of Health and Human Services.

PS 3365 **hiPSC-derived Sensory Neuron and Schwann Cell Co-culture as a NAM for Peripheral Neuropathy Risk Assessment**

X. Tang¹, J. E. Finley¹, D. Capunitan¹, G. Lee¹, C. Liu¹, and P. Treuting². ¹Drug Safety Research & Development, Pfizer Inc., Groton, CT; and ²Drug Safety Research & Development, Pfizer Inc., Bothell, WA.

Background and Purpose: Peripheral neuropathy (PN) is a common and dose-limiting side effect of chemotherapy including antibody drug conjugates (ADCs). Traditional animal models are limited in throughput and translational relevance. Human induced pluripotent stem cell (hiPSC)-derived sensory neurons (SN) offer a promising *in vitro* alternative but lack the cellular complexity of the peripheral nervous system. This study aims to evaluate a co-culture model of hiPSC-derived sensory neurons and Schwann cells (SN+SC) as a new approach methodology (NAM) for PN risk assessment, hypothesizing that the inclusion of Schwann cells enhances sensitivity and physiological relevance. **Methods:** Cryopreserved hiPSC-derived SNs and SCs were obtained from a vendor following approved regulatory and ethical protocols. The SNs and SCs were derived from the same healthy male donor which eliminated cross-individual variations. The culture was maintained for 3 weeks before 48-hour treatments with vincristine (VCR) or paclitaxel (PTX). Response to the compounds of the co-culture were compared to SN monoculture and neonatal rat primary dorsal root ganglia (DRG) neurons. Endpoint assessments included morphological evaluations via phase contrast and high-content fluorescent imaging, multi-electrode array (MEA) recording, RNA sequencing, and bead-based chemokine/cytokine release quantification. **Results:** Both the mono- and co-culture displayed PTX-specific swollen and retracted neurites like rat primary DRG neurons reported in our prior study, supporting its physiological relevance. This neurodegenerative phenotype was observed at a PTX concentration as low as 3 μ M. The SN+SC co-culture demonstrated a ~20% greater neurite loss compared with SN-only cultures under VCR (30 nM) or PTX (30 μ M) treatment. RNA sequencing results further supported the sensitivity of the co-culture by significant enrichments in microtubule function-related pathways reflecting leading mechanisms of VCR-induced PN. The top three impacted pathways in the co-culture at 10 nM VCR were microtubule motor activity, microtubule binding, and tubulin binding. These disruptions were not observed in the SN monoculture at the same VCR concentration. MEA data revealed that the spontaneous firing rate in both mono- and co-culture were sensitive to VCR exposures. At 3 nM, VCR induced a rise in mean firing rate while neurite retraction was not significant, indicating that functional changes can occur prior to noticeable structural damage. In addition, elevated monocyte chemoattractant protein-1 (MCP-1), interleukin-6 (IL-6), interleukin-8 (IL-8), and interleukin-18 (IL-18) was detected at the same VCR level, indicating the responsiveness of functional readouts to VCR exposure. **Conclusions:** The hiPSC-derived SN+SC co-culture model offers equal or superior sensitivity and functional potentials

over SN-only and rat primary DRG systems. Its ability to replicate key morphological, functional, and molecular features of PN positions it as a promising NAM for peripheral neurotoxicity risk evaluation in oncology drug development.

PS 3366 **Development of Microfluidic Chip-Based Multi-Cellular Model for Local Toxicity Test**

M. Kwon¹, H. Chae¹, T. Lee², S. Kyung², W. Park², J. Ko², K. Lim³, and B. Park¹. ¹Kolmar Korea Co., Ltd, Seoul, Korea, Republic of; ²Gachon University, Seongnam, Korea, Republic of; and ³Ewha Womans University, Seoul, Korea, Republic of.

Background and Purpose: In alignment with the U.S. Food and Drug Administration (FDA) Modernization Act, New Approach Methodologies (NAMs) have recently gained significant attention. There is a growing demand in the industrial sector for NAMs that not only emulate human physiology but also enable high-throughput-like screening strategies. However, conventional single-cell culture models for assessing local toxicity, such as skin, exhibit limited biological relevance and often fail to replicate the layered structure and barrier function of human skin. To address these limitations, an advanced tri-culture horizontal platform within a microphysiological system (MPS) is developed in this study. **Methods:** The microfluidic chip was fabricated using a 3D printer and treated with air plasma to induce a hydrophilic surface. A simultaneous skin and eye irritation test model was designed using human keratinocytes (HaCaT), human umbilical vein endothelial cells (HUVEC) and rabbit cornea epithelial cells (SIRC). Additionally, alternative combinations of cells, including HaCaT, HUVEC and human dermal fibroblasts (NHDF), were employed to replicate more advanced skin structures, enabling enhanced skin toxicity tests. The model was evaluated using proficiency test materials, including cyclamen aldehyde and glycerol, which are recommended under the Organisation for Economic Co-operation and Development (OECD) Test Guidelines 439 and 492. Test materials were applied for 5 minutes at concentrations of 0.05% and 5%. After 72 hours of incubation, cell viability (CV) was evaluated using a dual-modality approach: an absorbance-based cholecystokinin octapeptide (CCK-8) assay and a fluorescence-based LIVE/DEAD assay. Imaging analysis was conducted automatically using Python-based graphic user interface. **Results:** The jig was additionally designed to accommodate the chip devices and facilitate high-throughput screening using a standardized spectrophotometer during the study. The fibrin hydrogel matrix was optimized at a concentration of 1.0 mg/ml to support diffusion and interaction of test samples across channels during treatment. Based on CV measurements from three different channels, gradient graphs at each concentration were illustrated and the standard deviation among all test materials was calculated to below 15% (n=3). A scoring criteria system (0 to 3) was established based on CV significance between three cell channels: score 0 for non-irritating (CV >80%), score 1 for mild irritating (50% < CV ≤80%) and score 2 for severe irritating (CV ≤50%). The model demonstrated its ability to distinguish between irritants and non-irritants, aligning with the Globally Harmonized System (GHS) categories. The results indicate that the model successfully has its potential as a preliminary screening tool. **Conclusions:** The multi-cellular model was designed in a standardized 96-well plate format, incorporating chip devices and a corresponding analytical jig to ensure compatibility with conventional colorimetric assays. This chip-based assay represents a cost-effective and scalable screening tool within the MPS for safety evaluation, utilizing standardized absorbance and spatially resolved analysis. Furthermore, the model is expected to be applicable for assessing additional aspects of toxicity and efficacy in future studies.

PS 3367 **Unveiling Oral Vulnerability: A Human 3D Model of Sulfur Mustard-Induced Epithelial Injury**

L. Karchalla, L. Byers, V. Vuong, S. Ahmad, and P. M. McNutt. Wake Forest Institute of Regenerative Medicine, Winston Salem, NC.

Background and Purpose: Sulfur mustard (SM) is a highly reactive alkylating agent that penetrates epithelial barriers and causes severe tissue injury through DNA and protein adduction, inflammation, and cytotoxicity. While SM effects on skin, eyes, and lungs are well documented, the oral mucosa remains an understudied target despite clinical reports of acute necrosis, persistent ulceration, and epidemiologic associations with oral cancers. Mechanistic insights into oral SM toxicity are limited and rely primarily on retrospective human case reports with variable exposure histories. Commercial oral organoids exhibit deficits for toxicology studies, including poor epithelial stratification, lack of a proliferative basal layer, and short culture lifespan. These deficits are important for oral SM studies, as proliferating basal epithelial cells are particularly susceptible to SM-induced interstrand DNA crosslinks. To overcome these limitations, we developed a long-lived, human oral mucosal tissue equivalent (OMTE) composed of primary oral keratinocytes, fibroblasts, and endothelial cells. **Methods:** Primary human oral keratinocytes were seeded atop a fibrin hydrogel embedded with fibroblasts and endothelial cells. Cultures were grown at an air-liquid interface under conditions optimized for long-term viability and epithelial stratification. Tissue architecture was validated by histology (H&E), and phenotypic maturation was assessed via IHC for epithelial, stromal, and endothelial markers. SM vapor exposures were applied apically and quantified as concentration × time (CT), spanning subthreshold to overtly cytotoxic doses. Post-exposure analyses included H&E, IHC for DNA damage (γH2AX) and cell death markers, and quantification of

lactate dehydrogenase (LDH) release in basolateral media as a measure of cytotoxicity. **Results:** OMTEs maintained a proliferative basal epithelium and stratified architecture through at least 42 days. H&E revealed a non-keratinized epithelium with a columnar basal layer, polygonal stratum spinosum, and outer stratum superficialis, supported by a fibroblast-rich stroma with robust neovessel formation. IHC confirmed epithelial maturation (p63+, CK5+, CK13+), basal epithelial cell proliferation (ki67+), and stromal (vimentin+) and endothelial (CD31+) identity. SM exposure induced dose-dependent epithelial separation, progressing to widespread detachment and stromal disruption. IHC revealed activation of multiple cell death pathways: cleaved caspase-9 (intrinsic apoptosis) was present, while caspase-8 (extrinsic apoptosis) and phosphorylated RIPK3 (necroptosis) were absent. Cleaved gasdermin D indicated pyroptotic pore formation, and nuclear AIF co-localized with γH2AX foci, consistent with parthanatos and DNA double-strand breaks, while GPX4 downregulation suggested lipid peroxidation and ferroptosis. LDH release correlated with histologic injury severity, reflecting progressive cytotoxicity and barrier compromise. **Conclusions:** The OMTE model recapitulates SM-induced, dose-dependent DNA damage and reveals selective activation of intrinsic apoptosis, pyroptosis, ferroptosis, and parthanatos, with minimal evidence for extrinsic apoptosis or necroptosis. These mechanistic insights support quantitative dose response analysis and comparative injury profiling, positioning the OMTE as a robust, human-relevant platform for oral toxicology by vesicants and other toxicants. This work enables high-resolution mapping of epithelial vulnerability in a translationally relevant system. Future studies will explore targeted inhibition of cell death pathways to mitigate injury progression and improve tissue outcomes and extend to other oral toxicants.

PS 3368 Dual NR4A1 and NR4A2 Ligands Promote Ferroptosis and Inhibit Rhabdomyosarcoma Growth through CD71 Activation

A. R. Oany, S. Upadhyay, and S. Safe. Texas A&M University, College Station, TX.

Background and Purpose: Rhabdomyosarcoma (RMS) is the most prevalent soft tissue sarcoma in children and adolescents, with poor prognosis in metastatic or treatment-resistant cases. Conventional therapies often fail to eliminate aggressive tumor populations. Ferroptosis, a regulated form of cell death driven by iron accumulation and lipid peroxidation, has emerged as a promising therapeutic strategy for targeting RMS cells. This study investigates the potential of bis-indole-derived C-DIM compounds to induce ferroptosis in RMS cells by targeting the NR4A1/2-Sp1-CD71 axis, which regulates iron uptake and oxidative stress. **Methods:** Human RMS cell lines (RD and RH30) were treated with C-DIM compounds, and cell viability was assessed using the XTT assay. Intracellular ROS levels and lipid peroxidation were evaluated using H₂DCFDA and BODIPY™ 581/591 staining, respectively, while malondialdehyde (MDA) assays quantified oxidative damage. CD71 mRNA and protein levels were measured by qPCR and Western blot. siRNA-mediated knockdowns of NR4A1, NR4A2, and Sp1 were performed to examine their roles in regulating CD71 expression and ferroptosis. A CD71 promoter luciferase assay was used to assess Sp1-dependent transcriptional activity. **Results:** C-DIM treatment significantly reduced RMS cell viability by enhancing ferroptosis, as evidenced by increased ROS, MDA production, and lipid peroxidation. CD71 expression was markedly upregulated following treatment. Knockdown of NR4A1/2 or Sp1 led to a decrease in CD71 expression and protected RMS cells from ferroptosis. CD71 promoter assays confirmed that Sp1 regulates its transcription in response to C-DIMs. **Conclusions:** C-DIM compounds promote ferroptosis in RMS cells through an NR4A1/2-Sp1-mediated upregulation of CD71. These findings highlight a novel therapeutic strategy targeting the NR4A1/2-Sp1-CD71 axis to induce ferroptosis and overcome treatment resistance in rhabdomyosarcoma.

PS 3369 Beyond phthalates: cytotoxicity and obesogenic potential of emerging alternative plasticizers

A. Frescura, and R. Lavado. Baylor University, Waco, TX.

Background and Purpose: Plasticizers are widely used polymer additives, historically dominated by phthalates and bisphenols, both of which are now well recognized for their endocrine-disrupting and obesogenic properties. In response, the industry has shifted toward alternative plasticizers such as 2,2,4 trimethyl 1,3-pentanediol diisobutyrate (TPIB), di(2-ethylhexyl) adipate (DEHA), dipropylene glycol dibenzoate (DPGDB), tris(2-ethylhexyl) trimellitate (TOTM), polyethylene adipate (PEA), and diocetyl adipate (DOA). Despite their increasing use in food packaging, consumer products, and medical devices, toxicological information on these alternatives remains scarce. **Methods:** Here, these plasticizers were evaluated for their cytotoxicity in human mesenchymal stem cells (MSCs), mature human adipocytes, and hepatocytes (HepG2 cell line) following 24 h and 72 h exposures. Cytotoxicity was quantified using the MTT assay, a colorimetric technique that measures mitochondrial dehydrogenase activity as an indicator of cell viability. Dose-response curves were generated from the data to calculate half-maximal effective concentration (EC₅₀) values for each compound and cell type, providing a comparative assessment of their relative cytotoxic potency over time. **Results:** Most compounds showed very low acute toxicity, with EC₅₀ values >1,000 mM in differentiated adipocytes and hepatocytes (for DEHA, PEA, DOA). However, selective effects were evident in MSCs: TPIB and DPGDB induced moderate toxicity (EC₅₀ ~16-18 mM), and TOTM showed marked potency at

prolonged exposure (EC₅₀ = 0.4 mM). **Conclusions:** The lack of cytotoxicity in mature adipocytes suggests these compounds may exert non-lethal, metabolic effects. Ongoing studies are exploring whether alternative plasticizers disrupt lipid metabolism or promote adipogenesis, potentially contributing to obesity-related outcomes. These findings emphasize the need to evaluate such compounds beyond viability to understand their long-term metabolic impacts and prevent regrettable substitutions.

PS 3370 Identification of clozapine mediated protein modification with a novel strategy: welding click chemistry to advance clozapine toxicity research

S. Lockhart¹, Y. Tabana², S. Tabatabaei-Dakhili¹, D. Babu¹, N. Tran¹, O. Eldalal¹, F. G. West¹, J. R. Ussher¹, K. H. Barakat¹, R. P. Fahlman¹, and A. G. Siraki¹. ¹University of Alberta, Edmonton, AB, Canada; and ²University of Toronto, Toronto, ON, Canada.

Background and Purpose: Schizophrenia affects a significant proportion of individuals, wherein a subset of patients is described as treatment-resistant. Clozapine is an atypical antipsychotic that targets dopaminergic and 5-HT_{2A} receptors, which is reserved for these patients and is superior in its anti-suicidal activity. However, it carries numerous serious warnings, and is well-known for its risk of drug-induced agranulocytosis (severe neutropenia). The exact mechanism of toxicity remains unclear but may involve clozapine's covalent binding to proteins and off-target effects caused by its reactive metabolites. These metabolites are produced by neutrophil myeloperoxidase (MPO), the most prevalent neutrophil enzyme that supports immune responses and also generates reactive species metabolites. Therefore, the identification and protein network analysis of the protein-clozapine adducts could contribute to the current understanding of toxicity pathways. **Methods:** For protein identification, a novel clickable clozapine (Click-CLOZ) derivative was developed and the following click reaction protocol was designed for Click-CLOZ pull down. The Click-CLOZ covalent bound proteins were then captured, allowing for proteomic analysis. The HL-60 (human promyelocytic leukemia) cell line and isolated human neutrophils significantly express myeloperoxidase and were used to identify the protein covalent targets of Click-CLOZ. **Results:** Click-CLOZ and clozapine showed similar cytotoxic effects in HL-60 cells, with comparable reactive metabolite production in an isolated myeloperoxidase system. In HL-60 cells, liquid chromatography-mass spectrometry (LC/MS) analysis identified numerous proteins bound by Click-CLOZ in comparison to the vehicle control. Some captured proteins were known for their roles in DNA replication, immune responses and oxidative stress, such as cathepsin G, myeloperoxidase, ribophorin I and P1-MCM3. In neutrophils, Click-CLOZ bound proteins included myeloperoxidase, S100, and DEFA1B, which are also associated with neutrophil-mediated oxidative stress and immune responses. Interestingly, in both HL-60 cells and neutrophils, myeloperoxidase protein binding was common. **Conclusions:** In conclusion, the application of click chemistry proteomics has facilitated a novel approach to identify multiple clozapine-bound protein targets that will be used to advance the understanding of the toxicity of clozapine in future experimental models.

PS 3371 From Barrier Integrity to Clinical Outcome: A Machine Learning -Enhanced Human Intestinal Model for Diarrhea Risk Assessment Across Small Molecules and ADCs

V. X. Han, S. Gervacio, C. Toohey, H. Aidnik, C. Rosette, and K. E. Murphy. VivoSim Labs, San Diego, CA. Sponsor: C. Tyree

Background and Purpose: Drug-induced diarrhea remains a frequent dose-limiting toxicity with multifactorial mechanisms. Traditional animal models often fail to recapitulate human-specific gastrointestinal (GI) risk, and conventional 2D *in vitro* systems lack the complexity to model barrier function and microenvironmental interactions. Predictive tools that integrate barrier biology and computational analytics are needed to anticipate risk early across modalities. To address this gap, we validated a predictive platform that leverages a machine learning-enhanced 3D human intestinal barrier model for mechanism-aware assessment and early prediction of diarrhea risk across small molecules and antibody-drug conjugates (ADCs). **Methods:** We developed a 3D human intestinal barrier model (NAMkind™ intestine) for ileum and colon by incorporating epithelial and stromal cell components to preserve polarity and tight junctions. Assays measured barrier integrity (trans-epithelial electrical resistance) and cell viability/redox state (ATP, and Alamar Blue) under repeat dosing. A machine learning (ML) model was trained on assay features and clinical incidence and diarrhea severity data using 5-fold cross-validation with thresholds calibrated for high sensitivity. For ADC assessment, we performed comparative arms—intact ADC, antibody-only, and payload-only—using the same exposure schedule and endpoints to enable modality-aware interpretation. **Results:** The *in vitro* model achieved 95% accuracy across a diverse reference set, including NSAIDs, PPIs, TKIs, EGFR inhibitors, and GLP-1 agents. Mechanistic differentiation was evident within NSAID series (COX-1 vs. COX-2 selectivity) and PPI series. ADC comparative testing (intact vs antibody vs payload) demonstrates the model's ability to capture on-target off-site and off-target off-site liabilities, supporting preliminary risk ranking of conjugates and components. ML integration improved prediction granularity, enabling cross-tissue generalization (colon and ileum) and ranking of compounds by projected diarrhea incidence and severity. **Conclusions:** Inclusion of

fibroblast, endothelial, and smooth-muscle cells enables detection of broader micro-environmental stress beyond epithelial injury. ADC arm comparisons further parse barrier-centric versus systemic cytotoxic liabilities. Coupling a physiologically relevant intestinal barrier assay with ML calibration provides a translational framework for early GI safety assessment across small molecules and ADCs. This approach using our NAMkind™ intestine supports mechanism-aware risk stratification and informs candidate selection across therapeutic classes and modalities.

PS 3372 Recreating Scalp Inflammation Ex Vivo: A Human Hair Follicle-Preserving Model for Immunotoxicological and Therapeutic Assessment

E. Pagès¹, E. Braun¹, M. Péries¹, A. Ochando Descargues¹, R. Ismail², P. Mondon³, J. Ginesta⁴, and N. Gaudenzio^{1,5}. ¹Genoskin, Toulouse, France; ²Research Unit UR4312 CBSA, University Rouen, Evreux, France; ³Sederma, Le Perray en Yvelines, France; ⁴CFEB SISLEY, Paris, France; and ⁵Toulouse Institute for Infectious and Inflammatory Diseases (INFINITY), INSERM UMR1291, CNRS UMR5051, University of Toulouse, Toulouse, France. Sponsor: A. Ochando descargues, EUROTOX

Background and Purpose: Inflammation of the human scalp plays a critical role in various dermatological disorders, including seborrheic dermatitis, psoriasis, and alopecia. Reproducing these complex immune responses in a physiologically relevant system remains challenging. We present a novel inflammation model, a bio-stabilized ex vivo human scalp model, designed to mimic bacterial-induced inflammatory conditions and assess their impact on hair follicle integrity and immune response. **Methods:** The ex vivo skin models consist of 6 mm diameter human scalp biopsies obtained from five female donors (ages 51-72) with consistent hair density. Biopsies were embedded in a proprietary solid matrix, exposing the epidermis to an air-liquid interface, and maintained under standard cell culture conditions using serum-free medium. Inflammation was induced by 24-hour topical application of lipopolysaccharide (LPS), mimicking Gram-negative bacterial components. PBS served as a control. Tissue integrity was assessed via H&E staining on days 1, 2, and 5. A 36-plex cytokine panel was used to quantify pro-inflammatory mediators. Co-immunostaining of Ki67 and active Caspase-3 enabled automated quantification of proliferative and apoptotic responses within hair follicles, respectively. **Results:** At baseline (day 0), all samples exhibited preserved epidermal, dermal, and follicular architecture. LPS treatment led to mild pyknosis in the superficial epidermis in one donor. Cytokine profiling revealed that LPS induced a measurable inflammatory response characterized by elevated levels of GM-CSF, IL-8, and MIP-1β ($p = 0.062$). LPS exposure resulted in decreased proliferation as measured by Ki67 expression (notably in donor 2 at day 2) and increased apoptosis by day 5 (significant in donor 4). Despite these changes, overall tissue and follicle morphology remained intact throughout the study. **Conclusions:** The platform successfully models scalp inflammation induced by topically applied LPS, triggering a localized immune response and modulating hair follicle cell turnover. This ex vivo system offers a robust and reproducible tool for investigating scalp inflammation mechanisms and evaluating the efficacy of anti-inflammatory scalp therapies under physiologically relevant conditions.

PS 3373 Quantitative Estimates of Toxicodynamic Variability for New Approach Methodologies-Based Systemic Safety Toolbox Using a Population-Based Human *in Vitro* Model

I. F. Alshammari¹, L. C. Ford¹, H. D. Tsai¹, H. Lin¹, C. K. Negi¹, A. N. Dickey², F. A. Wright², A. M. Middleton³, M. T. Baltazar³, J. Reynolds³, S. Cable³, A. Punt³, W. A. Chiu¹, and I. Rusyn¹. ¹Texas A&M University, College Station, TX; ²North Carolina State University, Raleigh, NC; and ³Safety, Environmental & Regulatory Science (SERS), Unilever, Sharnbrook, United Kingdom.

Background and Purpose: Next-Generation Risk Assessment (NGRA) frameworks leverage New Approach Methodologies (NAM) to support regulatory decision-making without animal testing. While NAM-based methods for hazard and dose-response assessment are widely used, considerations of chemical-specific evidence for inter-individual variability are still largely reliant on the default uncertainty factors for toxicokinetic and toxicodynamic variability. However, chemical-specific estimates of inter-individual variability can be derived using human cell-based *in vitro* models. Accordingly, this study tested the utility of a NAM-based approach to derive toxicodynamic variability factors in the context of NGRA. We tested a hypothesis that by including chemical-specific data on toxicodynamic variability into risk characterization step of NGRA, more protective estimates of human risk will be derived. **Methods:** We used 131 human lymphoblastoid cells (LCLs) from four European and African subpopulations as an *in vitro* model of inter-individual variability. A broad range of substances ($n = 53$) to which humans are exposed in a variety of ways, including consumer use and industrial chemicals, pharmaceuticals, and pesticides were tested in concentration-response (0.3 nM to 300 μM) and viability measurements were collected. To derive quantitative estimates of cytotoxicity of each substance, Bayesian concentration-response modeling was conducted and points of departure calculated for each cell line. **Results:** Overall, 18 out of 53 tested substances had effects below the highest concentration tested and toxicodynamic variability factors 5% (TDVF05) were derived. The median TDVF05 was 3.8 [range from 1 to 46], which is in line with the default TDVF. In addition, we conducted a genome-wide association

study (GWAS) to explore potential genetic drivers of inter-individual variability and to further characterize potential mechanisms of toxicity. This analysis showed that for most substances with inter-individual differences in cytotoxicity, genomic loci containing transporters or metabolism genes conferred genome-wide suggestive effects underlying such variability. **Conclusions:** Overall, this study demonstrated that human LCLs can be used as an *in vitro* model to quantify inter-individual variability in the context of NGRA. These data will improve confidence in the overall risk predictions using NAM data and enable the development of testable hypotheses regarding the mechanisms of inter-individual variability.

PS 3374 Development of a Recirculating Liver-on-a-Chip Platform for Toxicological Application: Evaluation of Hepatotoxicity of Triphenyl Phosphate

J. Kang¹, M. Song¹, H. Jin¹, M. Shin³, K. Kim³, H. Moon², and K. Kim¹. ¹Seoul National University of Science and Technology, Seoul, Korea, Republic of; ²Hanyang University, Ansan, Korea, Republic of; and ³BioSpero, Inc., Jeju, Korea, Republic of.

Background and Purpose: Due to limitations of conventional animal testing, toxicity data of thousands of industrial and consumer chemicals remain insufficient, underscoring the need to introduce new approach methodologies (NAMs). Organ-on-a-chip (OOC) platforms are promising for toxicity assessment under human-relevant environments, but deployment has been constrained by usability, incomplete exposure profiling under flow (perfusion/recirculation), small working volumes, and limited biological replication. These hurdles impede their establishment as reliable tools for chemical toxicity assessment. In this study, we developed a recirculating, tubing-free, clamping-cartridge liver-on-a-chip (LOC) using human HepG2 cells to deliver uniform flow, parallel biological replicates, and quantitative exposure profiling. Using triphenyl phosphate (TPHP) as a case study, we assessed hepatotoxicity and biotransformation under physiologically relevant flow with the aim of evaluating the platform's applicability as a toxicological tool. **Methods:** A tubing-free recirculating clamping-cartridge enabled 12 parallel, time-resolved exposures (1.5 mL). HepG2 were stabilized 24 h, exposed to 10 μM TPHP for 48 h; LC-MS/MS quantified TPHP and metabolites (DHP, 4HO-DHP, 4HO-TPHP), hepatic biomarkers (albumin, urea, LDH, AST) were assayed, ten liver-function genes profiled, and RNA-seq performed. LOC results were benchmarked to 24-well plates; acellular recirculation quantified system-level recovery. **Results:** The LOC is a clamping-cartridge platform that allows 12 parallel biological replicates under software-controlled, unidirectional recirculating laminar flow. For chemical-recovery profiling, 10 μM TPHP was analyzed under acellular conditions in both systems. The LC-MS/MS analysis showed that about ~30% of nominal TPHP in the LOC was maintained with low variation among cartridges. The LOC showed reproducible exposure kinetics under recirculating flow (coefficient of variation, CV, 5.2% vs 14% in plates), demonstrating stable mechanical flow performance. The static 24-well plates retained ~70% after 48 h. At 10 μM TPHP, albumin remained largely stable with a mild decline, urea and LDH were altered, and AST rose ~24 h earlier than in plates. Basal hepatic function was higher on the LOC, with mRNA levels of CYP3A4, CYP2E1, and CYP1A2 increased by ~24-, ~5-, and ~30-fold, respectively. Of the three targeted metabolites (DHP, 4HO-DHP, 4HO-TPHP), only DHP—the hydrolyzed product—was detected, showing more active conversion in the LOC despite lower cellular exposure. RNA-seq revealed liver-injury-related pathways, including spliceosome and lipid metabolism. Overall, the LOC produced earlier and stronger toxicological responses, indicating greater sensitivity under uniformly controlled flow with high inter-chip reproducibility. **Conclusions:** The newly proposed modular recirculating LOC achieved the uniform flow, high reproducibility, and greater sensitivity to TPHP than plate-based assays, with desirable RNA-seq results providing mechanistic confirmation of hepatotoxic pathways at lower concentrations than previously reported. Collectively, this platform overcomes key hurdles and advances OOC toward practical toxicological application. The platform enables an exposure-contextualized linkage from mechanism to phenotype in the liver. Future work will refine exposure calibration and enhance the physiological fidelity through surface engineering and endothelial-epithelial co-culture. In this context, the platform is well positioned to serve as a NAMs for predicting complex hepatotoxicity poorly captured by static assays.

PS 3375 A Human Airway-on-a-Chip Microphysiological System for Modeling Chlorine Gas Toxicity

S. V. Murphy. Wake Forest Institute for Regenerative Medicine, Winston Salem, NC.

Background and Purpose: There is an urgent need to understand the physiological mechanisms involved in the initiation and downstream events of injury from acute exposure to chlorine gas (Cl₂) and to identify medical countermeasures (MCMs) that can be applied across the exposure spectrum. Limited information is available regarding the time course and mechanisms of injury after acute Cl₂ exposure due to the lack of human clinical data and ethical, cost and throughput challenges with large and small animal models. Our group has recently developed a 3D airway-on-a-chip *in vitro* model for the study of mechanisms of acute Cl₂ pulmonary toxicity and for identification and testing of MCMs. The purpose of this study was to develop and validate the airway-on-a-chip platform as a model of pulmonary toxicity resulting from exposure to Cl₂ and for identification and testing of potential MCMs. **Methods:**

The airway-on-a-chip model was developed and exposed to a range of Cl₂ doses, exposure times and evaluated across multiple post-exposure durations. Exposure outcomes were validated with numerous chemical, biological, and functional assays to evaluate physiological airway-on-a-chip responses to Cl₂ exposure, and transcriptomic, proteomic and metabolomic analyses were performed to identify candidate MCMs. MCM screening was performed to identify candidates that mitigated the detrimental impacts of Cl₂ exposure. **Results:** The airway-on-a-chip platform was validated to generate and deliver precise concentrations of Cl₂ across a wide range of doses, flow rates and exposure durations. Airway surface pH, ROS production, viability, barrier formation and inflammatory/fibrotic airway changes were evaluated. Extensive multi-omic analysis delineated expected and unique molecular, cellular, and physiological pathways involved in the toxic response to acute Cl₂ exposure. Finally integrated bioinformatic analysis of this data identified candidate MCMs for efficacy testing. MCM screening identified several promising candidate MCMs that could successfully mitigate airway-on-a-chip cell toxicity caused by Cl₂ exposure. **Conclusions:** This work represents a significant step towards application of the airway-on-a-chip platform for the rapid characterization of pulmonary toxins and informing the targeted screening of potential countermeasures

PS 3376 Utilizing Human Small Intestinal Organoids for Quantitative Prediction of Oncology Therapy Induced Diarrhea

S. Liu¹, K. Pryde¹, M. Beshiri¹, P. Yeung¹, C. Pin², and M. Coen². ¹AstraZeneca, Waltham, MA; and ²AstraZeneca, Cambridge, United Kingdom. Sponsor: M. Stamou

Background and Purpose: Diarrhea is a common adverse event associated with oncology therapies, significantly affecting patient quality of life and treatment adherence. Conventional preclinical models often fail to accurately predict these gastrointestinal toxicities before clinical trials. **Methods:** To address this limitation, we have developed an organoid-based platform for early safety assessment of GI toxicity risk, bridging the gap between simple *in vitro* studies and clinical diarrhea outcomes. **Results:** Using clinical back-translation, we show that a high-throughput 384-well organoid assay differentiates compounds that pose a diarrhea risk with high sensitivity (97%) and specificity (94%) across diverse small-molecule mechanisms of action, enabling improved hazard identification in early discovery. The model also detects mechanistic synergy in combination regimens, predicting clinically relevant exacerbation of diarrhea. By integrating clinical exposure data, we established two models validated against clinical positive and negative controls. A binary hazard identification model and a logistic regression model enabling the prediction of risk including the incidence and severity of human diarrhea risk. Beyond risk prediction, the organoid platform supports target safety deconvolution via genetic perturbation (e.g., shRNA), multi-omics profiling, and high-throughput, high-content imaging. Ongoing work extends validation to monoclonal antibodies and ADCs and operationalizes the screening workflow in early development, aiming to inform program strategy and combination design. **Conclusions:** Our efforts to predict and minimize clinical GI toxicity aim to improve outcomes for patients with advanced cancer and maximize the combinability of therapeutic options.

PS 3377 Optimizing Air-Liquid Interface Respiratory NAM Models for Acute Exposure Scenarios to Support Regulatory Screening and Safety Assessment

M. Hollings, A. Seymour, E. Rothwell, and R. Bedford. Labcorp, Harrogate, United Kingdom. Sponsor: S. Papineni

Background and Purpose: New Approach Methodologies (NAMs) are increasingly at the forefront of inhalation toxicity assessment, supporting regulatory safety evaluation. In alignment with the FDA Modernization Act 2.0 and its April 2025 roadmap to reduce, refine, and decrease animal studies, advanced human-relevant approaches—such as organ-on-a-chip systems, 3D tissue models, computational modeling, and *in vitro* assays—are being prioritized for investigational new drug (IND) applications and beyond. Creating aerosols for inhalation studies requires specialized systems tailored to the physicochemical properties of the test article. For gases, dynamic dilution and continuous-flow exposure systems are commonly used to deliver controlled concentrations under physiologically relevant conditions. Complex mixtures often employ whole-mixture generation chambers or nebulization systems that maintain chemical integrity while ensuring reproducible particle size distribution. Nanoparticles typically require high-precision aerosolizers such as electrospray or dry powder dispersers, which prevent agglomeration and allow control over particle size and number concentration. For fibers, rotating brush generators or fluidized bed systems are used to suspend fibers in air without altering their morphology, ensuring accurate representation of inhalation exposure scenarios. These technologies consistently deliver aerosols to *in vitro* platforms, supporting mechanistic studies and regulatory screening under NAM frameworks. **Methods:** This study leveraged air-liquid interface (ALI) 3D lung model MucilAir™ in combination with a continuous-flow gaseous exposure system (Vitrocell® 24/4) to examine acute inhalation hazards. Ethylene oxide (EtO), nitric oxide (NO), and sulfur hexafluoride (SF₆) were delivered for 60 minutes at defined ppm levels. Endpoints assessed after a 24-hour recovery included cell viability (WST-8), membrane integrity (LDH), barrier function (TEER), cilia beat frequency (CBF), and pro-inflammatory cytokine release. **Results:** EtO exposure produced

>50% reductions in WST-8 and LDH relative to controls, accompanied by significant TEER disruption, CBF alterations, and distinct cytokine responses—outcomes not seen with SF₆ and only moderate effects from NO. These findings demonstrate the discriminatory power of continuous-flow NAM platforms in detecting acute gaseous toxicities and elucidating mechanistic pathways. **Conclusions:** By integrating 3D ALI models with dynamic exposure technologies, this study supports the FDA's roadmap to reduce animal use and reinforces NAM-based frameworks important for modern, ethically responsible inhalation toxicity screening.

PS 3378 Benzalkonium Chlorides Alter Gene Networks Governing Cell Proliferation in Human Enteroid Monolayers

S. A. Katz¹, K. Wang², M. N. Brzoska³, V. A. Lopez³, R. P. Seguin³, E. J. Kelly^{1,2}, and L. Xu^{1,3}. ¹Department of Environmental And Occupational Health, University of Washington, Seattle, WA; ²Department of Pharmaceutics, University of Washington, Seattle, WA; and ³Department of Medicinal Chemistry, University of Washington, Seattle, WA.

Background and Purpose: Benzalkonium chlorides (BACs) are a subclass of quaternary ammonium compounds widely used as disinfectants in consumer and occupational settings. BAC usage has increased since the COVID-19 pandemic, resulting in elevated levels in human blood-serum and feces. Humans are exposed orally through unintended hand-to-mouth transfer and food processing, with both the general population and workers handling BACs for extended periods being at risk. The small intestine serves as the primary site of contact for ingested xenobiotics and is highly susceptible to toxicity. However, the behavior of the BACs in the gut remains understudied. The purpose of this study is to evaluate human intestinal uptake of BACs and characterize their potential toxicity at concentrations reflective of those detected in human feces. **Methods:** Human duodenal crypt-derived enteroids were first cultured and expanded in 3D spheroids and later seeded as single cells onto Transwell™ inserts (6.5mm) to form polarized monolayers. Confluent monolayers were differentiated with Intesticult® Organoid Differentiation Media (ODM) for 14 days to reach stable trans-epithelial electrical resistance (TEER) values. On day 14, monolayers were exposed to either DMSO or a BAC cocktail (40% C₁₂, 50% C₁₄, 10% C₁₆-BAC) at 50nM, 500nM, 3µM. Bidirectional transport was assessed by dosing apically and basally with 10 µM lucifer yellow in HBSS++ for 60 minutes, followed by collection of media and lysates for UPLC-MS/MS quantification of BACs and potential metabolites, normalized to a deuterated internal standard. Additional monolayers were exposed apically to the same BAC cocktails for 16 hours for RNA-sequencing analysis. Monolayer viability and cytotoxicity were measured by performing MTS and LDH assays on ODM collected after 16-hour exposure to DMSO or individual C₁₄- or C₁₆-BACs (0.05-40µM). **Results:** Monolayer integrity was confirmed with stable TEER values (1030-1680 Ω*cm²) and minimal lucifer yellow permeability (<1% diffusion). Targeted UPLC-MS/MS detected parent BACs in cell lysates, while metabolites were not quantifiable. Significant increased intracellular uptake of all BAC chain lengths was observed in 500nM and 3µM treatments compared to the control, whereas 50nM had no effect. MTS and LDH assays demonstrated no significant change in cell viability and cytotoxicity, respectively, for both treatments (C₁₄- and C₁₆-) compared to the control. RNA-sequencing revealed differential expression of 400, 492, and 355 genes (p < 0.05) at 50nM, 500nM, and 3µM, respectively. Compared to the control, all conditions showed significant upregulation in genes related to the canonical Wnt and PI3K/Akt signaling pathways, and downregulation of TGF-β related genes. Other processes significantly affected were bile secretion, glycosphingolipid biosynthesis, and tight junction organization. *CLDN1* and *CLDN23*, encoding tight junction proteins, were downregulated, whereas thiamine transporter genes *SLC19A3* and *SLC25A19* displayed upregulation across all treatments. **Conclusions:** These findings indicate that BACs can be absorbed following oral exposure and accumulate intracellularly, driving transcriptional changes linked to cell proliferation and barrier regulation. Notably, the most significantly altered biological processes were related to cell cycle progression, cell proliferation, and cell signaling. The transcriptional profile indicates upregulation of Wnt and PI3K/Akt signaling pathways, suggesting that the cells are in a proliferative state, potentially as a stress-induced adaptive response. Overall, C₁₄- and C₁₆-BAC exposures did not significantly affect cell viability or induce cytotoxicity after 16 hours. To understand long-term impacts, ongoing studies are examining the effects of two-week BAC exposure on monolayer integrity, including lucifer yellow permeability, TEER, tight junction protein localization via immunocytochemistry, and mRNA expression.

PS 3379 In Vitro Safety Profiling of ADCs Using an iPSC-Derived Human Tissue Screen to Support FDA Roadmap for Biologics

L. Smit, K. Pitsa, C. van Berkel, S. Schwengberg, and S. Holt. Ncardia Services B.V., Leiden, Netherlands. Sponsor: S. Schwengberg, Safety Pharmacology Society

Background and Purpose: Antibody-drug conjugates (ADCs) are a rapidly expanding class of targeted cancer therapies designed to enhance the therapeutic index of cytotoxic agents. Despite their specificity, many ADCs encounter clinical setbacks due to dose-limiting or off-target toxicities. Recent analyses of phase 1 ADC trials report grade ≥ 3 treatment-related adverse events in up to 58 % of patients [1]. More broadly, approximately half of investigational biologics fail in late-stage (phase 3)

development, with safety concerns contributing substantially to these failures [2, 3]. These observations highlight the limitations of traditional preclinical models and the need for predictive, human-relevant *in vitro* systems to better anticipate toxicity risks. The U.S. FDA's roadmap for biologics emphasizes functional safety profiling using mechanistically relevant assays that can assess tissue-specific toxicity risks early in development and support IND submissions. **Methods:** A novel *in vitro* safety profiling platform was developed and validated using seven fully human induced pluripotent stem cell (hiPSC)-derived cell types representing key tissues including lung, liver, heart, CNS, skin, intestine, and vascular endothelium. The cell types were selected based on target antigen expression and relevance to known ADC toxicities. Multiple ADCs, including *cetuximab-MMAE* (anti-EGFR) and *trastuzumab-emtansine* (anti-HER2), were evaluated for off-tumor toxicity using real-time impedance (xCELLigence). EGFR and HER2 expression were confirmed by High-Content imaging. **Results:** The platform demonstrated reproducible, tissue-specific cytotoxicity profiles across ADCs at concentrations up to 100 µg/mL. *Cetuximab-MMAE* induced dose-dependent toxicity in EGFR-low alveolar epithelial cells, melanocytes, and hepatocytes with up to 61%, 58% and 30% killing, respectively. *Trastuzumab-emtansine* caused moderate off-tumor effects with up to 17% cell death in HER2-low ventricular cardiomyocytes. Neurons and other antigen-negative cell types were minimally affected with less than 6% cell death, confirming assay specificity and sensitivity. **Conclusions:** This fully hiPSC-derived assay panel offers a human-relevant, functional approach for *in vitro* safety profiling of ADCs and other biologics. The impedance-based cytotoxicity readout, combined with imaging and cytokine profiling, enables early identification of tissue-specific risks and supports FDA guidance on functional safety assessment. The platform's reproducibility, scalability, and mechanistic relevance make it a powerful tool for de-risking targeted therapies in preclinical development.

PS 3380 Utilization of *In Vitro* Liver Models for the Toxicology Testing of Rat and Dog Hepatocytes

P. L. Deford¹, O. Lally², K. Rogy², Z. Sutake¹, A. Lehman¹, J. McKenna¹, W. Chen¹, E. Costa¹, J. Fitzpatrick¹, M. Terrill¹, A. Pappas-Garton¹, K. Johnson¹, J. LaRocca¹, E. Bianchi¹, and S. Khetani². ¹Corteva Agriscience, Indianapolis, IN; and ²University of Illinois Chicago, Chicago, IL.

Background and Purpose: Global regulatory requirements for the registration of agrochemical compounds are a complex process that relies on extensive animal testing that includes a 90-day non-rodent toxicity study, for which the dog is the selected species. To reduce the need for animal testing in regulatory submissions and early discovery programs, a suite of *in vitro* assays potentially could provide critical data on relative species sensitivity, to inform when animal studies, namely dogs, could be waived. **Methods:** Hepatocytes were co-cultured with fibroblasts in 2D and 3D *in vitro* liver models before being treated with either ketoconazole, cyclophosphamide, or triazolam in both acute (24-hour) and repeat dose (6-day with treatment refresh every 48 hours) testing paradigms. Treated media was collected for measurement of albumin by ELISA, as well as parent and metabolite quantification through LC MS/MS to assess metabolic competency. RNA was isolated from treated cells for sequencing to determine the transcriptional points of departure (tPODs). *In vitro*-derived endpoints were included in *In Vitro* to *In Vivo* Extrapolation (IVIVE) calculations, to compare *in vitro* outcomes to measured *in vivo* liver-specific PODs. **Results:** Albumin measured from treated media for both 2D and 3D models when using the administered equivalent dose 95 in IVIVE calculations resulted in a similar species sensitivity compared to the measured *in vivo* effects. Using RNA sequencing from treated cells to derive a transcription point of departure (tPOD) for IVIVE resulted in recapitulation of relative species sensitivity for all three chemistries for the 2D *in vitro* platform. **Conclusions:** This proof-of-concept study provides justification for the use of *in vitro* liver co-culture models (either 2D or 3D) to assess relative species sensitivity. While analysis using both albumin and RNA resulted in outcomes that recapitulated the measured species sensitivities of the molecules tested, RNA sequencing potentially provides a more comprehensive toxicity characterization, as it encompasses the effects on the entire transcriptome, instead of a single captured data point, which likely will provide greater use for a broader chemical test set. These data could be vital to demonstrate when dog studies currently required for agrochemical registration, would not add value to, or enhance human health risk assessment. There is a global push to further new approach methodologies that allow for the reduction of animal use for regulatory testing, and methods like this bring us closer to reducing and one day eliminating the need for such testing.

PS 3381 *In vitro* imaging and safety profiling of siRNA RyR2 delivered via inhalation in human models

V. Bettinsoli^{1,2}, M. Erlacher³, D. Wilflingseder³, V. Galbiati¹, G. Melzi¹, M. Marinovich¹, and E. Corsini¹. ¹Università degli studi di Milano, Milano, Italy; ²Università degli studi di Napoli Federico II, Napoli, Italy; and ³Ignaz Semmelweis Institute, Interuniversity Institute for Infection Research, Vetmeduni, Vienna, Austria.

Background and Purpose: Small interfering RNAs (siRNAs) are emerging therapeutics able to selectively silence gene expression. Among them, siRNA targeting ryanodine receptor 2 (RyR2) is a promising strategy for treating dominant catechol-

aminergic polymorphic ventricular tachycardia (CPVT). Inhalation represents the administration route, as oxygenated blood and drug molecules carried through the pulmonary circulation rapidly reach the heart. The aim of the study is to set up a new approach methodology (NAM) based on *in vitro* human cells model to evaluate the potential immune and respiratory toxicity of siRNA RyR2. **Methods:** Normal human bronchial epithelial (NHBE) cells differentiated at the air-liquid interface were employed as a 3D *in vitro* model to investigate respiratory exposure to siRNA RyR2. Cells were exposed for 48 h to 400 nM siRNA RyR2, scramble, and calcium phosphate nanoparticles (CaP NPs). Cellular uptake and internalization were assessed using Cy5-labeled siRNA and confocal microscopy. Gene expression analysis was conducted via rt-PCR to evaluate the modulation of key toxicity-related pathways, including mitochondrial stress, oxidative stress, endoplasmic reticulum stress, and autophagy. Pro-inflammatory cytokines release (TNF-α, IFN-γ, IL-8, and IL-6) was quantified from the cell culture supernatant. Immune cell interactions were further explored using human monocyte-derived dendritic cells and macrophages. Following 48 h exposure to 400 nM siRNA RyR2, scramble, and CaP NP, uptake was visualized via confocal imaging, and flow cytometry allows to characterize phenotypic characteristics and activation markers of the immune cells. **Results:** Confocal microscopy confirmed successful internalization of siRNA RyR2 in both epithelial and immune cells. Cytokines analysis showed a slight increase in IL-8 release induced by both siRNA and scramble, while IL-6 remains undetectable. Additional investigations are ongoing to profile gene expression associated with stress-related pathways, including oxidative stress, mitochondrial dysfunction, endoplasmic reticulum stress, and autophagy. Regarding the immune assessment, analyses focus on the secretion of pro-inflammatory cytokines (TNF-α, IFN-γ, IL-8, and IL-6) are also ongoing. **Conclusions:** Overall, these results provide initial insights into the safety and toxicological profile of inhaled siRNA RyR2 and support the application of human-relevant, animal-free *in vitro* systems for preclinical evaluation of nucleic acid-based therapeutics. This work is funded by the European Union - Next-Generation EU ("PNRR M4C2-Investimento 1.4-CN00000041").

PS 3382 Integrating *in vitro* and *in silico* approaches for assessing local respiratory effects in inhalation exposure safety evaluations

V. S. Patel¹, and N. Sadekar². ¹Institute for In Vitro Sciences, Inc., Gaithersburg, MD; and ²Research Institute for Fragrance Materials, Inc., Mahwah, NJ.

Background and Purpose: There is increasing interest in advancing non-animal approaches for inhalation exposure safety assessment. However, defined methodologies for predicting local respiratory effects from irritant exposures are lacking. Fragrance materials, which are typically organic and semi-volatile with low aqueous solubility, present additional challenges, as sensory irritation often complicates the interpretation of respiratory responses. Inhalation safety evaluations can be strengthened by integrating human odor and odor irritation thresholds with No Observed Adverse Effect Concentrations (NOAECs) derived from fit-for-purpose human *in vitro* models. The current fragrance safety assessment framework applies a weight-of-evidence approach that prioritizes existing data, read-across from structurally appropriate analogues, and, when data gaps exist, the inhalation Threshold of Toxicological Concern (TTC). For substances that exceed TTC values and lack adequate toxicological information, additional considerations include evaluating physicochemical properties, applying *in silico* exposure modeling, and using *in vitro* models to identify points of departure for risk assessment. The present study employed an integrated *in silico* and *in vitro* strategy to characterize the local respiratory effects of the fragrance ingredient acetic acid, evaluating both human-relevant exposure concentrations and levels associated with cytotoxicity. **Methods:** Local respiratory effects were examined using reconstructed human bronchial epithelium (RhBE) tissues (MucilAir™) maintained at an air-liquid interface. Tissues derived from five healthy adult donors were used to capture interindividual variability. Acetic acid dosing solutions (20, 40, 120, and 240 µg/cm²) were applied apically (25 µL), and endpoints were assessed at 2, 6, and 24 hours (h) post-exposure. The dose range reflects predicted tracheobronchial deposition levels, estimated using a modified Multiple-Path Particle Dosimetry (MPPD) model. Simulations incorporated chronic aggregate inhalation exposure of 0.001 mg/person/day and odor-based sensory effect thresholds of 12.3 mg/m³ (NOAEC) and 24.6 mg/m³ (LOAEC) during a 120-minute resting exposure. Endpoints included ciliary function (ciliary beat frequency and active area), barrier integrity (transepithelial electrical resistance), tissue viability, and inflammatory signaling (IL-6 and IL-8 release). The treatment groups were statistically compared to respective vehicle control groups using ordinary one-way ANOVA and Dunnett's multiple comparisons test. **Results:** Baseline variation across donors was evident in ciliary function, barrier integrity, and cytokine levels, reflecting biological diversity. At 120 µg/cm², reductions in barrier integrity were detected within 2 h, with increases in IL-6 observed within 6 h and IL-8 at 24 h. Significant cell viability loss occurred only at 240 µg/cm², where corresponding changes in ciliary activity and barrier integrity are likely attributable to generalized cytotoxicity. No adverse effects were observed at 20 and 40 µg/cm². Based on these responses, the NOAEC was determined to be 40 µg/cm², and the LOAEC was 120 µg/cm². Comparison of the *in vitro* NOAEC to the human deposition estimate of 0.000098 µg/cm² yielded a Bioactivity Exposure Ratio (BER) greater than 100, after applying conservative uncertainty factors for population variability and *in vitro* to *in vivo* extrapolation. **Conclusions:** The combined *in vitro* and *in silico* approach provided a human-relevant evaluation of acetic acid respiratory bioactivity. The *in vitro* NOAEC aligned with the sensory irritation threshold for acetic acid, and the high BER indicates a substantial margin of safety under typical

fragrance use conditions. While the RhBE model effectively represents the bronchial epithelium, a comprehensive assessment should also incorporate upper respiratory tract models coupled with Computational Fluid Dynamics deposition modeling. Further work is also needed to define the optimal number of donors required to represent population variability. Despite these considerations, the findings support the use of integrated non-animal approaches for inhalation safety assessment of fragrance ingredients.

PS 3383 Development and Characterization of Non-Human Primate iPSC-Derived Ventricular Cardiomyocytes for *in vitro* Safety and Toxicity Screening

S. Schwengberg, I. Veldkamp-Baak, P. van Loenen, J. Koepke, T. Smith, and M. Argenziano. Ncardia Services B.V., Leiden, Netherlands. Sponsor: S. Schwengberg, Safety Pharmacology Society

Background and Purpose: Human induced pluripotent stem cell-derived cardiomyocytes (Hu CM) are widely used in nonclinical cardiac safety studies but interspecies translation remains a limitation in early-stage pharmacology and toxicology. Non-human primates (NHPs) are physiologically close to humans, are often used as secondary species for *in vivo* studies, and can provide translational insights. However, there are limited *in vitro* models using primary NHP cardiomyocytes. We aimed to establish and characterize an *in vitro* platform of NHP iPSC-derived ventricular cardiomyocytes (NHP CM) suitable for translational *in vitro* safety and toxicity applications focusing on consistency, functional responsiveness, and pharmacodynamic sensitivity to known reference compounds. **Methods:** iPSCs from cynomolgus macaques were sourced from the German Primate Center (Tereshchenko, Y et al. *Cells* 2024, doi.org/10.3390/cells13060558) and differentiated into ventricular cardiomyocytes in stirred tank bioreactors. Expression of cTnT, α -actinin, and MLC2V was quantified via immunostaining. Cardiomyocyte function was assessed using micro-electrode arrays (MEA) and impedance-based contractility assays, and the response to cardioactive compounds was tested in these assays. **Results:** NHP CM showed >93% cTnT-positive cells post-thaw with co-expression of α -actinin and MLC2V, similar to their human counterparts (Hu CM). Spontaneous beating emerged by day 3 post-thaw and persisted for at least 10 days post-thaw with beat rates ranging from 28±4.8bpm and FPD of 528±57.8ms. MEA analysis revealed intra-well FPD variability of 2.19% and inter-well variability of 2.98%, indicating strong functional consistency across batches. Upon compound exposure, NHP CM revealed differences to Hu CM: in MEA, 100nM isoproterenol caused 28±7% vs 73±32% increase in beat rate; 10nM dofetilide caused more severe arrhythmia; and nifedipine caused beat arrest at all concentrations, but only > 100nM in Hu CM. In impedance contractility assay, 10µM pentamidine caused beat arrest at d3 vs d4 in Hu CM; 1µM blebbistatin caused 50% reduction in contraction for 48h in NHP CM but > 70% reduction in Hu CM for 7 days; and sunitinib caused time- and dose-dependent cytotoxicity and increased beat duration in Hu CM but no signs of toxicity in NHP CM. **Conclusions:** NHP CM can be differentiated at large scale, display high structural fidelity, stable function in MEA and impedance assays, and respond to cardioactive compounds. The observed species-specific differences (e.g., arrhythmia signatures, chronic sensitivity) highlight the translational value of the model for *in vitro* toxicity and safety studies.

PS 3384 Building Confidence in MPS Use in Regulatory Applications: The 3Rs Collaborative's & FDA-CDER's Cross-Platform DILI Project

W. Kang¹, M. R. LaFollette², S. Ferguson³, G. Marsh⁴, D. Dalmaz⁵, A. Daniel⁶, and N. Sadrieh⁷. ¹Merck & Co Inc, West Point, PA; ²The 3Rs Collaborative, Denver, CO; ³NIH/NIEHS, Durham, NC; ⁴Critical Path Institute, Tucson, AZ; ⁵Independent, Collegeville, PA; ⁶Inotiv, Research Triangle Park, NC; and ⁷CDER/FDA, Silver Spring, MD.

Background and Purpose: New Approach Methodologies (NAMs), combined with expanding interest in reducing reliance on animal testing in favor of more human-centric, physiologically relevant models, there is great potential for NAMs such as microphysiological systems (MPS) to address gaps in preclinical testing, improving drug discovery and development, and patient outcomes. However, there is a need to establish confidence in the performance of such methods to increase widespread integration of MPS in drug discovery and development including toxicological risk assessment. This may be achieved through standardized assessment of their accuracy, reliability, and technical characterization. **Methods:** The FDA's Center for Drug Evaluation Research (FDA-CDER) and the 3Rs Collaborative's MPS Initiative (3RsC-MPS) are conducting a collaborative project under a consortium agreement with involvement from the National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM) and the Critical Path Institute (C-PATH). The project's main goal is to perform an evaluation across 9 companies' liver MPS using standard conditions from a similar baseline protocol to evaluate drug induced liver injury (DILI) for a focused panel of hepatotoxicants using endpoints of toxicity. The choice to use liver MPS is based on their increasing use in drug discovery, and the fact that many MPS manufacturers have liver platforms which are considered relatively advanced in their development. The design and performance differences in each platform are expected to highlight the expected variabilities that might be observed in study reports which are ultimately submitted to regulatory agencies, for those endpoints of interest in the prediction of DILI risk in

humans. There is a need to understand the extent of this expected variability, such that the study results can be accurately interpreted. **Results:** The chosen context of use for the project was use of liver MPS as a tool for retrospective analysis of treatment-related liver injury signals observed in clinical trials. Across the nine platforms, five included only primary human hepatocytes (PHH), two had PHH + Kupffer cells (KC), one had iPSC-derived hepatocytes, one had HepG2 + TW + NT1 + THP1, and a finally had PHH, KC, and sinusoidal endothelial cells. Developers were provided 4 pairs of more and less toxic compounds analogues in a blinded fashion that spanned across 4 distinct indications and drug classes within the small molecule designation. Compounds were tested at least 3 dose levels with a maximum concentration of 10 times Cmax. At least 7 out of 9 technologies providers measured ALT, LDH, Albumin and ATP while only 5 measured CYP3A4 based on their optimized protocols. Initial results showed 5 providers correctly distinguished all 4 blinded hepatotoxicants from their less toxic analogues. Additionally, 2 providers correctly distinguished 2 hepatotoxicants. Results are still pending for 2 providers. **Conclusions:** This project is expected to support increased confidence in the use of MPS across platforms and study sites. In turn, it may lead to broader use of NAMs, including MPS into drug development and ultimately contribute to increased submissions of MPS-based studies in regulatory submissions, and decision making. Such projects are a step towards reaching the 3Rs (replace, reduce and refine) in the use of animals for the safety assessment of drugs before marketing.

PS 3385 Assessment of a 3D Primary Human Thyroid Microtissue Assay for Identifying Thyroid-Disrupting Chemicals

E. Rogers¹, K. Wolf², T. Stone², C. Deisenroth³, J. Chen¹, J. Klein¹, and E. LeCluyse².

¹LifeNet Health LifeSciences, Virginia Beach, VA; ²LifeNet Health LifeSciences, Research Triangle Park, NC; and ³U.S. Environmental Protection Agency, Research Triangle Park, NC.

Background and Purpose: The European Chemicals Agency (ECHA) and the European Food Safety Authority (EFSA) have jointly published guidance for identifying endocrine disruptors. Together with the U.S. EPA's Endocrine Disruptor Screening Program (EDSP), these initiatives emphasize the need for high-throughput screening (HTS) approaches to efficiently evaluate potential thyroid-disrupting chemicals (TDCs) and minimize reliance on traditional, low-throughput, animal-based methods. Deisenroth et al. previously developed a novel 3D human thyrocyte microtissue platform to identify TDCs that act through various mechanisms relevant to thyroid hormone synthesis. This study was designed to evaluate the within-laboratory reproducibility and performance of the assay using primary human thyrocytes from one donor lot, and to assess the applicability of the 3D model for characterizing responses to known TDCs using thyrocytes from a different single donor. **Methods:** Thyrocytes were derived from healthy donors (≤55 years, BMI ≤35) and cultured in a 96-well 3D format. Control groups included baseline (CT-1), TSHR agonism (CT-2), and TSHR antagonism (CT-3) conditions to assess model sensitivity and specificity. Cells were maintained for 14 days with medium changes every 2 days. Culture media were collected on day 14 for T3 and T4 quantification by ELISA, and microtissue viability was determined using the CellTiter-Glo® assay. Model performance was evaluated by dynamic range, precision, and screening quality metrics. For evaluation of the model with known TDCs, medium samples were collected on day 14 after a 6-day exposure (0.001-100µM) for T4 quantification by ELISA. The half-maximal inhibitory concentration (IC₅₀) for each compound was calculated using GraphPad Prism. **Results:** The thyrocyte lots met all specification criteria for screening applications. Microtissues were formed within 4 days and evenly distributed. Microtissues produced T4 concentrations exceeding 1.0 ng/mL at day 14, with robust dynamic ranges (RS/B >2.5-fold), coefficients of variation <30%, and Z'-factors >0.6 for T3 and T4. Dose-dependent inhibition of T4 synthesis was observed with 6-day exposures (Days 8-14) to three reference TDCs, methimazole (MMI), propylthiouracil (PTU), and sodium perchlorate (NaClO₄), yielding average IC₅₀ values of 0.50 (SE 0.01) µM, 0.96 (SE 0.18) µM, and 32.89 (SE 5.46) µM, respectively, while the negative control (methomyl) showed no effect. No cytotoxicity was observed for any of the reference compounds. **Conclusions:** In summary, the primary human thyrocyte 3D microtissue assay using ELISA represents a promising strategy for evaluating and prioritizing potential TDCs based on human hazard-related bioactivity. Moreover, the model enables the identification of compounds acting directly on the thyroid and supports simultaneous evaluation of multiple MIEs (e.g., TPO, NIS, TSHR) for small-molecule screening in both agriscience and therapeutic research.

PS 3386 Evaluating toxicity of polycyclic aromatic hydrocarbons from wildfire smoke in primary human bronchial epithelial cells in the presence and absence of THP-1 macrophages

K. S. Burns^{1,2}, J. M. Pennington¹, R. S. McClure³, A. Biggerstaff¹, K. A. Anderson^{1,2}, K. M. Waters^{1,2,3}, J. C. DeWitt^{1,2}, and S. C. Tilton^{1,2}. ¹Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR; ²Superfund Research Program, Oregon State University, Corvallis, OR; and ³Pacific Northwest National Laboratory, Richland, WA.

Background and Purpose: Wildfires are a growing public health crisis with wildfire occurrence, duration and intensity increasing in recent years; however, little is known about toxicity associated with inhalation of wildfire smoke, which are chemically complex emissions containing polycyclic aromatic hydrocarbons (PAHs) among other pollutants. In the respiratory system, induction of airway inflammation is orchestrated through signaling between airway epithelial cells and macrophages, which are two of the most abundant cell types in the respiratory tract contributing to the innate immune response. Activation of airway immune response and inflammation are critical events leading to adverse health effects and damage to the respiratory system after chemical exposure. To evaluate the combined contribution of airway epithelial-macrophage response to PAHs from wildfires, we established a co-culture model utilizing organotypic primary human bronchial epithelial cells (HBEC) differentiated at the air-liquid interface and THP-1 macrophages. **Methods:** HBEC in the presence and absence of THP-1 macrophages were exposed for 24 hours to mixtures of PAHs (0-600 μ M) previously identified from wildfires in the Pacific Northwest by passive air sampling. These mixtures were comprised of PAHs detected at the highest concentrations at sites in the PNW with an AQI > 100, with one mixture being based on abundance (SW12) and the other mixture only including abundant PAHs with 4 or more aromatic rings (SFM). Cultures were assessed for cytotoxicity, cytokine protein secretion, apoptosis and cell immunophenotype following treatment with wildfire mixtures. In addition, a panel of biomarkers were evaluated by qPCR for CYP450 induction and cytokine response in HBEC. To further explore pathways impacted by each mixture, global gene expression was assessed by RNA sequencing. **Results:** Each wildfire mixture resulted in unique patterns of toxicity and inflammatory response that was specific to each mixture and dependent on the presence of macrophages. For example, only SW12 caused significant cytotoxicity (p -adj<0.05) and only in the co-culture. SW12 and SFM also resulted in distinct responses for CYP1A1, CYP1B1, and inflammatory cytokine (IL-1 β , IL-6, IL-8, and TNF- α) gene expression in HBEC. Of interest, only SFM significantly (p -adj<0.05) induced both CYP1A1/1B1 transcripts in both models in a dose-dependent manner compared to SW12. **Conclusions:** Overall, it appears that signaling between epithelial and macrophage cells is necessary for a more sensitive cytotoxic response in HBEC. Furthermore, data show that unique mechanisms likely mediate toxicity by SW12 and SFM and that the macrophages have a distinct role in response to each mixture. These studies fill critical knowledge gaps regarding the role of inflammation in toxicity of inhaled PAHs from wildfires in an organotypic co-culture model.

PS 3387 The comprehensive cardiovascular toxicology assessment in multi-level of *in vitro* cell models

M. Lu, J. Xu, L. Wen, and F. He. Pharmaron Beijing Co., Ltd., Beijing, China. Sponsor: S. Luo

Background and Purpose: Cardiovascular toxicity remains a leading cause of drug attrition during development and post-market withdrawal. The limitations of traditional, siloed testing strategies—which often fail to capture the integrated physiology of the human heart—necessitate a more holistic and predictive *in vitro* approach. To establish and validate a comprehensive, multi-level *in vitro* platform that enables a mechanistic and functional assessment of cardiovascular toxicity across a spectrum of key biological processes, from molecular targets to integrated cellular responses. **Methods:** Our platform integrates a suite of complementary assays using recombinant systems, 2D and 3D human induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs): 1. Molecular Level (Ion Channel Function): Comprehensive profiling of compound interactions with key cardiac ion channels (e.g., hERG, Nav1.5, Cav1.2) utilizing a combination of manual and automated patch clamp, fluorescence-based assays, and radio-ligand binding techniques. 2. Protein-Level (Channel Trafficking): Assessment of chronic toxicity via hERG channel trafficking inhibition to identify compounds that cause channel mislocalization. 3. Integrated Cardiac Function in 2D Models: Functional phenotyping in 2D iPSC-CM monolayers, including action potential (AP) and field potential (FP) recordings, calcium transient analysis, contractility measurements and cell viability assay. 4. Integrated Cardiac Function in 3D Models: Assessment of compound effects in more physiologically relevant 3D cardiac organoids, evaluating cell viability, calcium transient dynamics, and field potential profiles. **Results:** We demonstrate that this integrated platform successfully provides a multi-parametric dataset for candidate compounds. Isoproterenol showed weak acute hERG block but shortened field potential duration. Geldanamycin had no effect on hERG current by patch clamp recording but caused cardiac toxicity by chronic effect of hERG trafficking inhibition. By correlating data across levels, we can deconstruct complex toxicological phenotypes. **Conclusions:** This multi-level *in vitro* platform offers a powerful and translational strategy for the comprehensive assessment of cardiovascular toxicity. It moves beyond standalone hERG testing to provide a systems-level understanding of compound effects, enabling earlier

and more informed decision-making in drug safety evaluation. This approach holds significant promise for reducing late-stage attrition and enhancing the cardiac safety profile of new therapeutic agents.

PS 3388 *In Vitro* Human Bronchiole Models as Promising Tools for Drug Screening with Potential Pulmonary Toxicity

X. Li, J. Xu, Y. Wang, and F. He. Pharmaron Beijing Co., Ltd., Beijing, China. Sponsor: S. Luo

Background and Purpose: Human bronchus is the key structure of the lower respiratory tract, which serves as the main passageway for air to travel from the trachea into the alveoli for gas exchange. Its wall is lined with a ciliated pseudostratified epithelium, which is composed of mucus-producing goblet cells. These cilia rhythmically beat to propel trapped dust and pathogens upward, which is essential for lung defense. Pulmonary toxicity is lung damage that can be caused by cancer treatment, environmental exposures, or genetics. Drug-induced lung disease (DILD) has been reported in many compounds, for example amiodarone and afatinib, as a key factor for discontinuation of drug therapy. To better identify potential drug toxicity, *in vitro* pulmonary models are crucial tools for assessing the toxicity of compounds and pharmaceuticals. Among the *in vitro* pulmonary models, three-dimensional (3D) organoid model grown in Matrigel and air-liquid interface (ALI) culture model are commonly used, which better mimic the human bronchial structure, allowing screening of cytotoxicity of various compounds and pharmaceuticals. In this study, 3D human bronchial organoid model (HBO) and human ALI airway model, both static and perfused (bronchi-on-a-chip), were established with the differentiation capacity into mature mucociliary airway structure, which served as tools for *in vitro* toxicity screening. **Methods:** HBO model was established under expansion state for model characterization and drug screening purpose. Three-dimensional CellTitre Glo (CTG) experiment was conducted for drug screening using compounds with reported pulmonary toxicity. HBO was differentiated for 14 days into mature airway organoids, which were characterized using immunofluorescence staining, immunohistochemical staining and RT-qPCR analysis. Normal human bronchial epithelial (NHBE) cell ALI model was established by transwell-based ALI culture for 21-28 days and characterized with immunofluorescence staining and RT-qPCR analysis. CNBio Physiomimix system was used for establishment of perfused bronchi-on-chip model using NHBE cells for 14 days, which was compared with static NHBE model in terms of differentiation outcome by RT-qPCR analysis and histological staining. Drug screening on reference compounds with reported pulmonary toxicity and with no reported pulmonary toxicity was conducted in static and perfused NHBE ALI model for parallel comparison. **Results:** HBOs under expansion state were mainly composed of basal cells, with minimal goblet cell composition. HBOs showed dose-responsiveness to Afatinib, Doxorubicin, STS and Amiodarone, with reported pulmonary toxicity, in terms of cell viability. After 14 days of differentiation, HBOs were capable of differentiating into goblet cells and ciliated cells, which can serve as a potential model for dome-based 3D mature airway model. NHBE cells were capable of forming mucociliary barrier model by day 21 post static ALI culture, which differentiation capability showed donor variation and passage limitation. Under perfused culture condition using bronchi-on-chip model, NHBE cells are capable to differentiate into mature mucociliary structure by day 14 post ALI, which showed superior differentiation outcome compared to static culture. Perfused bronchus-on-a-chip model showed dose-responsiveness to reference compounds with known pulmonary toxicity. **Conclusions:** Three-dimensional human bronchial *in vitro* model can be established as both 3D organoid model and transwell-based barrier model. Both models showed dose-responsiveness to compounds with reported pulmonary toxicity, which serve as potential tool for drug screening purpose for identification of drug side-effects.

PS 3389 An Engineered 3D Liver Tissue Model (in vivo) for Long-Term Culture Without Medium Exchange

Y. Naito¹, K. Hattori¹, T. Shinoda¹, Y. Yamada², S. Kitano¹, and M. Matsusaka³. ¹TOPPAN Holdings Inc., Saitama, Japan; ²Nihon Pharmaceutical University, Saitama, Japan; and ³The University of Osaka, Osaka, Japan. Sponsor: Y. Naito, Japanese Society of Toxicology

Background and Purpose: Accurate preclinical evaluation of drug safety requires *in vitro* models that recapitulate key functional attributes of the human liver. Although primary human hepatocytes are widely used, maintaining essential functions for extended periods remains challenging. This study aimed to construct a three-dimensional human hepatic model capable of sustaining long-term functional stability without medium exchange and to evaluate its hepatic functionality, including metabolic competence, transcriptional characteristics, bile canaliculus formation, and responsiveness to prototypical hepatotoxicants. **Methods:** Primary human hepatocytes prepared from humanized mice with chimeric liver (PXB-cells) were treated with heparin and collagen to induce the formation of a cohesive viscous cellular body. This viscous body was then embedded into a hydrogel matrix that supports cellular accumulation and promotes stable cell-cell adhesion, thereby enabling the organized formation of bile canaliculi and the emergence of enhanced hepatic functionality. The resulting three-dimensional tissue construct (in vivo) was subjected

to a series of evaluations encompassing metabolic function, transcriptomic signatures, bile canaliculus formation, and responsiveness to benchmark hepatotoxic compounds. Long-term culture stability without medium exchange was examined from day 8 onward. Additionally, the model was continuously exposed to carbamazepine for three weeks without medium exchange, and metabolite formation and concentration-dependent cytotoxicity were assessed using mass spectrometry and cell viability assays. **Results:** The invivo model exhibited hepatic functions that exceeded those of spheroid and sandwich cultures. Confocal imaging and bile acid transport assays showed a well-developed bile canaliculus network with clear MRP2/BSEP localization and CDFDA/CLF excretion. Transcriptomic profiling demonstrated comparable or greater expression of key metabolic genes, including CYP3A4, CYP2C9, CYP1A2, and MRP2. PCA of 61 ADME-related genes positioned invivo closer to human total liver than the comparator models, and pathway enrichment analyses highlighted metabolic and transporter-related processes. Functionally, invivo showed greater sensitivity to hepatotoxicants, particularly cholestasis-associated compounds. IC_{50} values for compounds such as bosentan, cyclosporine A, and danazol were substantially lower than in spheroids, indicating enhanced detection of cholestatic hepatotoxicity. Long-term culture evaluation demonstrated that invivo maintained viability, bile canaliculus function, hepatic gene expression, and metabolic activity for at least two weeks without medium exchange. Only limited numbers of differentially expressed genes were detected between medium-change and no-medium-change samples. Furthermore, induction of CYP1A2, 2B6, and 3A by omeprazole, CITCO and rifampicin, respectively, was retained, confirming functional robustness. Additionally, invivo enabled extended testing of low-clearance compounds. Three-week exposure to carbamazepine resulted in concentration-dependent toxicity and produced an S-cysteine conjugated metabolite detectable by LC-MS/MS, whereas such metabolites were not observed in prior spheroid studies. These findings indicate that invivo supports long-term metabolic evaluations and reveals metabolic profiles and metabolite-driven hepatotoxicity not captured by conventional *in vitro* systems. **Conclusions:** The invivo model exhibits higher liver functional performance and superior toxicity-prediction sensitivity compared with conventional *in vitro* systems. It supports long-term hepatic function and enables extended low-clearance compound exposure without medium exchange. These results indicate that the model is highly suitable for evaluating metabolite-driven toxicity, pharmacokinetic clearance behavior, and *in vitro-in vivo* extrapolation (IVIVE) in drug safety research.

PS 3390 Implementation of the LEAP assay in stem cell-derived cardiomyocyte to detect sodium channel blockers in pre-clinical safety

J. Treadway, M. Zafiratos, S. Zhang, X. Liu, O. Antic, G. Jasiek, B. Bird, A. Wilsey, J. Segreti, Y. Koshman, and M. Foley. AbbVie, North Chicago, IL.

Background and Purpose: Drug-induced QRS interval widening on an ECG is an uncommon but concerning effect as it typically is associated with a sodium channel blocker which results in a disruption of ventricular depolarization. QRS prolongation was identified on an anesthetized dog CV study as part of the screening progression for a discovery project. Sodium channel blockage is highly correlated with sudden death; therefore, the team evaluated and adapted the screening strategy to be able to detect this unwanted effect prior to running a dog CV study. **Methods:** First, the team established that the compound-associated QRS widening was consistent with other sodium channel blockers and could be detected in a modified anesthetized rat CV model that added ECG collection and analysis. This was a first key step as it allowed for screening for new compounds in rats and removed the dependence on using dog CV. Second, the team validated a new capability on our existing stem cell-derived cardiomyocyte (hiPSC-CM) platform, Local Extracellular Action Potential (LEAP), which allowed us to screen compounds using a plate-based *in vitro* system. The key endpoint in the hiPSC-CM *in vitro* platform assesses the rise time of the cardiac action potential which is sodium channel-dependent. **Results:** The team demonstrated that compounds that produce QRS widening *in vivo* also increase rise time in the LEAP assay, while compounds that did not impact QRS *in vivo* had no effect on rise time in the LEAP assay. **Conclusions:** This provided valuable proof-of-concept data to the project team that convinced them to run all additional compounds through the *in vitro* LEAP assay before progressing into an *in vivo* model. Furthermore, those compounds that do progress to the *in vivo* rat CV model are now run with ECG analysis to ensure this liability will not be an issue in a dog CV study.

PS 3391 Bridging In Vitro and In Vivo Inhalation Toxicity: Dosimetry and Deposition Assessment of Organic Solvents and Nanoparticles in Air-Liquid Interface Systems

J. Lee¹, H. Lee², K. Ahn³, M. Jo², J. Kim⁴, Y. Han⁵, C. Lee⁵, Y. Kwon⁴, E. M. Faustman⁵, and I. Yu¹. ¹HCT Seattle, Seattle, WA; ²HCTm, Icheon, Korea, Republic of; ³Hanyang University, Ansan, Korea, Republic of; ⁴H&H Bio, Asan, Korea, Republic of; and ⁵University of Washington, Seattle, WA.

Background and Purpose: Developing new approach methodologies (NAMs) is essential to reduce animal testing, driven by ethical and cost considerations, particularly in safety assessment. Reliable NAMs for inhalation toxicity are needed to ensure

consistency with traditional *in vivo* studies. This study evaluated key dosimetry and dose-metric parameters in *in vitro* inhalation toxicity tests for organic solvents and particles using an air-liquid interface (ALI) system, to align *in vitro* data with *in vivo* outcomes. **Methods:** Isopropyl alcohol (IPA) and acetone vapors were generated and exposed to the ALI system for 1-2 hours at various generation rates. Protein nanoparticles were also aerosolized for ALI exposure. Key dose metrics—including particle size, number, vapor, and particle concentration stability, and deposition variability—were assessed. Central deposition mechanisms (diffusion, impaction, and gravitational settling) were also analyzed. **Results:** *In vitro* ALI deposition experiments showed average coefficients of variation (SD/mean) below 10% for IPA and acetone vapors across 6-transwells, and below 20% for protein particles. Deposition across 6-transwell plates was uniform for the vapors, with no statistically significant variation among wells. For particles, deposition showed some variability across experimental series. **Conclusions:** Diffusion was identified as the dominant deposition mechanism for both organic solvent vapors and nanoparticles under *in vitro* ALI conditions. When *in vitro* deposition profiles and dose metrics align with *in vivo* data and regulatory criteria, NAM-based ALI systems can serve as reliable alternatives to traditional animal inhalation studies, supporting global efforts to reduce animal testing in toxicology.

PS 3392 High-Content Mechanistic Profiling in a 3D Mini-Testis Model: Integration of Proliferation and Epigenetic Markers for Comprehensive Toxicity Screening

L. Yin¹, J. C. Hu², and X. Yu². ¹Reprotox Biotech, Albuquerque, NM; and ²College of Nursing, University of New Mexico, Albuquerque, NM.

Background and Purpose: Increasing evidence linking environmental chemical exposures to the global decline in male reproductive health underscores an urgent need to develop efficient and mechanistically informed New Approach Methodologies (NAMs) for reproductive toxicity screening. Addressing this challenge requires advanced *in vitro* systems that can capture the complex cellular interactions and comprehensive mechanistic pathways disrupted by toxicants, enabling high-throughput, quantitative, and pathway-based evaluation of male reproductive hazards. Our group previously developed a 3D mouse mini-testis model integrated with high-content analysis (HCA), which demonstrated strong concordance with *in vivo* data using key markers of DNA damage (γH2AX) and cytoskeletal integrity (F-actin). To capture a broader spectrum of toxicological mechanisms, we expanded the assay panel to include additional mechanistic endpoints, cell proliferation and cell cycle (BrdU incorporation), and epigenetic modification (Methyl-CpG-binding protein 1, MBD-1), representing critical and distinct molecular targets of reproductive toxicants. **Methods:** A 3D mini-testis model consisting of murine spermatogonia, Sertoli, and Leydig cells embedded in an extracellular matrix (ECM) was used to evaluate 87 compounds from the National Toxicology Program library, including known reproductive toxicants and non-toxicants. Following exposure, 3D mini-testis were sequentially labeled for DNA damage (γH2AX), cytoskeletal structure (F-actin), and DNA Methylation (MBD-1) prior to cell proliferation marker of BrdU labeling. This sequential labeling strategy preserved cellular morphology and antigenicity before DNA denaturation required for BrdU staining. Multi-channel fluorescence images were acquired using an automated high-content imaging system (Arrayscan VTI, Thermo Scientific) and analyzed with AI-assisted pipelines to quantify nuclear intensity, cytoskeletal organization, proliferation, and co-localization metrics. Mechanistic endpoint scores were integrated into a composite toxicity index, and hierarchical clustering with ToxPi visualization classified compound-specific mechanistic fingerprints. **Results:** The newly incorporated proliferation (BrdU) and epigenetic (MBD-1) were successfully validated, showing robust, dose-dependent responses to known reproductive toxicants. MBD-1 chromatin signature, observed with methylmercuric chloride and tris (2-chloroethyl) phosphate (TCEP), revealed altered chromatin organization and DNA methylation associated with protein binding preceding overt cytotoxicity. This finding is biologically significant, as early chromatin remodeling in germline precursors may lead to persistent or heritable epigenetic changes. Anti-proliferative compounds such as colchicine and 5-fluorouracil showed significant BrdU suppression at 1-10 μM, consistent with S-phase inhibition in spermatogonial cells. Valinomycin exhibited an early broad cytotoxic profile, concurrently affecting viability, MBD-1, and BrdU endpoints. Notably, MBD-1 response preceded BrdU suppression, identifying epigenetic remodeling as an early mechanistic event. Top-ranked compounds within these distinct phenotypic patterns defined three major toxicity pathways: (1) anti-proliferative (colchicine, 5-FU), (2) broad cytotoxic (valinomycin), and (3) epigenetic/chromatin remodeling (TCEP, methylmercuric chloride). Integration of all five marker classes into a composite toxicological index (ToxPi) enabled higher hierarchical clustering analysis of compounds by their primary mechanism of action, substantially enhancing the platform's descriptive and predictive performance. **Conclusions:** The expanded multi-parametric 3D mini-testis model provides a robust and comprehensive platform for screening, classifying, and prioritizing male reproductive toxicants. Its ability to detect early epigenetic remodeling and mechanistic disruption without requiring long-term animal exposure highlights its value as a rapid and mechanistically informative NAMs. This enhanced platform strengthens predictive power for reproductive toxicity and advances the broader goal of reducing and ultimately replacing traditional animal testing in chemical risk assessment.

S. Choudhury^{1,2,3}, M. Arava^{1,2}, I. Sivankutty^{1,2}, J. Kim^{4,5}, Z. An^{1,2}, E. Matsui¹, D. Sahu¹, C. Cai¹, V. Patel⁶, B. Suki^{4,5}, R. Krishnan⁵, and H. P. Behrsing^{6,7}. ¹Boston Children's Hospital, Boston, MA; ²Harvard Medical School, Boston, MA; ³Broad Institute of MIT and Harvard, Cambridge, MA; ⁴Boston University, Boston, MA; ⁵Mechanobiologix, LLC, Boston, MA; ⁶Institute for In Vitro Sciences, Inc., Gaithersburg, MD; and ⁷Advanced In Vitro, LLC, Frederick, MD.

Background and Purpose: A powerful new approach methodology (NAM) for lung research is the human precision-cut lung slice (hPCLS). To prolong hPCLS use, we utilized cryopreservation and tested the hypothesis that cryopreservation retains cellular, transcriptional, and functional regulation of effector cell types/states in hPCLS from fibrotic lungs. **Methods:** Using the 10x Genomics Visium platform, we performed spatial sequencing of preserved cells within cryopreserved (up to 1 year) hPCLS from three healthy and three fibrotic donor lungs. Measurements were performed immediately upon tissue thaw and compared with published spatial transcriptomic datasets generated from never-frozen human lung fibrotic biopsies. **Results:** Enabled by marker gene expression profiles, we identified twenty-three cell populations within the cryopreserved healthy and fibrotic hPCLS. Further comparative analysis revealed enhanced fibroblasts, myofibroblast, and historically under-represented endothelial and rare cell type expression, and reduced AT1, AT2 and basal epithelial cell expression in the cryopreserved fibrotic hPCLS. These cellular changes were spatially co-incident with 1) collagen-rich regions enriched for extracellular matrix (ECM)-related genes (e.g., COL1A1, SPARC), 2) expanded fibroblast-endothelial crosstalk with enhanced chemokine signaling (CXCL12-CXCR4), 3) integrin-driven mesenchymal signaling targets (ANGPTL-integrin), 4) stress-adapted and immune-interacting Alveolar Type 2 cells with impaired surfactant gene expression, and 5) endothelial reprogramming toward a contractile and profibrotic phenotype. At a functional level, these spatially-defined fibrotic niches were characterized by increased immune responses (IGKC and IGHG1), fibrosis (collagen, fibronectin, and DCN), mechanotransduction (MYH11, TPM2, ACTG2, ACTA2), immune cell recruitment (CCL2, IL6, ICAM1), ECM remodeling (e.g. thrombospondin 1, THBS1), and surfactant production (SFTPB, SFTPC). At a molecular level, they coincide with activation of three fibroblast mediating signaling pathways: the matricellular glycoprotein, SPARC, Relaxin signaling, and immunoglobulin transcripts including IGHA1, IGHG1, IGHG3, and IGKC. Notably, these cryopreserved fibrotic hPCLS measurements closely resemble published findings with never-frozen human lung fibrotic biopsies. **Conclusions:** We verify model fidelity, identify known and new pro-fibrotic genes, and promote using cryopreserved human hPCLS for disease modeling (e.g. fibrosis) and more generally, for drug discovery and toxicity testing.

PS 3394 Establishing and Validating an *In Vitro* Seizure Liability Assay with hiPSC-Derived Glutamatergic Neurons and Astrocytes

H. Miyoshi, E. Watanabe, and A. Inomata. FUJIFILM Corporation, Bio Science & Engineering Laboratories, Ashigara-kami, Kanagawa, Japan.

Background and Purpose: Drug-induced seizures are serious adverse reactions that can arise during drug development. Current methods for assessing seizure liability primarily rely on animal studies; however, these approaches face limitations including low throughput, variable outcomes due to species differences, and decreasing societal acceptance of animal testing. Emerging new approach methodologies (NAMs) offer promising alternatives for evaluating the seizure liability of drug candidates and have gained increased attention. Human induced pluripotent stem cell (hiPSC)-derived neural cell models have been shown to recapitulate aspects of the central nervous system and predict the seizurogenic potential of test compounds. Nevertheless, establishing a robust assay that consistently delivers reproducible results remains challenging. Furthermore, there is a lack of comprehensive information regarding the applicability and limitations of these assay systems. **Methods:** We developed a co-culture system of hiPSC-derived neurons and astrocytes to record extracellular field potentials using a multi-electrode array (MEA) system. To achieve sufficient throughput for investigational toxicology, we cultured iCell® glutamatergic neurons and iCell® astrocytes (both from FUJIFILM Cellular Dynamics, Inc.) in 96-well Cytoview MEA plates (Axion Biosystems, Inc.) following the instructions published by manufacturer of iCell® products (FUJIFILM Cellular Dynamics, Inc.). We established a dose-escalation protocol to assess the dose-response effects of pharmaceutical compounds using up to four concentration levels. Extracellular field potentials were recorded at each dose, and neural activity parameters, including network burst frequency, were analyzed. **Results:** We confirmed that the system can detect the effects of 12 compounds with diverse pharmacological mechanisms, including GABA antagonists, D2R antagonists, K⁺ channel blockers, M2R agonists, A1R inhibitors, GLR antagonists, and an antipyretic agent as a negative control. The lowest concentrations at which effects on neural activity were observed and reproducible across two to four independent experiments, with variability within a 10-fold range. These findings are consistent with the published data such as the cerebrospinal fluid (CSF) concentrations associated with seizure induction in animal studies. **Conclusions:** In conclusion, we have established a robust and high-throughput *in vitro* assay using a co-culture of hiPSC-derived glutamatergic neurons and astrocytes combined with an MEA system (dose escalation protocol in 96-well plate format). This assay accurately detects known pharmacological effects of seizurogenic drug

compounds. It offers a valuable tool for assessing the safety profiles of candidate drugs at early stages of drug discovery, thereby contributing to more successful drug development by reducing the risk of seizurogenic adverse effects in later phases.

PS 3395 The use of multiple cell culture models for developing quantitative Adverse Outcome Pathways (qAOPs) for genotoxicity

C. Maggs¹, A. Cayley², A. Fowkes², S. Doak¹, and G. J. Jenkins¹. ¹Swansea University, Swansea, United Kingdom; and ²Lhasa Limited, Leeds, United Kingdom.

Background and Purpose: DNA damage can lead to a number of safety issues, and the development of adverse outcome pathways (AOPs) for chemical toxicity has been utilised to assess the risk of carcinogenicity and better understand the mechanisms involved. AOPs typically link a molecular initiating event to an adverse outcome via multiple causally related key events, and current genotoxicity AOPs are generally qualitative, but chemical risk assessment may be better supported by quantitative AOPs (qAOPs). **Methods:** This study aimed to support the development of qAOPs by providing robust data for different KEs on a network of genotoxicity AOPs using the cytokinesis-blocked micronucleus assay, assessing chemicals with different modes of action: electrophiles (MMS & B[a]P), radical species inducers (hydroquinone, sodium arsenite) & a topoisomerase II inhibitor (dexamethasone). **Results:** TK6 cells, HepG2 cells in a 2D model, and 3D HepG2 spheroids were dosed with each compound for 1.5 cell cycles and subsequently analysed for micronucleus induction using the Metafer semi-automated scoring system. MMS gave lowest observed adverse effect levels (LOAELs) of 9.1µM, 68.1µM, and 45.4µM in TK6 cells, the 2D HepG2 cell model and 3D HepG2 spheroids, respectively. When treating the TK6 cells and 2D HepG2 model with hydroquinone, LOAELs of 50µM were determined, although this was reduced to 40µM when treating the 3D HepG2 spheroid model. Further, there was a 1.65-fold increase in micronuclei over background when treating the 2D HepG2 model with 1µM AFB1, but a 1.86-fold increase when treating the 3D HepG2 spheroids with the same concentration. Additionally, treating the 3D HepG2 spheroid model with B[a]P at 15µM yielded a 2.17-fold increase in micronuclei over background levels. **Conclusions:** This data collectively demonstrates clear differences in sensitivity and metabolic activity between the cell culture models in determining chemical cellular toxicity. This demonstrates the clear differences between the cell culture models in determining cellular toxicity and this data will be used to support the development of qAOPs for chemical risk assessment. Moreover, ongoing work aims to perform dose-dependent analysis of reactive oxygen species (ROS) production and γH2AX investigation which will elucidate the mechanisms involved in eliciting genotoxicity and support the development of qAOPs by determining the point at which one key event tips into the next.

PS 3396 Building a predictive structure activity relationship tool to help avoid ion channel related central nervous system liability in novel compounds

L. A. Zolkiewski¹, K. L. Rockley¹, J. McDonagh¹, J. E. Stacey², E. J. Griffen², K. Jones¹, H. G. Jennings¹, M. Maizieres¹, K. Newman¹, R. A. Roberts¹, and M. J. Morton¹. ¹Apconix, Macclesfield, United Kingdom; and ²MedChemica, Macclesfield, United Kingdom.

Background and Purpose: Unwanted central nervous system (CNS) liability remains a significant cause of attrition throughout pre-clinical and clinical drug development. Human-based new approach methods are needed to provide an earlier prediction of CNS risks to influence medicinal chemistry and reduce reliance on costly animal studies. Previously we have demonstrated the value of iSLA, an *in vitro* CNS liability assay based on 1) a CNS-related ion channel panel evaluated via electrophysiology, and 2) an human induced pluripotent stem cell (hiPSC)-neuronal model analysed using microelectrode array (MEA) to measure electrical activity in response to known seizurogenic compounds. Therefore, to assist in the development of therapies without CNS liability, we embarked on a study to develop SAR (structure activity relationships) by identifying the structural characteristics of the compounds that were associated with ion channel inhibition. **Methods:** The Enamine REAL database is the largest database of synthetically feasible molecules that can assist in SAR investigations. 78 compounds were selected from the Enamine REAL database based on their structural similarity to the 10 selected test compounds (amoxapine, diphenhydramine, quetiapine, 4-AP, linopirdine, bepridil, NS1619, quinidine, verapamil, XE991). These 88 compounds were screened using cells expressing the human isoforms of Na_v1.2, K_v2.1, GABA-α₂β₂γ₂ or nicotinic-α₄β₂ ion channels with automated electrophysiology (QPatch II, Sophion) and the fingerprint of activity was compared to the parent compound for each ion channel. A subset of these compounds were also screened with hiPSC-neurons to assess whole cell responses across MEA parameters. **Results:** The 78 compounds tested showed a range of activities (IC₅₀ values) across the Na_v1.2, K_v2.1, GABA-α₂β₂γ₂ and nicotinic-α₄β₂ ion channels that were different to the 10 parent molecules. Initial analysis showed some structural features had a statistically significant higher potency at K_v2.1 suggesting these may present a significant risk, which may extend to other channels. Significant differences in MEA parameters were also observed in hiPSC neurons incubated with amoxapine, diphenhydramine and quetiapine compared to selected Enamine REAL compounds. For example, iPSC-neurons dosed with 1 µM amoxapine exhibited a clear seizurogenic

phenotype (increased firing rate and network burst frequency) whereas minimal changes in activity were detected with the derivative compound PV-002730229172. This is reflective of the decreased potency of PV-002730229172 across all 4 ion channels screened (IC_{50} at $Na_v1.2 = 64.8 \mu M$, $K_v2.1 = 15.1 \mu M$, $GABA-\alpha_1\beta_2\gamma_2 > 100 \mu M$ and nicotinic- $\alpha_4\beta_2 = 10.7 \mu M$) compared to the amoxapine parent compound (IC_{50} at $Na_v1.2 = 26.2 \mu M$, $K_v2.1 = 6.7 \mu M$, $GABA-\alpha_1\beta_2\gamma_2 = 2.6 \mu M$ and nicotinic- $\alpha_4\beta_2 = 7.4 \mu M$). The loss of the halogen group and replacement of a hydrogen molecule with a bulkier ethyl chain may contribute to the decreased potency observed with PV-002730229172. **Conclusions:** We have demonstrated that we can develop SAR for compounds that interact with neuronal ion channels. Future work testing the compound set across more ion channels will provide more evidence and help to build a predictive SAR tool. This will help structural chemists avoid CNS liability in the development of novel compounds and reduce attrition during pre-clinical drug development phases. Collectively, this approach can be utilised for early de-risking and optimised drug design using human-relevant models that will save time, money and resources resulting in a more streamlined drug discovery process and ultimately improved patient safety.

PS 3397 Utilising *in vitro* assays to assess drug induced central nervous system liabilities

L. A. Zolkiewski, K. L. Rockley, H. G. Jennings, K. Jones, M. Maizieres, K. Newman, R. A. Roberts, and M. J. Morton. Apconix, Macclesfield, United Kingdom.

Background and Purpose: Central nervous system (CNS) liabilities, such as seizures, sedation, tremors and cognitive impairments, remain a significant cause of attrition during pre-clinical and clinical drug development. However, they are typically not identified until late-stage *in vivo* toxicology studies where adverse findings can result in costly delays or project termination. Further, ~25% of clinical trial failures are due to safety concerns that were undetected in earlier *in vivo* studies highlighting translatability concerns. This emphasises the need for predictive, human-relevant *in vitro* assays that can be implemented earlier in the drug development process to assess CNS safety risks. We have previously developed two complementary *in vitro* CNS safety assays: 1) a CNS-related ion channel panel evaluated via automated electrophysiology, and 2) an human induced pluripotent stem cell (hiPSC)-neuronal model analysed using microelectrode array (MEA) to measure electrical activity in response to known seizurogenic compounds. In addition to seizure risk, sedation is a common adverse finding in preclinical studies. GABAergic signalling plays a crucial role in the sleep-wake cycle, with GABA_A receptor activation resulting in sedation. To address this, we aimed to validate our *in vitro* CNS assay for predicting sedative compound effects. **Methods:** We tested 16 compounds with reported sedative activity (targeting both GABA and non-GABA pathways) and 5 non-sedative controls in the hiPSC-neuronal model using MEA. Changes in activity from baseline across a range of parameters (weighted mean firing rate [WMFR], network burst frequency [NBF], synchrony) were assessed to determine the whole cell phenotypic response. These compounds were further screened with automated patch-clamp electrophysiology (QPatch II, Sophion) using Chinese hamster ovary (CHO-K1) cells expressing the human isoforms of, $K_v1.1$, $K_v2.1$, $K_v3.1$, $K_v7.2/7.3$, $Na_v1.2$, $GABA-\alpha_1\beta_2\gamma_2$, nicotinic- $\alpha_4\beta_2$ or TREK-1. **Results:** MEA analysis showed that GABA_A agonists (muscimol, etomidate, ethanol) and certain ion channel antagonists (valbenazine, dextromethorphan) reduced neural firing and network burst activity, indicating sedative effects. For example, hiPSC-neurons treated with 3 μM muscimol exhibited a 57% decrease in WMFR and 100% decrease in NBF and overall synchrony compared to vehicle treated cells. Similar effects were observed in cells incubated with 500 mM ethanol, 4 μM etomidate, 10 μM valbenazine or 6 μM dextromethorphan. Negative control compounds produced no significant changes in MEA parameters. Of the 21 known compounds screened, 90% were accurately classified. Automated patch-clamp electrophysiology further confirmed these findings by testing compound interactions with GABA_A and other CNS ion channels. For example, $K_v2.1$, nicotinic- $\alpha_4\beta_2$ and TREK-1 were most frequently hit and valbenazine was the most promiscuous compound, inhibiting all but 2 channels screened. **Conclusions:** These results support the use of our *in vitro* CNS models for detecting sedative and seizurogenic effects, thus enhancing translational relevance. These platforms offer valuable human-based tools for early hazard identification and prioritisation of drug candidates, as well as interpreting CNS-related findings from *in vivo* studies thus complying with the principles of 3Rs to minimise and replace the use of animals in scientific testing. Ongoing work is focused on expanding this model to evaluate additional sedation-related ion channels.

PS 3398 Application of a Human Reporter-Based Live-Cell Imaging Platform for Detection of Mitochondrial Toxicity

T. Meijer¹, B. Tangil¹, B. ter Braak¹, E. de Tombe¹, S. Scott², A. Wood², and G. Hendriks¹. ¹Toxys, Oegstgeest, Netherlands; and ²Unilever R&D, SERS, Sharnbrook, United Kingdom.

Background and Purpose: Impairment of mitochondrial function by drugs and chemicals represents a major mechanism underlying toxicity and a common cause of late-stage drug development failure. Early detection of mitochondrial liabilities is therefore crucial for strengthening chemical safety evaluation; however, many existing

screening strategies lack sensitivity and specificity, limiting their predictive value for chemical safety and human health risk assessment. **Methods:** To address this limitation, we developed a human reporter cell-based assay designed for confocal imaging of mitochondrial networks in living cells. The assay utilizes the HepG2 CYC1-GFP reporter line, where CYC1—part of complex III within the mitochondrial electron transport chain (ETC)—is tagged with Green Fluorescent Protein (GFP), enabling real-time visualization of mitochondrial morphology. Quantitative image analysis was performed using morphological (Symmetry-Threshold Compactness-Axial-Radial; STAR) and texture (Spot-Edge-Ridge; SER) parameters, which together capture distinct features of mitochondrial organization. These metrics reflect changes in mitochondrial network patterns and distribution, such as shifts from tubular to fragmented phenotypes, allowing sensitive detection of structural alterations linked to mitochondrial stress. **Results:** Validation was performed using a reference panel of 20 compounds with well-characterized mitochondrial or non-mitochondrial toxicity profiles (e.g. rotenone, antimycin A, and tunicamycin). The complex I ETC inhibitor rotenone induced pronounced changes in mitochondrial morphology, evident from a marked transition from tubular to punctate mitochondrial networks at a non-cytotoxic concentration (0.09 μM). In contrast, the non-mitochondrial toxicant tunicamycin did not induce changes in mitochondrial morphology, confirming the ability of the assay to distinguish mitochondrial-specific effects. **Conclusions:** In conclusion, these findings demonstrate that morphology-based analysis using a human reporter cell-based model provides a mechanistically informative tool for early and more accurate detection of mitochondrial toxicity.

PS 3399 Self-assembling Peptide Hydrogels As User-defined Synthetic Matrices for *In Vitro* Modelling.

J. Curd¹, V. Erdelyi¹, M. Shelton¹, C. Roper^{1,2}, and C. Merry¹. ¹PeptiMatrix Limited, Nottingham, United Kingdom; and ²Roper Toxicology Consulting Limited, Edinburgh, United Kingdom.

Background and Purpose: Current 3D *in vitro* models typically rely on animal-derived materials, such as those derived from Engelbreth-Holm-Swarm mouse sarcoma (e.g., Matrigel). However, these materials are ill-defined, have high batch variability, and do not accurately represent human matrices. Researchers require a more reliable, reproducible, and ethical model platform (Nitsche *et al.*, 2025, doi 10.3389/ftox.2025.1649393). **Methods:** A synthetic self-assembling peptide hydrogel (SAPH) platform has been developed that addresses all the current shortcomings of available 3D *in vitro* models. The SAPH is well-defined, has limited batch variability, and is fully customisable, both in terms of stiffness and composition, to mimic the composition of any target tissue type. The end stiffness of the hydrogel can be controlled by adjusting the concentration of gelator peptide used during preparation. This allows the design of different hydrogels which match the stiffness of different tissue types. Customisation with soluble matrix components or choosing a gel with amino acid motif functionalisation can influence end gel stiffness. However, this can be accounted for by adjusting the initial concentration of gelator peptide. **Results:** Brightfield and immunofluorescence images of mouse embryonic stem cells (mES), U937 acute myeloid leukaemia cells, MCF breast cancer cells, and human mammary fibroblasts cultured in unmodified PeptiMatrix™ Core hydrogels will be presented. These results demonstrated the compatibility of PeptiMatrix™ with a wide variety of cell types without matrix modification. The optical clarity of PeptiMatrix™ hydrogels enabled flexible, high-resolution assays of cell growth and pluripotency. Real-time quantification of growth will be presented. End-point immunostaining of mES and MCF7 cells demonstrated compatibility with fluorescence imaging and marker analysis. Pre-customised formulations containing integrin-binding motifs from key extracellular matrix proteins: fibronectin (RGD), laminin (IKVAV), and collagen (RGD+GFOGER) are covalently immobilised within the hydrogel scaffold, providing stable and biologically relevant signals. These pre-customised peptide-functionalised hydrogels influence cell adhesion, behaviour, and differentiation, often promoting the emergence of more physiologically relevant, *in vivo*-like responses. Human induced pluripotent stem cells (hiPSCs) were cultured on PeptiMatrix™ hydrogels. Colonies remained viable across all conditions, with enhanced viability and colony spreading observed in laminin-modified gels. Pluripotency was maintained in all cultures, as confirmed by positive Oct4 staining. A range of human leukemic cell lines remained viable and formed colonies within unmodified SAPH, confirming the suitability of this matrix for 3D culture. U937 cells showed sustained growth across increasing hydrogel concentrations, while phase-contrast imaging demonstrated colony formation at different seeding densities across cell lines. To evaluate translational relevance, THP-1 cells were encapsulated in SAPH and treated with candidate drugs. Distinct responses were observed between early-stage and established models, highlighting the potential of SAPH-based systems to capture treatment efficacy in physiologically relevant conditions. **Conclusions:** The use of a SAPH, which can be selectively customised to mimic the stiffness and composition of different tissues, provides a reliable, reproducible, and ethical platform for modelling a variety of different cell lines.

PS 3400 Delivery of mRNA-based fusion protein reporters in primary hepatocytes for real-time quantitative imaging of mitochondrial morphology and dynamics

J. Qiu¹, K. Goldstein¹, J. Stutz¹, B. Q. Lee², A. Irizarry¹, and T. Baker¹. ¹Lilly Research Laboratory, Eli Lilly and Company, Indianapolis, IN; and ²Lilly Institute of Genetic Medicines, Eli Lilly and Company, Boston, MA.

Background and Purpose: Mitochondria are critical sensing organelles essential for metabolism. ROS are common byproducts of oxidative phosphorylation. Mitochondria are the sites for producing the chemical energy molecule ATP via oxidative phosphorylation. Their structure, function, and fusion/fission are dynamically tuned in response to intrinsic and extrinsic stresses. Impact on mitochondria has proven to be an early mechanistic indicator. Their regulation is important because of their potential to cause oxidative damage to DNA, proteins, and lipids. *In vitro* cell-based high-content screening (HCS) technology combining automated microscopy and quantitative image analysis can address biological questions such as mitochondrial stress. However, we previously found that chemical dye-based approaches such as MitoTracker are not practical for primary hepatocyte real-time imaging and texture analysis due to their intrinsic limitations: 1) they permeabilize in less viable cells while fading significantly after approximately 1 hour; 2) they are harmful to cells during extended incubation; 3) they are not flexible for customization and multiplexing. We reasoned that multiplexed mRNA-based reporter (namely, MMR) transfection in primary hepatocytes may overcome those limitations and allow monitoring of mitochondria qualitatively and quantitatively in a robust manner. **Methods:** We engineered four *in vitro* transcribed mRNAs encoding distinct subcellular reporters (mito-MMR hereafter): 1) iRFP670-Fis1¹⁰¹⁻¹⁵² (iRFP670 fused with Fis1 amino acids 101-152, serves as a mitochondrial membrane reporter); 2) 53BP1¹²²⁰⁻¹⁷¹¹-mTagBFP2 (53BP1 amino acids 1220-1711 fused with mTagBFP2, serves as a nucleolus reporter); 3) mApple-LC3B (serves as the reporter of autophagosome/autolysosome); and 4) Cox8-roGFP2-GRX1 (Cox8 mitochondrial inner matrix targeting peptide fused with ROS sensing roGFP2 and GRX1 in tandem, serves as a mitochondrial inner matrix ROS sensor). The mito-MMR was delivered to rat, cynomolgus monkey, and human primary hepatocytes by either electroporation (EP:mRNA) or lipid-based delivery methods (LNP:mRNA). **Results:** Through optimized EP:mRNA and LNP:mRNA procedures, we achieved rapid and efficient expression of mito-MMR simultaneously in rat, cynomolgus monkey, and human primary hepatocytes. The expression of mito-MMR lasts for approximately six days, offering good windows for cell-based imaging assays. Importantly, by testing a series of known mitochondrial toxicants, we demonstrated that mito-MMR achieved single-cell-level real-time quantitative imaging of mitochondrial dynamics—including fusion, fission, and mitophagy. What's more, this approach allows us to multiplex with LDH release assay or other destructive cell viability assays in parallel to correlate the early morphological changes with cellular viability. We observed that mitochondrial morphology disruption by known toxicants at early time points aligned with decreased oxygen consumption rates (OCR) in Seahorse assays and predicted 24-hour viability outcomes. **Conclusions:** This MMR approach has advanced our current *in vitro* hepatotoxicity screening capabilities by providing early mechanistic insights, thus enhancing our understanding of compound-related safety risks. It has the potential to increase technical success rates by derisking potential mitochondrial toxicity and overt disruption of bioenergetic pathways, which supports acceleration of early safety screening and lead optimization involving diverse modalities including small molecules, protein degraders, and gene therapy. In summary, we are the first to report that multiplexed mRNA-based fusion protein reporter (mito-MMR) transfection in primary hepatocytes achieved real-time quantitative imaging of mitochondrial morphology and dynamics. Our collective findings demonstrated that we can use MMR with high-content live-cell imaging to investigate key biological processes in real time, paving the way for endless possibilities of other MMR assays in primary cells and complex culture systems.

PS 3401 Leveraging a Human-Based Microphysiological System for In Vitro Pharmacokinetic Assessment of Oral Drug Formulations

A. Salminen¹, D. Dies¹, D. Austin¹, J. A. Willoughby Sr¹, H. Walker², and J. McKim, Jr.¹. ¹LifeNet Health LifeSciences, Virginia Beach, VA; and ²Bayer Healthcare LLC, Whippany, NJ.

Background and Purpose: Pharmacokinetics plays a pivotal role in preclinical drug development, yet traditional *in vivo* studies are often limited by cost, complexity, and translational relevance. Microphysiological systems (MPS), which integrate reconstructed human organ models under dynamic flow conditions, offer a promising alternative for simulating absorption, distribution, metabolism, and excretion (ADME) *in vitro*. This study explores the utility of a three-organ MPS platform to evaluate the pharmacokinetics of an active pharmaceutical ingredient (API) delivered via a self-nano-emulsifying drug delivery system (SNEDDS), a formulation strategy designed to enhance oral bioavailability and protect APIs from degradation and first-pass metabolism. **Methods:** A human-based MPS platform comprising EpiIntestinal™ (intestine), TruVivo™ (liver), and HK-2 (kidney) cultures connected through a series of semi-permeable membranes and a micro syringe pump (McKim et al., 2024) was employed to assess the pharmacokinetics of an API formulated in a SNEDDS. Preliminary cytotoxicity (MTT for intestine; ATP, Urea, LDH for liver; ATP, KIM-1, β-NAG for Kidney) and intestinal absorption studies were conducted using three SNEDDS variants (A, B, and

C) at a final concentration of 0.4% v/v. Based on absorption performance and safety profiles, SNEDDS C was selected for full pharmacokinetic evaluation in the MPS. The API (200 µg/mL) was loaded in SNEDDS C in buffer and applied to the apical surface of the intestinal tissue, and media samples were collected from all organ compartments over 72 hours. API concentrations were quantified via liquid chromatography tandem mass spectrometry (LC-MS/MS). **Results:** Minimal to no cytotoxicity was observed in response to 24-hour exposure to the SNEDDS, whether delivered alone or loaded with the API (100, 10, and 1 µg/mL for the intestine mimicking oral exposure; 20, 2, and 0.2 ng/mL for liver and kidney mimicking predicted *in vivo* C_{max}). When compared to the API delivered in buffer, two of the three SNEDDS facilitated slightly increased intestinal absorption of the higher doses of the API (100 and 10 µg/mL) over the 24-hour exposure period, with permeability coefficient equal to 1.50 ± 0.03 x10⁻⁶ cm/s, 1.68 ± 0.05 x10⁻⁶ cm/s and 1.69 ± 0.04 x10⁻⁶ cm/s for API alone, API in SNEDDS B, and API in SNEDDS C, respectively. In the MPS platform, the candidate SNEDDS, SNEDDS C, permitted sustained absorption of the API through the intestinal culture, which was subsequently distributed throughout the liver and kidney compartments. **Conclusions:** This study demonstrates the value of MPS platforms for evaluating formulation-dependent pharmacokinetics in a human-relevant, interconnected organ system. While SNEDDS C modestly improved intestinal absorption, it did not significantly alter downstream pharmacokinetics, supporting its role as a protective oral delivery vehicle. Importantly, the findings underscore the MPS platform's potential as a translational tool for formulation screening, mechanistic ADME analysis, and physiologically based pharmacokinetic (PBPK) modeling, bridging the gap between *in vitro* and *in vivo* pharmacokinetics.

PS 3402 Quantifying signaling-perturbation kinetics for *in vitro* developmental toxicity testing

Y. Okubo^{1,2}, R. Matsuura¹, K. Murayama^{1,2}, K. Sato^{1,2}, S. Nakamoto¹, A. Ishikawa¹, M. Kuwagata³, H. Kojima⁴, D. Sasaki⁵, Y. Nakajima⁵, J. Fukuda², and Y. Hirabayashi¹. ¹National Institute of Health Sciences, Kawasaki, Japan; ²Yokohama National University, Yokohama, Japan; ³Teikyo Heisei University, Ichihara, Japan; ⁴Sanyo-Onoda City University, Yamaguchi, Japan; and ⁵National Institute of Advanced Industrial Science and Technology, Takamatsu, Japan.

Background and Purpose: Embryonic and fetal development is governed by coordinated signaling interactions that regulate cell proliferation, differentiation, tissue formation, and morphogenesis. Traditional animal studies have provided indispensable information through the evaluation of developmental outcomes such as malformations, growth retardation, and embryo-fetal death. These approaches have established the foundation of developmental toxicology, but ensuring reliability and interspecies translation requires substantial resources. While certain developmental processes can be modeled *in vitro*, it remains challenging to comprehensively recapitulate the morphological outcomes observed in animal studies. Therefore, identifying measurable surrogates that reflect developmental toxicity is essential for advancing human-relevant testing. We focused on intercellular signaling, which regulates developmental processes and can be quantitatively captured as dynamic responses to chemical exposure. To address this challenge, we aimed to establish an *in vitro* assay that quantitatively monitors signaling-perturbation kinetics as a surrogate indicator of developmental toxicity using human iPS cells. **Methods:** We established a human induced pluripotent stem (iPS) cell-based live-cell luciferase assay, termed DynaLux/c, to monitor dynamic changes in signaling responses. In this system, NanoLuc luciferase expression is controlled by Serum Response Factor (SRF), which primarily functions downstream of the MAP kinase pathway but can also respond to other developmental signaling inputs. Luminescence was continuously recorded during chemical exposure to quantify changes in SRF activation kinetics as a readout for signaling perturbation. The area between curves (ABC) was calculated between the solvent control and each test concentration, and the resulting ABC values were summed across concentrations to provide a quantitative index of signal disruption. **Results:** The DynaLux/c assay detected compound-dependent changes in SRF activation kinetics, including enhancement or attenuation of pathway activity at different time points. ABC-based analysis quantitatively distinguished known human developmental toxicants from non-toxic reference compounds. These findings suggest that quantifying signaling-perturbation kinetics provides a practical and reproducible approach for assessing chemical effects associated with developmental toxicity. **Conclusions:** The DynaLux/c system enables quantitative evaluation of chemical-induced perturbations in signaling responses using human iPS cells. This approach provides a human-relevant NAMs framework for developmental toxicity testing and supports the establishment of mechanism-based, non-animal assessment strategies.

PS 3403 RNA-seq can be used for gene expression quantification in the GARDskin method for assessment of skin sensitizers

R. Gradin, J. Andersson, A. Forreryd, and H. Johansson. SenzaGen, Lund, Sweden.

Background and Purpose: The GARDskin assay is a non-animal method for identifying skin sensitizers. Its development and validation have been described in a series of publications, and it is currently included in the OECD test guideline 442E. The assay infers the sensitization potential of test chemicals based on gene expression

profiles, generated according to the standard GARDskin protocol using NanoString nCounter technology. While the nCounter platform possesses several advantageous properties, including rapid sample acquisition, reproducible results, and easy data handling, it is relevant to explore alternative acquisition platforms. Broader platform compatibility could make the GARDskin technology more accessible and extend the ability to perform secondary exploratory analyses. In this work, we investigated whether RNA-seq could be used as an alternative acquisition platform within the GARDskin assay. **Methods:** The study was conducted in two main parts. Firstly, 24 paired samples were acquired using both Nanostring nCounter and RNA-seq. These were used to establish an RNA-seq quantification pipeline aimed at producing gene expression measurements as similar as possible to the nCounter-derived data. This involved a primary mapping between RNA-seq transcripts and nCounter probe targets based on sequence alignment and a subsequent optimization to reconstruct the nCounter signal. Concordance between the two platforms was evaluated using correlation metrics and linear regression. In the second part of the study, the predictive capacity of RNA-seq-derived data was evaluated. A new set of 24 treatments, including 14 well-recognized skin sensitizers and 10 non-sensitizers, were analyzed using RNA-seq. Based on the established processing pipeline, expression data compatible with the GARDskin assay were generated and analyzed with the standard GARDskin classification pipeline. Classifications were compared with reference labels to generate standard performance statistics (accuracy, sensitivity, specificity), and with historical outcomes obtained using the assay's standard protocol. **Results:** The RNA-seq data were first adapted for compatibility with the GARDskin assays. Transcripts corresponding to the 196 NanoString probes were identified through sequence alignment. All but one probe could be confidently assigned to at least one reference transcript. For the unmatched probe (*COX20*), all transcripts annotated with the same gene symbol were included. The initial mappings were refined by iteratively excluding transcripts to maximize similarity between RNA-seq and NanoString expression profiles. Following the refinement, a strong concordance between the platforms was observed. Normalized expression measurements showed a Pearson correlation of 0.69 and a Spearman correlation of 0.66. Effect estimates comparing the vehicle control with the assay's positive control also showed a strong linear relationship along the identity line. The Pearson and Spearman correlations were estimated to 0.87 and 0.95, respectively. Lin's concordance correlation coefficient was estimated to 0.87. The predictive capacity of data generated with RNA-seq was evaluated on the separate set of 24 treatments (14 sensitizers and 10 non-sensitizers). All samples were accurately classified, yielding accuracy, sensitivity, and specificity of 100%. The classifications also showed 100% concordance with historical GARDskin classifications. **Conclusions:** These findings demonstrated that RNA-seq could be effectively adapted for use within the GARDskin assay. The RNA-seq platform showed high concordance with NanoString nCounter data, and classifications generated from samples quantified with RNA-seq displayed 100% concordance with both historical GARDskin classifications and reference sensitizing categories.

PS 3404 Translational Toxicology: Adapting Liver Microphysiological System for Cross-Species Evaluation of Hepatotoxicity Risk

I. Georgiades¹, J. Then¹, O. Novac¹, E. Richardson¹, C. Roper², and T. Kostrzewski¹. ¹CN Bio Innovations, Cambridge, United Kingdom; and ²Roper Toxicology Consulting Limited, Edinburgh, United Kingdom.

Background and Purpose: Drug-induced liver injury (DILI) remains a leading cause of drug candidate attrition during development, underscoring the need for improved translational models that can predict human-specific toxicities. Traditional animal models, while informative for systemic toxicity, often fall short in forecasting human liver responses due to inherent interspecies differences. To address this translational gap, we leveraged the PhysioMimix® Organ-on-Chip (OOC) Core System to develop a robust DILI assay using primary hepatocytes from human, rat, and dog sources. **Methods:** Using the PhysioMimix Core System, human, rat or dog hepatocytes were cultured as 3D liver microtissues under dynamic perfusion in the Liver-12 plate for up to 14 days, maintaining stable species-specific functionality (CYP activity, albumin, urea). A panel of six reference compounds (Troglitazone, Pioglitazone, Nefazodone, Buspirone, Tolcapone and Entacapone) recommended by the IQ MPS Consortium, including high-risk DILI agents and structural analogues with low human liability, was applied across a 7-point dosing regimen over four days. Functional *in vitro* and clinical biomarkers (albumin, urea, LDH, ALT) were monitored to assess hepatocellular health. **Results:** The assay successfully captured known species-specific toxicities. For instance, nefazodone and troglitazone (DILI Rank 8) induced hepatotoxicity in human and rat models, while dog hepatocytes showed reduced sensitivity. Conversely, buspirone and entacapone exhibited minimal toxicity in animal models, though the human MPS detected subtle hepatotoxic signals at higher entacapone concentrations, highlighting its sensitivity to rare DILI events. Albumin consistently emerged as a sensitive cross-species marker, with dose-dependent decreases aligning with known toxic profiles. **Conclusions:** These findings demonstrate the value of integrating human and animal liver MPS models to enhance cross-species interpretation and improve *in vitro-in vivo* extrapolation (IVIVE). The PhysioMimix system can be simply adapted to test multiple species in parallel to determine species-specific toxicity. As regulatory interest in MPS technologies grows, this approach offers a promising path to refine liver safety assessments, reduce reliance on and numbers of animal models used, and better predict human hepatotoxicity risks earlier in the drug development pipeline.

PS 3405 Developing A Repeated Exposure Regimen Using A Buccal Epithelium-Fibroblast Tissue Model

X. Cao¹, J. Molignano², M. Farcas¹, J. Oldach², and M. Gutierrez¹. ¹ALCS, Richmond, VA; and ²MatTek Corporation, Ashland, MA.

Background and Purpose: Oral tobacco products (OTPs) are considered potentially reduced-risk alternatives to traditional combustible cigarettes within the tobacco harm reduction paradigm. However, their mechanistic toxicity profiles, particularly local effects on oral tissues, remain insufficiently characterized. Current mechanistic assays have largely focused on single-exposure scenarios, which do not capture the cumulative biological effects associated with repeated use, a pattern that better reflects real-world consumer use behavior. Therefore, evaluating repeated exposure is an essential step toward filling this knowledge gap and understanding oral tissue responses that may more accurately represent human outcomes. In this preliminary study, we established a feasible approach for performing up to five repeated exposures using a human buccal epithelium-fibroblast co-culture tissue model (ORL-300 FT, MatTek Corporation, Ashland, MA, USA). **Methods:** The Kentucky 1R6F reference cigarette condensate (prepared in ethanol) and CRP2.1 moist snuff extract (prepared in complete artificial saliva, CAS) were used as test articles (TAs). The 1R6F condensate was tested at concentrations of 1.5%, 6%, and 10% (v/v) and the CRP2.1 CAS extract was tested at 20%, 60%, and 100% (v/v). ORL-300 FT tissue models were exposed to each TA for 4 hours daily over five consecutive days. After each exposure, tissues were maintained either in the presence or absence of CAS on the apical surface until the next treatment. Cytotoxicity and IL-6 and IL-8 secretion were measured in the culture media after the third (T3), fourth (T4), and fifth (T5) treatments. Following the final exposure (T5), tissues were fixed in 10% formalin and morphological changes assessed by H&E staining. **Results:** Repeated exposure to 1R6F condensate resulted in a time- and concentration-dependent increase in cytotoxicity in ORL-300 FT tissue models, while CRP2.1 extract induced only marginal cytotoxicity, with the highest observed cytotoxicity being less than 25%. No significant difference in cytotoxicity was detected between conditions with or without CAS. 1R6F condensate markedly decreased IL-6 secretion in a concentration-dependent manner at T3 and T4 under both CAS conditions. By T5, IL-6 secretion was completely suppressed at all concentrations, regardless of CAS presence. For IL-8, inhibitory effects of 1R6F condensate were observed at the highest concentration at T3 and T4 and at mid and high concentrations at T5, irrespective of CAS conditions. In contrast, the CRP2.1 extract had minimal effects on IL-6 secretion at T3, regardless of CAS presence. At T4, CAS enhanced the reduction in IL-6 levels induced by CRP2.1 compared to the group without CAS. By T5, CRP2.1 extract reduced IL-6 secretion in a concentration-dependent manner, with CAS having minimal additional impact. The effects of CRP2.1 extract on IL-8 secretion were less pronounced; with decreases not exceeding 50%. Histological evaluation by H&E staining revealed time- and concentration-dependent epithelial and dermal toxicity in tissues exposed to 1R6F condensate and CRP2.1 extract, with significant changes observed at higher concentrations by T3 and moderate toxicity at lower concentrations by T5. CAS-exposed controls exhibited normal morphology at T3 and T4, while extended post-exposure to T5 resulted in compromised tissue health, as evidenced by pronounced epithelial cornification. **Conclusions:** This preliminary study demonstrates the feasibility of employing a repeated exposure regimen using a human buccal epithelium-fibroblast co-culture tissue model to evaluate local toxicity associated with oral tobacco products. Notably, the presence of CAS during the maintenance phase had significant, time-dependent effects on IL-6 secretion and histopathological outcomes, underscoring the need to consider CAS-related effects under extended exposure scenarios. These findings highlight the importance of developing standardized, reproducible protocols capable of capturing cumulative biological responses over extended timeframes.

PS 3406 Modeling CAR-T Cell Migration and Efficacy in a Microphysiological System

R. N. Stolberg¹, D. L. Wagner^{2,3}, P. Reinke^{2,3}, L. Koenig¹, and E. Dehne¹. ¹TissUse GmbH, Berlin, Germany; ²Charité - Universitätsmedizin Berlin, Berlin, Germany; and ³Berlin Institute of Health (BIH) at Charité, Berlin, Germany.

Background and Purpose: Microphysiological systems (MPS) offer a promising *in vitro* platform to evaluate the efficacy and safety of T-cell-based immunotherapies, including chimeric antigen receptor (CAR) T-cell therapies. This study aims to develop an MPS to assess CAR-T cell motility and migration across endothelial and epithelial compartments, simulating the process of tissue homing. By using induced pluripotent stem cell (iPSC)-derived endothelial cells, donor PBMC-derived T cells, and a transwell-based system, the study seeks to investigate CAR-T cell behavior in a controlled, physiologically relevant environment. **Methods:** CAR-T cells were engineered using CRISPR-Cas9-mediated knock-in and expanded for functional testing. Migration was evaluated under various chemokine gradients, and flow cytometry and imaging were employed to quantify both migration and activation of CAR-T cells. Cytotoxicity against CD19-expressing Nalm6 cells was assessed by measuring the relative abundance of wild-type GFP (WT) and knockout RFP (KO) Nalm6 cells in the apical compartment of the MPS model. **Results:** The study found that endothelial cells are essential for facilitating CAR-T cell migration, with chemokine gradients playing a significant role in motility. Allogeneic CAR-T cells exhibited reduced migration compared to autologous donor PBMC-derived T cells. Importantly, while the presence of Nalm6 target cells did not affect CAR-T cell migration, it confirmed robust

cytotoxicity, with selective depletion of CD19-expressing Nalm6 cells in the apical compartment, indicating effective tumor cell killing by CAR-T cells. **Conclusions:** This work highlights the potential of MPS to model CAR-T cell migration and tissue homing, offering a valuable tool for preclinical testing of cell-based immunotherapies for autoimmune diseases. The inclusion of autologous systems enhances the precision of testing, and the platform's ability to replicate key features of immune cell interactions reduces the need for animal models. This approach offers a promising avenue for optimizing CAR-T cell therapies and advancing personalized treatments for autoimmune disorders.

PS 3407 Opportunities in Toxicity Testing of New Drug Modalities with 3D *in vitro* Models

S. Shafiei, X. Spijkers, N. Wevers, K. Kosim, B. Duggan, W. Allen, V. van Duinen, F. Bonanini, H. Lanz, and D. Kurek. MIMETAS B.V., Oegstgeest, Netherlands. Sponsor: S. Kundu

Background and Purpose: Emerging drug modalities offer new opportunities to treat previously unmet diseases but also introduce complex, unpredictable side effects. Traditional nonclinical safety testing lacks translatability, driving the need for better methodologies. Human 3D *in vitro* models provide more physiologically relevant systems that may improve safety assessment by revealing modality-specific toxicities. **Methods:** The OrganoPlate® platform, a microphysiological system was used to generate organ models known to be affected by different drug modalities including small compounds, antibody drug conjugates (ADCs), and AAVs (adeno-associated virus). The OrganoPlate comprises up to 96 individual chip, patterned underneath a 384-well microtiter plate. This innovative platform allows researchers to explore a wide range of flow and co-culture conditions, in a set-up that is compatible with standard laboratory equipment as microscopes and plate readers. The limited volumes required for the individual models allows the use of a range of starting materials, including primary cells, iPSC (induced pluripotent stem) cells, and ASC (adult stem cell) derived organoids. **Results:** We have developed several organ-on-a-chip models suitable for detecting different forms of toxicity. A neurite outgrowth model based on iPSC motor neurons extending their neurites into an extracellular matrix was leveraged to predict toxicity levels of ADCs. We were able to generate colon tubules using Caco-2 cell line, and ASC colon organoids. Their barrier integrity could be monitored through measuring the transepithelial barrier resistance, which reduced over time upon exposure to a panel of known gastrointestinal toxicants. Finally, we developed a liver MPS which exhibits unprecedented fidelity with the organization and interactions found within the native tissue by embedding primary or stem-cell derived liver cells in a hydrogel. The resulting culture includes polarized hepatocytes, functional vasculature with associated stellate cells and functional resident immune cells. This liver model was used to detect small molecule liver toxicity, as well as AAV transduction efficiency and toxicity. **Conclusions:** In conclusion, the OrganoPlate® platform enables the development of physiologically relevant organ-on-a-chip models that enhance the detection of modality-specific toxicities. These models demonstrate strong potential to improve the predictive power of nonclinical safety testing across diverse drug modalities.

PS 3408 Co-mentoring: A novel approach to improve undergraduate retention in toxicology and other STEM fields

C. P. Curran¹, M. Kulkarni¹, C. Daniels¹, B. Russell¹, C. Thomas¹, K. Simonson¹, A. Brockman¹, S. Adjei¹, and N. Dillards². ¹Northern Kentucky University, Highland Heights, KY; and ²University of Minnesota, Minneapolis, MN.

Background and Purpose: Northern Kentucky University is in the final cohort year of an NSF-funded project to increase STEM retention and success for transfer students and other groups under-represented in STEM disciplines. The TRUE-ACCESS (TRansfer & Underrepresented minority Experiences for Autonomy, Competence, Connection, and Careers: Enhancing Systemic change in STEM) project uses a 4C model with activities focused on Careers, Community-Building, Content-Area Research and Co-mentoring to engage student Fellows and to connect them to the larger campus community. The methods and results presented here will focus on the co-mentoring aspect of the project. **Methods:** There were 72 students admitted to TRUE-ACCESS beginning in Fall 2023 and continuing with new cohorts each semester through Spring 2025. More than one-third of TA Fellows were transfer students. Each cohort participated in an onboarding event that included an introduction to the non-hierarchical nature of co-mentoring. The co-mentoring process provided an opportunity to address challenges that arose. Examples included student deference to older faculty, tensions between traditional-aged students and older transfer students, and inconsistent attendance due to job and family conflicts. The common theme was that all participants are experts in something and are able to contribute to others' growth. **Results:** Retention and STEM persistence varied across cohorts. Cohorts starting in the 2023-2024 academic year achieved 74% overall retention and 68% STEM persistence, indicating a strong alignment between program goals and student trajectories. Cohorts starting in 2024-25 show respectable renewal but weaker STEM persistence ranging from 40-42% across the two cohorts. The results of pre- and post-surveys showed significant improvement in STEM identity ($p = 0.003$). Qualitative data indicated additional improvements in autonomy,

competence and belonging. Examples of positive comments from students about the co-mentoring experience include "I met different types of people...and learning about them made me more confident." "Everyone is equal in the session." "I love my co-mentoring sessions. We built friendships." Modifications included giving second-year Fellows autonomy in developing an on-campus event "College is Hard; Let Us Help" where they shared their experiences and survival tips with the broader campus community. The experience of the faculty co-mentors was also overwhelmingly positive, especially for those who are not actively advising or mentoring undergraduates in research. Faculty reported being able to adapt the co-mentoring principles in the classroom on team projects, during advising/mentoring meetings with other undergraduate students, and in their research labs. **Conclusions:** The multi-pronged approach was highly successful in achieving the project goals, the inclusion of co-mentoring played a significant role in increasing students' STEM identity, confidence and autonomy with additional benefits to the faculty co-mentors' professional development. Funding: NSF RII-BEC 2225771

PS 3409 Cannabis Safety Considerations and Informed Decision Making by Cancer Patients: Drug Interactions

S. Griffith¹, M. E. Tisdall², I. M. Balodis³, D. Querney⁴, A. C. Rosenthal⁵, M. A. Siyam⁶, R. W. Kirchoff¹, and M. C. Leung⁷. ¹Arizona State University, Phoenix, AZ; ²Arizona State University, Glendale, AZ; ³Peter Boris Centre for Addictions Research, St. Joseph's Healthcare Hamilton and McMaster University, Hamilton, ON, Canada; ⁴City of Hamilton's Alcohol, Drug & Gambling Services, Hamilton, ON, Canada; ⁵Division of Hematology Medical Oncology, Mayo Clinic, Scottsdale, AZ; ⁶Michael G. DeGroote Pain Clinic, Hamilton Health Sciences, Hamilton, ON, Canada; and ⁷Division of Hospital Internal Medicine, Mayo Clinic, Cannabis Analytics, Safety and Health Initiative, School of Mathematical and Natural Sciences, College of Health Solutions, Arizona State University, Phoenix, AZ.

Background and Purpose: Cannabis use is becoming more common among cancer patients for managing symptoms. However, inconsistent regulation and limited education about toxicity create obstacles to safe use. Cannabis contains over 100 active phytochemicals, most notably Δ^9 -tetrahydrocannabinol (THC) and cannabidiol (CBD), which have the potential for adverse effects, drug interactions, and contamination. Despite legalization trends, many clinicians and patients are unaware of toxicological risks, highlighting the need for science-based education accessible to both professionals and the public. The goal of this work was to synthesize evidence on cannabis safety in cancer populations and to model how toxicologists can apply principles of exposure science, pharmacokinetics, and risk communication to enhance understanding among patients and providers. **Methods:** A narrative review was carried out using open-access and peer-reviewed literature, U.S. state and Canadian federal regulatory documents, and expert consultations with clinicians, dispensary staff, and cancer patients. Publications covering three safety areas—(1) adverse effects and misuse, (2) drug interactions, and (3) product safety—were included. The findings were adapted into a harm-reduction framework and combined with educational communication strategies for application in clinical and public settings. Case studies from oncology clinics were examined to illustrate real-world application of toxicological principles, including dose titration, pharmacokinetic monitoring, and contaminant risk assessment. **Results:** Three risk domains were identified. Adverse effects included cardiovascular (tachycardia, bradycardia), neurological (fatigue, dizziness, psychomotor impairment), psychiatric (psychosis, anxiety), and gastrointestinal events, including cannabis hyperemesis syndrome. Approximately 10-30% of users developed cannabis use disorder. Cannabinoid-drug interactions occurred through CYP450 enzymes (CYP2C9, CYP2C19, and CYP3A4), altering the metabolism of agents such as tamoxifen, warfarin, and chemotherapeutics. Product safety concerns included microbial, pesticide, and heavy metal contamination, particularly in unregulated markets, posing infection risk for immunocompromised patients. These findings informed educational modules emphasizing safe dose titration ("start low and go slow"), product verification, and non-inhalation routes of administration. **Conclusions:** This synthesis demonstrates how toxicological literacy can improve the safety and efficacy of cannabis use among vulnerable populations. Future toxicologists play a critical role in translating pharmacological and exposure data into accessible risk communication for clinicians and the public. Integrating toxicology education with real-world patient guidance strengthens the credibility of cannabis safety messaging and supports evidence-informed policy. Educating the next generation of toxicologists to communicate clearly about emerging toxicants, such as cannabinoids and their contaminants, will enhance public trust and advance the discipline's contribution to health literacy and harm reduction.

PS 3410 Interactive Learning Tools Improve Student Confidence and Learning in a Summer High School Program

A. R. Juenke, K. Otersen, C. R. Longoria, A. J. Gow, D. L. Laskin, L. M. Aleksunes, and G. Guo. Rutgers University, Piscataway, N.J.

Background and Purpose: The Rutgers University Toxicology, Health and Environmental Disease (THED) Program is aimed at teaching high school students core principles of toxicology, pharmacology, experimental design and common laboratory techniques, as well as career opportunities in these fields. Tailored for students

interested in environmental and public health related fields, THED provides a platform for hands-on training in experimental methodology and career-based exploration. Herein we evaluated the impact of an interactive learning tool, Poll Everywhere, on student understanding, confidence, and satisfaction with topics presented in the Genetics Laboratory during the 2025 THED program. **Methods:** A total of 56 students participated in the two one-week programs. On the first (n=52) and the last (n=46) day each program, students completed pre- and post-program surveys. Pre-surveys assessed prior knowledge and confidence in the topics and techniques taught during THED. Post-program surveys assessed knowledge and confidence using the same set of questions as the pre-survey, with additional questions aimed at assessing satisfaction with THED activities. Confidence and satisfaction were assessed using qualitative 5-point Likert scales with one scale each for the Genetics Laboratory. Understanding was assessed by a series of true/false questions, three of which pertained to topics that were covered during the session. During the laboratory, students identified their genotype and phenotype for an inherited bitter taste receptor present on cells collected by a cheek swab, DNA extraction, amplification, and visualization. Lectures were also presented to students on key genetics principles including Mendelian genetics and single nucleotide polymorphisms, as well as methodology for DNA extraction, polymerase chain reaction (PCR), and gel electrophoresis. Students from Week 1 received a traditional lecture format, while students in Week 2 received lectures with 10 interactive questions imbedded using the Poll Everywhere software (Poll Everywhere, Inc., San Francisco CA.) Students responded to questions via mobile devices and received real time feedback from the instructor during the lecture. After the lectures, students applied these principles and techniques to a hands-on lab activity aimed at identifying their individual and population genotypes within their cohort. **Results:** Comparing student pre- (Week 1 n= 24; Week 2 n=27) and post-surveys (Week 1 n= 20; Week 2= 26), we observed a greater increase in confidence explaining the relationship between genotype and phenotype for Week 2 (49%) compared to Week 1 (28%). Satisfaction with the genetics lab was not appreciably different between students in Week 1 and students in Week 2. In contrast, greater understanding of the material was noted in Week 2 as indicated by an increase in the percentage of students with correct answers to Questions 1 (22%), 2 (18%), and 3 (17%), compared to Week 1 (14%, -13%, -15%, respectively). **Conclusions:** The use of the interactive learning tool, Poll Everywhere, increased student confidence and understanding, but did not affect student satisfaction with the laboratory. These findings provide insight into how to better engage students during lectures to ensure confidence in applying and understanding of the materials presented. Funding provided by Bristol-Myers Squibb, Johnson and Johnson, T32ES007148 and P30ES005022.

PS 3411 NURA: Free Toxicology Training on Sunscreens, Xeno-free Reagents, and More in 2026

E. Slankster-Schmierer, A. Martin, J. McCord, and S. Krishna. Physicians Committee for Responsible Medicine, Washington, DC.

Background and Purpose: Animal-based methods have historically dominated the field of toxicology. Some of these methods, like the Draize test, have been used for as long as 80 years without questioning the reliability and reproducibility of the results. Today, most toxicology education is centered around these methods. Scientists are recognizing the ability of New Approach Methodologies (NAMs) to improve chemical assessments while providing a better understanding of the mechanisms of toxicology. Unfortunately, training is often cited as a key barrier to the use of NAMs. For this reason, easily-accessible training is needed to help overcome the barrier and enabling more widespread use and understanding of NAMs. **Methods:** The NAM Use for Regulatory Application (NURA) program coordinates with leading regulatory and policy experts and scientists across sectors to develop training programs that target the replacement of animal use with more effective nonanimal methods. To reduce financial and logistical barriers to NAMs training, NURA hosts free, live webinars that allow the audience to engage with experts via Q&A sessions, hands-on demonstrations, case studies, and more. Following the live sessions, all NURA webinars are added to our online learning platform where they are available on demand with manually verified English and Spanish subtitles. NURA also develops Continuing Education Courses and customized hands-on workshops to meet the individual needs of organizations or regulatory agencies. **Results:** Throughout 2025, NURA provided thousands of cumulative NAM training sessions. We coordinated eight virtual webinars. We hosted a timely training following the OECD's updated release of Guidance Document 497, Defined Approach to Skin Sensitisation, where our invited experts highlighted the SARA-ICE method. In our NAM Spotlight series, we featured ALIsens, ToxTracker, and NAMsNetwork as NAMs for use in regulatory applications. We developed the "NURA en Español" series with colleagues from the Institute for *In Vitro* Sciences (IIVS) and presented three webinars for our Spanish-speaking audience. In February, NURA presented a two-day customized training at the California Department of Pesticide Regulation with our IIVS partners that highlighted skin and eye irritation and sensitization, systemic toxicity, and the Integrated Chemical Environment. In October, NURA hosted an in-person continuing education course, "Demystifying QSARs," at the American Society for Cellular and Computational Toxicology Annual Meeting. **Conclusions:** NURA aims to remove barriers to NAM training by providing scientists and regulators with free, on-demand, accessible NAMs education to help modernize their toxicity assessments.

PS 3412 Research in action: An applied approach to understanding knowledge and preferred communication about chemical exposures in consumer and children's products.

M. TатаhMentan¹, C. Voyles², and B. Lange². ¹Minnesota Department of Health, St Paul, MN; and ²Hamline University, St Paul, MN. Sponsor: K. Klos

Background and Purpose: The Minnesota Department of Health (MDH), in partnership with a public health seminar course at Hamline University, conducted four focus group discussions with parents and caregivers to assess knowledge and preferred communication methods regarding chemical exposures in consumer and children's products. Students in this course had the opportunity to apply classroom learning on topics such as focus group facilitation, qualitative research coding, and health communication campaign design in a professional setting. **Methods:** From September to October 2025, eight students facilitated four focus group discussions with a total of 55 participants. The students conducted quality checks and coded the transcripts to identify key themes. Findings from the results will be used to develop a health communication campaign for parents and caregivers focused on chemical exposures in consumer and children's products. **Results:** Most participants (56%) identified as Black, African, or African American, 61% were male, and 45% were between the ages of 25 and 34. Many participants reported relying on a variety of sources for health information, including social media, parenting blogs, and government websites. In addition, healthcare providers were highlighted as trusted messengers whom parents and caregivers rely on to provide information about potential chemical exposures and related health effects. Some participants indicated that they checked product labels before making purchasing decisions; however, many others reported that they did not prioritize reviewing product information prior to buying. Economic constraints were also identified as a factor influencing purchasing decisions. Final results are being compiled and will be shared at the conference. **Conclusions:** Findings indicated that multiple factors influenced participants' purchasing decisions and that parents and caregivers used a range of sources to obtain health information. The insights generated from this project will inform MDH's future exposure reduction and health communication efforts to improve the public's understanding of the potential for harmful chemical exposures from consumer and children's products and their related health effects.

PS 3413 Interactive Lesson on Microplastics and Nanoplastics for Summer Undergraduate Interns

S. Adams¹, G. Moreno², L. M. Aleksunes¹, D. Laskin¹, and P. Stapleton¹. ¹Rutgers University, Piscataway, NJ; and ²NJ Department of Environmental Protection, Trenton, NJ.

Background and Purpose: Micro/nanoplastics are now recognized as ubiquitous in the environment. Exposure can occur via ingestion, inhalation, skin contact and potential health impacts include cytotoxicity, DNA damage that enhance absorption of other toxins and exacerbation of respiratory pathologies. To increase awareness of micro- and nanoplastic particle toxicology, we designed an interactive training lesson for college students participating in a 10-week summer research internship at Rutgers University. **Methods:** The session was comprised of a 1) 45-minute didactic lecture on polymer types, particle characteristics, and particle deposition, 2) two hands-on team-based activities, and 3) utilization of Applied Research Associates, Inc. Multiple-Path Particle Dosimetry Model (MPPD) Software. For the first team activity, students were provided with recyclable plastic items and asked to estimate the decomposition time for each product. For the second team activity, students were provided toys and balls as surrogate micro- and nanoparticles. Students were asked to first identify the physical and chemical properties of the particles, then compare and contrast the properties with a neighboring team and theorize how these differences may impact biological behaviors or cellular interactions. For the Dosimetry activity, students were provided 4-case studies consisting of a model system and particles differing in density and size distributions; they were then asked to compare human and rodent pulmonary deposition using the MPPD software. Thirteen knowledge questions were tested before the interactive session and one-week after the training. The activity was rated using a 5-point Likert scale (1-poor to 5-excellent). **Results:** Twenty-one summer interns participated in the micro- and nanoplastics training and response rates on pre-/post-test questions ranged between 91-100%. The scores on the assessment questions increased 24% between the pre- and post-test. Across the 13 questions, the mean normalized gain of knowledge was 23%, with large variation ranging between -42% and +95% depending upon the question asked. At the end of the internship, the micro- and nanoplastics lesson was one of the most favorably rated career development activities (mean: 4.5, SD: 0.7, N=17). **Conclusions:** An interactive approach that combines didactic instruction, case studies on a modeling platform, and a fun team-based activity can be used to teach undergraduate students about micro- and nanoplastic characteristics and their biological disposition after pulmonary exposure. Supported by R25ES020721, T32ES007148, R01ES036575, P30ES005022, and the SOT and ASPET SURF Intern Programs.

J. L. Plahovinsak. The Ohio State University, Columbus, OH.

Background and Purpose: Artificial intelligence (AI) is rapidly transforming drug development, safety assessment, and toxicological research. However, a critical workforce gap exists while many toxicologists recognize AI's growing importance, they lack confidence applying AI terminology and concepts within scientific and regulatory contexts. This disconnect between awareness and application creates a barrier to responsible AI integration in toxicology practice. Building on a 2024 pilot study that introduced AI literacy, this 2025 study examined how learners progress toward fluency, defined as the ability to translate AI concepts into professional practice. This study aimed to strengthen "AI bilingualism," helping adult learners bridge computational and toxicological languages to prepare the next generation of translational scientists. **Methods:** Graduate students (n=87) enrolled in health sciences courses completed pre- and post-intervention surveys assessing progression from AI literacy toward fluency with seven key terms: Generative AI, Large Language Models (LLMs), Ethical AI Use, AI Bias, TRACI (Task, Role, Action, Context, Input) Prompting Framework, Predictive vs Reasoning AI, and AI Audit Trail. Students rated their proficiency using a five-point Likert scale (1 = not familiar to 5 = can apply this term in context). Between surveys, students completed structured assignments requiring application of AI concepts to toxicology and drug development scenarios. This study was approved by The Ohio State University Institutional Review Board (Protocol 2024E0184, Amendment 1). **Results:** Proficiency scores increased across all seven terms (preliminary n=87 pre-intervention, n=57 post-intervention to date; final data collection ongoing). Foundational concepts such as Generative AI and Large Language Models showed moderate gains (mean scores increased from 3.02 to 3.95 and 2.15 to 3.16, respectively), while applied and ethical topics including Ethical AI Use and AI Bias showed strong improvements (2.92 to 3.88 and 2.71 to 3.89, respectively). The largest gains occurred in advanced reasoning and prompting frameworks: TRACI Prompting Framework showed the greatest improvement (1.60 to 3.65, $\Delta=+2.05$), followed by Predictive vs Reasoning AI (1.98 to 3.18, $\Delta=+1.20$) and AI Audit Trail (1.99 to 3.65, $\Delta=+1.66$). These findings demonstrate that structured learning substantially enhances AI fluency among graduate students. **Conclusions:** Embedding AI fluency into toxicology education helps learners progress from terminology recognition to practical application. As AI continues to evolve within toxicology, from modeling to automated literature reviews and regulatory submissions, graduates need true bilingual fluency. Building confidence with AI terminology prepares toxicologists to critically evaluate AI outputs, recognize algorithmic bias, and navigate ethical considerations essential for responsible integration and regulatory decision-making.

PS 3415 **Efficacy of StressCURE: A Course-Based Undergraduate Research Experience Focused On Biological Stress In Various Laboratory Courses at Four Institutions.**

J. L. Newell-Caito¹, M. Reynolds², S. Caito³, J. Hall⁴, J. Hartman⁵, J. Schroeder⁶, and J. Gray⁶. ¹University of Maine, Orono, ME; ²Washington College, Chestertown, MD; ³Husson University, Bangor, ME; ⁴Lincoln Memorial University, Harrogate, TN; ⁵Medical University of South Carolina, Charleston, SC; and ⁶US Coast Guard Academy, New London, CT.

Background and Purpose: Research has shown for undergraduates that earlier exposure to research leads to increased student retention in STEM, self-identification as a scientist, and progression towards graduate school. Course-based Undergraduate Research Experiences (CUREs) are an effective way to expose undergraduates to research in the regular course of instruction throughout their educational program. StressCURE is an NSF-funded program supporting six faculty members to develop a modular approach to CURE design which focuses on the concept of biological stress in the *C. elegans* model system. Biological stress is defined as anything that disrupts the homeostasis of an organism, which may include exposure to toxicants, radiation, temperature extremes, diets, and genetic alterations. **Methods:** Using the pathway model approach to program assessment, we linked key activities of the project with short-, middle-, and long-term outcomes and identified key assessment points needed to demonstrate programmatic success. With this trajectory in mind, StressCURE was implemented in two courses in the Fall of 2024: a biochemistry laboratory at the US Coast Guard Academy (N=12) and an organic chemistry laboratory at the University of Maine (N= 32); one course in the Spring of 2025: a toxicology laboratory at Washington College (N=11); and three courses in the Fall of 2025: a molecular genetics laboratory at Lincoln Memorial University (N=39), an organic chemistry laboratory at the University of Maine (N=35), and a biochemistry laboratory at the US Coast Guard Academy (N=11). Students were assessed using the Experimental Design Ability Test (EDAT) which is an open-ended response for students to design their own experiment to a prompt, before and after the course, assessed by the professor using a validated rubric. Students also took the laboratory course assessment survey (LCAS) to evaluate their perceptions of courses which contained the StressCURE. **Results:** Initial results of the EDAT (N=57) showed a statistically significant ($p < 0.05$) increase in all measured values in the ability of students to design experiments. As assessed by the LCAS survey (N=51), students perceived the courses employing StressCURE as having increased collaboration and iteration as shown by statistically significant ($p < 0.001$) increase in all measures.

Since retention in STEM and at institutions is important for growth in STEM disciplines, we assessed the sense of belonging in the course and institution. Results from this validated instrument, revealed there was an increase ($p < 0.05$) in students comfort, respect, and belonging in the course when results were compared in the pre- and post-survey. These data extended to the institution where students had an increase ($p < 0.05$) in feeling comfortable on campus and supported in the major and institution when comparing results in the pre-and post-survey. **Conclusions:** Taken together, these data show the importance of utilizing CURE approaches like StressCURE for increasing critical student skills needed for their development as scientists and sense of belonging in STEM and retention at institutions. This material is based upon work supported by the National Science Foundation under Grant Number 2416714 as part of the Improving Undergraduate STEM Education (IUSE EDU). StressCURE course materials are freely available at stresscure.org.

PS 3416 **Transforming Toxicology Education through Interactive Online Modules: The ToxMSDT Approach**

M. Reynolds¹, J. Gray², B. J. Eidemiller³, A. O'Connor⁴, E. Glibreth⁵, L. Blackshire⁶, J. A. Flaws⁷, and W. K. Rumbleha⁶. ¹Washington College, Chestertown, MD; ²United States Coast Guard Academy, New London, CT; ³Society of Toxicology, Reston, VA; ⁴Michigan State University, East Lansing, MI; ⁵Tuskegee University, Tuskegee, AL; ⁶University of California Davis, Davis, CA; and ⁷University of Illinois Urbana-Champaign, Urbana, IL.

Background and Purpose: A major component of the five-year Toxicology Mentoring and Skills Development Training (ToxMSDT) program was to develop engaging online curriculum resources that were accessible to learners and instructors worldwide free of cost. These resources introduce foundational toxicology concepts in ways that are relevant, thought-provoking, and accessible to students with introductory biology and chemistry backgrounds. Original pilot modules were updated and continued development has produced new modules on toxicology topics and case studies focused on particular toxicants. The ToxMSDT program was designed to inspire and prepare STEM undergraduates for graduate study and careers in toxicology through mentoring and professional skills development; 138 undergraduates were paired with mentors and participated in career development during a pilot project and the five-year grant. **Methods:** Undergraduate educators and subject experts were recruited to write updates for five modules that were originally released in 2018 and to create new materials. Changes for existing modules include updated content and increased interactivity. All modules and case studies were aligned with the SOT Undergraduate Toxicology Learning Framework and the SOT Eminent Toxicologist Lectures were integrated. In addition, new modules and case studies were developed by teams organized by SOT. Grant partners at Michigan State and Tuskegee University also created two modules. The SOT oversight team recruited authors, reviewed content, ensured interactivity and consistency, and coordinated programming and completion of the products. Module completion and competency were tracked through earned certificates, and website analytics provided complementary insights into broader global use and reach. **Results:** Teams organized by SOT, comprising 27 authors representing unique institutions, contributed to updating five modules, developing two new modules (Neurotoxicology and Developmental and Reproductive Toxicology), replacing the Regulatory Toxicology module with a case study, and creating seven additional case studies focused on specific toxicants. The SOT oversight team managed the final stages of production for two additional modules, one produced by an author at Michigan State, and one created by six authors at Tuskegee University. Data collected through June 2025 show steady engagement across the online learning modules. Among the most utilized are Genetics (175 certificates), Biochemistry (117), Regulatory Toxicology (150), Applied System Toxicology (116), Pathophysiology (164), Lead (150), and Vaping (79). Newer modules such as Aflatoxin (4) and Ethanol (46) continue to expand the program's topical reach, while a recent addition, Reproducibility and Rigor, has begun awarding certificates, with 3 issued to date. For those achieving certificates as a course assignment, learners represent a broad network of 23 institutions, including universities such as Rutgers, Saint Louis University, Michigan State University, and the University of Illinois. Certificate completers were from over a dozen countries and territories spanning the United States, Canada, Pakistan, Egypt, Puerto Rico, Uganda, and others, underscoring the program's growing international reach. The oldest module, ToxTutor, originally adopted from the National Library of Medicine, has provided 3,612 certificates and 1,148 quiz completions as of June 2025. **Conclusions:** The ToxMSDT modules and case studies developed and refined during the ToxMSDT project demonstrate the power of collaboration and innovation in advancing toxicology education. These engaging, evidence-based learning resources enrich undergraduate toxicology curricula, provide valuable training for ToxMSDT participants, and broaden the global accessibility of toxicology education. Ongoing use in a new project, MSOT-One Health, and in toxicology-related courses and programs, will amplify the impact of these materials, increasing understanding of toxicology. Funded by R25GM1139200 and 1R25GM113989.

S. Caito¹, J. Hall², M. Reynolds³, J. Hartmann⁴, J. L. Newell-Caito⁵, J. Schroeder⁶, and J. P. Gray⁶. ¹Husson University School of Pharmacy, Bangor, ME; ²Lincoln Memorial University, Harrogate, TN; ³Washington College, Chestertown, MD; ⁴Medical University of South Carolina, Charleston, SC; ⁵University of Maine, Orono, ME; and ⁶U.S. Coast Guard Academy, New London, CT.

Background and Purpose: StressCURE is a Course-based Undergraduate Research Experience (CURE) focused on the theme of biological stress in the *C. elegans* model system. CUREs are designed to bring authentic research experiences to undergraduates, a practice which increases student retention in STEM, increases student identity as a scientist, and provides other benefits. StressCURE is designed to offer faculty flexibility in choice of scientific problems to investigate, as biological stress can be induced through exposure to toxicants, dietary changes, genetic modification, and a variety of other parameters. The *C. elegans* model system is readily adoptable, inexpensive, and includes a wealth of genetic models, making it ideal for undergraduate research. StressCURE is designed to be used in any undergraduate course, from basic biology through upper level laboratories. The goal of StressCURE is to expose more undergraduates to research by facilitating the adoption of the CURE methodology by faculty. **Methods:** The StressCURE module design was developed and tested by faculty members and students in their courses for three semesters. Each module is focused on a laboratory protocol and includes a brief overview, difficulty rating, list of materials, prerequisite knowledge, faculty goals, student learning objectives, faculty instructions, sample data, student handout, and additional information. A detailed timeline contains instructor preparation instructions and student responsibilities to be completed for the module. Protocols were tested at the primary author's institution and at least one other institution, refined, and then evaluated by the advisory board. Protocols were then published on the StressCURE website (www.stresscure.org) and communicated at scientific conferences to encourage adoption. The Reproduction, Chemotaxis, Aversion, and Basal Slowing Response modules were tested. Efficacy of the overall StressCURE model was also assessed using validated survey instruments according to a pathway model approach to program assessment. **Results:** StressCURE was successfully deployed at four institutions: the US Coast Guard Academy, University of Maine, Washington College, and Lincoln Memorial University. Faculty reported that the modules significantly reduced the workload required to adopt a new laboratory protocol for the teaching laboratory and that they would continue to teach in this way. Website traffic grew as more modules were published and surged around the time of conferences. Fourteen individuals signed up to receive notifications regarding the StressCURE project. While many individuals reported interest in using CUREs for Introductory Biology, several are interested in Microbiology, Biochemistry, Molecular Biology, Genetics, Genomics, and Cell Biology. Individuals reported hearing about StressCURE through conferences and their professional networks. In 2025, there were 713 visits to the site. **Conclusions:** StressCURE's first six modules have produced significant interest and the launch of more modules over the remaining two years of the project. The modules have been successfully adopted in the laboratories of the investigators and several faculty members plan to adopt them as well. Future assessment instruments will determine efficacy outside of the investigator group through surveys and ongoing communication as a community of practice is developed. In the third year, a regional conference will present all of the modules (approximately 30). This material is based upon work supported by the National Science Foundation under Grant Number 2416714 as part of the Improving Undergraduate STEM Education (IUSE EDU). StressCURE course materials are freely available at stresscure.org.

PS 3418 **An Innovative National Research Education, Mentoring, and Skills Development Training Program in One Health and Toxicology: MSDT-One Health**

L. S. Van Winkle, L. Blackshire, and W. K. Rumbeiha. University of California Davis, Davis, CA.

Background and Purpose: The NIH NIGMS has awarded a new 5-year IPERT mentoring and skills development training grant (R25) in One Health (OH) to a consortium of institutions led by the University of California, Davis. Collaborating institutions include the Society of Environmental Toxicology and Chemistry (SETAC), Meharry Medical College, and Iowa State University. One Health research is an integrated approach aimed at optimizing the health of people, animals, and ecosystems in their shared environment. Environmental toxicants are environmental stressors that negatively impact the health of people, animals, and the ecosystem in their common environment. Currently, OH research is facing a major challenge: the lack of engagement of toxicologists and/or people with toxicology knowledge in OH transdisciplinary research. This is partly due to inadequate training of toxicologists in skills essential for successful transdisciplinary OH research and/or a lack of awareness of opportunities in this field, as OH is not offered as a major at most undergraduate institutions. MSDT-One Health is a national program targeting early career scientists and undergraduate students in STEM fields. **Methods:** The MSDT-One Health training program has three specific aims (SA). SA1: Develop and deliver a year-long mentoring program for STEM undergraduate students. SA2: Develop and deliver a year-long professional development training and mentoring program for early career

scientists (Post-docs, Fellows, Project Scientists, Assistant Professors) to increase their awareness of the opportunities in OH research and to increase their knowledge and ability to obtain funding necessary to conduct OH research, including community-engaged toxicology research. SA3: Develop case studies and e-modules at the intersection of OH and toxicology and make them widely available. The program, which is mostly virtual, is delivered through a combination of assigned modules and case studies, in-person and virtual workshops, webinars, attendance at a national OH conference, and 1:1 mentoring with near peer and senior mentors. Training duration is 1 yr. **Results:** For the 1st cohort (November 2025 to April 2026) we recruited 20 undergraduate mentees, 9 early-career scientists, and 18 mentors, from across the United States, including Puerto Rico and Hawaii, to foster skills development in toxicology and transdisciplinary OH research. **Conclusions:** Expected outcomes include: a) a total of 100 undergraduate students mentored in OH with a toxicology emphasis; b) 5-10 early career scientists securing intramural seed funding and 2-3 early career scientists securing extramural funding to conduct OH research with community engagement components; c) development of highly interactive case studies in one environmental health toxicology (5) and learning modules on OH (3) to be widely available for training undergraduates and early career researchers. Ultimately, this research education program in OH and toxicology will strengthen the biomedical research enterprise by increasing the number of scientists with the necessary knowledge, skills and networks to engage in transdisciplinary OH research. Supported by NIGMS R25GM160671

PS 3419 **Advancing Neural Exposome Research at NINDS: Strategic Initiatives and Scientific Priorities**

C. Figueroa-Romero, N. T. Dhruv, S. Sameni, A. Givens-Burton, and S. M. Spriggs. National Institute of Neurological Disorders and Stroke, Rockville, MD.

Background and Purpose: Most neurological diseases and disorders cannot be explained by genetic factors alone. The *neural exposome* encompasses the totality of physical, chemical, biological, and psychosocial exposures that influence brain health and disease across the lifespan. The Office of Neurological Exposome and Toxicology (ONETOX) at the National Institute of Neurological Disorders and Stroke (NINDS) was established to advance basic, translational, and clinical research on how these diverse exposures shape nervous system development, function, and pathology. This abstract describes ONETOX's strategic role in supporting neural exposome research and fostering multidisciplinary collaboration to accelerate discovery and improve neurological health. **Methods:** To guide near- and medium-term efforts to cultivate neural exposome research, NINDS launched a two-phase process to identify research priorities in neural exposome. Phase 1 was conducted in 2023-2024 by the Neural Exposome Top Priorities Working Group (NEXT WG) that brought together experts in neurobiology, neurological disorders, and exposomic science to define key needs for the field. Phase 2, led by ONETOX during 2025, involved a working group internal to NINDS that developed an implementation strategy to address these recommendations. **Results:** Phase 1 identified, six priority areas: 1) Identification of exposome factors that affect neurological health, 2) fundamental mechanistic research to determine how these factors influence neurological health, 3) Evaluation of exposome factors in human/population research studies, 4) Creation of a multidisciplinary research community, 5) Development of exposome assessment tools, and 6) fostering collaborations to accelerate progress. Phase 2 organized these recommendations into five implementation focus activities: (1) foster partnerships and amplifying research; (2) leverage resources and tools; (3) train investigators and build multidisciplinary teams; (4) convene workshops; and (5) support neural exposome research. Together, these efforts have strengthened the scientific foundation for neural exposome research by hosting scientific meetings, promoting team science, expanding access to exposure assessment tools and repositories, and funding neural exposome research. **Conclusions:** Neural exposome research offers significant potential to uncover disease mechanisms, identify modifiable risk and resilience factors, and improve the prevention and treatment of chronic neurological disorders. By coordinating resources, expertise, and collaborative networks, ONETOX drives innovation in exposomic science and strengthens the broader neuroscience research ecosystem. The Neural Exposome Program at NINDS underscores an enduring commitment to public health by advancing scientific understanding of how lifelong exposures shape brain and nervous system health.

PS 3420 **The Environmental Health Language Collaborative (EHL): Spotlight on Community-Driven Projects that Harmonize Toxicology Data**

M. Shatz¹, J. Freed², J. Wignall³, G. Chappell⁴, C. Duncan¹, K. Vinsonhaler⁴, H. Bledsoe⁴, and C. Schmitt¹. ¹National Institute of Environmental Health Sciences, Durham, NC; ²ICF, Atlanta, GA; ³ICF, Winooksi, VT; and ⁴ICF, Durham, NC.

Background and Purpose: The availability of data is rapidly advancing opportunities to answer large-scale, complex questions in toxicology and environmental health sciences (EHS). However, a significant challenge remains around the development and use of harmonized language to allow for streamlined and customized workflows to find, share, and reuse this data. The Environmental Health Language Collaborative (EHL), <https://www.niehs.nih.gov/research/programs/ehlc> was created to facili-

tate a community-of-practice-driven effort to advance the development and adoption of harmonized language approaches within toxicology and environmental health science fields. Central to EHLC's work are three use case working groups. These use cases are distinct, but parallel, efforts that seek to address unique challenges related to promoting environmental health science data interoperability, discovery, and reuse. This poster will share information on recent products, publications, and next steps from these use case working groups and how SOT attendees can become involved in ongoing or future efforts. **Methods:** EHLC has grown into a robust community of practice made up of transdisciplinary subject matter experts led by a leadership committee. EHLC currently supports use case working groups focusing on Data Discovery, Data Harmonization, and Biomarkers and Biological Processes of Exposure. These groups explore how language-based solutions can 1) make it easier to find and use published toxicology and EHS data and resources, 2) support the combination and cleaning of data sets across independent toxicology and EHS studies, and 3) generate a conceptual model linking potential sources of particulate matter to human exposures and respiratory health outcomes, respectively. In addition, EHLC hosts community workshop and webinar events to fill identified needs within the community of practice, advance potential topics for focused activities, and promote outreach opportunities to toxicologists and environmental health scientists. The Adverse Outcome Pathway (AOP) Standards Workshop, a virtual webinar event held in June 2025, focused on ways to improve the computability of AOPs through a range of approaches that leverage language standardization, expanded AOP information structures, AI, and lessons learned from biomedical knowledge base development efforts. Subsequent products developed based on discussions and presentations at the AOP Standards Workshop include a summary report, a proposal entitled "AOP Reporting Standards for Biomedical Data", and a discussion article entitled "The FAIR AOP roadmap for 2025: Advancing findability, accessibility, interoperability, and re-usability of adverse outcome pathways" (Mortensen et al., 2025). **Results:** Five public webinars on EHS topics—such as data annotation, ontology curation, and large language models—expanded knowledge and skills among the community. The AOP Standards Workshop fostered new collaborations and led to tangible outputs, including a workshop summary and a peer-reviewed article. The EHLC Executive Committee, a chartered group of volunteer experts from across the EHS field, coordinated these efforts to align with community needs. Of the three EHLC use case working groups, two are developing manuscripts to share best practices, while the Data Harmonization Use Case published recommendations now informing the field. These initiatives have deepened the understanding of data management gaps and are shaping future directions as AI and machine learning become more prominent in environmental health sciences. **Conclusions:** This presentation shares updates, resources, information about participating agencies, and opportunities to get involved with EHLC use case working groups focused on harmonizing and sharing toxicology data relevant to SOT participants. Upcoming opportunities for SOT attendees to contribute to the development of a harmonized language to ensure that toxicological and EHS data can effectively be shared and best used to answer the fields' most pressing questions have also been collated. The goal of this presentation is to inspire collaborative engagement with EHLC and bring awareness of available resources to help advance environmental health sciences.

PS 3421 Contamination in Pharmaceuticals: Public Health, Medico-Legal Implications, and Recent Incidents

M. Patnaik¹, M. Patnaik², and M. Singh³. ¹All India Institute of Medical Sciences Raipur, Raipur, India; ²NCR Institute of Medical Sciences, Meerut, India; and ³Maulana Azad Medical College, New Delhi, India.

Background and Purpose: Pharmaceutical contamination with toxic adulterants has emerged as a major toxicological and regulatory challenge, particularly in LMICs. Recent fatal outbreaks in India (2025), The Gambia (2022), and Uzbekistan (2023) were linked to diethylene glycol (DEG) and ethylene glycol (EG) contamination of pediatric cough syrups. These incidents highlight persistent vulnerabilities in drug manufacturing, excipient sourcing, and global supply-chain integrity. The objective of this study was to analyze recent contamination incidents, characterize associated toxicological outcomes, and evaluate the regulatory, medico-legal, and industrial implications. **Methods:** We conducted a multi-source review integrating toxicological data, regulatory reports (WHO, CDSCO, UNODC), and peer-reviewed literature. Cases were analyzed for contaminant type, exposure route, clinical presentation, mortality, and regulatory response. Legal and ethical dimensions were assessed through policy documents and published medico-legal analyses. Quantitative data on DEG levels and case-fatality rates were synthesized where available. **Results:** Across three major incidents, DEG and EG concentrations in contaminated syrups ranged from 1.5% to 48.6% (v/v), far exceeding pharmacopoeia limits (<0.1%). Reported mortality included more than 70 pediatric deaths in Gambia, 19 in Uzbekistan, and at least 20 in India (2025), primarily due to acute renal failure and metabolic acidosis. Root-cause investigations are either underway or those concluded have identified substitution of industrial-grade solvents, inadequate excipient testing, and documented GMP violations in affected facilities. Regulatory actions included WHO global alerts, product recalls, factory closures, and criminal proceedings against manufacturers and practitioners. **Conclusions:** Pharmaceutical contamination represents a convergence of toxicological hazard and governance failure. DEG toxicity remains preventable with robust quality control and supply-chain verification. These incidents underscore the need for toxicovigilance systems, internationally harmonized GMP enforcement,

and ethical accountability mechanisms. For toxicologists, such events highlight the societal role of the discipline beyond mechanistic toxicity toward prevention, policy engagement, and protection of global public health.

PS 3422 From Sensors to Solutions: Novel Co-Planning Frameworks to Guide Air Pollution Monitoring and Input into Environmental Public Health Policy in the Columbus, Ohio Metropolitan Statistical Area

C. O. Moore¹, D. B. Gingerich², C. Stephens², E. Chou³, M. Diaz Hernandez⁴, D. Asabere⁵, A. Modali⁵, M. Rayo⁵, and D. B. Hood⁶. ¹College of Public Health, The Ohio State University, Columbus, OH; ²Department of Civil, Environmental and Geodetic Engineering, The Ohio State University, Columbus, OH; ³College of Food, Agricultural, and Environmental Sciences, The Ohio State University, Columbus, OH; ⁴Mid-Ohio Regional Planning Commission (MORPC), Columbus, OH; ⁵Integrated Systems Engineering, The Ohio State University, Columbus, OH; and ⁶Division of Environmental Health Sciences, College of Public Health, The Ohio State University, Columbus, OH.

Background and Purpose: The College of Public Health of the Ohio State University led, in partnership with the City of Columbus via Sustainable Columbus, Mid-Ohio Regional Planning Commission, Power A Clean Future Ohio, and Impact Community Action, a low income and disadvantaged community (LIDAC) benefits analysis study as a component of Comprehensive Climate Action Plan (CCAP). The CCAP outlined a comprehensive strategy to coordinate pollution reduction and mitigation strategies for greenhouse gas emissions across 6-sectors while prioritizing LIDACs. In order to facilitate the collection and analysis of real time air contaminant data in LIDACs, SimpleAQ air monitoring system was utilized. The online platform retains the information gathered from the sensors with the goal of providing data on the concentrations of criteria air pollutants in LIDAC communities and a dashboard for environmental literacy. **Methods:** Our methodological approach utilized several frameworks: a) Public Health Exposome; b) Health Opportunity Index; c) Public Engagement to Re-imagine Community Co-Planning (PERCC); and d) an enhanced engagement model E6. Multiple (n=30) engagement sessions were held. The protocols focused on educating the public on strategies to strengthen environmental literacy and implement co-planning strategies between residents and environmental public health professionals for pollution reduction strategies. During these sessions, information, thoughts, and opinions were collected relevant to potential exposures to air contaminants and the burden of responsibility. These data were collated and analyzed. LIDAC residents expressed their preferences, stories, opinions, and beliefs onto a bullseye template. To determine whether the Simple AQ air monitors would be beneficial, informative, and contribute to the weight of evidence in LIDACs for PM2.5 potential exposures; we modeled the associations of PM2.5 with the Health Opportunity Index (HOI) contextualized by readiness-to-read test scores in a LIDAC preschool cohort (n=236 students). To assess the benefits and costs of the interventions, we combined techniques from environmental public health policy analysis, decision analysis, and engineering. **Results:** LIDAC engagement sessions identified 6-greenhouse gas and other harmful air pollutant sectors, 17-strategies were developed from which 65-measurable actions are being implemented that will reduce these emissions to promote equity, resilience, health, jobs, and affordability. The LIDAC benefits analysis identified 6 win-win outcomes. 1) Reductions in Criteria Air Pollutants by Tree Canopy Type; 2) Animal Husbandry; 3) Electric Vehicle Adoption; 4) Reduced Vehicle Dependence; 5) Electrified Building Systems; 6) Equipment and Process Emission Reductions; and 7) Expanded Waste Diversion; and 8) Improved Water Use Efficiency. The SimpleAQ air monitoring network was deployed, tested, calibrated and validated in Columbus, OH and now monitors pollutant exposures in LIDACs. Finally, our collective frameworks identified significant associations between PM2.5 pollutant exposures and readiness-to-read in an (n= 236) LIDAC preschool children's cohort. **Conclusions:** The conduct of a LIDAC community benefits analysis was grounded in the input of high-quality data integrated with CCAP measures, methodological rigor, that resulted in the integration of environmental, demographic, and health data to address latent disproportionate burdens on low-income, disadvantaged communities (LIDACs). The study demonstrates the important role of exposomics-informed data for use by local environmental public health policy-makers for the design of pollution adaptation, and mitigation strategies that support the MSA priorities and impact.

PS 3423 Effects of Asbestos Dosage on Kidney IgG Deposition

S. M. Rigby, and K. M. Serve. Idaho State University, Pocatello, ID.

Background and Purpose: Worldwide prevalence of autoimmune diseases is rising, which may be partially due to xenobiotic exposures. Numerous studies have linked amphibole asbestos exposures to autoimmune development, though only a couple of these studies have examined the impact of exposures at environmentally-relevant doses. Understanding the mode by which asbestos causes autoimmune conditions is essential to determining risk factors and treatments in exposed human populations. Immunoglobulin-G (IgG) is the most common serum antibody, making it a good indicator of immune activity. IgG deposits in the kidney have been associated with autoimmune disease, which has also been attributed to asbestos exposure.

Thus, in this study, we directly compare IgG markers of autoimmune development in mice exposed to high and low dose asbestos exposures. **Methods:** We exposed male and female wild-type C57/BL6 mice (n=48 total) to a high (100µg) or low (3µg) dose of Libby amphibole asbestos given in two treatments via oropharyngeal aspiration. These doses mimic occupational and environmental exposures in human populations. At four months post-exposure, kidneys and serum were assayed. Kidney structure and collagen deposition were assessed using Masson's Trichrome and Hemotoxylin & Eosin. Immunofluorescence staining techniques and image processing were used to determine the percent area of IgG deposition in mouse kidneys. IgG isotypes were measured, and all data was analyzed using two-way ANOVA to assess effect of fiber dose and sex. **Results:** Significant IgG deposition was found in the low-dose group (p adj<0.01) compared to control and high-dose groups. Although high-dose did have greater IgG deposition when compared to the control group, this difference was not significant. Sex was not a significant factor in IgG deposition. No apparent structural changes in kidneys were noted during preliminary examination, though follow-up analyses are underway. **Conclusions:** Our findings suggest that even small, environmentally relevant asbestos exposure may trigger immune dysfunction and autoimmune responses, and that these responses are likely similar in biological males and females. Environmental asbestos exposures pose an on-going human health risk due to the presence of legacy asbestos in older buildings and products as well as natural asbestos outcroppings found worldwide. Understanding the etiology of asbestos-induced autoimmunity can lead to improving diagnostic methods, treatments, and prevention techniques in exposed populations.

PS 3424 Humanized B-hIL4/hIL4RA mice model for efficacy and toxicity evaluation

J. Zhang¹, S. Niu², S. Zhao², C. Liu², and X. Zhou². ¹Biocytogen, Waltham, MA; and ²Biocytogen Pharmaceuticals (Beijing) Co., Ltd., Beijing, China, Beijing, China.

Background and Purpose: The emergence of alternative models for drug safety evaluation has become a critical need, particularly in light of the current shortage of non-human primates. One promising alternative is the humanized mice, where specific target genes in mice are substituted with their human counterparts. Recent trends indicate that many pharmaceutical companies are leveraging Biocytogen's humanized mice for toxicology studies, crucial for supporting Investigational New Drug (IND) applications to regulatory bodies such as the FDA in the United States and the NMPA in China. A noteworthy application of this technology is the development of the B-hIL-4/hIL-4RA mouse model, particularly relevant for studying the therapeutic monoclonal antibody Dupilumab, which targets IL4RA to inhibit IL-4 and IL-13 signaling pathways involved in asthma pathophysiology. **Methods:** To overcome the challenge that human IL-4 does not activate mouse IL4RA and vice versa, Double humanized B-hIL-4/hIL-4RA mice were generated for *in vivo* efficacy assessment. **Results:** B-hIL-4/hIL-4RA mice were characterized for physiological similarities to wild-type mice, including baseline leukocyte populations, body weight, and various blood biochemical indices, to ensure model validity and safety. Functional studies demonstrated that B-hIL-4/hIL-4RA mice could be successfully applied in asthma and atopic dermatitis (AD) models. Analysis revealed inflammation-related changes, such as elevated eosinophils, neutrophils, increased IgE levels, and distinct pathological changes in lung tissue. Notably, administration of a Dupilumab analog led to significant improvements in asthma-related phenotypes, confirming the model's suitability for evaluating therapeutic efficacy. **Conclusions:** The B-hIL-4/hIL-4RA mice represent a robust platform for both efficacy and safety evaluations of human-targeted therapies. These advancements could streamline human drug development and provide more ethically sound models for studying human disease mechanisms.

PS 3425 Woodsmoke as an Environmental Amplifier of Autoimmune Pathology in Experimental Autoimmune Encephalomyelitis (EAE) Mouse Model

C. Cevering, M. Montera, E. Suh, B. Baird, E. Barr, J. Begay, G. Herbert, H. Wondra, L. Santos-Medina, M. MazlouiBakshayesh, M. Campen, and S. Blossom. University of New Mexico, Albuquerque, NM.

Background and Purpose: Multiple sclerosis (MS) is an autoimmune disease of the central nervous system (CNS) that impacts nearly 2.9 million people worldwide and disproportionately affects women between the ages of 20-40. MS is driven by autoreactive CD4⁺ T cells, particularly proinflammatory subsets, Th1 and Th17. While disease is believed to initiate due to breakdown of peripheral tolerance, pathology is driven by autoreactive CD4⁺ cells that cross the blood-brain barrier and promote demyelination. Despite available disease-modifying therapies, there is no cure and no single known cause, underscoring the need to identify environmental factors that influence immune function and disease risk. One possible environmental risk factor for MS, is exposure to woodsmoke from wildfires. Woodsmoke (WS), a major source of fine particulate matter (PM_{2.5}) from biomass combustion, contains complex chemical mixtures that induce systemic and neuroinflammatory responses. Our laboratory has shown that WS exposure in C57BL/6 mice upregulates cerebrovascular adhesion molecules (VCAM-1, ICAM-1), activates microglia, and promotes infiltration of neutrophils and monocytes (Ly6G⁺, Ly6C⁺) into the brain. Because MS is associated with neuroinflammation and disruption of the blood-brain barrier, we hypothesize

that WS exposure will exacerbate disease severity in the Experimental Autoimmune Encephalomyelitis (EAE) mouse model of MS. This hypothesis is supported by our previous findings showing that WS exposure increases CD4⁺ T-cell infiltration into the brain and drives neuroinflammation lasting up to 28 days post-exposure. Additionally, WS exposure produced increases in splenic naïve CD4⁺ T cells and activated CD4⁺ T cells. This suggests that inhaled particulates can prime or expand peripheral CD4⁺ T-cell populations, potentially lowering the threshold for autoimmune activation.

Methods: To address this, the EAE model was used to test if WS exposure amplifies CD4⁺ T-cell activation, alters effector function, increases leukocyte trafficking into the CNS and worsens disease severity. Female C57BL/6 mice induced with EAE were exposed to WS or filtered air at 0.5 mg/m³ for 4 hours per session, twice weekly for two weeks. Clinical scoring and body weight quantified disease progression and flow cytometry characterized immune activation across CNS and peripheral tissues, using a brain panel to evaluate leukocyte infiltration, endothelial adhesion, and microglial activation, and a spleen panel to define T- and B-cell phenotypes associated with immune priming. To assess antigen specificity and effector function, whole splenocytes were cultured *ex vivo* with or without myelin oligodendrocyte glycoprotein (MOG₃₅₋₅₅) and stimulated with anti-CD3/CD28 as a positive control. After four days, proliferation was evaluated, supernatants analyzed by multiplex cytokine (MSD) assay and cell pellets processed for RT-qPCR to measure Th1, Th17, and Treg cytokines (IFN-γ, IL-17A, IL-10, TGF-β) and transcriptional markers (Tbx21, Rorc, Il17a, Foxp3), as well as trafficking and myelin-integrity genes (Icam1, Cxcr3, Mbp). **Results:** Findings elucidate the degree to which WS exposure enhanced peripheral CD4⁺ T-cell activation, increased CNS infiltration and microglial activation, and ultimately impacted EAE clinical outcomes. **Conclusions:** Together, these results shed light on a potential role for WS exposure in heightening immune activation and CNS infiltration, strengthening evidence that WS acts as an environmental driver of MS and potentially other autoimmune diseases.

PS 3426 Efficiency of Tdap in Pregnancy with PFAS Exposure and Altered Immune Cell Populations in Maternal Rabbit Model

K. Cuevas Mora, S. Barrow, C. Agina, H. Rawtani, M. Woldetensae, J. Wang, A. Erlanki, A. Garner, C. D. Landon, H. Staats, and L. Feng. Duke University, Durham, NC.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are widespread contaminants in water, air, and food, raising health concerns. PFAS can cross the placenta and breast milk, exposing the fetus during critical development. While linked to immunotoxicity and reduced vaccine efficacy in adults and children, the effects of PFAS mixtures and PFBS on maternal vaccination remain unclear. **Methods:** Using a rabbit model, we studied the immunotoxicity of the environmental levels of PFAS or PFBS exposure via drinking water during pregnancy. Female rabbits at six months of age were given either clean water or water contaminated with a mixture of PFAS compounds or PFBS alone to drink *ad libitum* for 30 days prior to pregnancy and throughout gestation. Rabbits were given two doses of a Tdap vaccine; the first dose was given seven days before pregnancy, and the booster was given during pregnancy at gestational day 11 (GD11). Dams and their fetuses were necropsied at GD25. To characterize body burden accumulation and validate exposure, maternal serum PFAS levels were quantified at three different time points (before exposure, day 23 of exposure, and day 55). Antibodies to the Tdap vaccine were measured using ELISA, and antibody titers were calculated by a 3-fold difference between GD-7 and GD25. Peripheral blood mononuclear cells (PBMCs) were analyzed by single-cell RNA sequencing (RNAseq), from which cells were computationally clustered and analyzed. **Results:** PFAS and PFBS Low exposure reduced maternal Tdap vaccine efficacy by decreasing diphtheria-specific binding antibodies and impairing their neutralizing capacity. Single-cell RNAseq of maternal PBMCs showed PFAS exposure alters immune cell composition, introducing myeloid lineage cells such as pDCs, while decreasing B cell proportions. The transcriptional profile revealed B-cell dysfunction, characterized by altered receptor signaling and antigen presentation, reduced ribosomal biogenesis, and impaired regenerative capacity, which explains the reduced vaccine efficacy. Monocytes showed a senescence-associated secretory phenotype that promotes chronic inflammation. However, maternal-fetal IgG transfer efficiency was preserved, suggesting that maternal immune dysfunction is the primary driver of reduced offspring immunity. **Conclusions:** This study demonstrates that exposure to a PFAS mixture or PFBS alone can alter the health of B cells in the mother and impact antibody production during gestation, potentially reducing the effectiveness of prenatal vaccination in protecting offspring from neonatal infectious diseases.

PS 3427 Cetylpyridinium chloride (CPC) disrupts phosphatidylinositol 4,5-bisphosphate (PIP₂) nanoscale clustering and protein interactions in immune cells

D. J. Wagner, B. M. Aho, I. O. Dostie, S. T. Hess, and J. A. Gosse. University of Maine, Orono, ME.

Background and Purpose: People are exposed to the widely-used, *positively-charged*, antimicrobial cetylpyridinium chloride (CPC) in cleaning supplies, personal products, and food. Previously we showed that CPC inhibits mast cell (MC) function at exposure-relevant, non-cytotoxic doses. MCs are immune cells which release granules

containing chemical and protein mediators (degranulation) in response to antigen stimulation to modulate the immune system. Phosphatidylinositol 4,5-bisphosphate (PIP₂) is a *negatively-charged* plasma membrane (PM) lipid critical for MC signaling. While PIP₂ clustering and dynamics have not been previously investigated in immune cells, we hypothesized that CPC may *electrostatically interfere* with this key signaling lipid. **Methods:** Due to the tiny length scales at which PIP₂ clustering may occur, we utilized live-cell super-resolution microscopy (FPALM; resolution 10-20 nm), coupled with total internal reflection fluorescence (TIRF), to investigate PIP₂ clustering in the RBL-2H3 MC model. PIP₂ cluster characteristics (area, density, perimeter, eccentricity) and dynamics (turn angles and diffusion coefficients) were investigated under a range of conditions including in resting and stimulated MC with or without CPC. Airyscan confocal microscopy and PIP strips (PIP₂ lipids immobilized on a strip) were utilized to investigate if CPC disrupted binding between PIP₂ and two binding partners. **Results:** We discovered that PIP₂ clusters in this immune cell model, and at sizes inaccessible to conventional microscopy. PIP₂ clusters ~220 nm in size or smaller were identified. CPC decreased PIP₂ cluster size and density, while increasing circularity. Furthermore, PIP₂ diffusion increased by CPC, suggesting interference of this drug with PIP₂. Antigen stimulation resulted in significantly larger PIP₂ clusters, and CPC treatment along with antigen stimulation counteracts this effect. Binding of a PIP₂ specific protein, Grip, to PIP₂ was also found to be disrupted by CPC via experiments with PIP strips: CPC increased the K_d of Grip-PIP₂ binding. Confocal microscopy experiments revealed that CPC also disrupts binding of another PIP₂ binding protein, the PM-resident mRFP-MARCKS-ED SA4. CPC (5 μ M for 1 hr) reduces the amount of mRFP-MARCKS-ED SA4 at the PM by approximately half. **Conclusions:** These results indicate that PIP₂ clusters grow larger due to antigen stimulation, and that PIP₂ clusters may arise as needed for various processes throughout a cell's lifespan. Our data also suggest that CPC's disruption of nanoscale PIP₂ clustering and of PIP₂ partner binding are mechanisms underlying CPC MC inhibition.

PS 3428 Protein Corona-Aware Multi-Task modeling for Nanoparticle Immunotoxicity

S. Gopala, W. Chou, K. Li, and A. Canchola. University of California, Riverside, Riverside, CA.

Background and Purpose: Nanoparticles (NPs) have become a vital part of biomedical innovation, with applications such as drug delivery, imaging or tumor therapy. Their size and surface chemistry give them unique advantages. However, once exposed to the bloodstream, nanoparticles are susceptible to plasma proteins coating their surface, forming a protein corona (PC). This PC alters the physicochemical identity of the NP, which not only can induce immune responses but also limits the therapeutic efficiency. Uncontrolled cytokine release and clearance by macrophages are the most significant consequences of protein corona formation. Traditional migration approaches have largely relied on a trial-and-error workflow that is slow, costly, and hard to generalize across NP design. As a result, there is a pressing need for predictive tools to forecast immune response before *in vivo* or *in vitro* trials. To address this, we built a multi-task neural network (MTNN) that learns nonlinear links between NP design and biological outcomes, leveraging shared patterns across endpoints while preserving task-specific signals. Our model ingests NP physicochemical properties and, when available, protein-corona features to jointly predict cell viability and cytokine responses as surrogate markers of immunotoxicity. We emphasize TNF- α and IL-10, two consistently reported, mechanistically informative cytokines, to deliver size- and design-aware predictions. **Methods:** We curated a compact dataset from 25 primary studies, harmonizing NP physicochemical descriptors (zeta potential, NP subtype, size, surface modification/charge), PC features (ApoA-I, fibronectin, complement factor H—selected for reporting consistency), and key experimental covariates (cell type, exposure time/ concentration, medium/serum). We train an MTNN model with a shared trunk and two task-specific heads to jointly predict continuous cytokine levels (TNF- α , IL-10) and their high/low immunotoxicity classes via calibrated thresholds. Inputs are z-scored; categorical fields are one-hot encoded; missingness is handled with simple imputation plus a missing-indicator. Data is split by study (to avoid leakage) into train/validation/test (~80/10/10%), with grouped k-fold cross-validation for robustness on the small N. We tune learning rate, L2 weight decay, hidden size/depth, dropout, and epochs with early stopping. Performance is reported for both regression (MAE, RMSE, R2) and classification (ROC-AUC, PR-AUC, balanced accuracy, MCC, precision, recall, F1); we plot ROC/PR curves for each cytokine and assess probability calibration (isotonic/Platt). Decision thresholds use literature-based or validation-optimized cutoffs, and uncertainty is estimated via bootstrap ensembling. **Results:** The proposed MTNN model demonstrated promising predictive performance for cytokine response classification. During cross-validation, the model achieved an ROC-AUC of 0.69, balanced accuracy of 0.80, Matthews correlation coefficient (MCC) of 0.68, overall accuracy of 0.83, precision of 1.00, recall of 0.60, and an F1 score of 0.75. These results indicate that the MTNN effectively distinguished between high and low cytokine release levels, with particularly strong precision suggesting a low false-positive rate. The model's ability to generalize across cytokine endpoints underscores its potential to capture the shared nonlinear relationships between NP properties, protein corona composition, and immune activation pathways. **Conclusions:** The study introduces a predictive framework that connects NP design, PC composition, and immune outcomes using an MTNN approach. Even with a limited dataset, the model demonstrates the feasibility of a computational approach to anticipate immunotoxicity and identify NP likely to induce strong cytokine responses. Future works will focus

on expanding the dataset, refining the model, and validating predictions against a controlled experimental study to strengthen its use as a computational tool for immune safety assessment.

PS 3429 Uncovering the Impact of Common Antimicrobial Cetylpyridinium Chloride on Mast Cell Degranulation-Associated Mitochondrial Dynamics

E. Biro, S. Plummer, J. Eom, B. Obeng, M. Tasker, D. Wagner, and J. A. Gosse. University of Maine, Orono, ME.

Background and Purpose: Consumers are exposed regularly to antimicrobial agent cetylpyridinium chloride (CPC) in personal care, cleaning, and food products. Mounting evidence suggests CPC breaches the blood-brain barrier, is bioavailable, and is toxic to eukaryotes at low doses, such as nanomolar toxicity to developing oligodendrocytes. Our lab previously showed that low-dose exposure to CPC causes mitochondrial toxicity on par with canonical mitotoxicant carbonyl cyanide-3-chlorophenylhydrazone (CCCP) in primary human keratinocytes, mouse NIH-3T3 fibroblasts, and RBL-2H3 cells. In addition, CPC limits function of the nervous and immune system cell type, mast cells (MCs), by an unknown mechanism, yet the research to fully explore the toxicology of this drug is sparse. In response to various stimuli, MCs undergo a functional response, degranulation, in which bioactive substances like histamine and serotonin are exocytosed from pre-formed granules. Upon exposure to the stimulant calcium ionophore, which enables the calcium influx precondition for the MC degranulation pathway without any IgE receptor crosslinking or early tyrosine phosphorylation, we have found CPC actually enhances MC degranulation, with a U-shaped dose response. This effect lies in stark contrast to the potent CPC inhibition of degranulation and early tyrosine phosphorylation we have observed when the activation pathway is initiated by antigen stimulation. We have also found that CPC causes mitochondrial fission, which is, curiously, both a sign of mitotoxicity and a requirement to energize immune signaling by promoting mitochondrial translocation to the plasma membrane. Thus, we hypothesize that CPC-induced mitochondrial fission is actually supporting and stimulating degranulation when CPC's inhibition of early phosphorylation events is alleviated through use of ionophore. **Methods:** Translocation of mitochondria in MCs was assessed via confocal microscopy and image analysis. RBL-2H3 rat MCs were cultured and activated, either using 0.7 ng/mL antigen or by bypassing it through 3.0×10^{-7} M calcium ionophore as determined by preliminary dose-response testing to represent low antigen response (~7% degranulation). Cells were incubated with 2.0×10^{-8} M MitoTracker Red FM and 1.0×10^{-7} M Hoechst 33342 dyes and treated with CPC (0-10 μ M). Images were taken via the Zeiss LSM 980 Airyscan confocal microscope, at 37°C. The oil-immersion 63X objective was used. Images were analyzed using a Fiji ImageJ software mitochondria plug-in. **Results:** The data show that antigen-stimulated degranulation as a result of receptor crosslinking coincides with enhanced mitochondrial translocation to the plasma membrane. This effect is dampened by the addition of 10 μ M CPC, in concert with CPC's degranulation inhibition at this dose. Stimulation with calcium ionophore also leads to a significant increase in mitochondrial translocation, but in this case, translocation is *enhanced* by low concentrations (2.5 μ M) of CPC, a result also aligned with CPC's increase in degranulation with ionophore. **Conclusions:** This study contributes to basic knowledge of mitochondrial involvement in immune signaling and also provides information regarding the complex effects that CPC and related quaternary ammonium antibacterials have on the immune system.

PS 3430 Investigating an *in vitro* method for determining the dermal and respiratory allergenic potential of proteins

S. Mochizuki¹, L. Yiting¹, Y. Satoda¹, H. Mizumachi¹, Y. Takahashi¹, T. Inoue², and Y. Ito¹. ¹Kao Corporation, Tochigi, Japan; and ²Frontier Co., Ltd., Fukuoka, Japan. Sponsor: H. Mizumachi, Japanese Society of Toxicology

Background and Purpose: Proteins can exhibit allergenic potential following dermal or respiratory exposure. However, no standardized *in vitro* test method currently exists to evaluate this potential. In contrast, the biopharmaceutical field has developed *in vitro* immunogenicity assays. This study investigated whether the enzyme-linked immunospot (ELISPOT) assay using cultured peripheral blood mononuclear cells (PBMCs), originally designed for immunogenicity assessment, could also be applied to determine the allergenic property of proteins. Furthermore, as the ELISPOT assay detects cytokine secretion at the single-cell level. The development of protein-induced allergic sensitization involves not only T-cell activation (IL-2) but also type 2 helper T cell (Th2) cytokines, we compared the predictive performance across different cytokine readouts (IL-2, IL-4, IL-5 and IL-13). **Methods:** Based on epidemiological data for allergy after dermal or respiratory exposure to naturally occurring proteins, we selected the test proteins as follows: those with several reported cases were classified as high-allergenic proteins, whereas those with limited evidence from clinical or experimental studies indicating a significant role in sensitization were classified as low-allergenic proteins. The high-allergenic proteins included papain (papaya-derived protease), Der p 1 (mite-derived protease), and Asp f 1 (fungal ribonuclease), whereas potato agglutinin (potato-derived lectin) was classified as a low-allergenic protein. Moreover, because certain enzymes had numerous occupational case reports and are considered potentially allergenic, we included two lipases

and two amylases as occupational exposure-related proteins. PBMCs collected from multiple healthy donors were exposed to each test protein and cultured for 2 weeks. The cells were then divided into an antigen restimulation group and a media control group, and the ELISPOT assay was used to quantify spot-forming cells that produced IL-2, IL-4, IL-5, and IL-13. The positivity rate was calculated using the stimulation index (SI), defined as the ratio of spot-forming cell counts in the restimulation group to those in the control group. **Results:** Among the naturally occurring proteins, high-allergenic proteins generally exhibited higher positivity rates than the low-allergenic protein not only across IL-2 but also across IL-4, IL-5, and IL-13. In contrast, Asp f 1 exhibited no detectable IL-2 response, and papain exhibited no detectable IL-5 response. Moreover, potato agglutinin demonstrated higher positivity rates for IL-4 and IL-13 than for IL-2 and IL-5, indicating protein- and cytokine-dependent differences in responsiveness. Among the occupational exposure-related proteins, allergenicity was detected in all enzymes. For some enzymes concordant responsiveness was detected across cytokines, with the same enzymes exhibiting the highest positivity rates across multiple cytokines. **Conclusions:** The ELISPOT assay may be useful for the *in vitro* evaluation of protein allergenicity. Nevertheless, the most appropriate cytokine readout may differ depending on the protein. Future research will expand the test set and further validate the mechanistic basis to establish an optimal *in vitro* method for determining protein allergenicity.

PS 3431 Involvement of damage-associated molecular patterns (DAMPs) in the immune checkpoint inhibitor-induced myocarditis in A/J mice.

J. Matsushita¹, C. Kazama¹, K. Miwa¹, M. Goto¹, K. Kumagai², and K. Chiba¹. ¹Daiichi Sankyo Co., Ltd., Edogawa-ku, Japan; and ²Daiichi Sankyo Inc., Basking Ridge, NJ. Sponsor: J. Matsushita, Japanese Society of Toxicology

Background and Purpose: Myocarditis is one of the adverse events induced by immune checkpoint inhibitors (ICI). The damage-associated molecular patterns (DAMPs) are endogenous molecules that induce potent inflammatory responses by activation of signaling pathways related to pattern recognition receptors (PRR) including Receptor for Advanced Glycation End products (RAGE) and Toll-Like Receptor 4 (TLR4). Although DAMPs have been presumed as aggravating factor of ICI-induced myocarditis, the details are not fully understood. This study was conducted to clarify the variations of DAMPs and their related factors in plasma and heart in the mouse model of ICI-induced myocarditis. **Methods:** Anti-mouse Programmed cell death 1 (PD-1) and anti-mouse Cytotoxic T-lymphocyte antigen-4 (CTLA-4) antibodies (200 µg/body each) or isotype control antibodies were intraperitoneally administered to male A/J mice (n=5/group) twice weekly for 12 weeks. Plasma cytokines and calprotectin were measured 4, 8, and 12 weeks after the first dosing. The immunophenotyping, expression analysis of DAMPs and their related protein, and histopathological examination in the heart were performed 12 weeks after the first dosing. **Results:** The levels of Th1, Th2, and pro-inflammatory cytokines, calprotectin, and effector memory CD8⁺ T cells in plasma were increased in the ICIs-treated group. In the protein expression analysis, the RAGE and TLR4 were detected in the heart of both control and ICIs-treated groups, with no noticeable differences observed. In contrast, the phosphorylation levels of JUN and NF-κB, which are downstream signaling of RAGE and TLR4, were significantly increased in mice given ICIs. In histopathological examination, loss of cardiomyocytes with inflammatory cells infiltration was observed in 40% of mice treated with ICIs. Increased protein expressions of HMGB1 and Galectin-3 were noted in the hearts of animals exhibiting cardiomyocyte loss accompanied by immune cell infiltration, whereas these changes were not observed in animals lacking cardiomyocyte loss, despite the presence of immune cell infiltration. **Conclusions:** Increased plasma calprotectin levels, accompanied by activation of downstream signaling pathways including JUN and NF-κB were observed in A/J mice treated with ICI, suggesting their involvement in the induction of local inflammatory response in the heart. Furthermore, increased cardiac HMGB1 and Galectin-3 are involved, at least in part, in the exacerbation of myocarditis observed in A/J mice treated with ICIs.

PS 3432 Glycolytic metabolism of CD8⁺ T cells affects susceptibility to human leukocyte antigen-mediated abacavir-induced hypersensitivity

T. Susukida^{1,2}, Y. Sun¹, N. Arakawa¹, T. Hirao³, T. Mizuno⁴, S. Aoki⁵, K. Ito⁵, and Y. Hayakawa². ¹National Institute of Health Sciences, Kanagawa, Japan; ²University of Toyama, Toyama, Japan; ³International University of Health and Welfare, Tochigi, Japan; ⁴The University of Tokyo, Tokyo, Japan; and ⁵Chiba University, Chiba, Japan. Sponsor: T. Susukida, Japanese Society of Toxicology

Background and Purpose: Drug hypersensitivity reactions (DHRs) associated with a specific human leukocyte antigen (HLA) allotype do not manifest uniformly in all individuals within an HLA model population. This scenario highlights the complexity of predicting DHR risk without considering additional factors. Furthermore, conducting prospective clinical studies of DHRs in humans is unfeasible. Therefore, this study aimed to investigate additional risk factors beyond HLA genetics that determine susceptibility to HLA-mediated abacavir (ABC)-induced hypersensitivity reactions by using a unique transgenic mouse line harboring HLA-B*57:01 (B*57:01-Tg).

Methods: B*57:01-Tg mice or their littermates were orally administered either an ABC-containing or a vehicle-only diet. Subsequently, analyses were performed on isolated CD8⁺ T cells collected from the lymph nodes, ear biopsies, or plasma of these mice. **Results:** RNA sequencing and proteomic data analyses performed on the isolated CD8⁺ T cells demonstrated that the expression levels of several glycolytic enzymes, including hexokinase 2, were significantly upregulated in ABC-treated B*57:01-Tg mice. Moreover, the glycolytic rate and metabolite production significantly increased in these mice. Although treatment with the pyruvic acid carrier inhibitor UK5099 did not affect CD8⁺ T cell activation, inhibiting glycolysis using 2-deoxy-D-glucose or diet-based calorie restriction attenuated the increase in IFN-γ-secreting effector memory CD8⁺ T cells. Consequently, this attenuation prevented CD8⁺ T cell dermal infiltration in ABC-treated B*57:01-Tg mice. **Conclusions:** Overall, these results suggest the indispensable role of glycolytic CD8⁺ T cell metabolism in HLA-mediated ABC-induced hypersensitivity reactions, which may further determine susceptibility to HLA-mediated DHRs in humans.

PS 3433 Comparing macrophage differentiation from monocytes isolated via negative or positive magnetic bead selection and performance in an immunotoxicity assay

M. Nautiyal, S. Kelsey, L. Nguyen, O. Monazah, A. Menezes, and A. Sharma. Lonza Durham, Morrisville, NC. Sponsor: K. Dunnick

Background and Purpose: Macrophages play a key role in immunomodulation, driving initial inflammatory responses to diseases, wounds, and toxins, while also inhibiting inflammation and promoting healing. The process of generating macrophages and then polarizing them into their distinct sub-forms while still retaining their desired functionality in immunological assays requires a delicate balance of many factors. Everything from monocyte isolation protocols to macrophage differentiation protocols can influence the sub-phenotype and behavior of the resultant macrophages. In this study, we compared the phenotypes of cryopreserved monocytes isolated from human peripheral blood mononuclear cells via negative or positive magnetic bead selection. We then compared the sub-phenotypes and phagocytic capacity of M1 and M2 macrophages differentiated from each type of monocyte with and without an immunotoxic inhibitor. **Methods:** Cryopreserved human monocytes were isolated from fresh peripheral blood mononuclear cells via either positive (selecting for CD14^{pos}) or negative (selecting against all other cell types; CD14^{neg}) magnetic bead purification (3 donors each). The resulting monocytes were seeded at 0.1 million cells/well in 96-well plates and differentiated into macrophages using a modified KuGM[®] medium supplemented with 35 ng/mL M-CSF for 6 days. On day 6, three different polarization media were used to differentiate monocytes into M0 (naïve), M1 and M2 macrophage sub-phenotypes. Cells were cultured in this media for 24 hours and harvested on day 7 for immunophenotyping. Additional wells were used on day 7 to assess phagocytic capacity of each macrophage subtype. The phagocytosis assay used live-cell imaging to quantify the rate at which naïve, M1 and M2 macrophages engulfed fluorescently labeled bioparticles loaded at 10 µg/well final concentration. As a negative control, 1 µM cytochalasin D, an immunotoxic inhibitor of phagocytosis, was included to confirm the assay's specificity by blocking actin polymerization. **Results:** Naïve, M1 and M2 macrophages derived from either CD14^{neg} or CD14^{pos} cryopreserved monocytes displayed cell morphology consistent with each of the respective macrophage subtypes. All three macrophage subtypes showed the same overall patterns of surface and intra-cellular marker expression as determined via FACS analysis, though CD14^{pos}-derived macrophages tended to have more distinct differences in CD80 (M1 macrophage marker) and CD206 (M2 macrophage marker) expression when comparing among naïve, M1 and M2 subtypes. In general, macrophage subtypes derived from either CD14^{neg} or CD14^{pos} cryopreserved monocytes behaved the same in the phagocytosis assay. The general pattern showed M1 macrophages having the lowest rates of phagocytosis, while M2 and naïve macrophages were tied for highest rates of phagocytosis across all but one donor. In the outlying CD14^{neg} donor, naïve macrophages had very low rates of phagocytosis, similar to M1 macrophages. Regardless of donor or macrophage subtype, cytochalasin D significantly inhibited phagocytosis. **Conclusions:** Isolating monocytes via positive or negative magnetic bead selection had no significant impact on the morphology, overall marker expression, or phagocytic activity of macrophages. M1 macrophages had the lowest rates of phagocytosis, likely due to their overall phenotype as well as the use of LPS as a differentiating compound, which can inhibit phagocytosis. The use of M-CSF to differentiate monocytes into macrophages and the use of magnetic beads to purify monocytes from peripheral blood can push monocytes and naïve macrophages towards anti-inflammatory M2-like phenotypes, which was generally observed in the phagocytosis assay. However, donor-to-donor variability can predisposition monocytes and naïve macrophages towards the inflammatory M1 phenotype, which was observed in one of the CD14^{neg} donors where naïve macrophages had very low rates of phagocytosis, similar to M1 macrophages. Despite this, there was still a very high degree of separation between M2 and M1 phenotype sub-populations across all donors, indicating that the protocol used for macrophage differentiation is effective in generating distinct macrophage sub-phenotypes, regardless of whether the parent monocytes are isolated via positive or negative magnetic bead selection.

PS 3434 tBHQ inhibits dendritic cell-mediated CD4⁺ T cell activation in a Nrf2-dependent manner

S. Awali, and C. E. Rockwell. Michigan State University, East Lansing, MI.

Background and Purpose: Dendritic cells (DCs) are professional antigen-presenting cells that bridge the innate and adaptive immune systems by activating naive T cells through antigen presentation on MHC class II molecules. Previous work from our lab demonstrated that tert-butylhydroquinone (tBHQ)—a widely used food preservative and potent activator of nuclear factor erythroid 2-related factor 2 (Nrf2)—reduces DC expression of key functional markers, including MHC II, CD80, and CD86. We also found that tBHQ suppresses CD25 and CD69 expression and decreases IL-2 secretion in CD4⁺ T cells, suggesting impaired T cell activation. However, it remains unclear whether the effects of tBHQ on T cell activation are a direct consequence of its impact on dendritic cells, given the essential communication between these two cell types. Since DCs are critical for T cell priming and activation, we hypothesized that tBHQ impairs DC-mediated CD4⁺ T cell activation in a Nrf2-dependent manner. **Methods:** To test this, splenic DCs were isolated from female wild-type or Nrf2-knockout mice, pulsed with OVA, and treated with vehicle (0.005% ethanol) or tBHQ (0.5, 1, or 5 μ M), then activated with LPS overnight. DCs were washed, counted, and co-cultured with splenic CD4⁺ T cells isolated from wild-type female mice for three days. T cell activation was assessed by measuring CD25 and CD69 expression, as well as CD44 and CD62L expression via flow cytometry and IL-2 secretion via ELISA. **Results:** tBHQ treatment significantly suppressed expression of T cell activation markers and reduced IL-2 production by T cells, but only when co-cultured with wild-type DCs. These effects were abolished in co-cultures using Nrf2-knockout DCs, indicating a Nrf2-dependent mechanism. **Conclusions:** Overall, our findings demonstrate that tBHQ impairs the ability of DCs to activate CD4⁺ T cells in a Nrf2-dependent manner, providing new insight into how this common dietary additive may alter adaptive immune responses.

PS 3435 Human cell-based miRNA investigation of occupational allergic asthma pathways

F. C. Passoni¹, F. Liviero², G. Melzi¹, E. Corsini¹, M. Marinovich¹, and V. Galbiati¹.

¹Università Degli Studi Di Milano, Milan, Italy; and ²Università Di Padova, Padova, Italy.

Background and Purpose: Asthma is a chronic and heterogeneous disease of the lower airways, affecting approximately 300 million people worldwide. The most prevalent and extensively studied form is allergic asthma, which occurs in both children and adults. Its primary pathological hallmark arises from complex interactions between immune cells and immunological mediators. Recent evidence has highlighted alterations in microRNA (miRNA) expression across various lung diseases, including allergic asthma. Several miRNAs have been linked to asthma and airway inflammation; however, for most studies, the identification of their specific targets remains unresolved. This study, conducted entirely on human cells, aims to characterize miRNA expression patterns and identify potential targets involved in occupational allergic asthma. **Methods:** The *in vitro* approach is based on the human lung epithelial cells, namely Calu-3, exposed to different chemicals classified as respiratory sensitizers, skin sensitizers and irritants through a liquid aerosols system (Cloud Alpha System - VITROCELL® Systems). Additionally, human biological samples derived from healthy patients and patients affected by common and occupational asthma have been collected collected in collaboration with Dott. Liviero, Occupational Unit of Padova University and evaluated. **Results:** The miRNAs expression is evaluated through microRNA panels (mircury Panel Qiagen) for the *in vitro* part while a miRNA sequencing have been performed on serum human samples. Results obtained suggest an involvement of several miRNAs, such as miR-17-5p, miR-21-5p, miR-135b-5p, and let-7a-5p induced by respiratory sensitizers, in particular HClPt. **Conclusions:** The final purpose of the project is to compare data derived from the two systems, human and 3D *in vitro* assay and to identify possible target involved in the regulation of the miRNAs after respiratory sensitizers exposure. The translational potential of the project is due to the use of an *in vitro* cell culture model as well as human samples. Furthermore, implementation of miRNA patterns could be useful as prevention tool (biomarkers for diagnosis) of allergic asthma. *This study was supported by a grant from Ministero dell'Università e della Ricerca (PRIN 2022, project number PRIN202223VGLB_01).*

PS 3436 Prenatal exposure to inorganic arsenic and immune cell abundances in newborns

S. Wang. National Health Research Institutes, Miaoli County, Taiwan. Sponsor: K. Mann

Background and Purpose: Inorganic arsenic (iAs) is a toxic environmental contaminant that poses a risk to chronic disease, endocrine disruption, and immune dysfunction, particularly *in utero* exposure. T cells, essential to the immune system, have been hypothesized to mediate certain biological processes and pathogenic effects of prenatal iAs exposure. This study aimed to investigate the association between maternal exposure to iAs and the abundance of cell types at birth. **Methods:** We

included 215 infant-mother pairs from the TIMICS (Taiwan Maternal and Infant Cohort Study), TIMCS-P (Taiwan Maternal and Infant Cohort Study-Pilot), and TEC (The Taiwan Early-life Cohort Study) cohorts. We estimated cell type abundances based on RNA sequencing and DNA methylation array data from cord blood samples. We determined concentrations of arsenic species, including arsenite [As(III)], arsenate [As(V)], monomethylarsonate (MMA), dimethylarsinate (DMA), and arsenobetaine (AsB), using high-performance liquid chromatography in maternal urine samples at 28 to 36 weeks of gestation. **Results:** The abundance of CD8⁺ T cells in cord blood was inversely associated with maternal iAs exposure in the TIMICS cohort ($\rho = -0.257, p = 0.005$) and validated in the combined TIMICS-P and TEC cohort (partial $\rho = -0.224, p = 0.028$). Gene set variation analysis revealed that maternal iAs exposure was inversely associated with unfolded protein response and Myc targets, but positively associated with estrogen response and bile acid metabolism ($p < 0.05$). **Conclusions:** Prenatal iAs exposure may reduce CD8⁺ T cell abundance in cord blood, potentially via the estrogen response, highlighting CD8⁺ T cells as a marker of iAs-related immunotoxicity. Further experimental validations are warranted.

PS 3437 Investigating the Impact of Irregularly-shaped PET Microplastics (1-20 μ m) on Macrophage Function Using a Comparative Biology Approach with *Xenopus laevis* and a Human Cell Line

R. Lombardo, F. De Jesús Andino, and J. Robert. University of Rochester School of Medicine and Dentistry, Rochester, NY.

Background and Purpose: Microplastics (MPs) (1 μ m-5mm) are ubiquitous in the environment and exhibit a variety of different shapes and compositions. Although the biological effects of pristine polystyrene microspheres at high concentrations (>1 mg/mL) have been extensively characterized, more realistic MPs with variable sizes (1-20 μ m) and irregular shapes (I-MPs) at lower concentrations have yet to be investigated. By employing a comparative biology approach with macrophages from the amphibian *Xenopus laevis* and a human monocytic cell line (THP-1), we hypothesize that artificially aging I-MP will increase the frequency of phagocytosis. In addition, we anticipate that internalization of I-MPs will induce macrophage dysfunction related to the expression and processing of major histocompatibility complex II (MHC-II). This macrophage dysfunction may ultimately increase susceptibility to pathogen infection. **Methods:** For this study, polyethylene terephthalate (PET) I-MPs were generated from cryomilled water bottles, sieved on silicone nanomembranes to 1-20 μ m, and subsequently stained using Nile red fluorescent dye. Primary macrophages from *Xenopus laevis* frogs were collected by peritoneal lavage and compared to macrophages differentiated from a human monocytic cell line (THP-1) using phorbol 12-myristate 13-acetate (PMA). Macrophages were exposed to PET I-MP concentrations of 0.1, 1, and 10 μ g/mL. The phagocytosis and the expression of MHC-II were assessed by confocal microscopy, ImageStream flow cytometry, and RT-qPCR. Ongoing studies are investigating techniques for artificially aging PET I-MP, which involve incubating PET I-MP in water samples from Lake Ontario or laboratory-generated freshwater under ultraviolet (UV) light for 7-14 days. **Results:** The early stages of this project have largely focused on method development. PET I-MP can be reliably stained using Nile red fluorescent dye and visualized by epifluorescence microscopy. Preliminary results from confocal microscopy and ImageStream flow cytometry indicate that PET I-MP are phagocytosed by macrophages even at low concentrations. However, the frequency of phagocytosis is low (7-10%) compared to polystyrene microspheres. Preliminary data also suggest that the phagocytosis of PET I-MP affects the relative MHC-II gene expression of both *Xenopus laevis* and human macrophages. **Conclusions:** The phagocytosis of PET I-MP by macrophages is observed at lower concentrations than currently found in the literature for pristine polystyrene microspheres. Our current studies are exploring the impact of PET I-MP or artificially aged PET I-MP internalization on MHC-II expression and processing in macrophages. Future studies will investigate the phagocytosis of I-MPs produced from other polymer types, the phagocytosis of I-MPs coupled to pathogen exposure, and the long-term effects of I-MP phagocytosis by following the macrophages in tadpoles over a longer period of time. Overall, this research will provide new insights across phylogeny into the potential of microplastic water pollutants to alter macrophage function.

PS 3438 Intracellular HLA-drug interaction in keratinocytes drives HLA-B*57:01-dependent abacavir skin toxicity

S. Aoki, A. Kazaoka, S. Fujimori, Y. Yamada, T. Susukida, and K. Ito. Chiba University, Chiba, Japan. Sponsor: S. Aoki, Japanese Society of Toxicology

Background and Purpose: Immune-mediated idiosyncratic drug toxicity often shows strong associations with specific human leukocyte antigen (HLA) alleles but remains difficult to model prospectively, particularly for skin-restricted reactions. Abacavir hypersensitivity (AHS) tightly linked to HLA-B*57:01 is a representative case. While HLA is classically viewed through surface antigen presentation, the determinants of skin tropism remain unclear. We set out to define cell-intrinsic mechanisms in keratinocytes that gate the onset of drug-provoked dermal immune responses. **Methods:** Primary keratinocytes from HLA-B*57:01-Tg, HLA-B*57:03-Tg, and their littermates were exposed to abacavir. ER-stress/UPR activation (e.g., Ca²⁺ flux), cytokine/chemokine induction, and T-cell chemotaxis were quantified. Mechanistic involve-

ment was tested with the chemical chaperone 4-phenylbutyrate (4-PB), and intracellular abacavir-HLA binding/aggregation were assessed by HLA immunocapture with LC-MS/MS and confocal microscopy. *In vivo*, HLA-B*57:01-Tg mice received abacavir $\pm$ 4-PB, and epidermal ER-stress markers (p-IRE1, XBP1), vascular permeability, serum CCL17, dermal CD8 infiltration, and CD8 effector-memory accumulation were measured. **Results:** Abacavir triggered rapid Ca^{2+} release and pro-inflammatory cytokine/chemokine induction in HLA-B*57:01 keratinocytes, but not in HLA-B*57:03 or their littermates, which drove T-cell chemotaxis toward keratinocyte supernatants. These responses were blunted by 4-PB. *In vivo*, HLA-B*57:01-Tg mice exhibited epidermal p-IRE1/XBP1 induction, increased vascular permeability, elevated serum CCL17, dermal CD8⁺ T-cell infiltration, and CD8⁺ effector-memory accumulation. 4-PB attenuated dermal readouts without reducing lymph-node effector-memory frequencies. Biochemically, abacavir co-purified with HLA-B*57:01 (but not HLA-B*57:03), coincident with higher-order HLA species and BiP engagement, consistent with intracellular HLA-drug binding and misfolding-driven ER stress. **Conclusions:** Our results clarify that HLA-mediated intracellular stress responses are pivotal to the onset of HLA-B*57:01-mediated AHS, suggesting that the intracellular behavior of HLA is a critical determinant of drug eruptions.

PS 3439 Single-cell analysis reveals AhR-dependent myeloid reprogramming and myeloid-derived suppressor cell migration following TCDD Exposure

S. Thada, C. Weyer-Nichols, T. H. Carter, A. Marudamuthu, M. Palrasu, P. Nagarkatti, and M. Nagarkatti. School of Medicine, UofSC, Columbia, SC.

Background and Purpose: Under inflammatory conditions, the immune system generates suppressor cell populations that migrate to affected areas to limit excessive activation. Activation of the aryl hydrocarbon receptor (AhR) by high-affinity ligands has similarly been shown by our lab to expand highly immunosuppressive myeloid-derived suppressor cells (MDSCs). However, the mechanisms by which AhR signaling governs the induction, trafficking, and functional polarization of MDSCs remain to be established. **Methods:** C57BL/6 mice and mast cell-deficient mice were injected intraperitoneally with 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD, 10 $\mu\text{g/kg}$) or the vehicle, Dimethyl sulfoxide (DMSO). Bone marrow (BM) & peritoneal exudate cells (PEC) were isolated for downstream analyses using Single cell RNA-seq (scRNA-seq). **Results:** TCDD induced high levels of MDSCs (CD45⁺, CD11b⁺, Gr-1⁺) at the site of administration compared to vehicle. This induction was significantly downregulated in mast cell-deficient mice, however reconstitution of these mice with wildtype BM cells restored the MDSC accumulation in the peritoneum. scRNA-seq revealed a marked expansion of polymorphonuclear and monocytic myeloid-derived suppressor cell (PMN-MDSC and M-MDSC) clusters in the peritoneal cavity compared to bone marrow. In the bone marrow, RNA-velocity and CytoTRACE analyses showed stable hematopoietic trajectories and unchanged differentiation potential, indicating that AhR activation does not affect MDSC differentiation. In contrast, peritoneal velocity vectors were long and directional towards MDSC, with higher CytoTRACE scores denoting incoming, transcriptionally immature myeloid cells that acquire suppressive functions. Differential gene expression and pathway analyses demonstrated that TCDD up-regulated (S100a8, S100a9, Cxcr2, Mmp9, Csf3r, Il1b, Trem3, etc.) genes enriched for granulocyte migration, leukocyte chemotaxis, and cytokine-mediated signaling. In contrast, TCDD-treated bone marrow samples showed enrichment of mitotic and chromosomal-organization pathways without chemotactic or suppressive signatures. CellChat network analyses revealed that AhR activation increased intercellular communication, and MDSCs as dominant signaling hubs sending and receiving chemokine signaling molecules (CCL, FN1, GALECTIN, MIF, CD86, CD80, BST2, CEACAM & LAIR1, CD52, SELPLG, SIRP, SEMA4, CXCL, SELL), whereas bone-marrow networks remained largely unchanged between Vehicle and TCDD. **Conclusions:** These data demonstrate that AhR activation by TCDD mobilizes myeloid precursors from the bone marrow through chemokine signaling and transcriptional reprogramming into suppressive MDSCs within the peritoneal cavity, a process partially involving mast-cell signaling (This work was supported in part by NIH grants R01ES030144, P01AT003961, P20GM103641, and R01AI123947, R01AI160896).

PS 3440 Optimizing Antibody Selection and Gating Strategy for Cynomolgus Monkey Bone Marrow Immunophenotyping by Flow Cytometry

X. Wang, G. Ling, and Y. Chen. Suzhou Frontage New Drug Development Co., Ltd., Suzhou, China.

Background and Purpose: Given the translational relevance to human immune system, accurate immuno-phenotyping of bone marrow immune cells in cynomolgus monkeys is essential for the immunotoxicological effects in toxicology studies. Repeat dose toxicology studies for the pharmaceutical drug development are generally conducted by the contract research organizations (CROs) who provide appropriate endpoint methods. Frontage-Suzhou developed and validated a flow cytometry-based method to optimize antibody selection and gating strategy for the quantification of key immune cell populations in the bone marrow of cynomolgus monkeys. **Methods:** Bone marrow from naïve cynomolgus monkeys was processed

by resuspending in PBS, filtering through a 70 μm mesh, and adjusting to 10^6 cells/ml. Cells were lysed with erythrocyte lysis buffer, and labeled with a high-specificity antibody panel (BD Biosciences and BioLegend). Staining was performed for 20 minutes, followed by washing and resuspension in staining buffer. Multi-dimensional gating strategies, including FSC/SSC gating to assess cell morphology and live/dead staining to exclude debris and non-viable cells, and dual-marker validation were implemented to identify T cells (CD3⁺), CTL cells (CD3⁺CD8⁺), Th cells (CD3⁺CD4⁺), monocytes (CD11b⁺CD66⁺CD14⁺), eosinophils (CD11b⁺CD66⁺Siglec-8⁺CCR3⁺), basophils (CD11b⁺CD117⁺CD123⁺FcεRIα⁺) and different stages of granulocytes. Data quality was assessed for reproducibility. **Results:** In a representative sample, live cells comprised 98.2% of events, confirming effective debris exclusion. Immunophenotyping revealed lymphocytes at 18.50%, monocytes at 5.63%, eosinophils at 0.03%, basophils at 0.10%, myeloblasts at 0.14%, promyelocytes at 0.26%, myelocytes at 17.28%, metamyelocytes at 25.82% and mature granulocytes at 39.27% of the parent population. The optimized gating strategy achieved high-resolution separation of cell subsets, with minimal non-specific binding. **Conclusions:** Flow cytometric immunophenotyping methodology with bone marrow in cynomolgus monkeys was established and validated using multiple fluorescently labelled antibodies and gating strategy was optimized to enable precise and robust assessment of immunotoxicological evaluations.

PS 3441 Development of human alveolar macrophage model cell lines for the assessment of immunotoxicity of nanoparticles

S. Toda¹, I. Mizoguchi¹, Y. Katahira¹, N. Yamaguchi¹, E. Horio¹, S. Miyakawa¹, M. Igarashi¹, N. Qu¹, E. Kuroda², T. Ashikaga³, and T. Yoshimoto¹. ¹Institute of Medical Science, Tokyo Medical University, Tokyo, Japan; ²Department of Immunology, Hyogo College of Medicine, Hyogo, Japan; and ³Division of Genome Safety Science, National Institute of Health Sciences, Kanagawa, Japan. Sponsor: T. Ashikaga, Japanese Society of Toxicology

Background and Purpose: The immunotoxicity of nanoparticles has recently attracted attention. Nanoparticles reach the deepest parts of the lungs through respiration, where they are phagocytosed and removed by alveolar macrophages (AMΦ). Some nanoparticles can cause severe allergic reactions, thus there are needs to develop alternative methods of predicting such reactions. However, primary cells are not reproducible and human AMΦ-like cell lines have not yet been established. These are obstacles to studying the immunotoxicity of nanoparticles in the respiratory system *in vitro*. Furthermore, the adverse outcome pathways (AOPs) of nanoparticles in the respiratory system remain unclear. Therefore, the purpose is to develop a method of assessing the immunotoxicity of nanoparticles by developing AMΦ model cell lines and examining their immune response to the nanoparticles. To create these cell lines, we adapted a recently reported method for differentiating human primary peripheral blood mononuclear cells into AMΦ like cells. **Methods:** We used two types of human monocytic cell lines, acute monocytic leukemia derived cells (THP-1 cells) and iPS-derived myeloid cells (iPS-ML). THP-1 cells were cultured in RPMI1640 containing FBS and iPS-ML cultured in MEM-α containing FBS, GM-CSF and M-CSF. These cells were differentiated by stimulation with GM-CSF, TGF-β, IL-10, and pulmonary surfactant (SURFACTEN), as previously reported. Differentiation into AMΦ was evaluated by examining the expression of surface markers (CD11b, CD14, CD45, HLA-DR, CD163, CD169, CD206, MARCO) using FACS. Also, the number of viable cells during differentiation was counted to evaluate cell proliferation. The function of AMΦ was assessed using ELISA to measure IL-1α production in response to stimulation with allergy-inducing aluminium hydroxide [Alum, Al (OH)₃], non-inducing aluminium oxide (Alumina, Al₂O₃). **Results:** As results of the differentiation method using surfactant cocktails, the expression of HLA-DR⁺, CD206⁺/CD169⁺ and CD206⁺/MARCO⁺ increased in differentiated THP-1 cells, compared with untreated THP-1 cells. Also, the expression of CD206⁺/CD169⁺ and CD206⁺/MARCO⁺ was higher in differentiated iPS-ML than in untreated iPS-ML. As AMΦ is known to express several scavenger receptors, these results suggest that the surfactant cocktail method has the potential to differentiate THP-1 cells and iPS-ML into AMΦ like cells. The number of viable THP-1 cells increased five-fold during differentiation, but the number of viable iPS-ML decreased. This may mean that M-CSF is an essential growth factor for iPS-ML proliferation. Primary mouse AMΦ have been reported to produce IL-1α in response to allergen-inducing nanoparticles; therefore, IL-1α was also used as an indicator in this study. IL-1α production increased in response to Alum stimulation compared to Alumina stimulation in untreated iPS-ML; however, untreated THP-1 cells did not produce IL-1α in response to both Alum and Alumina stimulation. Differentiated THP-1 cells produced IL-1α in response to Alum stimulation, but the amount remained low. Also, differentiated iPS-ML produced little IL-1α, and there was no difference between Alum and Alumina stimulation. These results suggest that IL-1α is a promising indicator when human AMΦ-like cell lines are exposed to allergic nanoparticles. We also investigated another method without using surfactant cocktails. Interestingly, continuous 7-day culture of iPS-ML in GM-CSF and M-CSF increased CD206⁺/CD169⁺ and CD206⁺/MARCO⁺ expression. 7-day cultured iPS-ML increased IL-1α production in response to Alum stimulation by twice compared to untreated iPS-ML. The differentiation mechanisms of iPS-ML during the 7-day culture with GM-CSF and M-CSF are currently under study. **Conclusions:** Our results suggest that iPS-ML and its differentiated cells could be used as AMΦ-like cell lines, with IL-1α serving as an indicator to evaluate the immunotoxicity of nanoparticles *in vitro*. However, the optimal differentiation method into AMΦ cell lines from iPS-ML is still under investigation.

L. G. Higgins¹, K. Morris-Schaffer², S. Hearon³, S. Dahlberg², E. Freeman⁴, F. Faulhammer⁵, N. Aygun Kocabas⁶, and M. Rooseboom⁷. ¹Penman Consulting Ltd/ LOA vzw, Brussels, Belgium; ²Exponent Inc, New York, NY; ³Exponent Inc, Austin, TX; ⁴Exponent Inc, Washington, DC; ⁵BASF SE, Ludwigshafen, Germany; ⁶TotalEnergies Refining & Chemicals, Seneffe, Belgium; and ⁷Shell Global Solutions International B.V., The Hague, Netherlands.

Background and Purpose: Xylene substances (xylene) are high production chemicals that are currently undergoing new data generation and dossier evaluation under European Regulation on the Registration, Evaluation, Authorization and Restriction of Chemicals (REACH). This includes consideration of an additional immunotoxicity testing cohort to an extended one-generation reproduction toxicity study (EOGRTs). Recently there has been a significant expansion to the dataset, providing an opportunity to evaluate the immunosuppressant potential of a legacy industrial chemical with a significant pre-existing animal and human dataset, and evaluate if an additional animal cohort is warranted. **Methods:** A systematic literature review and weight of evidence approach evaluation was conducted that included consideration of all available immunotoxicity information on xylene derived from relevant *in vitro*, *in vivo*, and epidemiology approaches including previously unpublished new studies of xylene substances. The specific mechanisms/modes of action of xylene and xylene metabolites that would indicate immunosuppression were reviewed. **Results:** Multiple high-quality guideline *in vivo* studies have repeatedly interrogated xylene's immunosuppressive potential including systemic haematological and clinical chemistry markers as well as pathological evaluations of bone marrow, lymph nodes, spleen, and thymus. Despite some statistically spurious and inconsistent immune system reported findings, overall, the dataset in its totality demonstrated no signal of xylene-mediated immunosuppression. The previously unpublished repeated dose studies also align with this conclusion. The limited available epidemiology data showed no xylene exposure-related effects on white blood cell counts, and EOGRTs data relevant to hippuric acid, a structural analogue of the xylene metabolite methyl hippuric acid, showed no indication of developmental immunosuppression. Similar data on ethylbenzene, a xylene reaction mass constituent, showed no indication of developmental immunosuppression. **Conclusions:** The evidence collectively supports that xylene substances are not immunosuppressants and does not support the need for an immunotoxicity cohort evaluation in any subsequent EOGRTs study per Regulations Commission Delegated Regulation (EU) 2015/ 282 of 20 February 2015 amending Regulation (EC) No 1907/2006.

PS 3443 Sex-Specific Immunotoxic Effects of Pesticides on Hematopoiesis

P. Ghatnekar, C. A. Baria, M. Gerami, L. Martin-Martinez, J. Navarro, J. Young, and J. O. Manilay. University of California Merced, Merced, CA. Sponsor: J. Manilay, American Association of Immunologists

Background and Purpose: The Central Valley is known for its agricultural productivity, and populations that are highly exposed to pesticides are known to manifest chronic dysregulation of molecular and cellular pathways eventually leading to disease. Some toxicology studies have established that broad-spectrum fungicides such as pyraclostrobin (PYRA) can cause mitochondrial dysregulation and oxidative stress in aquatic life such as zebrafish (Lin and Yeh 2025). However, the effects of such pesticides on cellular mechanisms and immunotoxicity in mammalian vertebrates remain unclear. Our objective is to investigate the effects of PYRA induced changes on hematopoiesis - the process of generating white blood cells, red blood cells and platelets - and the extent of its toxicity. The cell populations were extracted from primary lymphoid organs of bone marrow (BM), and thymus as well as a secondary lymphoid organ, spleen, to reveal early cellular toxicity. **Methods:** Eight to twelve-week-old female and male C57BL/6 mice, were intraperitoneally injected for 30-34 days with PYRA at a 10 mg/kg body weight dose. The control group received corn oil (vehicle). BM, thymus, and spleen samples from individual mice in each group were processed for cell counting and flow cytometric analysis. **Results:** Our findings indicate that PYRA exposure alters immune cell composition in a sex-dependent manner. In males, PYRA increased the percentage of myeloid-biased MPP2 progenitors without affecting their absolute numbers, and no additional changes in hematopoietic progenitor populations were detected. PYRA-treated females similarly exhibited no differences in any hematopoietic progenitor subsets, including MPP2s. These results suggest that PYRA's effects occur downstream of hematopoietic progenitors, primarily influencing differentiated immune cell populations. PYRA treatment induced sex-dependent remodeling of lymphocyte populations across primary and secondary lymphoid tissues. In males, PYRA increased both the percent and absolute number of bone marrow CD4⁺CD8⁻ T cells, whereas females exhibited no significant bone marrow changes. Within the spleen, males showed an increase in CD4⁺CD8⁻ (double-negative) T-cell percent without a corresponding rise in absolute numbers, along with a reduction in total CD3⁺ T cells and no change in overall splenic cellularity. In contrast, females displayed a pronounced increase in splenic cellularity, accompanied by increases in CD3⁺ T cells in both percent and number, resulting in elevated absolute counts across all splenic T-cell subsets. Females also exhibited an increase in splenic B-cell numbers, whereas monocyte and granulocyte populations remained unchanged, indicating that PYRA's effects were predominantly lymphocyte

specific. Thymic cellularity was unchanged in both sexes; however, female CD8⁺CD4⁻ thymocytes were decreased in percent and number. **Conclusions:** Collectively, these findings demonstrate that PYRA selectively modulates T-cell (and to a lesser extent B-cell) populations in a strongly sex-dependent and subset-specific manner, with minimal impact on myeloid lineages. Our results highlight the importance of accounting for sex specific outcomes so there can be more targeted and effective mitigation strategies. Building upon our previous work, we are beginning to experiment with a widely known herbicide, glyphosate (GLY) to investigate its potential hemotoxic and carcinogenic effects. This study will elucidate the pathway mechanisms of how certain immune cell populations are being disrupted by GLY, while contributing to cancer risks among highly exposed communities. Future studies will investigate the combined effects of exposure to GLY and PYRA, reflecting real-world scenarios. By studying the biological impacts of pesticide exposures, the study maintains its broader commitment to environmental stewardship in protecting vulnerable communities and promoting safer pesticide use.

PS 3444 Imaging analysis of the effects of Zn deficiency during pregnancy on placental tissues

T. Kido¹, H. Yanagisawa¹, M. Tsunoda², and M. Suka¹. ¹The Jikei University School of Medicine, Tokyo, Japan; and ²National Defense Medical College, Saitama, Japan.

Background and Purpose: Nutritional Zn deficiency induces immune dysfunction, including the development of inflammatory diseases. Zinc deficiency in pregnant women can restrict intrauterine fetal growth. However, the mechanism by which zinc deficiency causes intrauterine fetal growth restriction remains unclear. This study investigated the effects of zinc deficiency on placental tissue structure (basal and labyrinth layers) in zinc-deficient rats during pregnancy. **Methods:** Nine-week-old male SD rats and eight-week-old female SD rats were mated, and pregnant female rats were fed a standard diet (3 mg/day), a zinc-insufficient diet (0.3 mg/day), or a zinc-deficient diet (0.03 mg/day) for 19 days (n = 8 in each group). After dietary manipulation, implantation marks from uterus and amniotic fluid were collected, and the fetus and placenta were measured. Placental sections were stained with H&E, and the total areas of the placental tissue, basal layer, and labyrinth layer were measured using image analysis. **Results:** The final body weights of the zinc-deficient group were significantly lower than those of the other groups. The weight of the placenta and fetal rats in the zinc insufficiency or zinc deficiency groups was significantly lower than that in the standard group. Also, the miscarriage (%) of the zinc-deficient group was significantly higher than those of the other groups. For placental tissue imaging analysis using H&E staining, the total area, basal layer, and labyrinth layer of zinc insufficiency and deficiency groups were significantly lower than those in the standard group. **Conclusions:** It was suggested that zinc deficiency in rats during pregnancy leads to decreased serum zinc concentrations, resulting in atrophy of the placenta (basal and labyrinth layers). Consequently, it has been demonstrated that impaired supply of nutrients and oxygen to the fetus increases the risk of intrauterine growth restriction and miscarriage.

PS 3445 Recapitulating Immune-Driven Hepatotoxicity Using a Liver Microphysiological Platform

J. Then¹, I. Georgiades¹, E. Richardson¹, C. Roper², and T. Kostrzewski¹. ¹CN-Bio, Cambridge, United Kingdom; and ²Roper Toxicology Consulting Limited, Edinburgh, United Kingdom.

Background and Purpose: With the April 2025 U.S. Food and Drug Administration (FDA) roadmap promoting New Approach Methodologies (NAMs) for regulatory testing of monoclonal antibodies (mAbs) and other drugs, there is a need for models with greater complexity and human relevance. For biologics such as mAbs, immune-mediated drug-induced liver injury (IDILI) remains a significant concern in drug development. Human-specific immune system interactions with new modalities, such as therapeutic antibodies, can lead to unpredictable hepatotoxicity, which often fail to be captured in traditional animal models and high-throughput cell line models, leading to poor translational outcomes and high attrition rates. The FDA-recognised PhysioMimix® DILI assay was modified to incorporate peripheral blood mononuclear cells (PBMCs) to address this with an immune-competent, human liver relevant MPS model. The model aims to enhance translational relevance and improve safety profiling in drug development pipelines. **Methods:** Primary human hepatocytes were cultured under dynamic perfusion in Liver-12 plates by PhysioMimix Core to form 3D liver microtissues. The liver microtissues were analysed for functionality (CYP activity, albumin, urea) and clinically relevant injury markers (ALT, AST). Following four days of hepatocyte culture, HLA-matched PBMCs were added to the circulating media with the liver microtissues for a further four days and functionality assessed (cytokine profiling). Ipilimumab (anti-CTLA-4) or infliximab (anti-TNF-alpha) was dosed into the media of hepatocyte only and co-cultures for 48 hours and samples were taken at 1-, 4-, 8-, 24- and 48-hours post-dosing. The liver microtissues were evaluated for hepatotoxic responses while immune activation and inflammation was assessed by cytokine release. **Results:** Immune cell interaction and recovery from the Liver-12 was first completed to determine the ability of the PBMC to transverse the microfluidic channels and scaffolds unhindered (60-70% recovery). Following initiation of co-culture, maintenance of liver microtissue functionality and stable immune

phenotypes was demonstrated over four days of co-culture. Upon dosing with the mAbs in the co-culture model, immune-mediated hepatotoxicity was detected with significant elevation in LDH and ALT/AST, and reduction in the functional biomarkers, albumin and urea. Interestingly, significant cytokine increases were only seen in ipilimumab-treated conditions, aligning with clinical data which demonstrated a pro-inflammatory phenotype via activation of T-cells. **Conclusions:** This proof-of-concept study using two clinically relevant monoclonal antibodies demonstrates the ability of the PhysioMimix DILI assay to predict immune-mediated hepatotoxicity. Future studies will look to further profile immune alterations and interactions with the liver microtissues. Together, this assay provides a human-specific solution to the assessment of hepatotoxicity of large molecules. The FDA's endorsement of NAMs for investigational new drug (IND) applications marks a paradigm shift toward human-relevant, non-animal testing strategies, positioning the PhysioMimix® Core System as a pivotal tool for the future of immunotoxicity assessment and safer drug development.

PS 3446 Comparative uptake of perfluorooctanoic acid (PFOA) from water or milk matrices in an *in vivo* mouse model

K. M. Younce, M. Carroll, S. Streeter, E. Gupta, E. Hass, C. Schmokel, S. Mermer, and J. DeWitt. Oregon State University, Corvallis, OR.

Background and Purpose: Traditional oral gavage with water is an efficient and effective way to administer a dosing solution in an *in vivo* mouse model but may induce stress from inexperienced personnel. This study aims to investigate the efficacy of an alternative, potentially less stressful dosing approach using sweetened condensed milk (SCM) delivered with a micropipette as a way to administer per- and polyfluoroalkyl substances (PFAS). **Methods:** 64 C57BL/6 mice (32 males, 32 females) underwent 15-day exposures, with SCM compared to water gavage, using perfluorooctanoic acid (PFOA) as a model PFAS. The mice were divided into 4 groups (n=8 per group): water vehicle control, SCM control, water + 7.5 mg/kg PFOA, SCM + 7.5 mg/kg PFOA. Urine was collected and pooled per cage for both sexes and collected at 3 timepoints: pre-dosing, and after 24 hours and 5 days. Six days prior to study terminus, mice were injected with sheep red blood cells to elicit T cell-dependent antibody responses (TDAR). Terminal blood was collected and organ samples (liver, spleen, thymus, kidney) were collected, weighed, and archived for later analyses. **Results:** It appeared as if mice receiving SCM did not consistently consume the full dosing volume from the micropipette, leading to incomplete dosing in some individuals. Preliminary organ weight data illustrated this as liver weights in the PFOA-gavaged group was approximately double its control groups. Whereas liver weights in the SCM-PFOA group were increased by 110% on average. Observations suggested similar stress behaviors during handling for both techniques, although gavage was faster to administer. Quantitative analysis of PFOA in urine and blood samples is ongoing and the TDAR will be evaluated with an enzyme-linked immunosorbent assay. **Conclusions:** SCM as a dosing matrix has the potential to serve as an alternative to water gavage; however, incomplete consumption may reduce dosing accuracy. Differences in liver weights and in liver peroxisomal enzyme activity between PFOA-treated and control mice indicate treatment-related effects, but the data also indicate that SCM alone induces liver peroxisomal enzyme activity. These findings suggest that SCM may not be a viable alternative dosing matrix for PFAS with the potential to induce peroxisomal enzyme activity.

PS 3447 PET Imaging of Myeloid Cell Modulation in a Mouse Tumor Model

S. Kumar¹, K. Jiang¹, A. Giddabasappa¹, N. Keliher², K. Maresca², and V. Vaidya². ¹Pfizer, San Diego, CA; and ²Pfizer, Cambridge, MA.

Background and Purpose: Immunosuppressive myeloid cells play a critical role in tumor progression, metastasis, and therapy resistance. In solid tumors, myeloid cells can constitute up to 50% of the tumor mass, making them the most abundant immune population in the tumor microenvironment (TME). These cells promote tumor cell proliferation, metastasis, chemoresistance, and angiogenesis, and are emerging as key targets for therapeutic strategies such as depletion, repolarization, and recruitment inhibition. Quantifying myeloid cells is essential for preclinical drug development, providing insights into therapeutic efficacy and potential drug resistance mechanisms. Additionally, visualizing myeloid cells can support patient selection for myeloid-specific treatments and serve as a prognostic tool. A positron emission tomography (PET) imaging tracer targeting a myeloid biomarker, such as CD11b, enables quantification of these cells, facilitating preclinical immunosuppression studies and non-invasive prediction and monitoring of patient response. **Methods:** The human/mouse cross-reactive anti-CD11b antibody, M1/70, was selected for quantifying CD11b+ myeloid cells. In a proof-of-feasibility experiment, C57BL/6 mice were injected with fluorophore-conjugated M1/70 or an isotype control. Optical imaging (IVIS) and flow cytometry were used to quantify specific binding *in vivo*. Next, the antibody was conjugated with deuterium (DFO), and radiolabeled with ⁸⁹Zr, achieving high radiochemical purity (>99%) and immunoreactivity (>98%). To test the CD11b PET probe *in vivo*, mice were implanted with MC38R tumors and treated with Talazoparib or vehicle for 7 days to induce systemic myeloid depletion. Flow cytometry, PET imaging, and *ex vivo* γ-counting were performed across tissues to quantify changes in the myeloid cell population. **Results:** IVIS imaging revealed significant signal in myeloid-rich femur (9.7 % injected dose ID/g)

and spleen (6.4% ID/g) in fluorophore-labeled anti-CD11b injected mice compared to isotype (4.7 and 3.1 %ID/g respectively), demonstrating the imaging capability of this antibody. Flow cytometry confirmed these results with isotype group showing negligible binding in the blood and spleen. Talazoparib treatment resulted in significant depletion of CD11b+ myeloid cells in the tumor (1.6-fold), bone marrow (femur) (2.5-fold), and the spleen (3.3-fold) as quantified by flow cytometry. PET imaging and *ex vivo* γ-counting successfully validated this depletion showing reduced tracer uptake in the tumor (1.29-fold), femur (2-fold), and spleen (2-fold). No significant differences were observed in other organs such as the liver, kidneys, lungs, and heart indicating low non-specific uptake of the tracer. **Conclusions:** In conclusion, the specificity of anti-CD11b to quantify CD11b+ myeloid cells was demonstrated. The antibody was successfully radiolabeled to generate a PET tracer and was evaluated in a mouse tumor model. This technique provides a sensitive tool for assessing immunotoxicity and therapeutic interventions targeting the myeloid compartment. The approach supports preclinical evaluation of immunomodulatory strategies and has potential translational relevance for patient stratification and monitoring in oncology. All procedures performed on animals were in accordance with regulations and established guidelines and were reviewed and approved by an Institutional Animal Care and Use Committee or through an ethical review process.

PS 3448 Plant-derived compound sulforaphane suppresses activation and functional marker expression in primary murine NK cells

T. Fu, E. M. Gardner, and C. E. Rockwell. Michigan State University, East Lansing, MI.

Background and Purpose: Sulforaphane (SFN), a bioactive compound found in cruciferous vegetables, has gained considerable interest for its ability to modulate multiple cellular pathways, including those involved in antioxidant defense and inflammation. Through these pathways, SFN plays an important role in modulating immune responses. However, current studies have predominantly focused on T cells and dendritic cells, while research on its effects in natural killer (NK) cells remains limited. Previous work in our lab demonstrated that tert-butylhydroquinone (tBHQ), a well-characterized Nuclear Factor Erythroid 2-Related Factor 2 (Nrf2) activator, suppresses the upregulation of CD25 and CD69 in NK cells following activation with phorbol 12-myristate 13-acetate (PMA) and ionomycin. This suppression led to a more mature NK cell phenotype accompanied by significantly reduced NK cell function. Building on these findings, the present study investigates the effects of sulforaphane, another potent Nrf2 activator, on the activity of primary murine NK cells. **Methods:** Murine splenocytes were treated with 1, 3, 5, 10, 15, and 20 μM of L-SFN, followed by activation with either PMA/ionomycin or IL-12/IL-18 for 24 hours. Key NK cell activation events were assessed via flow cytometry by measuring the induction of surface markers CD25, CD69, CD107a, CD44, and NKG2D. Functional activity was evaluated through intracellular staining for interferon gamma (IFN-γ), granzyme B, and perforin. In addition to effector functions, NK cell maturation was also analyzed. Data were compared between cells activated by PMA/ionomycin, a robust yet non-physiological method that bypasses surface receptors and directly triggers intracellular signaling, and IL-12/IL-18, which provides a more physiologically relevant cytokine-driven activation. **Results:** Results indicate that treatment with SFN impacts NK cell biology by suppressing their expansion following activation in a dose-dependent manner. In addition to limiting proliferation, SFN decreases NK cell activation across both PMA/ionomycin and IL-12/18 stimulations, as evidenced by reduced CD25 and CD69 expression. Under IL-12/18 stimulation, SFN promotes an immature NK cell phenotype and a shift away from terminal maturation, whereas PMA/ionomycin stimulation does not show this effect. **Conclusions:** Correspondingly, SFN reduces NK cell effector functions, including cytokine production of interferon gamma, granzyme B, and perforin, in response to both PMA/ionomycin and IL-12/18 stimulation. Together, these findings suggest that SFN broadly dampens NK cell responses, affecting proliferation, activation, maturation, and effector function.

PS 3449 Δ⁹-tetrahydrocannabinol impairs enhanced IFNγ secretion associated with chronic HIV infection in primary human monocyte-CD8⁺T cell co-cultures.

J. Marty^{1,2,3}, R. Crawford^{1,3}, P. Gulick^{1,4}, and N. Kaminski^{1,3,5,6}. ¹Michigan State University, East Lansing, MI; ²Department of Microbiology Genetics and Immunology, East Lansing, MI; ³Institute for Integrative Toxicology, East Lansing, MI; ⁴Department of Osteopathic Medicine, East Lansing, MI; ⁵Department of Pharmacology and Toxicology, East Lansing, MI; and ⁶Center for Research on Ingredient Safety, East Lansing, MI.

Background and Purpose: The widespread implementation of combined antiretroviral therapy has shifted human immunodeficiency virus (HIV) infection to a manageable yet chronic disease. However, these individuals are at risk of developing HIV associated neurocognitive disorders (HAND), which is characterized by a persistent state of neuroinflammation which can result in impaired cognitive function. Monocytes and CD8⁺ T cells are known to enter the central nervous system (CNS) during chronic HIV infection, and IFNγ producing CD8⁺ T cells correlate with worse cognitive outcomes. The HIV+ population self-report *Cannabis sativa* use to mitigate symptoms of chronic infection, and the side effects from combined antiretroviral therapy. Δ⁹-tetrahydrocannabinol (THC) treatment suppresses monocyte interleukin

(IL)-1 β and CD8 $^{+}$ T cell IFN γ production. The objective of this study is to characterize the effects of THC on monocyte and CD8 $^{+}$ T cell interactions in the context of neuroinflammation. **Methods:** Peripheral mononuclear blood cells were isolated by Ficoll density gradient centrifugation from human donor. Subsequently, two independent secondary magnetic negative selection isolations were performed to isolate the CD8 $^{+}$ T cell and monocyte populations. CD8 $^{+}$ T cell and monocyte monocultures were established at 1x10 ^{6} cells/mL and monocytes were seeded at 2.5x10 ^{5} cell/mL, respectively. CD8 $^{+}$ T cell and monocyte cocultures were established at a 4:1 ratio. All cultures underwent a 30-minute pretreatment with either vehicle (0.03% DMSO) or THC (1, 5, or 10 μ M) at 37°C. The cultures were subsequently activated with 10 μ g/mL R848, 25 μ L/mL ImmunoCult, and supplemented with 5ng/mL IL-2. Supernatants and cells were collected up to 3-days post-activation and cytokine responses were quantified by ELISA and flow cytometry. **Results:** IFN γ secretion was observed to be upregulated in CD8 $^{+}$ T cell monoculture and coculture condition with a seven-fold increase in supernatant associated IFN γ from coculture samples. Furthermore, THC treatment suppressed coculture IFN γ secretion in a concentration dependent manner. Analysis by flow cytometry determined an approximately a two-fold increase in the geometric mean fluorescent intensity associated with IFN γ production in the CD8 $^{+}$ and CD8 $^{+}$ CD14 $^{+}$ populations. Utilization of trans-well inserts, recombinant cytokine treatment, in addition to neutralizing antibodies demonstrate that enhanced IFN γ secretion is associated with IL-12p70 (IL-12p70), which is also susceptible to suppression with THC treatment. Monocytes from HIV+ donors produce more IL-12p70 than those from HIV- donors. While there is no significant difference in IFN γ secretion by CD8 $^{+}$ T cells from HIV+ and HIV- donors, IFN γ secretion by all populations is suppressed with THC treatment. **Conclusions:** Monocytes and CD8 $^{+}$ T cells are both known to enter the CNS of HIV+ individuals, and IFN γ production by the CD8 $^{+}$ T cell population is associated with worse cognitive outcomes. This work demonstrates that monocyte-derived IL-12p70 enhances CD8 $^{+}$ T cell secretion of IFN γ . While IFN γ secretion is not directly enhanced during chronic HIV infection, there is an increase in monocyte production of IL-12p70. Furthermore, both IFN γ and IL-12p70 are susceptible to suppression with THC treatment. This demonstrates that enhanced inflammatory endpoints from monocyte and CD8 $^{+}$ T cell interactions are susceptible to suppression with THC treatment. This work is potentially generalizable to other disease states where IFN γ has been directly implicated.

PS 3450 Cholesterol esterification in macrophages: The effects of ACAT1 on macrophage activity

T. Hu, E. Abramova, C. Guo, H. Sandhu, J. Liu, and A. Gow. Rutgers, The State University of New Jersey, Piscataway, NJ.

Background and Purpose: Lipid laden macrophages (LLMs) are characterized by the formation of lipid droplets. Alveolar macrophages (AMs) are poised to form LLMs being bathed in lipid rich surfactant. LLMs have been observed in many inflammatory pulmonary pathologies and are largely associated with exacerbating injury: EVALI, sulfur mustard, silica dust, etc. LLMs are traditionally characterized by accumulation of oxidized low-density lipoprotein (oxLDL). To reduce lipid droplet formation in cells, we targeted acyl-coenzyme A: cholesterol acyltransferase 1 (ACAT1), the protein responsible for esterification of cholesterol for lipid droplet synthesis. Previously, we found intratracheal instillation of a pharmacological inhibitor reduces macrophage cholesterol accumulation and blunted lung injury. To further explore ACAT1's role in macrophage lipid handling, we generated a myeloid specific ACAT1 knock out (*Acat1*^{-M/M}). We hypothesize that *Acat1*^{-M/M} will reduce LLM formation and reduce lung injury. **Methods:** Male and female WT and *Acat1*^{-M/M} mice given intratracheal bleomycin (ITB) (3U/kg) to induce acute lung injury and necropsied after 7d. Daily body weight was measured to assess weight loss. Bronchoalveolar lavage (BAL) cells were cytospun to assess cell differentials, counted for enlarged foamy appearance, and stained for Oil Red O (ORO) to assess lipid content. A bone marrow derived macrophage (BMDM) model was established to assess *Acat1*^{-M/M} macrophages when treated directly with lipids. As a preliminary study, we treated BMDMs with oxLDL to induce a LLM phenotype. BMDMs of WT and *Acat1*^{-M/M} mice were isolated and differentiated for 7d and treated with oxidized LDL (oxLDL) on d5 or LPS and IL-4 on d6. BMDMs. On d7 macrophages were stained for ORO, Seahorse glycolytic and mitochondrial metabolism, and qPCR for lipid related genes: *Scarb1*, *Msr1*, *Cd36*, *Abca1*, *Cpt1a*, *Nr1h3*. **Results:** Within *Acat1*^{-M/M} mice ITB led to increased weight loss (5.77 $\pm$ 1.94% vs 10.10 $\pm$ 1.32%), worse histological lung injury, and increased neutrophils in bronchoalveolar lavage (BAL) fluid (3.99 $\pm$ 0.65% vs 7.82 $\pm$ 1.66%). *Acat1*^{-M/M} mice treated with ITB had significantly higher numbers of enlarged cells than WT ITB (21.14 $\pm$ 4.43% vs 39.52 $\pm$ 5.74%). When stained for ORO, *Acat1*^{-M/M} BAL cells, both PBS (vehicle) and ITB, did not stain positively for neutral lipids, while WT BAL cells, both PBS and ITB, both stained positively. This is consistent with a lack of ACAT function leading to increased phospholipid accumulation. Both WT and *Acat1*^{-M/M} derived BMDMs stained positively for ORO when treated with oxLDL. *Acat1*^{-M/M} BMDMs show a trend of increased glycolytic metabolism (404.6 $\pm$ 51.2% relative to WT), glycolytic capacity (514.1 $\pm$ 222.6% relative to WT) mitochondrial basal respiration (156.6 $\pm$ 38.5% relative to WT) and mitochondrial maximal respiration (147.8 $\pm$ 13.8% relative to WT). But when treated with oxLDL there is a trend of an increase in glycolytic metabolism in WT, which is not seen in *Acat1*^{-M/M}. The qPCR results showed a general increase in lipid handling genes in WT with oxLDL treatment, consistent with an LLM phenotype. But *Acat1*^{-M/M} oxLDL BMDMs showed a decrease of these genes, showing oxLDL did not induce a similar LLM phenotype in *Acat1*^{-M/M}. **Conclusions:** These results show, unlike a whole lung targeted pharmacological inhibition, a myeloid specific loss of

ACAT1 function results in exacerbated lung injury and increased number of LLMs. LLMs from WT stained positively for ORO while *Acat1*^{-M/M} were negative, indicating either an accumulation of free cholesterol or non-neutral lipid within *Acat1*^{-M/M} macrophages. When trying to induce a foam cell phenotype in BMDMs by treating with oxLDL, both WT and *Acat1*^{-M/M} showed positive ORO staining, contrasting with LLMs seen *in vivo*. This indicates the lipid species accumulating *in vivo* *Acat1*^{-M/M} ITB macrophages is not cholesterol but rather a non-neutral lipid, such as phospholipid from lung surfactant. *Acat1*^{-M/M} BMDMs treated with oxLDL did not show the shifts in metabolism and transcriptional activity of lipid handling genes found in WT oxLDL BMDMs. Indicating that cholesterol is not driving *Acat1*^{-M/M} macrophages into an LLM phenotype. These results contrast the current paradigm which assume LLMs can only be formed from cholesterol and triglycerides. Future work will assess the lipid species found in LLMs of injured *Acat1*^{-M/M} by treating BMDMs directly with BAL lipids of injured animals.

PS 3451 A Novel Method for Enhanced Bone Marrow Collection in Non-human Primates: Improving Yield and Cell Viability for Downstream Analysis

J. M. Hilditch¹, Q. Zhang², and A. LaRochelle¹. ¹Biomere, Worcester, MA; and ²JOINN Laboratories, Suzhou, China.

Background and Purpose: Bone marrow tissues are valuable and essential samples to diagnose, monitor and research a wide range of hematologic and systemic diseases. As the primary site of blood cell production, bone marrow tissues are valuable samples for studies on hematopoiesis and immune cell status, and to detect malignant or abnormal cells. In both preclinical and clinical settings, bone marrow collection is an important method to obtain samples to further scientific understanding of therapeutic responses in hematopoietic and immune systems and advance patient care. Therefore, proper collection techniques to ensure adequate volumes of high-quality samples are critical to ensure cell viability and assay accuracy. **Methods:** The centrifugation of whole bones is an effective and widely used technique for post-mortem bone marrow collection in animal research models, usually in mice and rats. After harvesting long bones such as the femur or humerus, the distal epiphyses are removed and the bone is placed vertically in a collection tube for centrifugation, with the proximal epiphysis at the top of the conical tube. This process uses centrifugal force to rapidly expel marrow from the medullary cavity, providing a high-yield, minimally diluted sample. Biomere has expanded this technique to non-human primates to further collection methods and optimize the terminal bone marrow yield. **Results:** A comparison was performed to further validate the centrifugation method as the superior collection method in comparison to manually scraping. Terminal humerus samples were collected from N=2 cynomolgus macaques. Comparing collection yield through total live cell counts and cell viability (%) showed that centrifuging method yielded a significantly increased count compared to scraping. The left humerus for both animals was scraped and yielded 332.5 million live cells at 89% viability for the first animal and 289.3 million live cells at 90% viability for the second animal. The right humerus for both animals was centrifuged and yielded 737.5 million live cells at 89% viability for the first animal and 602 million live cells at 90% viability. **Conclusions:** Both methods showed comparable viability while a clearly significant increase in total live cell counts were detected in samples prepared using the centrifugation method.

PS 3452 Comparison of Immunological Function and Ability to Produce ADA to Drug Products for Neo-Thy versus CD34 Immune-Humanized Mouse Models

E. Svyatova¹, S. Gharaie¹, E. Elsheikh¹, R. Becker¹, M. Chow¹, N. Smith², A. Bell³, K. Gabrielson⁴, J. Resiliac¹, K. Shea¹, J. Richardson⁵, and K. Howard¹. ¹Division of Applied Regulatory Sciences, OCP/OTS/CDER/U.S.FDA, Silver Spring, MD; ²Taconic Bioscience, Rensselaer, NY; ³Taconic Biosciences, Rensselaer, NY; ⁴Department of Pathology, School of Medicine, Johns Hopkins University, Baltimore, MD; and ⁵Taconic, Rensselaer, NY.

Background and Purpose: Immune-humanized mouse models are increasingly used to evaluate biological therapeutics. However, differences in immune reconstitution and function between model types could impact interpretation of results. Here, we compare the immune reconstitution, function and ability to produce anti-drug antibodies between Neo-Thy and CD34 immune-humanized mice using two products, infliximab and salmon calcitonin (sCT), both known to cause immunogenicity in patients. Neo-Thy immune humanized mice are produced through implantation of human thymic tissue under the kidney capsule, followed by CD34 $^{+}$ hematopoietic stem cell (HSC) transplantation, supporting human thymopoiesis. CD34 immune-humanized mice only have HSC transplantation and T cells are trained by the vestigial murine thymus. **Methods:** Immune humanized mice were produced in paired groups, with half receiving a neonatal human thymus and all receiving HSC from the same donor, using a total of four unique HSC donors. Following humanization, they were administered infliximab, sCT, a combination of these treatments, positive or negative control on treatment schedules appropriate to each therapeutic over 9-weeks. Longitudinal blood/serum sampling (day 0, 21, 42) and collection of blood/serum, bone marrow, spleen, and lymph nodes were completed at necropsy. Immune

function and antibody responses were evaluated through quantification of total IgM and IgG (by isotype), anti-drug antibody (ADA) assays, flow-cytometric phenotyping, intracellular cytokine production and proliferation. **Results:** Neo-Thy mice had higher frequencies of activated/mature T cells and B cells in PBMC, spleen and lymph nodes; and greater IFN γ and IL-2 cytokine responses, compared to CD34 mice. IgM and IgG Isotype antibody production were measured. In general, all humanized mice produced IgM, with some CD34-humanized mice having levels greater than the upper limit of quantitation (ULOQ) at Day 0. Many CD34-humanized mice produced IgG1, including saline treated, with some having high levels at Day 0. In contrast, Neo-Thy humanized mice had significantly fewer mice producing IgG1, however, when produced, showing a treatment responsive pattern. For both IgG2 and IgG4, CD34 mice produced more of both isotypes than Neo-Thy mice, but depending on the donor, levels were high at Day 0. Despite increased IgG1 production by CD34 mice, only Neo-Thy mice produced neutralizing antibodies to infliximab. With respect to sCT, both produced donor dependent binding antibodies; however, Neo-Thy tended to show a dose response, whereas CD34 mice generally did not. Binding antibodies to KLH for both mouse types showed responsiveness, however, both KLH-treated and saline mice produced responses, when saline treated mice had never encountered the antigen. **Conclusions:** Overall, Neo-Thy mice produced from the same donor as CD34 mice exhibited more functionally relevant and specific anti-drug immune responses. This study shows that presence of human thymus is critical to development of neutralizing ADAs and suggests they may support immunogenicity assessment in the drug-development/nonclinical space. Our results further highlight critical model-dependent differences that can influence interpretation of results and inform selection of appropriate humanized mouse models for regulatory-oriented immunosafety studies. **Disclaimer:** This abstract reflects the views of the author and should not be construed to represent FDA's views or policies.

PS 3453 Neo Thy immune humanized mice can produce anti-drug antibodies to support immunogenicity assessment for biological drug products

S. Gharai¹, R. E. Becker¹, E. A. Svyatova¹, M. Chow¹, E. Elsheikh¹, N. A. Smith², A. J. Bell², M. Singh¹, K. Gabrielson³, K. I. Shea¹, J. Richardson⁴, and K. E. Howard¹. ¹U.S. Food & Drug Administration, Silver Spring, MD; ²Taconic Biosciences, Rensselaer, NY; ³Johns Hopkins School of Medicine, Baltimore, MD; and ⁴Taconic Bioscience, Rensselaer, NY.

Background and Purpose: Immunogenicity can be a critical determinant of safety and efficacy for biological drug products, yet conventional animal models typically fail to recapitulate human immune responses, as human drug products are recognized as foreign by their immune systems. Neo-Thy immune humanized mice develop a functional human immune system and may provide a translational platform to assess anti-drug antibody (ADA) formation, and immune cell activation. In this study, we evaluated the immunogenicity of two therapeutics known to induce ADAs in patients, infliximab and interferon- β (IFN- β), administered individually and in combination, in Neo-Thy immune humanized mice derived from multiple human donors with distinct HLA profiles. **Methods:** Neo-Thy immune humanized mice were generated using neonatal thymus and CD34⁺ hematopoietic stem cells (HSC) at two different locations, creating six donor-defined experimental groups. Mice (4-6 per treatment per group) received infliximab, IFN- β , a combination of infliximab and IFN- β , positive or negative control with treatment schedule appropriate to the therapeutic. Peripheral blood/serum was collected on day 0, 21, 42, and 63; tissues (BM, spleen, lymph nodes) were harvested at necropsy (day 63). Immune reconstitution and treatment effects were assessed by multiparameter flow cytometry, intracellular cytokine (ICC) assays, proliferation, multiplex total IgM/IgG isotyping, ADA ELISAs for infliximab and IFN- β , and histopathology. **Results:** Neo-Thy immune-humanized mice showed robust human immune reconstitution with donor-dependent differences in B, T, and NK cell subsets. Treatment with infliximab, IFN- β , and KLH induced marked modulation of B-cell populations shown through changes in CD27⁺IgD⁺ and CD27⁺IgD⁺; and shifts from naïve (CD45RA⁺) to memory (CD45RO⁺) T cells. ICC and proliferation assays demonstrated antigen-specific IgM/IgG production and enhanced lymphocyte proliferation, respectively, upon drug re-stimulation *ex vivo*. In several cases, humanized mouse serum immunoglobulin levels approached or exceeded those from normal human serum, which served as a control. As expected, most immune humanized mice produced significant amounts of IgM, with some individual mice produced levels comparable to human control serum. IgG levels were measurable for all IgG isotypes for each donor group, regardless of treatment. Some mice in Groups 2 and 4, that were infliximab or combination-treated *in vivo*, produced IgG1, IgG2 and/or IgG4 at levels that approached the human control. Binding ADAs to IFN- β and neutralizing ADAs to infliximab were detected in multiple mice in a donor- and treatment-dependent manner. **Conclusions:** Neo-Thy humanized mice mount human-like, donor-dependent immune responses to biologics, including class switching, antigen-specific proliferation, and ADA formation. These findings support Neo-Thy humanized mice as a translational preclinical model for immunogenicity risk assessment and evaluation of immune modulation by biological drug products. **Disclaimer:** This abstract reflects the views of the author and should not be construed to represent FDA's views or policies.

PS 3454 Associations Between Tobacco Smoke Exposure and Cadmium Exposure in the U.S. Population: Findings from NHANES 2015-2020

N. Sarker¹, T. Roh², and G. Sansom¹. ¹Department of Environmental and Occupational Health, School of Public Health, Texas A&M University, College Station, TX; and ²Department of Epidemiology and Biostatistics, School of Public Health, Texas A&M University, College Station, TX.

Background and Purpose: Cigarette smoke contains toxic chemicals, such as cadmium, which accumulate in the body and lead to serious health problems. Overall, smoking rates in the U.S. have decreased significantly due to prevention and cessation efforts. However, it is still uncertain how much tobacco smoke exposure currently contributes to cadmium burden at the population level. This study examines the current effect of tobacco smoke exposure on cadmium levels using biomonitoring data from the U.S. population. **Methods:** We analyzed data from the National Health and Nutrition Examination Survey (2015-2020) for children, adolescents, and adults in the U.S. The association between serum cotinine levels and blood and creatinine-adjusted urine cadmium levels was investigated. Smoke exposure status was categorized by serum cotinine levels into no exposure, light secondhand exposure, heavy secondhand exposure, and active smoking. Survey multivariable linear regression was conducted to estimate geometric means (GMs) and the ratios of GMs, adjusting for all covariates. **Results:** Among the adult population, compared to non-exposure, high secondhand smoke exposure and active smoking were associated with 1.55 times and 3.20 times higher blood cadmium levels, respectively, with evidence of a dose-response relationship (p -trend<0.001) after adjusting for all covariates. However, for urinary cadmium, active smokers showed significantly elevated levels (1.58 times higher), while no significant elevation was observed for secondhand smoke exposure. Among children and adolescents, cadmium levels did not differ across smoke exposure statuses. Additionally, older age, female sex, lower poverty-income ratio, lower education, and racial minority status were associated with higher cadmium exposure. **Conclusions:** This study demonstrates that tobacco smoke exposure and key socioeconomic and demographic factors remain important drivers of cadmium burden in the U.S. population. It emphasizes the importance of addressing these factors in public health interventions and environmental risk reduction efforts.

PS 3455 Cytotoxicity of Freebase Nicotine and Its Analogs Using Cellular and Statistical Methods

K. L. Griffin¹, T. Jefferis¹, D. Pruss¹, M. Sengupta², R. X. Sturdivant¹, A. K. Charlton-Sevcik¹, R. M. Strongin², and C. M. Sayes¹. ¹Baylor University, Waco, TX; and ²Portland State University, Portland, OR.

Background and Purpose: (S)-nicotine has been used for decades in traditional cigarettes and, more recently, in modern e-cigarettes. However, (S)-nicotine induces adverse health effects, particularly in the lungs. Analogs of (S)-nicotine, such as (R,S)-nicotine, 6-methyl nicotine, nicotinamide, nicotine lactate, and nicotine benzoate, are growing in popularity as (S)-nicotine replacements. These analogs are marketed as 'safer alternatives,' yet little information is available on their induced health effects or toxicological properties. **Methods:** In this study, we systematically investigated methods for predicting the lethal concentration (LC) values of (S)-nicotine and five of its analogs using cell cultures and statistics. Human bronchiolar epithelial lung cells (BEAS-2B) were exposed to five nicotine analogs over a 24-hour exposure period. Cellular metabolism and cellular membrane integrity were measured and subsequently modeled using a four-parameter dose-response function in RStudio. Both models (culture- and statistics-based) were used to rank the chemicals in order of potency. **Results:** Out of the 5 analogs of interest, 6-methyl nicotine had the most adverse effects on cell health according to the overall ranking. However, all the analogs showed differential responses depending on which endpoint was being analyzed. **Conclusions:** The methods used in this study establish a framework for comparing toxicological evaluations and provide important insight into the lethality of emerging nicotine analogs.

M. J. Oldham¹, K. Yoshino², M. Gaca³, L. Simms⁴, Y. Kanemaru⁵, U. Doshi⁶, R. Wiecek⁷, I. Shigeki⁸, H. Ohara⁹, A. A. Rostami¹⁰, A. Salehi¹¹, A. K. Madh¹², M. Hollings¹³, S. Dudi¹⁴, J. Zhang¹⁵, A. K. Kuczaj¹⁶, B. Keyser¹⁷, R. Leverette¹⁸, S. Gilliland III¹⁹, A. Gupta²⁰, A. R. Kolli²¹, R. Labib²², F. K. Lucci²³, K. Papikinos²⁴, and T. Antonijevic²⁵, et al. ¹JUUL Labs, Washington, DC; ²JTI SA, Yokohama, Japan; ³British American Tobacco, London, United Kingdom; ⁴Imperial Brands, Bristol, United Kingdom; ⁵JTI SA, Geneva, Switzerland; ⁶Altria Client Services, Richmond, VA; ⁷Imperial Brands, Hamburg, Germany; ⁸Valeo Sciences LLC, Ladera Ranch, CA; ⁹LabCorp, Harrogate, United Kingdom; ¹⁰Phillip Morris Products S.A., Neuchâtel, Switzerland; ¹¹RAI Services, Winston-Salem, NC; ¹²Sapphire Sciences, Richmond, VA; ¹³Battelle, Columbus, OH; and ¹⁴ScitoVation, LLC, Durham, NC.

Background and Purpose: Extrapolating *in vitro* toxicology results to humans would be more meaningful if clinically relevant exposure doses were known. For both Electronic Nicotine Delivery Systems (ENDS) and Heated Tobacco Products (HTP) clinical studies reporting plasma nicotine values were used to calculate clinically relevant *in vitro* exposure doses for the extrathoracic, tracheobronchial and alveolar regions of the human respiratory tract on a mass of nicotine/cm² - min basis. **Methods:** A recently published PubMed search was duplicated and identified 95 papers as of November 2024, which were compared with previous summaries of pharmacokinetic studies of ENDS product use. Elimination of duplicates resulted in 65 and 15 unique clinical studies reporting nicotine plasma levels after ENDS and HTP use, respectively. To calculate the total amount of absorbed nicotine from each clinical study reporting *ad libitum* ENDS use, reverse dosimetry was performed using 3 recently published nicotine specific physiologically based pharmacokinetic (PBPK) models and one commercial PBPK model. To calculate nicotine vapor and particle deposition within regions of the human respiratory tract (ET, TB, AL regions), 3 published aerosol dosimetry models specifically designed for semi-volatile ENDS aerosols were used. Finally, the surface of each respiratory tract region was used to determine the clinically relevant *in vitro* exposure doses on a nicotine mass/cm² - min basis. Forty of the 65 clinical trials conducted around the world reported plasma nicotine values from *ad libitum* ENDS product use by 1323 participants. Participants used a variety of ENDS products with nicotine concentrations ranging from 0-59 mg/ml (0 - 5% nicotine) and product use from 4.5 minutes to 24 hours. Nine of the 15 clinical trials reporting *ad libitum* use of HTPs also reported plasma nicotine values (C_{max}) that were similar to nicotine C_{max} values from *ad libitum* use of ENDS products. **Results:** The range of total absorbed nicotine predicted by the four PBPK models using reverse dosimetry from these 40 clinical trials was 0.0018 - 2.04 mg nicotine/min. The three semi-volatile aerosol deposition models predicted absorbed nicotine that ranged from 0.016 - 775 µg in the ET region, 0.022 - 483 µg nicotine/min in the TB region, and 1.01 - 1,977 µg nicotine/min in the AL region. When these absorbed nicotine values are divided by the surface area of these respiratory tract regions, the clinically relevant *in vitro* exposure dose range for the ET region is 0.00009 - 5.0 µg nicotine/cm² - min. The clinically relevant *in vitro* exposure dose range for the TB region is 0.008 - 102 ng nicotine/cm² - min, and for the AL regions is 0.0014 - 4.6 ng nicotine/cm² - min. **Conclusions:** Based on the similarity of nicotine C_{max} values between *ad libitum* use of HTP and ENDS products, the same clinically relevant *in vitro* exposure dose ranges should be used for *in vitro* studies using HTP. Additionally, nicotine reverse dosimetry should allow extrapolation to clinically relevant doses of other ENDS and HTP constituents (i.e., flavors and HPHC) from characterized aerosols. These clinically relevant *in vitro* exposure dose ranges for nicotine are up to 370 times lower than levels of ENDS flavors tested in some *in vitro* studies with tracheobronchial cells. The magnitude of this difference is conservative since nicotine is typically used in ENDS products at a higher concentration than individual flavors. Here we show the utility of using the PBPK reverse dosimetry models to determine relevant exposure dose ranges for *in vitro* testing.

PS 3457 Impact of Benzaldehyde and Veratrylaldehyde on Acrolein-Induced Cytotoxicity

Y. B. Twum¹, G. Pagan², L. Fox¹, A. Rebok¹, V. R. Ungarala¹, Z. Bitzer¹, and T. E. Spratt¹. ¹Penn State College of Medicine, Hershey, PA; and ²Penn State University, University Park, PA.

Background and Purpose: Artificial flavors have become widespread in e-cigarettes (e-cigs), with over 14,000 classified e-liquid products currently available on the market. These flavoring agents significantly contribute to the appeal and uptake of e-cigs, particularly among the youth, raising concerns about their potential pulmonary toxicity. Since many flavor compounds are aldehydes, and potentially reactive with proteins, there is a need to assess the impact of the flavoring agents with known e-cig toxicants, such as acrolein. Therefore, the objective of this study is to assess the potential synergistic interactions between benzaldehyde (BA) and veratrylaldehyde (VA) in enhancing acrolein-induced cytotoxicity. **Methods:** BEAS-2B human bronchial epithelial cells and A549 human lung carcinoma cells were seeded into 96 mm cell culture plate inserts and treated with increasing concentrations of acrolein, either alone or in combination with BA or VA, for 24 and 48 h. Cell viability was evaluated through a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay and colony-forming assay. Oxidative stress was assessed using the dichlorodihydrofluorescein diacetate (DCFDA) assay. **Results:** A549 cells exhibited significant

cytotoxicity to acrolein (IC₅₀: 60 µM at 24h and 58 µM at 48h), while the aldehydes were less cytotoxic, BA (IC₅₀: 2.5 mM at 24h and 2.0 mM at 48h) and VA (IC₅₀: 1.2 mM at 24h and 3.8 mM at 48h). Similarly, acrolein was toxic to BEAS-2B cells (IC₅₀: 34 µM at 24h and 30 µM at 48h), while the aldehydes were much less toxic, BA (IC₅₀: 2.0 mM at 24h and 1.1 mM at 48h) and VA (IC₅₀: 2.10 mM at 24h and 2.18 mM at 48h). The combination of BA or VA with acrolein, produced an additive cytotoxic effect. Our colony-forming assay supported the results obtained from the MTT assay. We also found that the combination of acrolein with BA or VA induced oxidative stress in A549 and BEAS-2B cells in a dose-dependent manner. In a similar manner, acrolein produced a dose-dependent increase in oxidative stress in both A549 and BEAS-2B cell lines. The IC₅₀ values for the aldehydes were in the millimolar range. The addition of BA or VA to the acrolein-treated cells did not synergistically increase the levels of oxidative stress. **Conclusions:** Altogether, our findings indicate that neither BA or VA impact the toxicity nor oxidative stress caused by acrolein in cell culture. However, further studies are warranted to elucidate the combined effects of acrolein with BA or VA in inducing pulmonary oxidative damage following e-cig exposure in humans.

PS 3458 High Levels of Toxic Aldehydes in High-Puff Number Disposable E-cigarettes

E. Omaiye¹, W. Luo², K. McWhirter², M. Wong¹, J. Pankow², and P. Talbot¹. ¹University of California Riverside, Riverside, CA; and ²Portland State University, Portland, OR.

Background and Purpose: Despite concerns regarding the potential health risks associated with e-cigarette use, their design, obtainable puff count, and e-liquid formulations have continued to evolve. Aldehydes are a key class of thermal degradation by-products of e-liquid constituents generated during the vaporization process. **Methods:** This study investigated the concentrations and toxic effects of chemicals and aldehyde reaction products in previously vaped and discarded disposable, higher puff number e-cigarettes. E-fluids were extracted from vaped devices obtained from users or collected from the field, and analyzed using gas chromatography-mass spectrometry to quantify a range of chemicals, including solvents, nicotine, coolants, flavor chemicals, and aldehydes. Pulmonary cells were exposed to aerosols and analyzed for toxic effects in multiple assays. **Results:** The percentage of e-fluid consumption averaged 46% - 77% across multiple brands. Levels of chemicals in e-fluids varied significantly by brand and mode of collection. Total Flavor chemicals varied across brands (means = 34 mg/mL ± 21.6 for Elf Bar and 9.7 mg/mL ± 7.9 for FLUM) and significantly decreased in vaped fluids. Compared to unvaped fluids, methylglyoxal, glyoxal, and formaldehyde significantly increased in vaped fluids, acetaldehyde and acrolein both decreased in vaped fluids, and glyceraldehyde and dihydroxyacetone were present only in vaped fluids. Increased concentrations were particularly pronounced in devices collected in the field, in contrast to those donated by users. Aldehyde levels were generally higher in Elfbar than in FLUM products. Methylglyoxal and acetaldehyde significantly disrupted BEAS-2B cell morphology and increased mitochondrial ROS in a concentration-dependent manner. **Conclusions:** Several factors influence the formation of aldehydes, which are subsequently inhaled by users, potentially leading to adverse health effects. These findings heighten important concerns regarding the safety of e-cigarette products, particularly with the long-term health implications of aldehyde exposure as a result of extended use. Public health policies and regulations can address these findings by considering the implications of puff count, device design, and e-liquid formulation on the formation of toxic by-products. Further research is needed to explore the cumulative health effects of aldehyde exposure from e-cigarettes, particularly among users with high consumption rates.

PS 3459 Thirdhand Vape Exposures Induce Immune Dysregulation and Epigenetic Alterations in a Mouse Model

C. Igwe, K. Sharma, M. Babayev, D. Rousselle, C. D. Ekpruke, A. Buechlein, C. Hemmerich, D. B. Rusch, P. Silveyra, and S. Commodore. Indiana University Bloomington, Bloomington, IN.

Background and Purpose: The widespread adoption of Electronic Nicotine Delivery Systems (ENDS), including e-cigarettes, has been driven in part by perceptions of reduced harm relative to combustible tobacco products. Despite reductions in conventional smoking, the rise in ENDS use has introduced new challenges for toxicology and public health. A growing body of evidence suggests that ENDS emissions can persist on surfaces long after active use. These residues contribute to a phenomenon known as thirdhand smoke (THS). When derived from ENDS product use, this is referred to as thirdhand vape (THV), and the toxicological and molecular consequences of THV exposures remain poorly understood. **Methods:** In this study, we sought to investigate the toxicological impacts of THV exposure *in vivo* using a mouse model. We hypothesized that chronic exposure to ENDS residues deposited on surfaces would drive measurable alterations in immune responses, transcriptomic regulation, and epigenetic stability. To test this, we conducted controlled exposure experiments, integrating cytokine profiling, RNA sequencing, DNA methylation analysis, and environmental residue confirmation through towel assays for nicotine and heavy metals. Nine-week-old C57BL/6J mice were indirectly exposed to ENDS residues via cotton towels pre-exposed for 1 hour to ENDS aerosol (6 mg/mL nicotine in 50/50 propylene glycol/vegetable glycerin) and placed in

cages as bedding for 1 hour daily/5 days a week, over 3 or 4 weeks. Control mice received unexposed towels. Nicotine and metal residues on towels were quantified via LC-MS/MS and ICP-MS. Bronchoalveolar lavage fluid (BALF), & serum were collected for cytokine profiling, lung and liver for RNA sequencing, and DNA methylation analyses. Cytokine/chemokine levels were measured using MILLIPLEX® MAP Mouse Cytokine/Chemokine Magnetic Bead Panels (MilliporeSigma). Group differences were assessed using ANOVA ($p < 0.05$). **Results:** A significant deposition of nicotine was observed on exposed towels compared to control towels, with nickel and chromium levels consistent with previous reports of ENDS aerosol constituents. Compared with control mice, thirdhand-exposed mice at a 3-week exposure time point had significantly elevated IL-13 levels in BALF ($p = 0.016$), with particularly strong increases in females ($p = 0.026$). Female BALF IL-1 α was reduced ($p = 0.039$), suggesting suppression of local pro-inflammatory signaling, while male BALF IFN- α was elevated ($p = 0.035$), indicating sex-specific antiviral responses. Systemically, serum IL-7 was decreased ($p = 0.003$), implicating disruptions in lymphocyte homeostasis. Serum KC (CXCL1) was elevated ($p = 0.045$), pointing to enhanced neutrophil recruitment, while serum IFN- α was decreased in females ($p = 0.038$). At the 4-week exposure time point, female BALF IL-7 was decreased ($p = 0.037$), while male BALF LIX (CXCL5) was reduced ($p = 0.009$). Systemically, serum LIX was also decreased ($p = 0.042$). These findings indicate a temporal shift from early Th2-skewed inflammation toward broader immune suppression with prolonged exposure. Compared with controls, exposed mice also showed overexpression of liver Socs2 (adjusted $p = 0.002$) and lung Gm22068 (adjusted $p = 0.012$) and reduced CpG methylation in liver (83.3%) and lung (99.5%) tissue. Pathway analyses highlighted enrichment of AP-1 signaling and dysregulation of metabolic networks. Differentially methylated regions overlapped with immune-related and cancer-related genes. **Conclusions:** This study provides evidence that exposure to THV from ENDS residues may be harmful. Environmental analyses confirmed that ENDS aerosols deposit nicotine and metals on surfaces, creating reservoirs of exposure that can lead to subsequent immune dysregulation and epigenetic alterations. Given the vulnerability of children and other sensitive populations to thirdhand exposures, our findings underscore the need for translational studies and public health policies that regulate indoor ENDS use.

PS 3460 E-Cigarette Modulation of T Helper Cell Subsets: Impaired IL-17 Production in Th-17 Cells

O. Hiltebrand^{1,2}, N. Kukolj^{1,2}, and K. K. Mann^{1,2}. ¹Lady Davis Institute, Montréal, QC, Canada; and ²Department of Pharmacology & Therapeutics, McGill University, Montréal, QC, Canada.

Background and Purpose: Electronic cigarette (e-cigarette) use is rising, representing a growing public health concern among youth and young adults. E-cigarettes are electronic nicotine delivery systems designed to aerosolize liquid formulations for inhalation using a metal coil, a process termed vaping. Despite widespread use, e-cigarette effects on the developing immune system remain poorly understood. CD4+ T helper (Th) lymphocytes play an important role in orchestrating the antigen-dependent immune responses. Different Th subsets can direct either pro- or anti-inflammatory responses: Th1 produce interferon- γ (IFN γ), Th2 cells produce interleukin-4 (IL-4), IL-5, and IL-13; Th17 produce IL-17; and T regulatory cells (Tregs) act as immune suppressors to limit the immune response. We hypothesize that e-cigarette exposure will modulate T cell populations. **Methods:** We combined *in vivo* and *in vitro* murine models to assess the effects of e-cigarette aerosols and their components on helper T cell populations. Male and female mice were exposed for 2 weeks to air, propylene glycol and vegetable glycerin (PG/VG), nicotine salts, or tobacco-flavoured e-cigarettes. Splenocytes were analyzed by spectral flow cytometry for T cell subpopulations. Separately, lymph nodes from unexposed mice were processed into single cell suspensions, with or without CD4+ cell isolation, and cultured under Th17-polarizing conditions (anti-CD3/CD28, TGF- β 1, IL-6) in the presence of tobacco-flavoured e-cigarette extracts. Components of total extract including nicotine salts, PG/VG, tobacco flavouring (without nicotine) were also individually assessed *in vitro*. Cells were then profiled for T cell subtypes. **Results:** Two-week *in vivo* exposures induced sex-specific changes in splenic T cell subsets. Despite an increase in total CD4+ T cells, tobacco-flavoured e-cigarette aerosol exposure decreased Th1 and Th17 populations in female mice. In males, nicotine salt aerosol exposure decreased Th2, Th17, and Tregs populations. Exposure to PG/VG did not significantly alter any T cell populations. We further studied the effects on Th17 cells as they were affected in both males and females. To understand whether exposure to e-cigarette aerosols inhibited differentiation of Th17, differentiation of Th17 cells from lymph nodes was performed *in vitro* in the presence or absence of e-cigarette extracts. Th17 differentiation was not impaired, but IL-17A production was significantly suppressed. Furthermore, this was a direct effect on CD4+ T cells and did not require other lymph node-resident cells. *In vitro*, inhibition of IL17A was observed with nicotine salts and tobacco flavouring alone, suggesting that both components may impair Th17 responses. **Conclusions:** Our findings suggest that e-cigarette exposure may compromise T cell populations, particularly Th17 responses; these responses are particularly important in autoimmune diseases, recruitment of neutrophils, and defence against fungi. Future experiments will characterize gene expression changes in Th17 cells upon exposure and use a Th17-dependent murine model of psoriasis to provide insight on how vaping alters these responses.

PS 3461 Oral-Immune Co-Culture Model Reveals Significantly Lower Toxicity of Tobacco-free Nicotine Pouches Compared to Cigarettes

M. Stevenson¹, L. Scott², J. Kelsall², E. Hoffman², V. Hutter², F. Chapman¹, R. Wiczorek³, E. Trelles-Sticken³, S. Pour³, T. Evenburg³, and L. Simms¹. ¹Imperial Brands PLC, Bristol, United Kingdom; ²ImmuONE Ltd, Stevenage, United Kingdom; and ³Reemtsma Cigarettenfabriken GmbH, An Imperial Brands PLC company, Hamburg, Germany.

Background and Purpose: Tobacco-free Nicotine Pouches (TFNP) are an emerging category of nicotine products gaining popularity with adult smokers. As TFNP don't contain or burn tobacco, research demonstrates they contain significantly fewer and substantially lower levels of harmful chemicals compared to cigarette smoke, therefore offering adult smokers a potentially less harmful way to consume nicotine. Initial *in vitro* investigations of these products reveal marked reductions in cytotoxicity when compared to cigarette smoke extracts (>200 fold less cytotoxic) and no genotoxicity (under the conditions of Ames and *In Vitro* Micronucleus tests). Building on this data, we sought to better reflect the complex cellular interactions occurring at the oral mucosal interface, by employing a novel oral-immune co-culture model to assess the potential impact of TFNP and cigarette smoke extracts. **Methods:** The coculture system, utilised TR146 buccal mucosa cells (supplied by SkinEthic™) on Transwell® inserts combined with wells containing ImmuPHAGE™ (ImmuONE Ltd) macrophages. The TFNP product (obtained from the European market) was extracted using ISO-10993-12:2021 methodology, in PBS. Cigarette smoke (CS) extracts were generated via bubbling through PBS (CS-PBS) or via DMSO extraction of Cambridge filter pads (e.g. CS-Total Particulate Matter (TPM)). Using nicotine as a dosimetry marker, cigarette samples were tested at concentrations between 0.7 - 23 μ g/ml nicotine, while the TFNP extracts were assessed at 90 and 180 μ g/ml nicotine. These concentrations were chosen based on experience of the biological impact of cigarette smoke extracts on similar co-culture systems. Macrophage morphological and stress assessment were performed using high content image analysis at 48 hours post exposure to test articles. Images were acquired using an InCell Analyser 6000 system (GE Healthcare). Images were analysed and quantified for cell morphology (cell area, number of vacuoles and total area of vacuolation) and cell health (mitochondrial and caspase 3/7 activity). Cytotoxicity of was determined at the same timepoint using PrestoBlue™ measurement. **Results:** Both CS extracts elicited dose-dependent toxicological effects. CS-TPM increased caspase 3/7 activity, displayed reduced PrestoBlue metabolism and induced a foamy macrophage phenotype (enlarged cells with increased numbers of vacuoles). CS-PBS caused cell death at the highest concentration, marked by reduced cell count, low PrestoBlue metabolic activity and smaller cells without vacuoles. For the TFNP extract, the highest test concentration increased caspase 3/7 activation, however, no significant changes in macrophage morphology were observed at any concentration. The responses to TFNP extracts were observed at concentrations approximately 7 to 250-fold higher than those elicited by CS extracts. **Conclusions:** The results presented here add to the growing body of scientific evidence supporting a promising role for TFNPs in THR strategies, however, further chemical characterisation, pre-clinical, clinical, and behavioural studies are proposed for further scientific substantiation.

PS 3462 Progressive Immunologic Dysregulation with Exposure to Tobacco Smoke in a Model of Chronic Obstructive Pulmonary Disease (COPD)

K. E. Pinkerton, C. W. Wu, T. J. Cannon, A. Durainath, and L. Wang. University of California, Davis, Davis, CA.

Background and Purpose: Our research objective is to examine the role of dysregulated immune responses in disease progression and changes in lung physiology in a rat model of COPD. **Methods:** Spontaneously hypertensive rats were exposed to tobacco smoke (TS) (90 mg/m³) or filtered air (FA) for up to 12 weeks. Necropsy timepoints of 4, 6, 8, 10 and 12 weeks were chosen to define the immunological and pathophysiological changes in the lung. Rats exposed to TS showed significant increases in macrophage, neutrophil and lymphocyte number in bronchoalveolar lavage compared to FA at all weeks examined. **Results:** The influx of inflammatory cells detected in the bronchoalveolar lavage was significantly elevated at all timepoints measured (4, 6, 8, 10, and 12 weeks). Increased inflammatory cells included macrophages, neutrophils, and lymphocytes. Proinflammatory cytokines IL-1 β , IL-6 and IFN- γ in whole lung homogenates were significantly increased following exposure to TS compared to FA controls. However, exposure to TS over time dampened IFN and TNF levels in whole lung homogenates. Physiological airway obstruction due to TS exposure was noted by significant elevations in central airway resistance and tissue damping. Central airway resistance was significantly increased at 4 weeks, decreased at 6 weeks, but returned to significantly elevated levels at 10 and 12 weeks following TS exposure. Lung tissue damping showed a peak at 4 weeks, then a decreasing trend, although remaining significantly elevated through 12 weeks of TS exposure. Strong positive correlations were noted between proinflammatory cytokines IL-1 β , IL-6, IFN- γ , TNF- α and the degree of lung tissue damping. These changes were associated with increases in central airway squamous epithelial metaplasia and distal airway mucous metaplasia. **Conclusions:** These findings suggest progressive airway obstruction with an abnormal inflammatory response to TS exposure.

in this rodent model of COPD. We conclude a dysregulated immunologic response, along with airway inflammation are strongly associated with the impairment of physiological lung function in TS-exposed rats.

PS 3463 Low dose, sub-chronic exposure to Dihydroxyacetone (DHA) causes increased heart strain, alters cardiac mitochondrial metabolism, and induces DNA damage

H. J. Levi¹, A. Hernandez¹, J. Hedlich-Dwyer¹, J. Masjoan-Juncos¹, S. Aggarwal², and N. Gassman¹. ¹University of Alabama at Birmingham, Birmingham, AL; and ²Florida International University, Miami, FL.

Background and Purpose: Electronic cigarettes (e-cigarettes) have become increasingly popular in the last decade and evolved with various devices and e-liquid components. E-liquids are heated to create the aerosol the user inhales, and dihydroxyacetone (DHA) is produced by the oxidation of glycerol and propylene glycol in the e-liquids. DHA is also an active ingredient in sunless tanning products. While DHA has been considered safe for external exposures, the risks from vaping and spray tanning have raised concerns about inhalation exposures. Exposures to DHA vary between e-cigarette devices with micromolar to low millimolar doses potentially inhaled. Once inhaled and absorbed by cells, DHA is incorporated into several metabolic pathways through its conversion to dihydroxyacetone phosphate (DHAP). Given the metabolic incorporation, DHA exposure affects highly energetic tissues like the heart are needed. **Methods:** Using human cardiomyocytes (AC16) dosed with 0.2mM DHA, we analyzed DNA lesion content and DNA repair protein changes. We examined mitochondrial and metabolic changes utilizing immunoblotting, qPCR, and microscopy. We then used cardiac tissues from A/J mice sub-acutely exposed to 5 µg of DHA for 14 days. We looked at mitochondrial changes, using qPCR for mitochondrial dynamics and mitochondrial DNA copy number, TEM for structure and counts, and echocardiograms for heart function. Additionally, we looked for oxidative DNA damage, mitochondria content, structural changes, and pro inflammatory markers. **Results:** Overall, we found an increase in mitochondrial copy number after 2 weeks of exposure to the exposed cells. Additionally, we found that there is an increase in oxygen consumption, increased mitochondrial proteins and mitochondria number as well. We also see an increase in DNA oxidative and alkylating lesions. However, we see a change in the DNA lesion profile across 4 and 8 weeks with altered levels of DNA crosslink-type lesions and uracil content. We also see altered mitochondria copy number and mitochondrial protein measurement changes, where we see a decrease at 4 weeks and a return at 8 weeks compared to time-matched control cells. In the mice 2 weeks after exposure to 5 µg DHA, we saw a significant increase in mitochondria DNA copy number and mitochondria number in male and female mice. Additionally, we saw an increase in proinflammatory markers, most notably IL-6, in the female mice. We also saw an increase in collagen levels within the males only, with no change in the females. Conversely, we looked at oxidative DNA damage and found an increase in oxidative damage in female mice. Subsequently, when we performed echocardiograms, we saw an increase in ejection fraction and fractional shortening in the males, but a decrease in the females. There was also an overall increase in global stain, suggesting that the males are undergoing cardiac hypertrophy and the females are undergoing cardiotoxicity. **Conclusions:** This work is the first to examine genotoxicity of DHA in cardiomyocytes and characterize physiologically relevant exposures to understand potential long-term effects on cardiovascular health. Additionally, this is the first time sex specific responses to DHA exposure were observed.

PS 3464 Effects of long-term electronic-cigarette (E-cig) aerosol exposure on kidney health in diabetic mice

A. Raja¹, C. Awada¹, A. Veerappan¹, T. Gordon¹, J. T. Zelikoff¹, and E. Jaimes². ¹NYU Grossman School of Medicine, New York, NY; and ²Memorial Sloan Kettering Cancer Center, New York, NY.

Background and Purpose: Diabetes is one of the most important risk factors for chronic kidney disease (CKD), and end stage kidney disease. Tobacco smoking accelerates the progression of CKD of different etiologies, including diabetes. However, whether e-cig use also has a deleterious effect on CKD progression, is unknown. The aim of this study was to examine whether inhalation exposure of diabetic adult male mice to e-cig aerosols, with and without nicotine, alters gene expression and histology associated with kidney injury. **Methods:** For studying the effect of e-cig on progression of kidney disease, 7-8-wk-old BTBR obese male mice (a model of type II diabetes) with pre-existing kidney injury were exposed to either: 1) filtered air (control); 2) Propylene glycol/Vegetable glycerin (PG/VG; 1:1); or 3) PG/VG (1:1) + Nicotine (36 mg/ml) for 10-wk (3hr/d; 5d/wk). Kidneys were collected, flash frozen and subsequently stored at -80°C until needed. RNA was extracted from the kidney and after extraction, bulk RNAseq was performed, followed by RNAseq libraries preparation with TruSeq Stranded Total RNA kit (Illumina). Libraries were sequenced and aligned against the mouse genome. Differential gene expression analysis was performed with DESeq2 R/Bioconductor package. Ingenuity Pathway Analyses (IPA) was then used to comprehensively analyze the differentially expressed genes (DEGs) in order to infer the underlying causes of the observed fold-changes and predict downstream health events. One kidney from each mouse was fixed in formalin,

followed by transfer to ethanol after 24-hr and then used to assess kidney injury in PAS-, trichrome stained slides, and fibronectin (a kidney injury marker) by immunohistochemistry (IHC). **Results:** Inhalation exposure of diabetic mice to PG/VG + Nicotine resulted in gene expression changes in 724 genes, while only 3 genes were differently expressed in the PG/VG group, compared to controls. Kidney injury-related (i.e., Rorc, Col4a3, EGFR, LRRK2, VDR), cancer-related (e.g., Adamts1, Ccn1, Akr3) and immune-regulatory genes (e.g., Ace2, Cxcl6, Ccn1), were up-regulated in the PG/VG + Nicotine exposure group compared to controls. In the PG/VG only group, pro-inflammatory (Rorc) was up-regulated, while inflammation-protective Nr1d and kidney injury-associated Mt1 genes were down-regulated. IPA analyses of the DEGs from the PG/VG + Nicotine vs the Filtered Air group revealed cancer, organismal injury and tumor growth as the top three diseases/disorders. IPA further demonstrated about 50 significant canonical pathways which were affected in PG/VG + Nicotine group. These pathways included collagen biosynthesis, IL-10 signaling, mitochondrial dysfunction, Elf2 signaling, and oxidative phosphorylation. Pathways specific to the diabetic kidney injury i.e., transcriptional regulators (Hippo signaling pathway, YAP/TAZ), and transforming growth factor (TGF-β)/Smad signaling pathway, were activated. However, metabolic processes i.e., IL-10 (anti-inflammatory and renal production), synaptopodin (podocyte integrity and maintenance), STK11 (regulator energy homeostasis), SIRT6 (a sirtuin involved in mitochondrial protection and anti-fibrotic activity), MLXIP1 (a regulator of glucose and lipid metabolism) were downregulated. While IHC analyses revealed significantly higher glomerular fibronectin expression in the PG/VG-only and PG/VG + Nicotine groups, compared to air controls; the highest levels of fibronectin expression were observed in mice exposed to e-cig with nicotine. However, PAS-stained kidneys revealed mesangial expansion consistent with diabetic nephropathy, there were no significant differences between the 3 exposure groups. **Conclusions:** This study indicates that long-term, repeated exposure of adult diabetic male mice to e-cig aerosols alters gene expression and physiological markers related to kidney injury. Exposure of diabetic mice to e-cig aerosols containing nicotine produces significant changes in genes involved in CKD, diabetic nephropathy, cancer, and inflammation. Enhanced fibronectin expression in e-cig exposed mice also demonstrates the increased vulnerability to e-cig aerosols in diabetic mice. This groundbreaking study reveals the kidney as a target of e-cig use and opens the door for further studies concerning the impact of e-cig use on kidney health.

PS 3465 Multi-Omics Profiling Reveals Sex-Specific Oral Health Disruptions Associated with Vaping

X. He¹, M. Meister¹, J. Jeon², A. Pitchai³, Q. Zhang¹, P. Cushenan⁴, S. Weaver⁵, I. Yang², J. H. Shannahan³, and C. Wright¹. ¹UL Research Institutes' Chemical Insights, Marietta, GA; ²Emory University, Atlanta, GA; ³Purdue University, West Lafayette, IN; ⁴Soft Smiles LLC, Marietta, GA; and ⁵Georgia State University, Atlanta, GA.

Background and Purpose: Electronic nicotine delivery systems (ENDS), or e-cigarettes, are marketed as safer alternatives to combustible tobacco, yet accumulating evidence links their use to gingivitis, periodontitis, and other oral diseases. However, sex-specific molecular and microbial responses to ENDS in the oral environment remain largely unexplored. This knowledge gap is particularly concerning given that e-cigarette aerosols may result in greater nicotine retention in the upper respiratory tract than combustible tobacco smoke, potentially amplifying localized oral effects. **Methods:** We conducted an integrated multi-omics analysis of 73 adults (47 females, 26 males; 67% vapers, 33% non-vapers) to investigate sex-specific biological responses to vaping. Subgingival plaque and saliva samples were analyzed using 16S rRNA sequencing, untargeted proteomics, and metabolomics, while exhaled emissions were characterized for volatile organic compounds (VOCs) and aldehydes. The study protocol was reviewed and approved by the Advarra Institutional Review Board (Protocol No. H22081). **Results:** Although vaping exposure was comparable between sexes, males exhibited higher systemic nicotine and cotinine levels, consistent with slower nicotine metabolism. Male vapers showed pronounced alterations in amino acid, lipid, glycan, and bile acid pathways, elevated aldehydes in exhaled breath, and upregulated aldehyde dehydrogenase 3A1 (ALDH3A1), indicating enhanced detoxification and oxidative-stress responses. Female vapers exhibited broader metabolic shifts, elevated dopamine, and upregulation of fibrinogen beta chain (FGB), reflecting elevated inflammatory and immune activation. Arginine depletion was common to both sexes, representing a shared metabolic signature of ENDS use associated with oral-health decline. Microbiome analysis identified sex-specific enrichment of pathogenic taxa, *Saccharibacteria* (TM7) and *Granulicatella* in females; *Serratia*, *Achromobacter*, and *Absoconditabacteria* (SR1) in males. These molecular and microbial perturbations correlated with higher Community Periodontal Index of Treatment Needs (CPITN) scores and elevated salivary IL-1β. **Conclusions:** ENDS use induces metabolic reprogramming that amplifies inflammatory signaling and weakens mucosal-barrier integrity, thereby increasing periodontal-disease risk. While both sexes are susceptible, males and females exhibit distinct biological trajectories, underscoring the need for sex-specific frameworks in oral-health and exposomics research.

V. Caruana, R. Juran, N. Kukolj, C. Jafaar, C. J. Bagloli, and K. K. Mann. McGill University, Montreal, QC, Canada.

Background and Purpose: E-cigarettes are often marketed as safer alternatives to traditional cigarettes, yet their effects on metabolism remain unclear. Recent studies suggest vaping may disrupt lipid metabolism and contribute to fatty liver disease. This study examines how e-cigarette exposure influences hepatic metabolism and fibrosis and whether these effects occur independently of metabolic co-morbidities such as hyperlipidemia. We hypothesize that exposure to e-cigarette aerosols disrupts hepatic proteins involved in lipid metabolism and fibrosis. Contributing factors such as a high-fat diet and prolonged exposure duration may exacerbate these effects but are not required for their initiation. **Methods:** C57BL/6 mice were injected with AAV-PCSK9 and fed a high-fat diet to induce hyperlipidemia. Mice were then exposed to air, STLTH, or Vuse aerosols twice daily for 16 weeks. Livers were collected and protein was extracted for proteomic analysis. Validation studies used IHC, IF, and qPCR for major hits. Additional proteomic analysis was performed in wild-type mice exposed to STLTH or Vuse aerosols twice daily for two weeks, in the absence of AAV-PCSK9 and a high-fat diet. **Results:** Proteomics revealed distinct, device-specific hepatic alterations. Proteomic analysis revealed hepatic alterations following 16 weeks of e-cigarette exposure, characterized by changes in mitochondrial, oxidative phosphorylation, and lipid metabolism pathways, indicative of early metabolic dysfunction. Similarly, in short-term exposures, wild-type mice exhibited comparable disruptions in hepatic lipid metabolism despite the absence of diet-induced hyperlipidemia or prolonged exposure, suggesting that vaping alone is sufficient to perturb liver metabolism. **Conclusions:** E-cigarette use induces early, device-specific hepatic metabolic changes before visible fibrosis occurs. Importantly, comparable proteomic changes in wild-type mice indicate that e-cigarette exposure alone can initiate hepatic alterations, while co-morbidities such as high-fat diet and hyperlipidemia likely exacerbate, but are not required for, this phenotype. These findings underscore vaping as an independent risk factor capable of altering liver metabolism even in the absence of underlying metabolic disease.

PS 3467 Pancreatic Ductal Adenocarcinoma: Enduring Transcriptomic Changes Resulting from Smoking History

E. Im, and G. Acquah-Mensah. Massachusetts College of Pharmacy and Health Sciences (MCPHS University), Worcester, MA.

Background and Purpose: Pancreatic Ductal Adenocarcinoma (PDAC) is a deadly disease. Like several other cancers, tobacco smoking is a notable risk factor for the disease. Among other things, smoking affects detoxification processes and the response to oxidative stress. It remains unclear the extent to which PDAC patients with a history of smoking are impacted after diagnosis. The purpose of this study is to characterize enduring changes in gene expression patterns in PDAC and their impact on processes associated with disease progression. **Methods:** We leveraged data associated with PDAC tumor samples from the Cancer Genome Atlas (TCGA-PAAD). Comparing different groups of PDAC patients on the basis of their smoking histories, (lifelong non-smokers, n=68; former smokers, n=60; current smokers, n=20), RNA-seq data were analyzed using the DESeq2 package. Differentially expressed genes (DEGs) were subjected to over-representation analyses using *enrichR* and network characteristics were further examined in Cytoscape. In parallel, Gene Set Enrichment Analysis (GSEA) was performed on ranked gene expression data to identify coordinated pathway-level changes across smoking groups. **Results:** A total of 127 DEGs were identified between non-smokers and former smokers, 28 between non-smokers and current smokers, and 18 between current and former smokers, all at an adjusted p value < 0.1. In non-smokers vs former, DEGs were enriched for detoxification and nuclear receptor signaling, and CYP2E1 and CYP2C8 appeared as hub genes with high connectivity in the STRING protein-protein interaction (PPI) network. In non-smokers vs current smokers, enrichment included inflammatory and lipid metabolic pathways, with WNT11 enriched in Reactome and a PLIN1-centered PPI cluster by MCODE and annotated by GO Biological Process (GOBP) terms related to lipid metabolism. GSEA of the non-smoker vs former-smoker comparison further revealed significant enrichment of the MUNSHI_MULTIPLE_MYELOMA_UP gene set in non-smokers (Normalized Enrichment Score = 1.70, p = 0.004), suggesting that immune-metabolic programs related to plasma-cell differentiation remain incompletely recovered after smoking cessation. **Conclusions:** Our study suggests that any smoking exposure leaves incompletely recovered transcriptomic marks in PDAC, especially in detoxification and immune-metabolic pathways. Even former smokers show persistent changes, which may influence pancreatic cancer biology after diagnosis.

PS 3468 Evaluating the direct impact of heated tobacco and cigarette smoke exposure on lung adenocarcinoma cell biology

G. P. Barros, P. R. Scharf, and S. P. Farsky. Universidade de São Paulo, São Paulo, Brazil.

Background and Purpose: Smoking remains a significant public health concern due to the harmful effects of the wide range of toxic compounds generated during tobacco combustion. Many of these substances can induce DNA damage and increase the risk of carcinogenesis. The lungs are particularly vulnerable to such detrimental effects of smoking, which promote chronic inflammation and tumor development. As part of harm-reduction strategies, non-combustible tobacco products have emerged and gained popularity as alternatives to conventional cigarettes (CC), including e-cigarettes and heated tobacco products (HTPs). Notably, HTPs and CC differ in their mechanisms of aerosol generation: CC rely on combustion, whereas HTPs use controlled heating, resulting in lower levels of toxicants. Despite this, comprehensive toxicological data on these products remain limited, and their potential health risks remain unclear. In this context, the present study aimed to evaluate the effects of CC and HTP exposure on the biology of lung adenocarcinoma cells (A549), using an alternative *in vitro* model, providing insights into their potential role in cancer progression. **Methods:** The air-liquid interface (ALI) exposure system used simulates the physiological conditions of smokers by allowing direct interaction between smoke aerosols and the apical cell surface. The model was established and coupled with a puff-based delivery protocol to assess the direct effects of these exposures. Cells were exposed for 30 minutes to HTP (IQOS device), CC (Marlboro Red Selection), or airflow (control). To isolate the effect of nicotine, cells were treated with increasing concentrations of nicotine (0.2-20 μ M) for 30 minutes. Following the exposure or treatment, cells were collected and plated for functional assays, including migration assay, spheroid formation, proliferation, and colony formation. **Results:** Even relatively low nicotine concentrations significantly affected spheroid development and colony formation. Compared with the control group, treatments with 0.2 μ M and 2.0 μ M nicotine led to consistent reductions in spheroid area and diameter. Although cells exposed to 20 μ M nicotine also formed smaller spheroids than the control group, the decrease did not follow the same reduction trend observed at lower doses, suggesting a plateau effect at higher concentrations. A similar pattern was observed in the colony formation assay, indicating that increasing nicotine concentrations beyond a certain threshold does not further intensify the inhibitory response. Exposure to both tobacco products also influenced spheroid growth dynamics. CC smoke exerted a more pronounced inhibitory impact than HTP aerosol. In the spheroid formation assay, all groups initially presented comparable areas and diameters, indicating similar baseline growth. Over time, however, cells exposed to CC maintained significantly smaller spheroid dimensions than those in the air control, while HTP exposure caused a milder but noticeable suppression. Consistently, the proliferation assay showed decreased proliferation rates following both HTP and CC exposure. Notably, neither treatment induced cell death, suggesting that both tobacco products are able to modulate tumor cell behavior without causing cytotoxicity. **Conclusions:** Nicotine modulates tumor cell behavior, particularly proliferation and three-dimensional growth. The observed plateau suggests receptor saturation, indicating that maximal activity occurs at a specific nicotine concentration. These findings highlight the need to evaluate the risks associated with nicotine-containing products, regardless of their delivery method. Exposure to HTP and CC alone did not significantly promote tumor growth, suggesting that additional factors, such as the tumor microenvironment and immune modulation, are required for cancer progression. However, even short exposures altered cell behavior, reinforcing that these products are not biologically inert. Although HTPs showed milder effects than CC, both modified essential cellular features. Overall, these results reveal that non-combustible tobacco products still pose biological risks and underscore the importance of further studies to clarify their mechanisms of toxicity and aid in the formulation of effective public policies as well as therapeutic interventions regarding tobacco products.

PS 3469 An integrated Lung-on-Chip platform investigating molecular responses to whole cigarette smoke exposure

A. Sengupta¹, N. Grangier¹, O. Wisser², P. Zamprogno³, T. Krebs², O. T. Guenat⁴, and N. Hobi³. ¹Alexis Technologies, Bern, Switzerland; ²Vitrocell Systems GmbH, Waldkirch, Germany; ³AlveoliX AG, Swiss Organs-On-Chip, Bern, Switzerland; and ⁴ARTORG, University of Bern, Bern, Switzerland. Sponsor: A. Stucki

Background and Purpose: COPD is a major global health concern and the third leading cause of death worldwide, placing a significant burden on both patients and healthcare systems. The inhalation of tobacco products not only contributes significantly to the progression of COPD but is also implicated in conditions such as E-cigarette or Vaping-product Use-Associated Lung Injury (EVALI) and lung cancer, due to the presence of highly reactive chemicals that disrupt and inflame alveoli. However, current research *in vitro* models often study only single cell types, which fail to represent the complex microenvironment of the distal lung, including its dynamic stretching. Additionally, cigarette smoke exposure in these models is commonly performed using cigarette smoke extracts in submerged cultures, resulting in experimental conditions that are far from reflective of true *in vivo* environments. **Methods:** In this study, we present a novel inhalation setup utilizing a continuous flow smoke exposure platform (CFAX12), coupled with the ^{AX}Lung-on-chip technology (AlveoliX

AG) [Stucki et al., 2018; Sengupta et al., 2023], to mimic realistic inhalation exposure to whole cigarette smoke (CS). The AX12 lung-on-chip system enables physiological exposure by integrating a co-culture of human alveolar epithelial cells (A⁴IECs) [Sengupta et al., 2022], human lung microvascular endothelial cells, and macrophages together mimicking the air-blood barrier of the distal lung. These cells were cultured within the chip under air-liquid interface (ALI) conditions with and without breathing-like dynamic stretch. This advanced co-culture system was directly exposed to CS, thereby more accurately reflecting the conditions of human inhalation. Moreover, porcine-derived native surfactant (Curosurf) was added onto the cells on-chip to study the protective effect of surfactant lining in cigarette smoke studies. **Results:** Our results demonstrated significant destruction in the air-blood barrier and cytotoxicity after cigarette smoke exposure, which was sighted in a significant decrease in Transepithelial/trans endothelial electrical resistance (~ 80% drop in TEER) and visible cell barrier disruptions. At 48 hours post-exposure, a notable elevation in LDH levels (~3 folds higher than control samples) was detected. This significant increase indicates acute cytotoxicity because of cigarette smoke exposure. Gene expression analysis additionally indicated increased inflammatory gene expression (like IL6, IL8, TNF- α). Moreover, enhanced secretion of IL8 cytokine (~3 folds higher than control samples) was measured in cigarette smoke-exposed cells on-chip. Furthermore, increased reactive oxygen species (ROS) generation (~50% higher than control samples) was measured post-smoke exposure. Interestingly, the addition of surfactant on the cells on-chip indicated strong protective effects post-smoke exposure when compared to the control samples without surfactant inclusion (Sengupta et al., 2025). **Conclusions:** This integrated CFAX12 platform significantly advances our understanding of the molecular mechanisms underlying tobacco-related diseases. It plays an essential role in toxicological testing of emerging new tobacco products, including e-cigarettes and heated tobacco devices, offering a reliable means for assessing their safety and health impacts. Ultimately, this research also supports the identification of novel biomarkers and therapeutic targets, contributing to more effective and personalized treatments for tobacco-induced lung diseases, while bridging critical gaps in preclinical testing to improve both public health and regulatory standards.

PS 3470 PDGF-BB as a Mediator of Pulmonary Microvascular Injury Following E-Cigarette Exposure

H. Alkhadrawi, J. Abdalrahman, D. M. Panchal, K. Dese, C. Bartilson, K. Day, and M. Bennewitz. West Virginia University, Morgantown, WV.

Background and Purpose: E-cigarettes are frequently perceived as a less risky alternative to traditional cigarette smoking. However, there is a growing body of evidence that this perception is flawed, as e-cigarette aerosol (EC) exposure leads to altered immune function and injury to the cardiovascular and pulmonary systems. Currently, the cellular and molecular mechanism of EC-mediated lung vascular damage is poorly defined. Recent studies have shown that platelet-derived growth factor-BB (PDGF-BB) was elevated in the plasma of e-cigarette users compared to non-smokers. Here, we investigate the behavior of immune cells in the lung microcirculation following nicotine-free EC exposure. The goal of this study is to define the role of PDGF in recruiting neutrophils and enhancing neutrophil-platelet aggregates (NPA). Neutrophils are the most abundant type of white blood cells, and when stimulated, release neutrophil extracellular traps (NETs). These webs of extruded DNA fibers provoke an inflammatory response and vasculature damage. We hypothesize that EC exposure triggers PDGF-mediated neutrophil-platelet aggregates and NET release in the lung microcirculation, leading to lung injury. **Methods:** Male and female BALB/c mice underwent 150 puffs/day of nicotine-free EC exposure for 3, 6, or 9 days. Control mice received room air (RA). Other groups of mice received either PDGF-BB to activate PDGFR or imatinib mesylate to inhibit PDGFR. The last experimental group received both EC exposure and imatinib mesylate for 9 days. The following day, lung fluorescence intravital microscopy (IVM) was performed to assess inflammation by observing fluorescently labeled neutrophils and platelets within the pulmonary microvasculature. Collected lungs were assessed with multiplex immunofluorescence staining and protein mass spectrometry. A mouse cytokine array evaluated harvested whole blood from the different exposure groups to analyze the change in cytokine expression. **Results:** Lung IVM revealed a significant increase of neutrophils and neutrophil-platelet aggregates in the pulmonary microvasculature for both male mice (650 μm^2 at day 6) and female mice (700 μm^2 at day 9) compared to the RA groups (250 μm^2). The PDGF-BB groups produced similar inflammation as the 9-day EC groups. Imatinib mesylate treatment blocked neutrophil-platelet aggregate formation in EC exposed mice. The cytokine array showed dysregulation of 9 pro-inflammatory cytokines in the male and female EC exposed mice compared to RA. Mass spectrometry showed a host of upregulated and downregulated proteins post EC exposure, with the most interesting being a downregulation of surfactant protein A post 9 day EC exposure. Surfactant protein A is responsible for lowering surface tension, which helps to prevent alveoli from collapsing. Lung immunofluorescence staining for the presence of PDGF-BB, PDGFR, and ROS is ongoing. **Conclusions:** In conclusion, the immune response is heightened in mice treated with EC. PDGF-BB recapitulated the inflammatory responses in EC exposed mice, while imatinib mesylate prevented aggregate formation. This research explores the pathway in which PDGF contributes to lung inflammation post EC exposure to educate the public about the dangers of EC.

PS 3471 E-Cigarette Aerosols Induce Oxidative Stress and Inflammation in Corneal Epithelial Cells: Potential Risk of Vaping to Ocular Surface

T. Lin, and Y. Huang. Missouri University of Science and Technology, Rolla, MO.

Background and Purpose: Electronic cigarette (E-cigarette; EC hereafter) is a nicotine delivery device that generates aerosols by evaporating e-liquid containing humectants, nicotine, and flavorings. EC has become a commonly used tobacco product, among adolescents, with 1.63 million middle and high school students reporting current use of EC. Compared to conventional cigarette smoke generated by combustion, EC produces aerosols by heating which results in less tar, carbon monoxide, and tobacco-specific nitrosamines (TSNAs) emission. However, the thermal degradation of e-liquid emits potentially harmful compounds, such as volatile organic compounds (VOCs), polycyclic aromatic hydrocarbons (PAHs), and metals. Recently, studies found that EC users reported moderate-to-severe eye dryness and tear film instability after vaping. Shorter tear breakup time, altered tear production, and loss of meibomian glands were observed in vapers, suggesting a possible correlation between EC exposure and dry eye symptoms. Our goal is to investigate the adverse effects of e-cigarette aerosols on eyes at the molecular levels, focusing on biomarkers related to eye dryness. **Methods:** Human corneal epithelial cells (HCE-2) were exposed to aerosols generated by electronic cigarettes with different device wattages (W) and e-liquid that contains varying nicotine levels and flavorings. Exposure program was controlled by Arduino-uno microcontroller board with servo motor to simulate human vaping behavior. Following exposure, cellular responses were evaluated using biochemical and molecular assays. Cytotoxicity was assessed by MTT cell viability assay. Oxidative stress was determined by measuring intracellular reactive oxygen species (ROS). Potential inflammatory response was examined by pro-inflammatory cytokine expression level using both quantitative real-time PCR (qPCR) and enzyme-linked immunosorbent assay (ELISA). **Results:** Cell viability was reduced by 10% at 10 W, 28% at 25 W, and 50% at 35 W after cells were exposed to 60 puffs of aerosols generated by e-liquid containing 12 mg of nicotine. ROS level exhibited a wattage-dependent increase of 1.5- to 2-folds at 4- and 6-hours post-exposure, indicating elevated intracellular oxidative stress. Further, we detected surged cytokine expression, including IL6, IL1 α , IL1 β at the RNA level, with IL1 β also upregulated at the protein level, suggesting that aerosol exposure contributed to activation of pro-inflammatory response in HCE-2 cells. Together, these results indicate that e-cigarette aerosol exposure induces cytotoxicity, oxidative stress, and inflammatory activation in HCE-2 cells in a wattage- and time-dependent manner. **Conclusions:** Oxidative stress can damage cellular components such as DNA, lipid, and protein, leading to cellular dysfunction and even cell death. The damage contributes to numerous eye diseases, such as cataracts, glaucoma, dry eye, and age-related macular degeneration. Moreover, inflammation triggered by oxidative stress can worsen existing conditions and promote disease progression. Our study shows that e-cigarette aerosols lead to elevated oxidative stress and pro-inflammatory response in human corneal epithelial cells. Together, these findings demonstrate that e-cigarette aerosols pose a potential hazard to eye surface health and highlight the need for further investigation into vaping-associated ocular damage.

PS 3472 Polycyclic aromatic hydrocarbons measured following electronic dabbing of Cannabis and Cannabis-derived products

A. K. Bauer¹, F. Friday¹, G. Brusoe¹, M. Armstrong¹, S. Goldman², and N. Reisdorph¹. ¹University of Colorado Anschutz Medical Center, Aurora, CO; and ²Kaycha Laboratories, Denver, CO.

Background and Purpose: Electronic dabbing is the consumption of concentrated Cannabis and Cannabis-derived products vaporized at temperatures as high as 1000° F. Terpenes found naturally in Cannabis and added in excess are responsible for the flavor and aroma profiles characteristic of dabbing. At high temperatures, terpenes such as α -cedrene and β -caryophyllene are known to undergo pyrolysis, forming polycyclic aromatic hydrocarbons (PAHs), but the production of PAHs from dabbing Cannabis is largely unknown. PAHs pose a risk to human health; 16 are U.S.E.P.A priority pollutants and many are known or suspected carcinogens. Our hypothesis is that electronic dabbing of Cannabis products, especially those with high terpene concentrations, will lead to production of PAHs and subsequent toxic exposure. **Methods:** We developed a method for analyzing PAHs produced during electronic dabbing by collecting vapor produced at 1000° F from an electronic dabbing rig. Vapor was captured using C18 SPE cartridges, followed by measurement of the 16 EPA priority PAHs using gas chromatography/mass spectrometry (GC/MS). Control testing with multiple terpene mixes was performed at CU Anschutz, and various Cannabis concentrates with or without added terpenes were dabbed and prepared at Kaycha Labs in Denver, Colorado, for analysis at CU Anschutz. The Cannabis products, control oils, and terpene mixes that we tested are common in the Colorado market. Our protocol was validated by measuring samples spiked with PAHs before and after dabbing. **Results:** Our findings suggest the presence of multiple priority PAHs, particularly those of lower molecular weight, such as naphthalene and its methylated derivatives, in vapors produced from the dabbing of both control and Cannabis-derived samples, and PAH concentrations increase upon addition of terpenes. However, some PAHs were present at low concentrations in undabbed samples. Notably, the addition of terpenes to multiple Cannabis products resulted in significantly increased concentrations of four PAHs, including anthra-

cene. **Conclusions:** These results support the successful development of a method for the collection and analysis of PAHs from dab vapors. Additionally, our findings suggest that the addition of terpenes to electronic dabbing results in significantly increased production of PAHs. Further testing is underway to compare the effects of various added terpene mixes on PAH production, and current results will be analyzed for unknown metabolites using the NIST17 GC/MS database. Because current U.S. *Cannabis* testing facilities do not test for PAHs, our overall goal is to understand potential user exposures to prevent and protect the public health of Coloradans by providing evidence to improve regulation of device temperatures and product formulations. This research was supported by the Institute for *Cannabis* Research.

PS 3473 Characterization of Flavored E-cigarettes via Untargeted Mass Spectrometry to Identify Flavor Specific E-cigarette Markers of Exposure

T. Rodriguez, D. Jones, Y. Siu, and K. Farrell. NYU Langone, New York, NY. Sponsor: T. Gordon

Background and Purpose: The use of flavored e-cigarettes is a public health concern due to previous exposure studies (both *in-vitro* and *in-vivo*) that have uncovered e-cigarette flavor-specific pathologies including gut inflammation, and immune dysfunction. Prior research studies on flavored e-cigarettes identified over 200 constituents, but the complete exposome has yet to be characterized due to the chemical diversity of e-liquids between flavor ingredients and brands. Determining associations between human health outcomes and flavored e-cigarette exposure has been hindered by the lack of flavor-specific biomarkers and comprehensive molecular characterizations. To overcome these challenges, we characterized the constituents of flavored e-cigarette street products within the New York City area. **Methods:** Street-circulating e-cigarettes were donated in the Fall of 2024 by the "We Are Atlas" organization, which collects used e-cigarettes in the Brooklyn area for recycling. Brand and flavor content of the donated used e-cigarettes (n=341) were recorded. The e-liquid was harvested from the sponge of each e-cigarette, then diluted with methanol to a final concentration of 80% methanol and centrifuged. The supernatant was analyzed via Reverse-Phase Untargeted Liquid Chromatography-High-Resolution Tandem Mass Spectrometry (LC-MS/MS) analysis. Molecular constituents were analyzed with standard in-house informatics methods, and two complementary approaches were applied and merged with novel scripts (Python, R) to annotate and cluster features by MS2 library matching and empirical feature annotation. Sample features were compiled into a large-scale feature library for consistent annotation across all samples. **Results:** The donated used e-cigarettes included 25 brands and 130 uniquely named e-cigarette flavors, with "clear" (n=65, 19.5%) and watermelon ice (n=36, 10.8%) being the most abundant flavors. The 130 uniquely named e-cigarette flavors were organized into 34 unique "flavor notes" so that nominal flavors could be associated with specific molecular constituents. For example, the flavor name "strawberry kiwi" would be annotated with two flavor notes; strawberry and kiwi. The most abundant flavor notes included; menthol/mint (n=206, 38.7%), berry (n=92, 16.9%), and melon (n=69, 12.7%). Twenty-six e-cigarettes from various brands that spanned the 34 flavor notes were selected for LC-MS/MS analysis. In total 19,480 putatively named and unnamed molecular features were detected. A subset (n=6,746) of high abundance features (>100X SNR) was used in a Principal Component Analysis Biplot Graph to identify shared molecular features within e-liquids associated with the same flavor note. We putatively identified such features that were unique to a flavor note, including but not limited to; berry (n=276), menthol/mint (n=189), watermelon (n=116), kiwi (n=16), and pineapple (n=13). Identification of flavor features present in multiple samples from assorted brands indicates that while flavor brand variation may exist, there is significant overlap in the constituents used to create a specific flavor. **Conclusions:** The donated e-cigarettes gave insight on e-cigarette flavor and brand usage within the Brooklyn area. From this analysis, we putatively characterized the chemical flavor landscape of over 26 flavored e-cigarettes highlighting the molecular composition of human exposures to e-liquids. The e-liquid flavor-specific features will be used in a novel prediction algorithm to blindly assign e-cigarette flavor exposure within an independent Human Vape Cohort (urine) with known flavor usage to test the hypothesis that flavor exposure can be determined by the urine exposome profile. Metadata from the positive control cohort, self-reported e-cigarette consumption with flavor preference, will be used to validate our assignment methodology. Our continuing work will build a molecular flavor library which can be used to putatively determine e-cigarette flavor exposure within human cohorts.

PS 3474 Disposable E-Cigarettes, Hidden Toxic Metals: Implications for Human Exposure

M. R. Salazar, X. C. Li, L. Saini, C. N. Corley, R. L. Evans, K. E. Pinkerton, A. K. Madl, T. B. Nguyen, and B. A. Poulin. University of California, Davis, CA.

Background and Purpose: Disposable pod e-cigarettes (dPODs) are currently the most popular type of e-cigarette on the market, particularly among adolescents and young adults. The majority of these products are not authorized for sale in the U.S. and come in a wide variety of designs and flavors, enhancing their appeal to youth. Despite their immense popularity, scientific research has only recently begun to

investigate the chemical compositions of dPOD aerosols and e-liquids, as well as the potential health risks associated with their use. A recent study by our group published in *ACS Central Science* (2025) (DOI: 10.1021/acscentsci.5c00641) identified nickel (Ni), antimony (Sb), and lead (Pb) in aerosols from three popular dPOD brands at concentrations exceeding established cancer and non-cancer risk thresholds, raising health concerns. This study revealed two major concerns with dPODs. First, the use of lead-based alloys for metallic internal components was identified in one brand, resulting in exceptionally high Pb concentrations in its aerosols, exceeding those found in a single pack of cigarette smoke by as much as 19-fold based on one day's worth of puffs (100 puffs). Second, the accumulation of toxic elements such as Pb, Ni, and Sb was observed with increased device use, possibly due to the closed system design of dPODs. While these findings are specific to the brands tested, they underscore a broader concern regarding the unknown toxicological profiles of the many dPOD brands on the black market. To provide an initial assessment of the human health implications of dPOD use, we conducted a controlled whole-body exposure study using C57BL/6 mice. Mice were exposed to an aerosol derived from a commercial dPOD e-liquid containing high concentrations of Pb, Ni, Sb, copper (Cu), and zinc (Zn). The objective was to determine whether toxic metals and metalloids from dPOD aerosols can enter systemic circulation, accumulate in vital organs, and induce immune responses. **Methods:** C57BL/6 mice (n = 12 per group; 6 males and 6 females, 12 weeks old) were exposed to aerosols generated from a commercial dPOD e-liquid previously found to contain high concentrations of Pb, Ni, Sb, Cu, and Zn. Exposures were conducted for 3 hours per day over either short-term (3 days) or prolonged exposure (4 weeks, 5 days per week). Control mice were exposed to HEPA-filtered laboratory air. Exposure chamber aerosols were collected and analyzed for gravimetric aerosol mass (mg/m³), total elements, and carbonyls. Following exposure, the lungs, olfactory bulbs, brain, liver, kidneys, blood, and femur were collected from all animals. Tissues were digested using microwave-assisted acid digestion, and elemental concentrations of Pb, Ni, Sb, Cu, and Zn were quantified by inductively coupled plasma mass spectrometry (ICP-MS). Immunohistochemistry (IHC) was conducted on lung tissues to identify changes in Club Cell Secretory Protein (CCSP) immunomodulatory function. **Results:** No significant differences in element concentrations were observed in mice following 3-day dPOD aerosol exposures for any element relative to controls. Conversely, significant increases in Pb concentrations were quantified in the bones and kidneys of mice exposed for 4 weeks (p = 0.03 to 1.3 x 10⁻⁶), in both males and females, compared to control mice. No significant increases in Pb or any other measured elements (Ni, Sb, Cu, Zn) were observed in the remaining tissues (p>0.05). Qualitative tissue staining identified subtle changes in inflammation, but with marked changes in airway integrity. **Conclusions:** Our *in vivo* exposure study demonstrated that sub-chronic (4-week) exposure to a commercial dPOD aerosol led to significant Pb accumulation in the bones and kidneys of exposed mice and alterations in airway epithelium. These findings indicate that e-cigarettes containing elevated Pb levels can promote systemic metal deposition and possibly disrupt airway immunomodulatory function, posing potential long-term health risks. Given the lack of toxicological characterization for most dPOD brands, consumers may be at risk of exposure to toxic metals from products that have not undergone proper safety evaluations.

PS 3475 Contribution of Metals, Carbonyls and TSNA's to the Excess Lifetime Cancer Risk of Illicit Flavored Disposable E-cigarette Products Available on the US Market

N. V. Ivanov, A. Pennington, F. Ayala-Fierro, M. J. Oldham, and I. G. Gillman. Juul Labs, Washington, DC.

Background and Purpose: To date, the U.S. Food and Drug Administration (FDA) has authorized only tobacco and menthol flavored electronic nicotine delivery systems (ENDS). Despite this, illicit flavored disposable ENDS have become widely accessible in the United States (US). Recent data show that illicit flavored disposables represent approximately 80% of the US ENDS market. While some studies have analyzed flavored disposable ENDS, to date, no comprehensive studies have examined the Excess Lifetime Cancer Risk (ELCR) of the e-liquids in these illicit products. The FDA's Center for Tobacco Products (FDA CTP) released two memoranda dated June 3, 2024, outlining recommendations for identifying genotoxicity hazards and classifying ENDS constituents according to carcinogenicity tiers and detailing methodologies for calculating ELCR in ENDS products to support Premarket Tobacco Product Applications (PMTA). Our objective is to apply the approach outlined in the FDA memos to calculate the contribution of the metals, carbonyls and tobacco specific nitrosamines (TSNAs) to the ELCR values of the selected 73 illicit ENDS products available in the U.S. market. **Methods:** Following the FDA CTP approach and incorporating inhalation unit risk (IUR) values from supplementary sources, we calculated ELCR attributable to metals, carbonyls and TSNAs measured in the e-liquids of the 73 illicit flavored disposable ENDS, assuming 100% transfer to the aerosol. We also included an IUR for antimony (Sb III) proposed by the California Office of Environmental Health Hazard Assessment. ELCR values were first calculated per gram of an e-liquid, then normalized per milligram (mg) of nicotine (for nicotine-containing e-liquids only) and subsequently adjusted by 40 mg daily nicotine consumption rate, cited by FDA CTP. For non-nicotine containing ENDS, the ELCRs were compared after normalization per weight of e-liquid. **Results:** High concentrations of chromium, nickel, antimony, and lead were observed in some illicit e-liquids, significantly contributing to their ELCR values. The Cr(VI) Inhalation Unit Risk (IUR) was applied to the total measured chromium concentration in ELCR calculations. Neither

cadmium nor arsenic were detected above the limits of quantification. The highest metal concentrations, and thus the highest ELCR values, were observed in non-nicotine e-liquid normalized per e-liquid weight. Some e-liquids contained TSNAs, which also contributed to the ELCR values. Finally, a moderate negative correlation was observed between concentrations of metals and e-liquid pH. **Conclusions:** Our work demonstrates that metals, carbonyls and TSNAs detected in the e-liquids of the illicit ENDS available on the US market significantly contribute (with maximum over 700) to the e-liquid ELCR values and some are higher than the median ELCR value of 31 calculated from measured Tier 1-3 HPHCs levels of authorized ENDS. However, as noted in the U.S. CTP memos, other factors, including e-liquid ingredients, and potential leachable compounds from ENDS aerosol components, may also contribute to the overall ELCR. Thus, the calculated ELCR values for the illicit ENDS are likely underestimated because these comprehensive data are largely unavailable for the illicit products.

PS 3476 Exposure assessment of toxicants in slim cigarette consumers

C. Ma. Zhengzhou Tobacco Research Institute of CNTC, Zhengzhou, China.
Sponsor: R. Meng

Background and Purpose: Slim cigarettes often being chosen by consumers due to a perceived reduction in health risks. However, whether the consumption of these products genuinely lowers systemic toxicant exposure remains a critical unanswered question. To address this, a large-scale population-based pilot study was conducted across several cities in China. This research utilized urinary biomarker analysis to accurately assess and compare the exposure levels of various harmful constituents among slim cigarette smokers, regular cigarette smokers, and non-smokers, thereby providing essential real-world data for risk assessment. **Methods:** A robust cohort study was executed across six major Chinese cities, enrolling 1,141 volunteers (regular smokers, slim smokers, and non-smokers). Following a five-day smoking phase using designated products, 24-hour urine samples were collected. Utilizing a biomarker-based exposure assessment methodology, the study compared exposure levels to various toxicants, including nicotine, tobacco-specific nitrosamines (TSNAs, NNK), polycyclic aromatic hydrocarbons (PAHs, pyrene and naphthalene), volatile carbonyl compounds (acrolein and crotonaldehyde), and volatile organic compounds (VOCs, 1,3-butadiene, acrylonitrile, benzene, ethylene oxide) among slim cigarette, regular cigarette smokers and nonsmokers. **Results:** Compared to non-smokers, the consumption of slim cigarettes was found to significantly elevate exposure levels for nearly all measured toxicant biomarkers ($p < 0.05$). No statistical difference was observed in the average number of cigarettes consumed per day between the slim cigarette group (16.7 sticks/day) and the regular cigarette group (17.0 sticks/day, $p = 0.35$). Crucially, consumption of slim cigarettes was associated with significantly lower exposure to nicotine ($p = 0.001$), total NNK ($p = 0.02$) and naphthalene ($p = 0.02$) compared to regular cigarettes. Conversely, no statistically significant differences were detected for the biomarkers of VOCs. A strong positive correlation ($R^2 > 0.9$) was established between the number of slim cigarettes smoked and the measured toxicant exposure levels, confirming that daily cigarette consumption is a primary determinant of toxicant exposure. **Conclusions:** 1) Compared to non-smokers, slim cigarette smoking significantly increased exposure to all measured toxicants; 2) Exposure levels were positively correlated with the number of cigarettes smoked; 3) Compared with regular cigarettes, smoking slim cigarettes can significantly reduce user exposure to nicotine, TSNAs and naphthalene.

PS 3477 Accounting for Population Variability in Simulation Modeling of Tobacco Product Constituents

M. Jacketti, B. Asgharian, O. Price, A. Meade, D. Oldson, S. Beaulieu, and J. Schroeter. Applied Research Associates, Inc., Raleigh, NC.

Background and Purpose: Electronic nicotine delivery systems (ENDS) and combusted cigarettes contain chemical constituents that may be hazardous to human health when inhaled. Human health risk assessment of individual exposures provides critical information associated with the use of different inhaled tobacco products; but does not account for variability in the population or provide insights regarding risk to specific demographics. Capturing this variability illustrates how risks may differ across demographics, use patterns, and product types, offering valuable information for regulatory decision making. **Methods:** We simulated synthetic populations through statistical sampling from representative demographic, physiological, and behavioral distributions to assess tobacco-related health risks. U.S. Census data, the National Health and Nutrition Examination Survey (NHANES), and regression equations were used to generate demographic and physiological characteristics, while the Population Assessment of Tobacco and Health (PATH) and studies in the literature were used to represent behavioral patterns in tobacco product use. As a case study, we generated 1,000 individuals for a baseline population (Population A) using an 18 mg/mL nicotine fixed power ENDS and 1,000 individuals for a population using reduced-nicotine ENDS with compensatory puffing (6 mg/mL nicotine fixed power ENDS) (Population B). These synthetic individuals were then used as inputs to previously developed respiratory dosimetry and nicotine physiologically-based pharmacokinetic (PBPK) models to assess the effects of compensatory behavior for reduced nicotine devices on daily dose of nicotine and its metabolite cotinine, and the potential byproducts acetaldehyde, acrolein, and formaldehyde.

Results: Uptake and deposition of tobacco product constituents depends on properties such as flow rate, physico-chemical properties, clearance rates, and deposition mechanisms. Because these underlying parameters are not substantially altered between the two populations, the similarity in uptake/deposition fractions between the two populations can be expected. Compensatory puffing with the lower nicotine concentration ENDS led to 2-4 times higher median daily doses of formaldehyde, acetaldehyde, and acrolein across all regions of the respiratory tract. In addition, the standard deviation of aldehyde exposure was also higher in Population B, specifically in the mouth/throat. For example, the standard deviation for acrolein exposure is over 4 times higher in Population B ($0.036 \mu\text{g}/\text{cm}^2/\text{day}$) than in Population A ($0.0081 \mu\text{g}/\text{cm}^2/\text{day}$). In contrast, daily maximum nicotine and cotinine concentrations in venous blood and brain tissues were approximately twice as large in Population A due to the higher nicotine concentration in the e-liquid, despite reduced puffing intensity. For example, median concentrations in the venous blood were $2.69 \mu\text{g}/\text{L}$ for Population A compared with $1.17 \mu\text{g}/\text{L}$ for Population B. **Conclusions:** The modeling framework incorporates behavioral and physiological variability and allows for the comparison of risks between two populations that may have different tobacco use behaviors and device formulations. The approach enhances the ability to characterize variability in both dose and risk estimates by producing full distributions to estimate the full range of exposures. For example, such a framework provides estimates of the extremes within the population, which may be particularly important in identifying sensitive individuals and estimating the likelihood of exceeding the relevant health thresholds. Our findings from this case study suggest that compensatory puffing in response to reduced nicotine formulations can offset intended harm reduction by increasing exposures to byproducts.

PS 3478 Cancer Reference Estimates for Non-Mutagenic Flavoring Substances of Potential Concern

F. Ayala-Fierro, and M. Oldham. Juul Labs Inc, Washington, DC.

Background and Purpose: Flavoring substances are used in many consumer products including e-liquids for electronic nicotine delivery systems (ENDS). Health hazard characterization, including the potential for cancer effects, is critical in the risk assessment of any ingredient. The cancer risk assessment can follow a nonlinear dose response model based on a threshold, below which there is no effect, or a no-threshold linear dose response model. The nonlinear model is applicable for non-carcinogenic effects; however, it is often used for cancer effects attributed to non-mutagenic mode of action (MoA), resulting in the estimate of the reference dose (RfD). The no-threshold linear model has been adopted as the default approach because it is considered health-protective. The linearity of the model allows the calculation of the cancer slope factor (CSF). CSFs are estimated using the benchmark dose level (BMDL) associated with a 10% response (BMDL₁₀) (i.e., 10% extra risk of carcinogenic effect in exposed test animals) to serve as the point-of-departure (PoD). The excess lifetime cancer risk (ELCR) characterization is used by the U.S. Food and Drug Administration's Center for Tobacco Products (USFDA CTP) to support Premarket Tobacco Product Applications (PMTA) for ENDS. ELCR characterization relies on cancer potency factors (CPF) for each ingredient which are inhalation unit risk (IUR) values, adjusted to daily exposure levels corresponding with a cancer risk of 1 in 100,000, over 52-year exposures. The CPF is similar to the non-significant-risk-level (NSRL), established by California's Office of Environmental Health Hazard Assessment (OEHHA), for cancer-causing chemicals listed under Proposition 65. The NSRL is a threshold of daily intake that is considered to pose no more than a 1 in 100,000 lifetime cancer risk. The USFDA CTP Memorandum states that additional information for specific constituents should be considered to increase the accuracy of the CPF, and therefore the ELCR analysis. This procedure was used to determine the potential contribution, if any, of five flavoring substances to the overall cancer risk assessment. The CPF estimates were compared to NSRL estimates to demonstrate validity in this approach. Additionally, for non-mutagenic substances the CPF was compared to the RfD to determine the presence of a buffer for potential non-mutagenic health hazards. **Methods:** The methodology described in the 2024 USFDA CTP Memorandum for calculating ELCR in ENDS products was used to estimate CPFs for the synthetic flavoring substances Benzophenone, Furfural, Methyl Eugenol, β -Myrcene, Pulegone, and Pyridine. The NSRL was estimated according to CalEPA OEHHA guidelines. Data used for the analysis primarily included the 2018 USFDA review that concluded these flavoring substances induce tumors by a non-genotoxic mechanism of action. First, if not available, oral CSFs were estimated using the BMDL₁₀ adjusted to a human equivalent dose (BMDL_{10(HED)}). Then, the IUR was calculated according to US EPA methodology and finally adjusted to CPF according to the USFDA CTP Memorandum. For comparison purposes, the RfD was also estimated following USEPA guidelines. **Results:** The adjusted IUR (CPF) estimates corresponding with a cancer risk of 1 in 100,000, for all flavoring substances using the linear model from a health-protective approach, were approximately 6-100x lower than the adopted default value of $1.5 \mu\text{g}/\text{day}$ in the USFDA CTP Memorandum. CPFs were found similar to NSRL estimates. In general, CPFs were approximately 250X lower (more conservative) than RfDs (considered protective for non-mutagenic cancer effects), when estimated using the nonlinear model appropriate for non-mutagenic substances. **Conclusions:** A method was employed to calculate IURs for flavoring substances in ENDS potentially carcinogenic via non-genotoxic MoA. The CPF estimate is aligned with NSRL indicating validity in the procedure. CPF estimates were higher than the proposed default CPF of $1.5 \mu\text{g}/\text{day}$ for single ingredients suggesting

a potential to overestimate the cumulative ELCR. The overestimate is even larger for those substances with a non-mutagenic MoA. The RfD estimate suggest a buffer may exist above the CPF for non-mutagenic carcinogens.

PS 3479 Tobacco and Nicotine Product Assessments: Quantitative Derivation of Excess Lifetime Cancer Risk for Oral Route of Exposure

C. K. West. Reynolds American Services Company, Winston-Salem, NC.

Background and Purpose: In 2024 the United States Food and Drug Administration (FDA) Center for Tobacco Products (CTP) published two toxicology memoranda focused on the hazard identification and carcinogenicity tiering of analytical constituents in Electronic Nicotine Delivery System (ENDS) products and the calculation of Excess Lifetime Cancer Risk (ELCR) as part of Premarket Tobacco Product Application (PMTA) evaluations. ELCR estimates the likelihood of cancer development over a lifetime of exposure to one or more substances. Globally there are over 300 million consumers of smokeless tobacco products such as snus, moist snuff, and nicotine pouches. Unlike combustible and ENDS products, smokeless tobacco products are generally placed in the mouth in direct and prolonged contact with the oral mucosa, resulting in a different absorption route for nicotine and Harmful and Potentially Harmful Constituents (HPHCs) - oral versus inhalation. This quantitative risk assessment approach centers on calculating the cumulative ELCR for smokeless tobacco products via the oral route of exposure, based on FDA CTP's toxicology memoranda for ENDS products published in 2024. **Methods:** To apply FDA's approach to calculating ELCR for smokeless tobacco products, oral cancer slope factors and average human body weight were utilized in lieu of inhalation unit risk factors and inhalation rate. HPHC data from CORESTA Smokeless Tobacco Reference Products, along with product usage assumptions under "average" and "heavy" consumption scenarios were applied to the model to estimate ELCR and demonstrate the feasibility of this approach which could be applied to smokeless tobacco product PMTA applications and evaluations. Additionally, non-cancer hazard quotients and indices were calculated based on EPA guidance. **Results:** Cumulative ELCR analysis of smokeless tobacco consumption under both the "average" and "heavy" use scenarios resulted in overall lower cancer risk profiles compared to that of the combustible reference cigarette 1R6F, which FDA CTP estimates to be 10,000 excess incidences of cancer in a population of 100,000 consumers. Non-cancer hazard indices were also below the regulatory level of unity (1) indicating that exposure to the constituents evaluated over the period of a lifetime are unlikely to result in the occurrence of deleterious non-cancer effects. **Conclusions:** This method demonstrates that FDA CTP's approach to calculating cumulative ELCR estimates for ENDS products can be modified for use via the oral route of exposure and applied to evaluate smokeless tobacco products.

PS 3480 G Protein Coupled Estrogen Receptor Modulation of Pulmonary and Neuroinflammatory Responses to Acute Inhaled Wood Smoke

S. Yazzie, E. Lim, M. Oh, E. Barr, T. Vue, E. Prossnitz, E. Prossnitz, B. Phinney, S. Leng, J. Gillette, and K. Zychowski. University of New Mexico, Albuquerque, NM.

Background and Purpose: Wood smoke (WS) exposure is an emerging environmental health concern linked to systemic and neurological inflammation. Estrogen signaling, particularly through the G protein-coupled estrogen receptor (GPER), has been implicated in modulating immune responses, yet its role in pulmonary and neuroinflammation following WS exposure remains unclear. To address this, we investigated how loss of GPER signaling influences inflammatory outcomes following acute WS exposure. **Methods:** 10-12wk old GPER knockout (KO) and wild-type (WT) mice were exposed to either filtered air (FA) or WS (4h/d for 2d, ~0.575mg/m³) (n=8 per group/exposure). Brain tissue and bronchoalveolar lavage fluid (BALF) were collected to evaluate immune responses. In a separate cohort (n=5 per group/exposure), cerebral blood flow dynamics were assessed within 24 h of the last exposure using laser speckle imaging. **Results:** Laser Speckle Imaging revealed that WS significantly increased cerebral blood flow in WT mice but not in GPER KO mice (20.99 ± 9.553 SEM, $p=0.0335$, Welch's t test). Flow cytometry analysis of BALF revealed decreased resident alveolar macrophages in WT mice after WS exposure ($p=0.0309$, Nonparametric T test), accompanied by increased monocyte-derived macrophages in GPER KO/WS versus WT/FA (mean diff. = -0.388 ± 0.137 , $p=0.0243$, two-way ANOVA). We also observed elevated monocyte-derived macrophages in GPER KO/WS versus WT/FA ($p=0.0128$, Nonparametric T test). Additionally, T cell abundance was reduced in GPER KO mice compared to WT FA controls ($p=0.0070$, Nonparametric T test). **Conclusions:** Together, preliminary results demonstrate that GPER signaling influences immune responses and cerebrovascular adaptation following acute WS exposure. Future work will include evaluating mRNA cytokine gene expression in brain regions such as the hippocampus, cortex, and cerebellum, as well as to assess glial activation through IBA-1 and GFAP staining in the hippocampus and cortex.

PS 3481 HIF-1 α Regulates Acrolein-Induced Oxidative Stress and Antioxidant Signaling in Differentiated Human Bronchial Epithelial Cells under Hypoxic Conditions

A. Ashraf, and E. Bruce. Baylor University, Waco, TX.

Background and Purpose: Exposure to acrolein, a hazardous environmental pollutant commonly found in industrial emissions and e-cigarette vapor, induces significant oxidative stress and cellular damage, particularly in hypoxic conditions. This oxidative stress and cellular toxicity is especially concerning for respiratory health. Hypoxia-inducible factor 1 alpha (HIF-1 α) is a critical regulator of cellular responses to low oxygen levels and plays a protective role by activating pathways involved in cell survival, antioxidant defenses, and stress response. However, the exact mechanisms by which HIF-1 α mitigates the toxic effects of acrolein on respiratory cells remain unclear, especially when comparing normoxic and hypoxic conditions. To address this, we differentiated primary normal human bronchial epithelial (NHBE) cells into pseudostratified epithelium at an air-liquid interface. After differentiation, we silenced the HIF-1 α gene in NHBE cells using RNA interference and exposed the cells to acrolein under both normoxic and hypoxic conditions. This study aimed to elucidate how HIF-1 α modulates oxidative stress and apoptosis through regulation of MAPK, PI3K/Akt, and Nrf2 signaling pathways and their downstream antioxidant and survival gene networks under normoxic and hypoxic conditions. This work will deepen our understanding of cellular resilience to environmental toxins and contribute insights toward developing public health strategies for mitigating pollutant-related respiratory damage. **Methods:** Differentiated normal human bronchial epithelial (NHBE) cells were cultured under air-liquid interface conditions and exposed to 40 or 80 μ M acrolein under normoxia (21% O₂) or hypoxia (1% O₂). HIF-1 α expression was silenced using siRNA transfection prior to exposure. Total RNA and protein were isolated to evaluate the expression of oxidative stress-related and apoptotic markers. Quantitative RT-PCR was performed to assess transcriptional regulation of MAPK, PI3K/Akt, and Nrf2 pathway genes. Western blot analysis was conducted to evaluate protein activation, including phosphorylated and total forms of JNK, p38, PI3K, and Caspase-3, along with Nrf2 protein expression and band intensities were quantified using densitometric analysis. Data were obtained from three independent experiments and expressed as mean $\pm$ SEM. **Results:** Western blot analysis revealed that acrolein exposure increased phosphorylation of JNK and p38 in a dose-dependent manner under hypoxic conditions, indicating activation of the MAPK stress pathway. However, HIF-1 α silencing altered this pattern: while phosphorylation of p38 increased at 40 μ M acrolein, both p-JNK and p-p38 levels were markedly reduced at 80 μ M, suggesting dysregulated stress-kinase signaling. Phosphorylated PI3K was also diminished in HIF-1 α -deficient cells, consistent with impaired pro-survival signaling. In parallel, Nrf2 protein expression was reduced following HIF-1 α knock-down, indicating attenuation of antioxidant pathway activation. RT-qPCR results also supported the protein findings. HIF-1 α -silenced cells exhibited lower mRNA expression of Nrf2-regulated antioxidant genes (NQO1, HMOX1, GCLM) and the survival-related gene AKT1 compared with control cells. The combined data demonstrate that HIF-1 α is essential for maintaining MAPK, PI3K/Akt, and Nrf2 pathway integrity under acrolein challenge, and its loss compromises both antioxidant and survival responses, particularly under hypoxia. **Conclusions:** This study highlights the critical protective role of HIF-1 α in mitigating acrolein-induced oxidative stress and apoptosis, particularly under hypoxic conditions and at lower acrolein doses. Silencing HIF-1 α exacerbated oxidative damage, disrupted antioxidant signaling, and heightened cellular susceptibility to acrolein toxicity. These findings underscore the importance of HIF-1 α in maintaining redox homeostasis and cellular resilience to environmental pollutants. In the broader context of toxicology, this work advances understanding of how airway epithelial cells adapt to oxidative stress and supports future strategies aimed at strengthening antioxidant defenses to reduce respiratory injury in vulnerable populations.

PS 3482 Vinyl chloride potentiates liver injury caused by chronic alcohol consumption in mice

J. Chen, C. Vanderpuye, P. Muddasani, S. Chaudhary, J. Li, G. E. Arteel, and J. I. Beier. University of Pittsburgh, Pittsburgh, PA.

Background and Purpose: Vinyl chloride (VC), an industrial chemical, causes liver injury at high concentrations, but low-level exposure (<1 ppm) is currently considered safe. The consequences of sub-OSHA exposure on human health are not well understood, especially in the context of VC as a risk-modifying agent. Previous work from this group confirms the role of VC in exacerbating experimental dysfunction-associated steatotic liver disease (MASLD) caused by Western diet. Both MASLD and alcohol-associated liver disease (ALD) have similar liver pathologies, and the impact of VC exposure in ALD has not been investigated. Moreover, the prevalence of ALD worldwide raises concerns about how VC exposure can enhance disease progression to more severe stages of injury. The purpose of this study was to determine if VC exposure worsens liver damage caused by chronic alcohol (EtOH) consumption. **Methods:** C57Bl/6J mice, pair-fed or fed a Lieber-DeCarli EtOH diet, were exposed to VC (<1 ppm), or room air for 6 hrs/d, 5 d/wk for 6 weeks. Plasma and liver samples were collected for determination of injury. **Results:** VC exposure exacerbated EtOH-induced liver damage and oxidative stress, and moderately increased inflammation. Although the increase in lipids caused by ethanol was not impacted by VC exposure, the pattern of steatosis shifted to more micro-vesicular fat, which is often indicative

of mitochondrial dysfunction. In line with that VC also changed mRNA expression of genes regulating metabolism. **Conclusions:** Various environmental toxicants are known to modify or enhance liver injury in MASLD models. Findings from the present study suggest that VC interacts also with other lifestyle factors such as alcohol consumption resulting in exacerbated alcohol-associated liver damage. This emphasizes that environmental chemical exposure, such as to VC, potentially drives inter-individual risk for developing or enhancing disease.

PS 3483 Aryl hydrocarbon receptor signaling in club cells promotes Th17-driven lung injury following inhalation exposure to environmentally persistent free radicals

R. Pathak^{1,2}, A. Kumar^{1,2}, A. Ferrier^{1,2}, D. Burk^{1,2}, and S. A. Cormier^{1,2}. ¹Louisiana State University, Baton Rouge, LA; and ²Pennington Biomedical Research Center, Baton Rouge, LA.

Background and Purpose: Environmentally persistent free radicals (EPFRs) are redox-active combustion by-products generated during thermal combustion processes, including hazardous wastes remediation, and have been implicated in respiratory disease. We previously demonstrated that EPFR inhalation induces neutrophilic asthma associated with marked lung injury. This phenotype is driven by T helper 17 (Th17) cells, which secrete IL-17. We further identified the aryl hydrocarbon receptor (AHR) as a central regulator of EPFR-induced pulmonary Th17 responses and found that airway club cells are a primary site of AHR activation following EPFR exposure. The present study aimed to investigate the role of club cell-AHR signaling in mediating EPFR-induced pulmonary responses. **Methods:** Conditional knockout mice lacking AHR in club cells (*Ahr* Δ CC) were generated by crossing *Ahr*^{flx} mice [*Ahr*^{tm3.1Bra/J} strain] with *Scgb1a1*-Cre^{ERTM} mice [B6N.129S6(Cg)-*Scgb1a1*^{1tm1cre/ERT1Blh/J} strain]. Littermate (LM) control and *Ahr* Δ CC mice were exposed to air or EPFRs (30 min/day for seven consecutive days; average concentration = 200 μ g/m³) via inhalation. Pulmonary immunopathophysiological responses were assessed following the final day of exposure. **Results:** Targeted deletion of AHR in club cells was confirmed by flow cytometry and immunofluorescence. Following EPFR inhalation, LM controls exhibited a robust Th17-biased pulmonary immune response, increased neutrophil recruitment in bronchoalveolar lavage fluid (BALF), and elevated cytokines associated with IL-17 signaling (KC/GRO, IL-6, IL-1 β) compared to air-exposed controls. In contrast, *Ahr* Δ CC mice exposed to EPFRs failed to induce these responses. Histopathological analysis revealed that EPFR exposure induced airspace enlargement, peribronchiolar fibrosis, mucus hyperproduction, and decreased lung function in LM mice, but these pathophysiological changes were absent in *Ahr* Δ CC mice. **Conclusions:** These findings identify club cell-specific AHR signaling as a critical determinant of EPFR-induced epithelial-immune crosstalk, driving neutrophilic inflammation, remodeling, and functional decline in the lung. This work provides mechanistic insight into the pulmonary toxicity of redox-active pollutants and highlights epithelial AHR as a potential therapeutic target in pollutant-induced lung disease.

PS 3484 Exposure to Hazardous Waste Emissions Alters Human Physiology: Findings from a Community-Based Pilot Study

A. Kumar^{1,2}, C. Guo³, Q. Sarumi⁴, C. Courtney⁴, S. Campagna⁴, J. Richmond-Bryant³, and S. A. Cormier^{1,2}. ¹Louisiana State University, Baton Rouge, LA; ²Pennington Biomedical Research Center, Baton Rouge, LA; ³North Carolina State University, Raleigh, NC; and ⁴University of Tennessee, Knoxville, TN.

Background and Purpose: Open burn/open detonation (OB/OD) is used for the disposal of explosive and hazardous wastes, releasing toxic gases and particulate matter into the environment. Colfax, Louisiana, hosts the only commercially operated OB/OD thermal treatment (TT) facility in the United States, raising concerns about its potential impact on surrounding communities. This pilot study aimed to investigate metabolic changes associated with residential proximity to the facility using untargeted urine metabolomics. **Methods:** Urine samples were collected from 51 residents living within a 30-km radius of the facility, with proximity, sex, and race considered as key variables. Samples were analyzed via ultra-high-performance liquid chromatography coupled with high-resolution mass spectrometry. Metabolic alterations and potential biomarkers of exposure were identified, followed by pathway enrichment analysis. **Results:** A total of 217 metabolites were identified. Individuals residing closer to the facility exhibited significant metabolic shifts, particularly in pathways linked to energy metabolism, amino acid metabolism, and oxidative stress. Elevated glutathione sulfonamide (GSA) levels and altered glutathione/glutathione disulfide (GSH/GSSG) ratios indicated increased oxidative stress and redox imbalance. Pathway enrichment highlighted disruptions in glycolysis, the citric acid cycle, sulfur metabolism, and nucleotide metabolism, which are essential for cellular energy and DNA repair. Differences in metabolite profiles were also observed across sex and racial groups, emphasizing the combined influence of biological and environmental factors. **Conclusions:** Proximity to the TT facility was associated with measurable metabolic alterations and increased oxidative stress in residents, suggesting potential health risks from chronic exposure. Further research is crucial

to understand the long-term health implications of these metabolic alterations and to develop strategies to mitigate the environmental and health risks associated with the TR of hazardous wastes.

PS 3485 Characterization of Murine Microglial Interactions Induced by Chronic Exposure to Diesel Exhaust

J. G. Domaaol¹, G. Merrihew¹, D. Lundblad¹, H. C. Dye¹, E. T. Scott¹, R. Gupta², A. Louie², M. Riffle¹, J. W. MacDonald¹, T. K. Bammler¹, M. J. MacCoss¹, M. T. Kleinman³, J. A. Araujo², and J. Marsillach¹. ¹University of Washington, Seattle, WA; ²University of California, Los Angeles, CA; and ³University of California, Irvine, CA.

Background and Purpose: Air pollution is one of the leading causes of mortality, contributing to about 6.7 million premature deaths annually. Diesel exhaust (DE) is a significant contributor to particulate matter (PM) in urban traffic-related air pollution, resulting in adverse respiratory, cardiovascular, and reproductive health effects. Research has suggested that PM can also affect the brain and central nervous system, triggering neurodegeneration. Microglia, the brain's resident immune cells, play a crucial role in regulating PM-induced toxicity. To protect the brain from damage, resting microglia are activated to eliminate foreign substances and dead cells, while initiating an inflammatory response. Though initially beneficial to maintain homeostasis and repair damage, prolonged exposure to PM can cause microglia to promote a pro-inflammatory environment due to oxidative stress and cell death, leading to disease escalation. While there is increasing research to uncover how PM impacts neurodegeneration, the specific molecular mechanisms are not well understood. The purpose of this project was to conduct a morphological assessment of the hippocampal region of the brain to distinguish possible microglial change using immunohistochemistry (IHC) and to use proteomics to characterize any possible changes in underlying mechanisms due to exposure in the hippocampus and olfactory bulb. **Methods:** This study examined mechanisms of PM-induced neuroinflammation and cognitive dysfunction, focusing on proteomics and microglia. Six-week-old low-density lipoprotein receptor knockout (Ldlr KO) mice were exposed to freshly-generated DE (~250 μ g/m³) or filtered air (FA) over 18 weeks. Mice (n=12 per sex and exposure) were fed a high-fat (HFD) or chow diet and exposed for 6 h/day, 5 days/week. At the end of 18 weeks, mice were sacrificed and perfused with PBS. The left brain hemispheres were fixed in paraformaldehyde, embedded in optimal cutting temperature compound, cryosectioned at 40 μ m, and used in immunohistochemistry (IHC). Hippocampus and olfactory bulb were isolated from right brain hemispheres, flash frozen in liquid nitrogen, and then processed for proteomics and analyzed via data-independent acquisition liquid chromatography with tandem mass spectrometry (DIA LC-MS/MS). **Results:** Using IHC, microglia, cells expressing TMEM119 and IBA1, and infiltrating macrophages, cells with IBA1 expression without colocalization of TMEM119, were distinguished. Differences in the soma of microglia were identified between the male FA and male DE HFD groups, suggesting possible microgliosis due to DE exposure. Comparing the male chow FA and DE groups showed the least differences in microglial size. Protein analysis revealed significant changes (FDR<0.05) in protein abundance based on exposure (FA or DE), sex, and/or diet (HFD or chow). An initial pathway analysis of the hippocampus identified a dysregulated actin cytoskeleton and Fc gamma R-mediated phagocytosis in HFD DE males, both associated with cognitive decline. In the olfactory bulb, the pathway analysis also revealed impacts on the actin cytoskeleton and calcium signaling in HFD DE females, which are associated with neurodegeneration. **Conclusions:** Overall, this project demonstrates that diet and DE exposure affect microglia and related proteins, exacerbating neuroinflammation that may lead to neurodegeneration. Additional research is underway to understand microglial states and related sub-populations to clarify their role in neurodegenerative diseases.

PS 3486 Co-Exposure of 4th Generation E-Cigarette and Environmentally Persistent Free Radicals Impairs Lung Responses in Male Mice

Z. Myles¹, T. Cook², M. Schexnayder³, and A. Noel². ¹Southern University and A&M College, Baton Rouge, LA; ²Louisiana State University, Baton Rouge, LA; and ³IDEXX Laboratories, Westbrook, ME.

Background and Purpose: Fourth-generation electronic cigarette (EC) devices that use the novel formulation of nicotine, i.e., synthetic nicotine salt, may present distinct respiratory hazards due to its formulation. These novel e-liquid formulations raise concerns, particularly given the increasing popularity of such devices among young adults. While EC represents potential risks for pulmonary diseases, environmental sources of airborne toxicants such as particulate matter also contribute to inhalation exposures. Of interest is particulate matter containing environmentally persistent free radicals (EPFR(PM)) formed during the thermal remediation of hazardous waste at Superfund sites. EPFR(PM) has been shown to generate reactive oxygen species (ROS) that drive oxidative stress, which promote pulmonary dysfunction. Given the rising prevalence of EC and the omnipresence of air pollution, including PM, this study investigates the pulmonary consequences of co-exposure to EC aerosol and EPFR(PM). We hypothesized that co-exposure to EC aerosol and EPFR(PM) will synergistically exacerbate lung inflammation and oxidative stress. **Methods:** Male C57BL/6J mice (N=8 per group) were exposed to one of the following conditions: air; blue razz ice-flavored EC aerosol for 1.5 hours/day, 7 days/week for 7 weeks, at

a concentration of 0.32 mg/puff $\pm$ 0.1; EPFR(PM) aerosol, 4 hours/day for 5 days at a concentration of 0.34 mg/m³ $\pm$ 0.1; or a combination of EC aerosol (for 7 weeks) plus EPFR(PM) (during the last 5 days of the 7-week exposure). Exposure concentrations were determined gravimetrically, and real-time exposure concentrations were monitored using a DustTrak II. EC aerosol particle size distribution was measured using a scanning mobility particle sizer (SMPS). At the end of the study, lung function was assessed using whole-body plethysmography and the flexiVent system. Bronchoalveolar lavage fluid (BALF) was collected for cytology analysis. Lung tissue samples were collected for histopathological assessment and for gene expression analysis via PCR, for genes associated with biotransformation, inflammation, oxidative stress, airway remodeling, barrier integrity, and lipid metabolism. **Results:** SMPS data revealed that blue razz ice-flavored EC aerosol had a geometric mean of 143 nm for its particle size distribution. Exposure to this EC aerosol temporarily altered lung function at two weeks, with increased minute volume compared to the air group (83.1 $\pm$ 12.8 vs 66.8 $\pm$ 11.1 mL/min, respectively) followed by recovery, and at 7 weeks, an upward shift in the pressure-volume loop (p <0.05 vs. air). These changes suggest an early transient effect on minute volume and an obstructive pulmonary disease phenotype at 7 weeks. While no BALF inflammation was noted, transcriptomic analysis revealed upregulation of 11 genes following EC exposure: *Mmp9* (4.8-fold), *Mmp12* (2.1-fold), *Col4a1* (2.0-fold), *Ahr* (1.6-fold), *Cyp1a1* (2.9-fold), *Cyp26a1* (1.8-fold), *Hmox1* (1.5-fold), *Il-1 β* (4.3-fold), *Ifn- γ* (1.5-fold), *Tnf* (1.6-fold), and *Cxcl5* (11.9-fold). These dysregulated genes are supportive of the EC aerosol exposure impairing signaling pathways associated with airway remodeling, biotransformation, oxidative stress, and inflammatory responses. In contrast, at the molecular level, EPFR(PM) up-regulated 7 genes: *Mmp9* (6.2-fold), *Cyp1a1* (23-fold), *Cyp1b1* (10-fold), *Nqo1* (2.49-fold), *Il-1 β* (2.7-fold), *Occludin* (1.5-fold), *Sp-d* (1.6-fold). These results are consistent with the known pro-oxidant properties of EPFRs. Regarding the co-exposure group, EC+EPFR(PM) upregulated 5 genes: *Cy1a1* (58.9-fold), *Cyp1b1* (8.6-fold), *Aldh3a1* (1.7-fold), *Nqo1* (1.9-fold), and *Cxcl5* (2.2-fold). Notably, *Cy1a1* showed a synergistic induction, suggesting enhanced activity of lung detoxification pathways following concomitant exposures to both inhaled toxicants. **Conclusions:** These findings reveal distinct lung molecular profiles and underscore the importance of assessing co-exposures in inhalation toxicology. Also, our study highlights the need for studies that account for further investigation into the long-term health effects of emerging nicotine formulations.

PS 3487 Neurotoxic consequences of chronic exposure to concentrated ambient fine and ultrafine matter in a novel mouse model of late-onset Alzheimer's disease

J. P. Vu, S. Lim, H. Hsu, M. M. Ortega, Y. Yumiketa, H. Su, R. Kim, A. Farias, I. Hasen, A. Ting, D. Herman, K. Sumikawa, M. T. Kleinman, and M. Kitazawa. University of California Irvine, Irvine, CA.

Background and Purpose: Chronic exposure to ambient particulate matter (PM) is increasingly recognized as a modifiable environmental risk factor for Alzheimer's disease (AD). Epidemiological studies link long-term exposure to fine and ultrafine PM (PM_{2.5} and UFP) with cognitive decline and amyloid pathology, but mechanistic evidence remains limited by the use of overexpression transgenic models that do not recapitulate late-onset Alzheimer's Disease (LOAD). This study addresses that gap by evaluating the neurotoxic consequences of prolonged exposure to environmentally relevant levels of concentrated ambient PM in the humanized amyloid- β knock-in (hA β -KI) mouse, a model that exhibits gradual accumulation of soluble A β , synaptic dysfunction, and age-dependent cognitive impairment. We hypothesize that chronic PM exposure accelerates early synaptic and glial alterations that precede overt plaque deposition in LOAD. **Methods:** Male and female hA β -KI and wild-type littermates were exposed to filtered air or concentrated ambient fine and ultrafine PM for 7 or 13 months using the Versatile Aerosol Concentration Enrichment System (VACES) to simulate long-term exposure. Following exposure, cognition was assessed via object recognition and location memory tasks. Hippocampal long-term potentiation (LTP) was evaluated electrophysiologically to assess synaptic plasticity. Post-mortem analyses included immunohistochemistry such as homer-1 and bassoon staining to quantify post- and presynaptic integrity. Glial activation was characterized using Iba1, GFAP, Clec7a, and C3 immunolabeling. High-resolution confocal microscopy and hyperspectral imaging (CytoViva Imaging Core) were used to assess refractive particle deposition in multiple brain regions. Data were analyzed using two-way ANOVA to evaluate genotype-by-exposure interactions. **Results:** Chronic PM exposure produced age- and genotype-dependent synaptic impairment in hA β -KI mice. After 7 months, LTP amplitude was modestly reduced in hA β -KI mice compared with air-exposed controls, while wild-type animals remained unaffected. After 13 months, PM-exposed hA β -KI mice exhibited a significant 25-30% reduction in LTP magnitude relative to air controls (p < 0.001), indicating cumulative synaptic dysfunction. Behavioral testing revealed corresponding trends toward impaired recognition memory. Immunohistochemical analyses showed increased Iba1-positive microglial density and morphological activation in the hippocampal CA1 and dentate gyrus of PM-exposed hA β -KI mice, along with elevated Clec7a and C3 expression, consistent with a shift toward a neurotoxic glial phenotype. Preliminary Homer-1 and Bassoon staining demonstrated reduced synaptic puncta density, while hyperspectral imaging revealed elevated particle deposition in PM-exposed olfactory bulbs of the hA β -KI mouse cohort. **Conclusions:** Chronic exposure to fine and ultrafine particulate matter accelerates synaptic dysfunction and microglial activation in a physiologically relevant late-onset AD model. These findings support the hypothesis

that air pollution promotes early neurodegenerative processes through maladaptive glial responses and oxidative stress preceding plaque pathology. The integration of synaptic marker analysis and hyperspectral imaging provides mechanistic insight into PM-induced neurotoxicity and positions the hA β -KI mouse as a translational platform for assessing environmental contributions to Alzheimer's disease.

PS 3488 Vascular endothelial dysfunction induced after exposure to environmentally persistent free radicals is mediated by the release of miRNA from the air-blood interface

R. A. Morales, A. Noël, and T. R. Dugas. Louisiana State University, Baton Rouge, LA.

Background and Purpose: Particulate matter containing environmentally persistent free radicals (EPFRs) is produced when Superfund wastes are thermally remediated. EPFRs form when organic pollutants are incompletely combusted and adsorb onto the surface of particles containing redox-active metals. Previous studies in mice showed that EPFRs reduce vascular function downstream of the lung. However, this effect was abolished in mice lacking the aryl hydrocarbon receptor (AhR) in alveolar type II (AT-II) cells, which form the air-blood interface in the lung and promote the systemic release of miRNAs. We hypothesize that at the air-blood interface, EPFRs alter the miRNA profile released into the plasma, which, in turn, alters the expression of genes essential for controlling function in peripheral lung vessels. **Methods:** To test our hypothesis, we isolated and cultured mouse AT-II cells at the air-liquid interface (ALI) and exposed them to aerosolized EPFRs (~30 μ g/cm²) using a Vitrocell exposure system. At 24 h after ALI exposure, the basal medium was collected, filtered, and then exposed to commercially sourced murine lung microvascular endothelial cells (mLMVEC). The expression and activation of vascular eNOS, as well as NO production, were then measured. **Results:** Compared to vehicle, activation of the AhR was observed in AT-II cells exposed to EPFRs, evidenced by increased *Ahr*, *Cyp1a1*, and *CYP1b1* mRNA levels. Activation of AT-II-AhR resulted in a decreased release of miR-1906 and miR-542-3p into the basal medium. In mLMVEC exposed to conditioned medium, we observed reduced nitric oxide levels, decreased *Nos3* and *Pik3r2* mRNA expression, and increased *Edn1*. **Conclusions:** Our findings suggest that miRNAs released into basal medium after EPFRs exposure of AT-II cells grown at the ALI regulate endothelial cell gene expression required for maintaining vascular homeostasis, including genes that regulate eNOS expression/function. These findings aid in our evaluation of human health risks of EPFR exposure and could offer an intervention to help communities address the health impacts of EPFRs.

PS 3489 Sex differences in the innate immune response to woodsmoke protect the lung function of female mice

M. G. Miller, M. Buford, B. Postma, A. Holian, and C. Migliaccio. University of Montana, Missoula, MT.

Background and Purpose: With the increased prevalence of wildfires, understanding long-term health effects of exposure to the smoke is of obvious importance. In both a community exposure study and murine model, delayed decreases in lung function following woodsmoke (WS) exposure were observed, with a greater lung function decline observed in males. Sex differences were likewise observed in alveolar macrophage (AM) functions and phenotype that suggest a tissue remodeling phenotype in males. **Methods:** Mice or murine cells were exposed to WS in our facility. Additionally, female mice were treated with fulvestrant, an estrogen receptor antagonist, to elucidate the observed sex bias. Lung function was measured and *ex vivo* lung tissues samples were assessed for oxidative stress, inflammatory response, and markers of epithelial mesenchymal transition (EMT). **Results:** While fulvestrant treatment did not result in WS-induced changes to lung function, *ex vivo* AM studies showed increased TNF- α levels for male and fulvestrant-treated female mice in response to WS. qPCR analysis of AMs revealed a higher basal NRF2 activation level in females and early markers of EMT in the lung tissue of males. *In vitro* studies showed sex-specific effects on macrophage inflammatory responses including key cytokines IL-33, IL-6, TNF- α and IL-1 β as well as heightened NRF2 activation in response to WS. **Conclusions:** These studies contribute to defining the mechanism of sex as a biological variable on WS-induced adverse health effects. The results suggest that a higher basal level of redox scavengers in the female lung have a protective effect and EMT is attributable to the decrease in lung function observed in males. While fulvestrant treatment did not impact lung function, it did modulate the inflammatory response to WS. This suggests a more temporal or developmental effect of estrogen in the response to WS between AM and parenchyma.

T. Fukuyama¹, C. Ohira¹, K. Tomita², Y. Ota², K. Yano², M. Amano², M. Kaneki¹, A. Yamada³, R. Usui³, Y. Nagai³, M. Nagane¹, and S. Takagi¹. ¹Azabu University, Kanagawa, Japan; ²Shimizu Corporation, Tokyo, Japan; and ³Fuji Industrial Co., Ltd., Kanagawa, Japan.

Background and Purpose: Indoor air quality is increasingly recognized as a key determinant of respiratory health. Among indoor pollutants, volatile organic compounds (VOCs) are of particular concern because they can induce oxidative stress, modulate immune responses, and disrupt the integrity of the airway epithelial barrier. Our previous studies demonstrated that even 0.1 ppm ozone—commonly regarded as a “safe” indoor level—can exacerbate lung injury and allergic inflammation in mice. VOCs are ubiquitous in indoor environments, yet their effects on vulnerable airways at “permissible” concentrations remain unclear. In this study, we investigated whether VOC removal could mitigate pulmonary disease in murine models of chronic allergic asthma and acute lung injury (ALI). **Methods:** Mice were housed under either normal indoor air or air filtered through activated carbon/HEPA chemical filters that reduced VOCs to near the detection limit. In the ALI model, mice received an intranasal instillation of 25 µg lipopolysaccharide (LPS) dissolved in 25 µL phosphate-buffered saline (PBS) 48 h before sacrifice. The allergic asthma model was sensitized intranasally with 25 µg of *Dermatophagoides farinae* (Der f) extract on days 1, 8, and 15, followed by intranasal challenges of 5 µg/day on days 21–23. Mice were euthanized 24 h after the final Der f administration. At the end of the experiment, the lung-draining lymph nodes, bronchoalveolar lavage fluid (BALF), and skin tissues were collected for immunological and histological analyses. **Results:** In both models, exposure to chemically filtered (CF) group significantly improved arterial oxygen saturation and alleviated histopathological lung injury. No significant immunological effects were observed in the ALI model mice. In the asthma model, the number of eosinophils in BALF was significantly lower in the CF group than in controls, indicating attenuated Th2-type airway inflammation. Both CD4⁺ T cells and IgE⁺ B cells in the pulmonary (hilar) lymph nodes were significantly decreased in CF group, accompanied by reduced levels of Th2-related cytokines and type 2 innate lymphoid cells (ILC2s). Notably, these beneficial effects were evident even when VOC concentrations in the control air were below current guideline limits. In the asthma model, combined exposure to VOC-reduced air and treatment with the histamine H1 receptor antagonist fexofenadine further suppressed inflammatory cell infiltration and histamine-induced neurohypersensitivity, demonstrating a synergistic effect between environmental and pharmacological interventions. **Conclusions:** To assess clinical relevance, total VOC concentrations were measured in five animal hospitals differing in building structures and ventilation conditions. Considerable variation was observed, ranging from below 50 µg/m³ in well-ventilated facilities to over 600 µg/m³ in small clinics. Solvent, detergent, and building material-derived chemicals were identified as the major VOC sources in high-concentration facilities. These levels were comparable to or exceeded those shown to aggravate lung pathology in mice. Collectively, our findings indicate that even “low-level” VOC exposure can amplify airway inflammation and impair therapeutic responsiveness. VOC removal not only attenuates disease severity but also enhances drug efficacy. These results highlight indoor air quality as a modifiable determinant of respiratory health and underscore the importance of active VOC management in indoor environments, including medical facilities.

3491 Characterization of combustion emissions from fossil-based vs bio-based plastics

A. Ranpara¹, W. T. Goldsmith¹, T. P. Batchelor¹, H. Leonard¹, V. Nguyen¹, D. Footz², and T. R. Nurkiewicz¹. ¹Department of Physiology, Pharmacology & Toxicology, Center for Inhalation Toxicology (iTOX), West Virginia University, Morgantown, WV; and ²Nexx Innovations, Windsor, ON, Canada.

Background and Purpose: Waste disposal through open-air combustion (OAC) at military burn pit and under-resourced healthcare systems emit complex aerosols. Inhalation exposure to particles and chemicals in these complex aerosols is linked with acute and chronic health effects. Annually, over 1 trillion single-use medical devices made of fossil-based plastics - polypropylene (PP) and polyvinyl chloride (PVC) are disposed in OAC. Bio-based alternatives like polylactic acid (PLA) have been reported to be safer but a lack of comprehensive studies comparing their combustion emissions has been a critical knowledge gap. To address this gap, this study focused on identifying toxicants and their respective amounts. OAC is a dynamic process that loops between material heating, smoldering, and flaming to emit diverse particles and chemicals. Our objectives were to: 1) evaluate chemicals when heating PVC and PLA at different temperatures, 2) combust PVC and PLA and characterize the emitted particles and chemicals in real-time and off-line, and 3) compare respective emissions. **Methods:** The WVU iTOX has established a novel surrogate combustion generator that produces emissions and mimics real-world inhalation exposures with commercial wood-pellets (CWPs). CWPs were fed at 6 gms/min (range: 1–100) to begin and sustain combustion. Three boluses of 10 gms PVC or PLA were added at 10 mins intervals during three trials. Emissions were sampled from the stove flue placed in line between the generator and the exhaust. Combustion emissions were characterized in real-time and off-line for particles (size distribution, and concentrations) and gases (total and speciation) including head-

space analysis with gas chromatography mass spectrometry (GCMS: µg/m³). The number of chemicals was evaluated qualitatively by heating 1 gm of material at 80 °C and 120 °C in GCMS and compared using the NIST library. Primary combustion gases [carbon mono- (CO) and dioxide (CO₂)], and hydrogen cyanide (HCN) in parts per millions (PPM) were analyzed using Fourier transform infrared spectroscopy (FTIR). Total volatiles (PPM) were measured using a photoionization detector. Total particle mass (mg/m³) and number (#/cc) were determined by gravimetric measurements with 37 mm laminated polytetrafluoroethylene filters with a 0.45 µm pore size and a condensation particle counter (CPC), respectively. Particle size distribution (PSD) was reported using an electric low-pressure impactor by count median diameter (CMD: nm) ± geometric standard deviation (GSD). **Results:** Heating at 80 °C and 120 °C released a greater number of chemicals from PVC (38 chemicals) than PLA (1 chemical: Dioxane). Combustion temperature (°C) for PLA (309.1 ± 16.7) and PVC (307.9 ± 26.8) were similar. PLA emitted ~ 8-fold less total aerosol mass (mg/m³: 11.9 ± 0.9 vs 94.1 ± 0.8) and ~ 2-fold less volatiles (PPM: 5.9 ± 0.5 vs 10.5 ± 1.0) than PVC. However, CPC measurements revealed similar total particles from combustion emissions with PLA vs PVC (#/cc: 1.4E7 ± 1.7E5 vs 1.4E7 ± 4.8E5); ~ 3-fold more deviations with PVC. The emissions from both PVC or PLA with the CWPs resulted in respirable particles (<10 µm) with polydisperse PSD (GSD>1.5). Directly after the bolus of material was fed for combustion (0–2 mins), the PSD emitted from the CWPs + PVC was larger (CMD: 129 nm ± 1.98) than the CWPs + PLA (CMD: 48.5 nm ± 1.80). FTIR (PPM) measured 12,034 ± 5000 CO₂, 292 ± 238 CO, and 3.5 ± 1.5 HCN in PVC compared to PLA: 11,435 ± 4828 CO₂, 186 ± 169 CO, and 0.7 ± 0.6 HCN. GCMS analyzed (µg/m³) higher vinyl chloride (1492 ± 57.2), formaldehyde (219 ± 3.4), acenaphthylene (1501 ± 37.1), benzene (558 ± 29.6), furan (2205 ± 56.9), and phenol (1312 ± 20.6) than in PLA. However, emissions from PLA resulted in higher ethane (1407 ± 71.5), and decane (1456 ± 256.7) than in PVC. Chemicals/derivatives identified by GCMS are human carcinogens/possibly carcinogenic as per the IARC. **Conclusions:** Whether heating or combusting, bio-based PLA emits fewer toxicants (qualitatively + quantitatively) than fossil-based plastic PVC. Future studies will include PLA from different sources and other commonly used plastics PP. These assessments will allow categorization by rank order of the materials based on their toxic potentials and to develop mixtures that scale least-to-worst emissions from OAC. **Funding:** NIH P20-GM103434, U54-GM104942, R21-ES034942 (TRN), T32 ES032920 (TRN, VTN)

3492 Open-air combustion emissions simulation and characterization of various wood species and synthetic materials

W. T. Goldsmith¹, A. Ranpara¹, T. Batchelor¹, H. Leonard¹, V. Nguyen¹, R. Burns², J. Schuler², D. Kalafut³, M. Wilson³, C. Choo³, D. Harper⁴, D. Footz⁵, and T. Nurkiewicz¹. ¹Center for Inhalation Toxicology (iTOX), West Virginia University, Morgantown, WV; ²School of Natural Resources and the Environment, West Virginia University, Morgantown, WV; ³Underwriters Laboratories Research Institutes' Chemical Insights, Marietta, GA; ⁴Center for Renewable Carbon, University of Tennessee, Knoxville, TN; and ⁵NEXE Innovations, Windsor, ON, Canada.

Background and Purpose: Open-air combustion (OAC) is prevalent in many parts of the world that lack adequate waste management infrastructure, and during one-off events, such as wildfires. Unlike modern incineration, OAC typically occurs at lower temperatures where smoldering can occur. The resulting incomplete combustion emissions significantly add to air pollution and promote the formation of toxic chemicals which pose significant risks to human health and the environment. To better understand these emissions and to study their health effects, it is important to recreate the OAC process in a laboratory setting. Because of the dynamic process of combustion and the myriad of items burned in OACs, this can be challenging to adequately replicate and analyze. Extensive chemical and aerosol measurements of the emissions are needed to comprehend the dangers present from the various constituents of an OAC. The objective of this study was to utilize our custom combustion emissions generator to simulate and characterize OACs that occur in various settings such as military burn pits, wildfires, wildland-urban interface fires or during waste disposal of plastic materials, such as those used to fabricate medical supplies. **Methods:** The WVU iTOX surrogate combustion generator was developed to burn custom pellets made from wood sawdust + synthetic materials of interest. Wood types used in the pellets included: 1) red oak, 2) loblolly pine, 3) Douglas fir, and 4) ponderosa pine. Synthetic materials included 1) rubber, 2) acrylic, 3) oriented strand board (OSB), 4) foam board insulation (FB), 5) vinyl flooring (VF), 6) polyvinyl chloride (PVC), and 7) polylactic acid (PLA). Pellets were fed into the combustion generator at 6 g/min and combusted with an airflow rate of 12 LPM. Sampling was conducted from the exhaust flue of the generator and measurements included: 1) total aerosol mass concentration (TAMC), 2) particle size distribution (PSD) reported in terms of count median diameter (CMD), and 3) gas chromatography-mass spectrometry (GC-MS) for speciation and concentration levels of specific chemicals. **Results:** All wood types and synthetics were successfully combusted, and their emissions were analyzed. Wood-species-only pellets produced TAMCs in the range of (17–49 mg/m³) with lower CMDs (37–54 nm). Chemicals released included formaldehyde (318–1229 µg/m³) and acetaldehyde (102–373 µg/m³). Some synthetics produced additional larger particles which increased the CMDs of the PDS and TAMC, respectively. Some notable examples include PVC (129 nm, 94 mg/m³) and VF (69 nm, 119 mg/m³). Additionally, the synthetics added high levels of toxic chemicals to the emissions (presented as: chemical, highest concentration in µg/m³). These included OSB (acrolein, 923), FB (styrene, 241), VF (bromochloro-

methane, 315), rubber+acrylic (methyl-methacrylate, 56), PVC (vinyl chloride, 1492). **Conclusions:** The combustion of wood pellets resulted in fairly similar emissions across the wood species. This included aerosols with smaller (nano-size) PSDs with relatively lower TAMCs. Chemicals released in the emissions included formaldehyde and acetaldehyde. As synthetics were added, larger particles increased the CMDs of the PSDs and, in some cases, increased the TAMC significantly. Additional chemicals and much higher concentrations of potentially harmful toxicants were released in the synthetic emissions. This included chemicals such as styrene, methyl-methacrylate, vinyl chloride, and others which have been classified as human carcinogens/possibly carcinogenic by the International Agency for Research on Cancer. **Support:** NIH P20-GM103434, U54-GM104942, R21-ES034942 (TRN), T32 ES032920 (TRN, VTN), UL Research Institutes

PS 3493 High-throughput toxicity assessment of ambient particulate matter enabled by a microfluidic cellular exposure platform

A. Kaehr, M. Moe, H. Lu, and N. Ng. Georgia Institute of Technology, Atlanta, GA.

Background and Purpose: Particulate matter (PM) exposure is a top environmental risk factor affecting public health and is associated with both acute respiratory and chronic lung disease. PM exposure is linked to oxidative stress, inducing downstream inflammatory response and cell damage. Ambient PM is chemically complex and physically diverse, and the mechanisms of aerosol damage depend on the chemical composition. Thus, there is a need to screen a wide range of aerosol compounds for their toxicity. However, traditional 96-well plate-based assays are low-throughput and hard to implement in large-scale screens due to their time and resource intensiveness. In this study, we utilize microfluidics to develop a high-throughput platform with a 10-fold reduction in sample and reagent requirements. We use this platform to assess the impact of ambient PM samples on murine alveolar macrophage cells, an *in vitro* model of immune response in the lungs upon PM exposure. **Methods:** We designed a microfluidic platform with sixteen individual microfluidic devices for unique dose response experiments. All devices have continuous perfusion, driven simply by gravity, enabling equipment-free cell loading and PM delivery. Each device has an upstream mixing module that allows for the automatic dilution of the PM solution into eight different doses. Downstream of the mixing modules, hundreds of cells are compartmentalized for accurate detection and temporal monitoring. As the precise dilution is device specific, each device is calibrated with a fluorescent dye to estimate the delivered dose. We recorded cellular activity in all devices through automated timelapse imaging on an imaging plate reader. We simultaneously measured three cellular responses, including intracellular reactive oxygen species (ROS), mitochondrial membrane potential (MMP), and cell death. For ROS and MMP, we used fluorescent probes H2-DCFDA and TMRE, respectively. For cell death, we trained a neural network [Shappell bioRxiv 2025] for identifying single cells and classifying them as live or dead in a label-free manner from brightfield images. Ambient filter samples were collected during 2017-2018 at the Jefferson Street site in Atlanta. This sampling site has been extensively used in characterizing urban Atlanta air quality [Xu PNAS 2014]. The water-soluble parts of the PM samples were extracted into cell media for exposure to cells in the microfluidic devices [Gao ACP 2020]. **Results:** Caspase 3/7 apoptosis reporter was used as the ground truth fluorescent label to help train the neural network. The classification model was trained on hundreds of annotations with nearly equal amounts of live and dead (killed by H2O2) cells making up the training set. The model was also tested on hundreds of annotations of similar quality but different images from those used for training. The resulting model performance approached 90% precision and 80% recall. We validated the performance of the model with a control experiment with 200 μ M H2O2 exposure while tracking Caspase response and dead cell count over time. We found that the increase in dead cell count aligned to the increase in dead cells until the entire population of cells was dead. Finally, we demonstrated the operation of the devices with exposure to ambient PM samples. ROS response and cell viability were dose-dependent, following sigmoidal trends. Intracellular ROS production activated 1-2 hours before the onset of cell death. Key metrics reported include area under the dose-response curve and activation threshold for ROS and TMRE as well as LC50 for cell death. **Conclusions:** This microfluidic platform is a rapid and cost-effective alternative to traditional well plate assays. Small assay volumes reduce the use of expensive probes and extensively characterized aerosol samples. Single cells monitoring of hundreds of cells exposed to the same experimental condition provides statistical power in detecting differences in cellular response and forgoes the need for large bulk cell culture. This new technology serves to increase the feasibility of cellular toxicity screening for predicting adverse health effects from PM exposure. Future work includes running a large-scale screen of a comprehensive set of ambient PM samples to study the impact chemical composition on cellular response and associated toxicity.

PS 3494 HEPA Filtration Modifies Pulmonary Responses to Episodic Eucalyptus Smoke Exposure in Male Long-Evans Rats

B. R. Yoo¹, C. N. Miller², J. A. Dye³, H. H. Nguyen¹, M. C. Schladweiler², M. L. Moore¹, P. Evansky³, M. Higuchi³, M. Monsees³, M. I. Gilmour³, and W. C. Williams³. ¹ORISE/US EPA, Research Triangle Park, NC; ²US EPA, Research Triangle Park, NC; and ³Retired, US EPA, Research Triangle Park, NC.

Background and Purpose: As wildland fires increase in frequency and severity, their threat to both human and ecosystem health grows. Epidemiological studies have shown associations between wildland fire smoke inhalation and increased hospitalizations for cardiorespiratory-related health effects. Smoke from wildland fires is a complex mixture made up of two distinct chemical phases, gas and particulate. The gas phase is primarily comprised of carbon monoxide, carbon dioxide, nitrogen oxides, and a variety of other volatile organic compounds. The particle phase is made up of suspended carbonaceous particulates, with the primary concern for health effects being fine particulate matter (PM_{2.5}). Understanding the contribution of each phase to pulmonary toxicity provides critical information that can be used to inform effective solutions to better protect human health from wildland fire smoke exposure. As such, the purpose of the current study was to characterize the toxicity of HEPA filtered smoke, in comparison to whole smoke in a rodent model. **Methods:** 12-week-old male Long-Evans rats were exposed to filtered air, whole eucalyptus smoke (3.52 mg/m³ PM), or HEPA filtered smoke (0.2 mg/m³ PM) for 1 hour per day for 4 consecutive days, followed by a 3-day break, then 3 more consecutive days (7 days total across a ~2-week period). Ventilatory function was assessed using whole body plethysmography (WBP) on exposure days 1, 4, 8, and 10, both 0- and 2-hours post-exposure. Bronchoalveolar lavage fluid (BALF) was collected for analysis of lung injury, immune cell differentials, and cytokines. RNA from lung tissue was sequenced to evaluate changes in response to smoke exposure. **Results:** Immediately following exposure, WBP revealed an overall decrease in breathing frequency for the whole smoke group ($p < 0.05$). Exposure to filtered smoke had the opposite effect, increasing breathing frequency ($p < 0.05$). Expiratory time was increased overall due to whole smoke exposure ($p < 0.05$), while the filtered group experienced an overall decrease ($p < 0.05$). 2-hours post-exposure, tidal volume was increased due to whole smoke exposure ($p < 0.05$), while exposure to filtered smoke resulted in an overall decrease in tidal volume ($p < 0.05$). A significant reduction in BALF n-acetyl-glycosaminidase, a marker for macrophage activation, was detected following exposure to both whole and filtered smoke ($p < 0.01$). Furthermore, exposure to filtered smoke reduced neutrophils in the BALF ($p < 0.05$) for the filtered group only. This was consistent with reductions in some of the inflammatory cytokines measured, namely IL13 ($p < 0.01$) and KC/GRO ($p = 0.05$). Such effects were not present in BALF from rats exposed to whole smoke. A limited number of differentially expressed genes were detected between the whole smoke- and air-exposed lung tissue ($n = 2$). However, 69 differentially expressed genes were detected in the lungs of rats exposed to filtered smoke, compared to air-exposed controls. These included fatty acid binding protein 1 (FABP1), FXRD domain-containing ion transport regulator 5 (FXRD5), as well as high mobility group box 2 (HMGB2), all of which have been associated with lung disease or injury. **Conclusions:** This data demonstrates exposure to filtered eucalyptus smoke results in worsened pulmonary outcomes when compared to whole smoke from both a molecular and physiological standpoint. However, further study is needed to understand the dynamic relationship between the gaseous and particle phases that drive adverse health effects. (This abstract does not necessarily reflect US EPA policy.)

PS 3495 Predicting Mixture Toxicity of Volatile Organic Compounds in Air-Liquid Interface Cultures Using a Component Based Approach

O. C. Lampe, E. C. Vitucci, C. L. Cannon, W. A. Chiu, and N. M. Johnson. Texas A&M, College Station, TX.

Background and Purpose: Volatile organic compounds (VOCs) are a persistent air pollutants in both indoor and outdoor environments. There are limited studies on the respiratory effects of most VOCs, and even less knowledge on how VOC mixtures affect the lung epithelium. **Methods:** Human bronchial epithelial (16HBE) cells cultured at the air liquid interface were exposed to four gases commonly detected following environmental disasters: acrolein, acetone, acetaldehyde, and formic acid. After an acute 2-hour exposure to occupationally-relevant doses of an individual VOC or our designed VOC mixture, each with matched, filtered air control, cells were allowed to recover for 24 hours before being harvested for further analysis. Media was collected for a cytotoxicity assay. Cell lysate was collected to evaluate gene expression using Taqman qPCR, and live cells were used to conduct barrier permeability assays. Additionally, benchmark concentration (BMC) modeling was conducted for all endpoints where a significant effect was observed to compare derived points of departure (PODs) to predicted PODs using a component-based approach. **Results:** Individual VOCs, acrolein, acetone, and formic acid all induced the release of lactate dehydrogenase (LDH), indicative of cytotoxicity, and decreased barrier integrity as shown by increased FITC-Dextran permeability. Acetaldehyde did not appear to affect the viability or barrier function of 16HBE cells. Genes that were consistently upregulated between VOCs were the pro-inflammatory cytokines *IL-6*, *IL-8*, and *TNF α* . However, acetaldehyde was an exception to this trend. *IL-6* and *IL-8* were significantly downregulated, and *TNF α* showed no significant change in expression compared to the filtered air controls. Concentration-response modeling was employed to predict

the effective concentration of the VOC mixture that would induce a 10% change in viability and barrier permeability in exposed lung epithelial cells. This approach led to a prediction that a 10% change in barrier permeability would be observed in cells exposed to 1326 ppb of the VOC mixture, and a 10% change in cytotoxicity would be observed in cells exposed to 1419 ppb of that same mixture. However, following data collection of the actual VOC-mixture exposed cells, the BMC modeling proved to be a conservative prediction. The toxicity of the mixture was slightly over-predicted for each endpoint as visualized with a potency ratio (actual BMC/predicted BMC). The potency ratio for barrier permeability was 1.04, and the potency ratio for cytotoxicity was 1.13. **Conclusions:** While both endpoints resulted in a ratio close to 1, barrier permeability appeared to be the most suitable endpoint for conducting BMC modeling when investigating this set of VOCs. These findings demonstrate that acute exposure to select VOCs can disrupt epithelial integrity and induce cytotoxicity and inflammatory signaling in bronchial epithelial cells, with acrolein, acetone, and formic acid exerting the greatest effects. The component-based approach provided a conservative yet accurate prediction of mixture toxicity, supporting its utility for estimating mixture effects in the absence of direct experimental data.

PS 3496 Effects of exposure to Canadian wildfire particulate matter on airway reactivity, mucus production, and inflammation in advanced *in vitro* and *ex vivo* models.

L. Bazina¹, G. M. Deloid¹, J. Jude¹, T. Bruggemann², M. Rahman², R. Panettieri¹, B. Levy², Y. Tesfaigzi¹, and P. Demokritou¹. ¹Rutgers University, New Brunswick, NJ; and ²BWH, Cambridge, MA.

Background and Purpose: Wildfires have been rapidly increasing in both frequency and intensity over the last four decades due to climate change, and are expected to continue to escalate. In the US each year, over 63,000 wildfires burn an average of 7 million acres of land. Exposures to wildfire smoke has adverse impacts on respiratory, cardiovascular, and other diseases, but their specific mechanistic effects remain unknown. In June 2023, smoke from wildfires in Quebec drifted into the US east coast, resulting in a 3-day event with PM_{2.5} (particulate matter ≤ 2.5 μm) at concentrations > 700 μg/m³, from NYC to central NJ. During this event, we deployed instruments to collect real-time and time-integrated data on PM and gaseous co-pollutants, and to collect size fractionated PM for offline physico-chemical characterization and toxicological assessment. In this study we sought to investigate (1) the impact and mechanisms of PM-induced effects on human small airways; (2) the potential activation of the SPDEF promoter (which regulates airway mucus production) by PM exposure; and (3) the effect of PM exposure on the lung inflammatory response to an allergen. **Methods:** The PM_{0.1} (≤ 0.1 μm) fraction of the collected Canadian wildfire PM (WFPM_{0.1}) collected during the June 2024 event were employed in these studies. To assess effects of WFPM_{0.1} exposure on small airways, precision-cut human lung slices (hPCLS) prepared from human lung donors were treated with WFPM_{0.1} for 24 hours, followed by measurement of carbachol-induced bronchoconstriction, isoproterenol-induced bronchodilation, and expression of selected alarmin gene expression levels. Assessment of SPDEF activation by WFPM_{0.1} exposure was performed in HEK293 cells stably transfected with an SPDEF promoter-luciferase construct. The cells were exposed to WFPM_{0.1} for 6, 24, or 48 hours, and luciferase was measured in cell lysate supernatants. To assess the effects of WFPM_{0.1} exposure on lung inflammatory responses, mice were sensitized intranasally with the house dust mite (HDM) allergen, followed by intratracheal instillation with WFPM_{0.1}, and bronchoalveolar lavage (BAL) fluid was collected for phenotyping after 24 hours. **Results:** In the hPCLS model, WFPM_{0.1} increased CCh-induced bronchoconstriction, following 24 h treatment, with little effect on isoproterenol-induced bronchodilation. In addition, WFPM_{0.1} exposure increased the expression of IL-33 and CYP1A1 transcripts in hPCLS following 24 h exposure. In SPDEF promoter-luciferase expressing HEK293 cells, exposure to WFPM_{0.1} for 6 or 24h resulted in a dose-dependent significant increase in SPDEF promoter activity. In mice pre-sensitized with HDM allergen, tracheal instillation of WFPM_{0.1} significantly augmented the inflammatory response in the lung, as indicated by significantly greater numbers of total leukocytes, eosinophils, macrophages, neutrophils, and lymphocytes in BAL fluid. **Conclusions:** Collectively, our findings indicate that (1) Exposure to WFPM_{0.1} increases bronchomotor tone by increasing agonist-induced bronchoconstriction in human small airways, and increases expression of the 'alarmin' cytokine IL-33 (released in response to cell damage), and of CYP1A1, a key xenobiotic metabolism enzyme; (2) Exposure to WFPM_{0.1} increases activation of the SPDEF promoter (which induces differentiation of airway goblet cells and promotes mucus production), suggesting that exposure to WFPM_{0.1} could increase airway mucus production via this mechanism; and (3) *In vivo* exposure to WFPM_{0.1} can greatly exacerbate inflammation in the lung.

PS 3497 Quantitative Assessment of Indoor Asbestos Fiber Resuspension: Comparing Theoretical Predictions to Empirical Data

Q. Perry¹, B. Deckard¹, M. Stevens², G. Abele², and D. Paustenbach¹. ¹TRC Companies, Jackson, WY; and ²TRC Companies, Denver, CO.

Background and Purpose: For over six decades, regulatory agencies have asserted that asbestos is readily resuspended by indoor activities such as walking and sweeping. Numerous aerosol physicists have challenged this claim for the past 60 years, arguing that based on fundamental particle adhesion theory, resuspension is unlikely, particularly for biologically relevant fibers. Yet, the courts continue to be flooded with claims that asbestos fibers can be easily relaunched back into the air and deposition (Guth JH. 2018. Deposition of Joseph H. Guth, Ph.D. - Volume I. Dated August 27, 2018). Some experts have even indicated that a worker performing clean-up activities such as sweeping with a broom or cleaning with an air hose could receive a much higher concentration of fibers than the original worker who performed the hands-on work with a product that released those fibers (Guth JH. 2018. Deposition of Joseph H. Guth, Ph.D. - Volume II. Dated August 28, 2018). **Methods:** For two types of simulations (walking and sweeping), two grams of pure chrysotile asbestos were distributed over a 3 meter by 3 meter (3 m × 3 m) square area. Wipe sampling before each simulation discovered fiber surface loadings of 2.91 × 10¹¹ and 2.56 × 10¹¹ fibers for the walking and sweeping trials, respectively. Airborne fibers were sampled on the lapels of the volunteer (to represent personal samples) and around the grid (to represent area samples). These samples were characterized across a spectrum of widths and lengths, including fibers as short as 0.5 μm and up to 74 μm, with a range of aspect ratios. Particular attention was given to OSHA-classified fibers (≥5 μm in length: ≥3:1 aspect ratio). **Results:** Despite the presence of nearly 300 billion fibers on the floor surface, only about 100,000 were resuspended into the air. Asbestos fibers, especially those in the size range of concern from a health risk perspective (OSHA-classified fibers), were also not easily resuspended. Roughly four OSHA-classified fibers were resuspended per 10,000,000 originally deposited when walking was performed and roughly one OSHA-classified fiber was resuspended per 1,000,000 originally deposited when sweeping was performed. **Conclusions:** Ultimately, fiber resuspension observed in both walking and sweeping scenarios was minimal or de minimis, even under the study's considerable fiber-loaded floor. This is one of the only studies validating theoretical predictions that small structures/fibers cling tenaciously to flat surfaces—a phenomenon also observed during studies of the World Trade Center. The proportion of resuspended structures greater than 5 μm in length (fibers) was significantly less during walking and sweeping trials than initially deposited. This was predicted, as 5 μm fibers have greater surface areas for contact with the adhesive surface compared to smaller non-OSHA fibers (e.g., <5 μm). This supports the theory that the surface area-to-volume (SA-V) ratio dictates adhesion effectiveness. Typical fiber loadings on floors due to the vast majority of historical (pre-1985) industrial environments are expected to be significantly less than what was used in this study. Consequently, the resulting airborne concentrations and corresponding health risks from the historical scenarios seen would ultimately be *de minimis*.

PS 3498 Sex-Dependent Effects of Chronic Traffic-Related Air Pollution Exposure on Pulmonary Macrophage Polarization and Neuronal Atrophy

H. Park¹, M. Cheng¹, A. E. Valenzuela¹, M. C. Domanico², J. Manzano², A. Ikeda¹, B. A. Martinez-Sammons², K. J. Bein^{3,2}, A. S. Wexler^{3,4}, L. S. Van Winkle^{2,5}, and P. J. Lein^{1,3}. ¹Molecular Biosciences, University of California, Davis, Davis, CA; ²Center for Health and the Environment, University of California, Davis, Davis, CA; ³Air Quality Research Center, University of California, Davis, Davis, CA; ⁴Mechanical and Aerospace Engineering, University of California, Davis, Davis, CA; and ⁵Anatomy, Physiology and Cell Biology, University of California, Davis, Davis, CA.

Background and Purpose: Air pollution is a known risk factor not only for respiratory diseases but also neurodegenerative diseases, such as Alzheimer's disease (AD). Clinical studies linking respiratory disease and cognitive deficits have prompted animal studies to investigate mechanisms connecting traffic-related air pollution (TRAP) effects on the lung and brain. One prevailing hypothesis is that inflammatory mediators originating in the lung reach the brain via the systemic circulation where they exacerbate neuroinflammation and neurodegeneration. To test this, we assessed pulmonary inflammation, neuroinflammation, and neuronal atrophy, and compared these changes with pulmonary and plasma levels of TGFβ, a key mediator in fibrogenesis and neuroinflammation, in TgF344-AD rats that overexpress human AD risk genes following chronic exposure to TRAP. We further examined the relative contribution of particulate matter (PM) vs. gases to TRAP effects. **Methods:** Leveraging the Caldecott Tunnel Exposure Facility, female and male TgF344-AD rats were exposed to emissions drawn from a highway tunnel and delivered to animals in real-time for 11 months (M) starting at 1M of age. Animals were exposed to TRAP fractionated into gas, PM, or gas+PM from either light- and heavy-duty vehicles (LDV+HDV) or LDV only. Controls housed in the same vivarium were exposed to filtered air (FA). When exposures were completed, animals were transported back to UC Davis to collect brain, lung, and plasma. Quantitative immunohistochemistry (qIHC) was performed on fixed left lung lobes and brain hemispheres. Lung sections were immunostained for macrophages (CD68), profibrotic macrophages (CD206), and pro-inflammatory phenotype (iNOS), while hippocampal sections were stained

for homeostatic microglia (TMEM119), synaptic markers (MAP2, PSD95, synaptophysin), and tyrosine hydroxylase (TH) as a biomarker of adrenergic innervation. Since TGF β is a profibrotic cytokine, we correlated pulmonary TGF β 1,2 levels with counts of CD206 immunopositive cells using Pearson's correlation. Additionally, pulmonary TGF β was correlated with plasma TGF β . **Results:** After 11M of exposure, PM+Gas(LDV+HDV) significantly (p .adj<0.1) shifted alveolar macrophages towards a profibrotic phenotype in male lungs, evidenced as increased CD206⁺ cells. In contrast, PM+Gas(LDV) had the opposite effects, significantly reducing CD206⁺ cells in the male lung. While all TRAP exposures significantly increased TGF β -2 in male lungs, PM+Gas(LDV+HDV) showed the strongest correlation between TGF β level and CD206⁺ cell counts. However, TRAP effects on plasma TGF β showed inconsistent correlations with lung TGF β . TRAP did not significantly change macrophage phenotype or TGF β levels in females. Similarly, male-specific effects of TRAP were observed in the brain. LDV+HDV emissions reduced hippocampal TH innervation and excitatory synapses in the male hippocampus. Specifically, Gas(LDV+HDV) reduced TH area (p .adj=0.15) while PM(LDV+HDV) reduced excitatory synapses (p .adj<0.1). TRAP exposures did not affect homeostatic TMEM119 microglia; however, disease-associated microglia remain to be analyzed. **Conclusions:** These results suggest sex-dependent effects of TRAP on pulmonary profibrotic macrophage polarization, TGF β , and hippocampal synaptic and noradrenergic atrophy. Because homeostatic balance of macrophages is critical for maintaining a healthy microenvironment in lung, divergent polarization of alveolar macrophages suggests distinct profiles of immune dysregulation occur with different vehicular exhausts. While these changes in the lung did not directly correlate or affect plasma TGF β or expression of homeostatic microglia at this timepoint, they were associated with synaptic and TH atrophy in the brain. Supported by the NIH (grant# R01 AG074709, T32 HL007013, T34 GM136469, P30 ES023513).

PS 3499 Limited PAHs exposure to ESCs leads to neurodevelopmental alterations in human brain organoids

B. Jeong, N. Sarodaya, K. Olesen, W. Kuenzinger, R. Dey, L. Li, H. Jin, and Y. Han. St.Jude Children's Research Hospital, Memphis, TN.

Background and Purpose: Polycyclic aromatic hydrocarbons (PAHs) are widespread environmental contaminants associated with adverse neurodevelopmental outcomes. However, their precise cellular and molecular effects in the human context remain poorly understood. This study aimed to investigate whether early and transient exposure to PAHs during the pluripotent stem cell stage could cause lasting alterations in brain organoid development. **Methods:** Human embryonic stem cells (hESCs) were transiently treated with benzo[a]pyrene (BaP) or phenanthrene (Phe) for one week during the ESC stage and subsequently differentiated into brain organoids. Morphological, immunohistochemical, and transcriptomic analyses were performed to assess structural and molecular changes induced by PAH exposure. **Results:** Limited PAH exposure did not affect hESC viability or proliferation but markedly disrupted later neurogenesis in the resulting brain organoids. Organoids generated from PAH-treated ESCs exhibited lasting morphological abnormalities, including smaller and fewer neural rosettes with ectopic neuronal protrusions. Immunostaining revealed that the early PAH exposure induced premature neurogenesis and depletion of the neuronal progenitor pool. Transcriptomic profiling of PAH-treated hESCs showed no significant global gene expression changes, suggesting that immediate transcriptional changes are unlikely to be the primary cause of the observed neurogenic defects. **Conclusions:** Transient early-life exposure to PAHs can program lasting defects in later brain development, underscoring the vulnerability of early developmental stages to environmental toxicants. Further analyses focusing on transcriptomic and epigenetic changes will be necessary to fully elucidate the underlying molecular mechanism.

PS 3500 Pathway-Based Assessment of PAH Mixture Toxicity Utilizing Benchmark Dose Modeling

M. L. Ramirez¹, V. C. Colvin¹, R. S. McClure², G. Many², K. M. Waters^{1,2}, and S. C. Tilton¹. ¹Oregon State University, Corvallis, OR; and ²Pacific Northwest National Laboratory, Richland, WA.

Background and Purpose: Polycyclic aromatic hydrocarbons (PAHs) are a large family of organic molecules composed of two or more benzene rings that are ubiquitous in the environment, associated with petrochemicals and burning of fossil fuels. PAHs identified from ambient air have been linked to adverse health effects, including lung cancer; however, little is known about how PAHs in mixtures contribute to toxicity in the lung. **Methods:** In this study, we broadly assess global genes and pathways by RNAseq from primary human bronchial cells cultured at the air-liquid interface (ALI-HBEC) after exposure to the PAH mixture (11-275 uM), which is derived from air sampling at a creosote site during wildfires, compared to two primary components, retene and benzo[b]fluorene (BBF), at equivalent concentrations. To identify the genes and pathways most sensitive after treatment with a PAH mixture compared to individual components, benchmark dose modeling was performed on transcriptional dose-response data with BMDExpress3 software. **Results:** Overall, a majority of genes differentially expressed (q <0.05) by retene and BBF at each concentration were not reflected by the mixture. Similarly, unique genes and path-

ways were identified at the threshold level between the mixture and components suggesting that the response of cells to PAH mixtures may not be a simple reflection of its components. **Conclusions:** These studies provide a global assessment of the mechanistic processes modified by PAHs in a dose-dependent manner and support our understanding for how PAHs contribute to toxicity of mixtures in lung cells.

PS 3501 Integrated Dosimetry Quantification for Aerosol Delivery at the Air-Liquid Interface in a Lung Cell Co-Culture System

T. Jefferis, D. Stevens, W. Su, and C. Sayes. Baylor University, Waco, TX.

Background and Purpose: Exposure to aerosolized environmental contaminants may elicit acute or chronic effects depending on the inhaled dose. Researchers frequently test the effects of aerosolized substances with *in vivo* animal models and *in vitro* lung cell models using a known potential dose; however, the applied or internal dose is often not reported. **Methods:** This work expands upon previous studies by developing laboratory experimental methods to measure U.S. EPA-relevant dose types: (1) potential dose, (2) applied dose, (3) internal dose, and (4) biological effect. A multiple-cell co-cultured human lung model using epithelial cells and macrophages was developed for aerosol exposure to occupationally relevant substances, namely, aluminum oxide nanoparticles. To control the initial dose, a dry particle generator was used for aerosol production of the particles. The resultant aerosol was characterized by particle size distribution and was collected on filter cassettes to determine potential dose via inductively coupled plasma-mass spectrometry (ICP-MS). The applied and internal doses were also determined by using ICP-MS to analyze samples of spent cell culture media and cell lysate. The biological effect is measured through orthogonal methods probing for multiple mechanisms of action. **Results:** The potential dose was demonstrated as significantly different from the applied and internal dose, with each being less than 4% of what was aerosolized. Therefore, this study shows that applied and internal doses are important and should be reported in toxicological studies. **Conclusions:** This work demonstrates methods for dosimetry data collection, which can then be included in human health risk assessments of aerosolized toxicants to increase understanding of uptake and subsequent toxicological effects.

PS 3502 Sex- and Fuel Type-Specific Effects of Wood Smoke Condensate Exposure in Primary Human Airway Epithelial Cells

M. J. Rodriguez¹, Y. Kim², and M. E. Rebuli¹. ¹University of North Carolina at Chapel Hill, Chapel Hill, NC; and ²U.S. Environmental Protection Agency, Research Triangle Park, NC.

Background and Purpose: Wildfire-derived particulate matter (PM) varies in toxicity by fuel source, and sex may be an important mediator in health outcomes from exposure. PM produced by wood burning is associated with reduced lung function and increased infection susceptibility which are potential markers for lung injury and has become a global concern due to escalating prevalence and severity of wildfires. Smoke from fuel types across the United States, such as red oak (eastern and central US), peat (peatlands/coastal, midwestern and southeastern US), ponderosa pine (western US), and eucalyptus (chaparral, southern California), have shown differential mutagenic and toxic effects in animal models, but effects by fuel type in human-derived models have not been investigated. Individual characteristics, such as sex, are also known to modulate the effects of biomass smoke exposure, though the mechanisms remain unclear. We aimed to fill these knowledge gaps by addressing the hypothesis that both fuel type and sex play a role in modulating respiratory health effects of smoke exposure using an *in vitro* model. **Methods:** Primary human bronchial epithelial cell (hBEC) cultures (n=4 Male, n=4 Female) were grown at air-liquid interface, and exposed apically to wood smoke condensates (WSCs) generated from red oak, peat, pine, and eucalyptus biomass at 5 μ g/cm² (low dose) and 25 μ g/cm² (high dose) for 4 hours. Apical washes, basolateral supernatants, and cell lysates were collected and analyzed for cytokine production via multiplex ELISA and transcriptional changes via RNA sequencing. **Results:** Across all WSCs, there was a consistent induction of IL-1 β and IL-8, while eucalyptus and peat exposures were uniquely associated with IL-2 induction. Pine and red oak exposures had unique IL-6, IL-12, and IL-13 induction. When analyzed by sex, male hBECs exhibited a consistent IL-1 β and IL-8 response across all WSCs and a unique IL-2 response to eucalyptus and peat WSCs. In contrast, female hBECs showed IL-8 induction specifically in response to eucalyptus and peat exposures. Overall, *in vitro* WSC exposure results in distinct inflammatory cytokine profiles based on fuel type and sex. Our RNA-seq analysis identified 202 differentially expressed genes (DEGs) across fuel types, with 51 DEGs overlapping between fuel types. Sex-specific analysis revealed 351 DEGs in male cultures and 108 DEGs in female cultures. Transcriptional pathway analysis utilizing GSEA and Hallmark MSigDB revealed upregulation of ROS production and fatty acid metabolism across all exposures, indicating cellular stress responses. Eucalyptus exposure downregulated protein secretion, while peat and red oak upregulated unfolded protein response, indicating endoplasmic reticulum stress. Downregulation of Notch signaling in both high dose pine and red oak exposures may reflect reduced cell proliferation and repair. Eucalyptus and pine exposure both led to upregulation of IL6/STAT3 signaling, while peat exposure caused upregulation of xenobiotic metabolism and cell proliferation. When disaggregated by sex, glycol-

ysis was downregulated only in female hBECs for eucalyptus and peat exposure, while G2M checkpoint was downregulated in females for eucalyptus and peat and in males for eucalyptus and pine. Estrogen response was downregulated in females following eucalyptus and peat exposure, while only downregulated in males for pine exposure. Androgen responses were downregulated for multiple exposures across both sexes. Oxidative phosphorylation had opposite directions of induction for pine exposures between male and female hBECs. **Conclusions:** This research has the potential to advance the field of toxicology by revealing new insights into individual susceptibility and potential geographical variations in the respiratory health effects of wildfire smoke exposure. Mechanistic insight into fuel type or sex-based susceptibility can provide a basis for personalized treatments and targets for mitigating the toxic effects of wildfire smoke.

PS 3503 Investigation of Cellular and Molecular Mechanisms of PFAS-Induced Lung Inflammation in a Human Alveolar Epithelial Cell Line

S. Macheri, A. Ashraf, and E. Bruce. Baylor University, Waco, TX.

Background and Purpose: Per- and polyfluorinated alkyl substances (PFAS) form a class of chemicals used in various commercial products, including non-stick cookware, firefighting foam, furniture, and waterproof clothing. These substances demand significant attention due to their environmental persistence and association with adverse health effects such as immune and thyroid problems, as well as liver, kidney, and pancreatic cancers. From a toxicology perspective, the inhalation of PFAS, particularly its impact on lung cells, remains notably understudied. While much focus has been on PFAS exposure through drinking water and food, emerging evidence indicates that inhalation—mainly occurring in workplaces and household dust—also plays a significant role in introducing PFAS into the human body. Despite existing research, a major knowledge gap persists in how PFAS causes lung toxicity at the cellular and molecular levels. This limits the development of effective prevention and treatment options for PFAS-related respiratory conditions. This study examines three key factors associated with cellular stress and inflammation: reactive oxygen species (ROS), hypoxia-inducible factor 1 alpha (HIF-1α), and the NOD-like receptor protein 3 (NLRP3) inflammasome. Human alveolar epithelial cells (A549) were exposed to PFAS compounds—perfluorooctane sulfonic acid (PFOS) and perfluorobutane sulfonate (PFBS), representing long-chain legacy and short-chain emerging PFAS. It is hypothesized that PFAS causes lung toxicity by increasing ROS, activating HIF-1α, and triggering the NLRP3 inflammasome, leading to inflammation and cell death. **Methods:** A549 cells were cultured in DMEM supplemented with 10% (v/v) FBS and 1% antibiotics at 37°C in a humidified incubator with 5% CO₂. PFOS and PFBS stock solutions were prepared in DMSO, maintaining a final DMSO concentration of 0.01% in the dosing solution, which is non-cytotoxic to A549 cells. The cytotoxicity of PFOS and PFBS was evaluated using an MTT assay after 24 hours of acute exposure at concentrations of 10, 25, 50, 100, 150, and 200 µg/mL. Following viability testing, reactive oxygen species generation was assessed with the DCFH-DA assay. HIF-1α and NLRP3 protein levels were measured via Western blotting, with protein bands quantified and analyzed using Image Lab software. To observe the stabilization of NLRP3 and HIF-1α in both the cytoplasm and nucleus at all concentrations, immunocytochemistry was performed. **Results:** The results showed an IC50 value of 179 µM for PFOS, and all tested concentrations of PFBS were non-cytotoxic to A549 cells; therefore, we only evaluated PFOS for subsequent downstream analyses and assays. PFOS caused a dose-dependent rise in ROS levels, shown by increased green fluorescence, indicating reactive oxygen species. Exposure to PFOS even at low, non-toxic concentrations (10, 50, 100, and 150 µM) caused a temporary increase in nuclear HIF-1α levels, which then decreased in a dose-dependent manner. PFOS exposure resulted in a dose-dependent increase in NLRP3 protein levels, as confirmed by Western blot analysis. Levels increased starting at 10 µM, peaked at 100 µM, and then slightly decreased at 150 µM, suggesting threshold-dependent activation. Immunocytochemistry revealed greater NLRP3 presence in the cytoplasm and around the nucleus. **Conclusions:** This study shows PFOS, even at non-cytotoxic levels, causes oxidative stress and inflammation in human alveolar cells. Increased ROS and HIF-1α stabilization suggest early involvement of oxidative and hypoxia pathways, likely triggering NLRP3 inflammasome activation, inflammation, and cell injury. PFBS showed minimal effects, indicating lower toxicity. Overall, the findings highlight the ROS-HIF-1α-NLRP3 signaling pathway as a key mechanism linking PFOS exposure to lung inflammation.

PS 3504 Maresin 1 Selectively Enhances Pro-reparative IL-22 Production in Alveolar Macrophages Following Organic Dust Exposure

E. O. Oyewole^{1,2}, K. Jones^{1,2}, C. McDermott^{1,2}, and T. M. Nordgren². ¹Colorado State University, Fort Collins, CO; and ²University of Nebraska Medical Center, Omaha, NE.

Background and Purpose: Occupational dust exposure is a significant health concern, driving the progression of chronic lung diseases such as asthma and COPD. Agricultural dust contains endotoxins and microbial components that activate innate immune pathways, leading to sustained inflammation. Recent evidence highlights the importance of specialized pro-resolving mediators (SPMs), derived from dietary omega-3 fatty acids, in counteracting dysregulated inflammatory responses. Notably,

Western diets are often characterized by an imbalanced omega-6 to omega-3 ratio, which may impair the biosynthesis and function of SPMs. Our laboratory has identified that alveolar macrophages are a source of the pro-reparative cytokine IL-22, which plays a protective role in response to dust-induced lung injury. The present study investigates the role of a specific class of SPMs, including maresins and their biosynthetic derivatives, in modulating IL-22 signaling in the context of organic dust exposure (ODE) *in vitro*. **Methods:** MH-S cells (immortalized murine alveolar macrophages) were pretreated for 1 hour with 1nM, 10nM or 100nM dose of Maresin 1 (MaR1), Maresin 2 (MaR2), or Maresin Conjugates in Tissue Regeneration (MCTR1, MCTR2, MCTR3) prior to exposure with 1% dust extract. Cytokine concentrations (IL-10, IL-22, TNF-α, and IL-6) were quantified using sandwich ELISA. Data were analyzed using two-way ANOVA with Tukey's post hoc test, with significance set at $p < 0.05$. **Results:** All SPMs tested led to a significant suppression of proinflammatory cytokines TNF-α and IL-6 in a dose dependent manner. However, MaR1 pretreatment uniquely enhanced IL-10 (MaR1 x organic dust effects, $p=0.0429$) and IL-22 (MaR1 x organic dust effects, $p=0.0368$) production, peaking at 10 nM following ODE, whereas MaR2 and MCTRs did not elicit a similar pro-reparative response. Instead, MCTRs induced a dose-dependent suppression of IL-22. These divergent outcomes suggest that while MaR1 and its other biosynthetic derivatives potentially reduce inflammation, MaR1 appears to selectively promotes anti-inflammatory and pro-reparative IL-10 and IL-22 signaling. **Conclusions:** Our findings highlight distinct functional roles among maresins and their conjugates in shaping alveolar macrophage responses to organic dust. The selective ability of MaR1 to augment IL-22 suggests a receptor-mediated mechanism, potentially through LGR6 activation. Given the critical role of IL-22 in protecting lung tissue from dust-induced injury, delineating the molecular crosstalk between SPMs and IL-22 signaling could inform novel therapeutic strategies. Future directions include extending these findings to mouse models and defining receptor-specific pathways linking dietary omega-3 metabolites to macrophage-driven lung repair.

PS 3505 Toxicity of diacetyl or 2,3-butanedione, a flavor enhancer, and its implications on aberrant bronchial epithelial repair

M. Malalage, J. Dunn, S. Macheri, and E. Bruce. Baylor University, Waco, TX.

Background and Purpose: Diacetyl or 2, 3 - butanedione is a widely used volatile chemical that is used to enhance different types of flavors in vape liquids. In the early 2000's, it is reported to cause the disease, obstructive bronchiolitis which is an irreversible fibrotic disease in populations of popcorn factory workers who were exposed to aerosolized diacetyl. However, the mechanisms of diacetyl toxicity remains poorly understood and explored. The purpose of the current study is to elucidate how diacetyl causes epithelial cell injury, and to evaluate the possible outcomes of long-term exposure to diacetyl. The current study hypothesizes that diacetyl exposure causes the stabilization of the alpha sub-unit of HIF-1 transcription factor, which is responsible for oxygen regulation in the cells, where it is hypothesized as an initial inflammatory response. While HIF-1 alpha gets stabilized under hypoxic conditions in the cells, several other factors such as cytokines (TNF-α and IL-1 beta) and reactive oxygen species (ROS) are reported in recent literature to stabilize the sub-unit. Furthermore, TGF-β is a regulator of cell repair in physiological repair after injury. However, in pathologic repair TGF-β could stimulate aberrant repair in cells through pathologic epithelial-to-mesenchymal transition, where epithelial markers get downregulated and mesenchymal markers get upregulated compromising the epithelial barrier. Moreover, due to continuous inflammation the epithelial cell layer would be in a constant state of repair leading to a compromised barrier. The overall objective is to understand how diacetyl alters the airway epithelium. **Methods:** 5 mM, 10 mM, and 15 mM concentrations were used to dose the immortalized bronchial epithelial cells (BEAS-2B) and 16-HBE cells in submerged culture for 2 or 1 hour respectively. DCFH-DA cellular ROS (reactive oxygen species) assay was used to evaluate the presence of general ROS in the cells after exposures. The fluorescence intensity was measured using Bio-Tek Lionheart instrument. HIF-1 alpha expression was evaluated using western blot. Primary antibody against HIF-1 alpha was used at 1:500 dilution and a secondary HRP antibody was used at 1:10,000 dilution. The membrane was visualized using Bio-Rad ChemiDoc MP imager. The images were quantified using Bio-Rad Image Lab software. The 16-HBE cell line was used for barrier integrity studies. The 16-HBE cells were dosed intermittently for one hour on day 1, 3 and 5. TEER (Trans epithelial electrical resistance) was measured using EVOM instrument. To quantify the expression of epithelial markers (ZO-1 and E-cadherin), and mesenchymal markers western blotting was used. Immunofluorescence studies were performed to visualize ZO-1 and E-cadherin localization in the cells. The cells were incubated with primary antibodies against ZO-1 and E-cadherin at 1:200 dilution. The secondary fluorochrome conjugated antibodies were used at 1:700 dilution. The cells were visualized with a confocal laser scanning microscope. The results were analyzed using GraphPad Prism 10.4.2. with ANOVA test together with Tukey HSD post-hoc test to get the group comparisons. The significance was set at $p < 0.05$. **Results:** The results for western blotting indicated that HIF-1 alpha expression increased up until 10 mM dose dependently. 5 mM and 10 mM concentration were statistically significant. However, 15 mM had a lower expression compared to other experimental concentrations but showed more expression compared to the untreated control. ROS were detected in the cells dose dependently. All three concentrations showed statistically significant increase in the generation of ROS. The TEER values for the dosed cells were lower compared to the untreated cell monolayers. The cells exposed to 15 mM concentration did not recover after

the dosing period. The expression of ZO-1 and E-cadherin proteins in the 16-HBE cells decreased dose dependently and were statistically significant compared to the untreated cells. **Conclusions:** HIF-1 alpha was observed to be stabilized under normal oxygen conditions possibly due to the presence of ROS in the cells due to diacetyl exposures. The barrier integrity of the 16-HBE cell monolayer was compromised as monitored through TEER values and ZO-1, E-cadherin and alpha-SMA, vimentin protein expression levels.

PS 3506 Deriving a Mixture of Combustible Materials in American Homes and Fire-prone Biomes to Elucidate the Toxicity of Wildland-Urban Interface Fires

C. K. Chou¹, A. L. Holder², S. Masood¹, A. Nored³, G. Walters¹, W. Bai¹, I. Pavlovic⁴, P. Tellez⁴, D. R. Weise⁵, J. Samet³, M. I. Gilmour³, Y. H. Kim², and J. E. Rager¹.

¹UNC Chapel Hill, Chapel Hill, NC; ²Office of Air Quality Planning and Standards, US EPA, Research Triangle Park, NC; ³Center for Public Health and Environmental Assessment, US EPA, Research Triangle Park, NC; ⁴US EPA Pacific Southwest, Region 9, Los Angeles, CA; and ⁵USDA Forest Service, Pacific Southwest Research Station, Riverside, CA.

Background and Purpose: Wildfires in the Wildland-Urban Interface (WUI) are an increasing concern, with approximately 33% of homes in the U.S. now located in the WUI and thus at elevated risk of burning during wildfires. WUI fires are unique as they emit a complex mixture of inorganic and organic compounds derived from the combustion of anthropogenic materials in addition to those produced by biomass-only wildland wildfires. A standardized fuel mixture is vital to characterizing exposure chemistries and toxicological impacts of WUI-relevant smoke exposures. **Methods:** We developed two novel mixtures representing WUI materials and a mixture of biomass common to California's plant biome. To develop the WUI mixture, we first integrated 61 combustible materials typically found in the average American WUI home, a 2,016 sq. ft. single-family home with four bedrooms and three occupants. Materials included structural, plumbing, wiring, paint, appliances, furniture, and furnishing materials. We found that the total combustible mass of an average American family home was around 46,500 kilograms, including 81% wood materials, 10% petroleum-based products (asphalt shingles), 6% plastics, and 2% metals. To develop the California biomass mixture, we identified the vegetation types and their proportions in the chaparral biome, which represents regions in California where some of the most destructive wildfires have occurred. The chaparral mixture consisted of 60% coastal sage, 30% chamise, and 10% eucalyptus. Each mixture was processed, homogenized, then burned in a lab-scale furnace system to generate WUI and chaparral smoke condensates from smoldering and flaming combustion conditions. The smoke condensates were then evaluated for toxicity in primary human airway epithelial cells cultured at air-liquid interface in 12-well plates. In the initial dose response experiment, 250 μ L of smoldering WUI smoke condensate was applied as an aqueous dilution to the apical compartment for four-hours at concentrations of 1, 3, 10, and 30 μ g/cm² for three donors, following which cytotoxicity and changes in cellular mRNA expression were evaluated. **Results:** Initial gene-specific RT-qPCR indicated that IL-6 mRNA release was significantly increased at a dose of 30 μ g/cm² of WUI condensate. Notably, cellular transcriptional responses occurred in the absence of cytotoxicity. Subsequent studies treated 12 donors to 3 and 30 μ g/cm² doses of smoldering WUI or chaparral condensates for four hours, and results suggest that 30 μ g/cm² doses of WUI or chaparral condensates decrease cell barrier integrity across all donors when compared to vehicle and lower doses. Next steps being pursued include analysis of transcriptomic, proteomic, and lipidomic signatures to inform more global disruptions in cellular biology resulting from WUI fires, including interleukin and immune response signaling changes. Chemical and particle characterization of the mixture condensates are also in progress. **Conclusions:** Treatment of airway epithelium cells with WUI condensates induced changes in interleukin release, suggesting potential modulation of immune pathways, which is an effect that will be further evaluated across multiple -omics endpoints. Collectively, the WUI and chaparral biome fuels can serve as standardized fuel mixtures representing WUI fires that can be used to investigate chemical and mechanistic determinants to health effects of exposure to smoke and to inform future risk assessment and regulatory efforts that will protect our communities. (This abstract does not reflect EPA policy.)

PS 3507 A Novel *in vitro* Toxicity Assay for Predicting Inhalation Toxicity in Rats

M. Gi, A. Vachiraarunwong, M. Fujioka, Y. Kawamura, A. Kakehashi, H. Wanibuchi, and S. Suzuki. Osaka Metropolitan University Graduate School of Medicine, Osaka, Japan.

Background and Purpose: The development of alternative *in vitro* methods for assessing acute inhalation toxicity is a critical step toward reducing animal testing and aligns with the principles of the 3Rs (replacement, reduction, and refinement). This study aimed to develop and optimize a neutral red uptake (NRU) assay using human lung adenocarcinoma cells (A549) as a predictive model (A549-NRU assay) for evaluating acute inhalation toxicity. **Methods:** The assay was improved by introducing two key modifications: (1) reducing the incubation time to 15 minutes

to enable rapid and high-throughput screening, and (2) using glass 6-well plates for chemicals reactive with polystyrene to prevent chemical-induced degradation and ensure assay consistency. LC₅₀ values were determined for 49 chemicals and compared with reported LC₅₀ values from 4-hour rat inhalation studies. Correlations between A549-NRU LC₅₀ values and physicochemical parameters (molecular weight, octanol-water partition coefficients) were also analyzed. **Results:** A significant positive correlation was observed between A549-NRU-derived LC₅₀ values and *in vivo* LC₅₀ values for water-soluble compounds and chemicals containing aldehyde, ketone, alcohol, ether, and epoxide functional groups, suggesting predictive potential. In contrast, A549-NRU LC₅₀ values showed significant negative correlations with molecular weight and octanol-water partition coefficients, indicating lower cytotoxicity for larger or more lipophilic compounds. The A549-NRU assay demonstrated a stronger correlation with *in vivo* LC₅₀ values than the conventional NRU assay using mouse 3T3 fibroblast cells. **Conclusions:** The optimized A549-NRU assay provides a rapid, reliable, and human cell-based *in vitro* method for assessing acute inhalation toxicity. It can be applied to estimate starting doses for *in vivo* studies and holds promise as an alternative approach to predict acute inhalation toxicity without animal testing.

PS 3508 A Modular Smoke Exposure Platform for *In Vitro* Modeling of Burn Pit Emissions

J. E. Blackburn, W. Crowe, K. Luthy, A. Atala, and S. V. Murphy. Wake Forest University, Winston-Salem, NC.

Background and Purpose: Inhalation exposure to open-air burn pits presents serious health risks, particularly for military personnel deployed in affected regions. Many veterans exposed to toxic smoke from these pits continue to suffer from persistent and often unexplained health problems. A clearer understanding of the mechanisms linking burn pit exposure to long-term illness is essential for preventing future health impacts and for developing effective treatments for those already affected. In alignment with the FDA Modernization Act 2.0 and the growing emphasis on human-relevant, non-animal models, we developed a real-time smoke exposure system tailored for exposing airway organ tissue equivalents (OTEs) matured at an air-liquid interface. **Methods:** We engineered a modular burn chamber capable of generating controlled combustion profiles that replicate real-world burn pit emissions. The materials used represent those most burned in a burn pit, which include plastic, cardboard, and wood, combusted at both smoldering and flaming phases. Real-time monitoring of carbon monoxide, carbon dioxide, particle size distribution, temperature, and humidity was achieved using integrated sensors. Smoke from each burn material and burn phase was chemically characterized for polycyclic aromatic hydrocarbons (PAHs) and volatile organic compounds (VOCs). Human airway OTEs were exposed at the air-liquid interface, enabling direct interaction with both gas and particle-phase constituents. Post-exposure, tissues were assessed for biochemical and functional toxicity markers. **Results:** The exposure system successfully delivered reproducible smoke profiles with tunable combustion conditions that matched burn conditions from real-world burn pits. Sensor data confirmed dynamic shifts in particulate and gas-phase composition across burn phases. Airway OTEs tolerated the exposure protocol and exhibited measurable changes in barrier integrity and oxidative stress markers. Preliminary data suggest phase-dependent toxicity signatures and material response differences in airway OTEs. **Conclusions:** This novel exposure platform enables physiologically relevant modeling of burn pit smoke inhalation *in vitro*. By integrating real-time combustion analytics with human airway tissue models, we provide a scalable and reproducible system for toxicological assessment. This approach supports the transition toward non-animal testing strategies and enhances our ability to evaluate complex airborne exposures with translational relevance.

PS 3509 Using computational fluid dynamics to estimate the efficiency of dosing by varying the respiration rate and tidal volume of the rat and changing the position of the rat snout using an inhalation directed flow chamber

S. Moore. Labcorp, Huntingdon, United Kingdom.

Background and Purpose: • Inhalation administration is a common dose route used in nonclinical development for delivering drugs to the lungs. The standard approach is to evaluate drug safety in both rodent and non-rodent species. • With the continued use of both New Chemical Entities (NCEs) and biopharmaceuticals, rats continue to be the rodent species of choice. • The standard method for delivering the aerosol to rats is using a snout-only inhalation chamber called a direct flow chamber. During the exposure period, the rats are restrained in plastic clear restraint tubes. • Consistent dosing is pivotal in supporting effective study conduct and data interpretation to draw accurate conclusions about the safety of the test article, however, it is known that animals, like humans, have varying respiration rates and tidal volumes • In this study, Labcorp wanted to establish whether varying the breathing respiration rates and tidal volumes and changing the position of the rat compared to the end of the aerosol chamber delivery tube contributed towards the greater level of animal-to-animal dose variability that is observed with the inhalation compared to other routes of administration like oral or intravenous. • This poster presents new data and expansion of the next stage of the initial data published at SOT 2025 (Moore S, Using

computational fluid dynamics to estimate the efficiency of delivery by changing the position of the rat snout and airflow received using an inhalation directed flow chamber, Society of Toxicology, 2025). **Methods:** • Labcorp designed a computational fluid dynamics (CFD) model of a rat head including the snout using 3d scanning software. Details of the 3d scanning methodology have been presented previously (Ford T and Moore S, Development of using 3D scanning, 3D printing and computer modelling techniques to improve inhalation systems, Association of Inhalation Toxicologist, 2024). • The dimensions of the inhalation chamber and standard restraint tube were measured and incorporated into the model. • Five different combinations of respiration rate and tidal volume were chosen to encompass the full range of potential options based on internal rat data • Five positions were evaluated - 1mm from the end of the tube, 10mm from the end of the tube and 5mm to the side, 5mm up and 5mm down. • A fixed airflow rate per port of 0.94 L/min was chosen to ensure a direct comparison across conditions. **Results:** • The highest % delivery efficiency for the CFD model across all head tube positions was with a respiration rate of 190 breaths/min and tidal volume of 1.9 mL with values between 31.8% and 35.5%. • The lowest % delivery efficiency for the CFD model across all head tube positions was with a respiration rate of 110 breaths/min and tidal volume of 1.2 mL with values of 12.9% and 14.2%. • The sequence of the delivery efficiency appears to correlate directly with the respiratory tidal volume. • In all 5 cases, the delivery position of 1mm away from the end of the delivery tube, then 10mm away, then 5mm to the side, 5mm when the position was upwards then finally when the snout position was angled 5mm downwards. **Conclusions:** • In conclusion, the CFD data suggests that the larger the respiratory tidal volume of the animal, the rat will receive a higher delivery efficiency and thus dose • This research is important in assessing the impact on study integrity and data interpretation.

PS 3510 Evaluating Chemical and Clinical Spaces: The Bifunctional Reactivity of Respiratory Sensitizers in Comparison to Skin Sensitizers and Non-Sensitizing Irritants

N. Sadekar¹, J. Muldoon¹, D. Botelho¹, A. M. Bowden², C. Ryan³, and F. Gerberick⁴.
¹Research Institute for Fragrance Materials, Mahwah, NJ; ²Unilever Safety, Environmental & Regulatory Science, Colworth Science Park, Sharnbrook, United Kingdom; ³ToxTech Solutions, Milan, IN; and ⁴GF3 Consultancy, Olde West Chester, OH.

Background and Purpose: Respiratory sensitization is a complex condition characterized by a spectrum of clinical symptoms, ranging from mild rhinitis to severe, debilitating asthma. In contrast to skin sensitizers, the chemical space of low molecular weight respiratory sensitizers is minimal, largely dominated by diisocyanate and anhydride functional groups. Currently, no validated methods exist that are specific to the detection of respiratory sensitizers. Although the proposed adverse outcome pathway (AOP) for respiratory sensitization shares similarities with that of skin sensitization, it has been hypothesized that the mechanisms of chemical reactivity involved in hapten formation, identified as the first key event, differ between respiratory and skin sensitizers. In this study, eighteen chemicals (including non-fragrance skin sensitizers, fragrance skin sensitizers, respiratory sensitizers, and non-sensitizing irritants) were reviewed for existing clinical case summaries, evaluated for chemical reactivity mechanisms, and analyzed using the TIMES (Tissue Metabolism Simulator) *in silico* model to predict their metabolic transformations. The goal was to identify differences in chemical reactivity mechanisms, compare metabolic processes in the skin and lung environments, assess their impact on sensitization potential, and align these findings with clinical observations to distinguish between skin sensitizers, respiratory sensitizers, and non-sensitizing irritants. **Methods:** Existing reviews summarizing clinical data on selected eighteen chemicals were evaluated to document clinical cases of skin sensitization and respiratory sensitization. These chemicals were also examined for predicting chemical reactivity mechanisms and metabolic transformations using the TIMES software. Two models were applied: 1. *In vivo*, non-kinetic skin sensitization with autooxidation2. *In vitro*, lung metabolism Both models predicted the most probable metabolic pathways and the relative quantity of metabolites. **Results:** A review of clinical case summaries for the eighteen chemicals revealed that patients with skin sensitization symptoms from skin sensitizers did not exhibit concurrent respiratory issues. Similarly, workers occupationally sensitized to respiratory sensitizers did not exhibit simultaneous skin sensitization. No clinical cases for either skin sensitization or respiratory sensitization were reported from exposure to non-sensitizing irritants. These observations do not take into consideration the patients' medical history of skin or respiratory allergies. The TIMES *in silico* evaluation showed that strong skin sensitizers, included in this study, interacted directly with skin proteins. Prohaptens, such as piperazine (a respiratory sensitizer), require metabolic activation to a reactive metabolite, with a higher probability of formation in the lung model than in the skin model. Non-sensitizing irritants (alcohols, amines, and carboxylic acids) showed high affinity for Phase II conjugation and excretion. The common structural feature of respiratory sensitizers, in this training set, was that they were bifunctional electrophiles. Compounds with highly reactive functional groups—such as diisocyanates, anhydrides, and bisaldehydes—are recognized as respiratory sensitizers, likely due in part to their strong protein crosslinking capacity, which leads to neoantigen formation. **Conclusions:** Observations from chemical space evaluations and clinical case reviews highlight the bi-functional specificity within lung tissue and the importance of lung-specific immune cells in characterizing the AOP for respiratory sensitization. The *in silico* simulations had two key limitations: (1) the skin sensitization model

was trained on a substantially larger dataset (1,405 chemicals) compared to the lung model (150 chemicals), and (2) the skin model was developed using historical *in vivo* data, whereas the lung model relied on *in vitro* data. These observations provide a foundation for developing new approach methodologies (NAMs) for respiratory sensitization assays.

PS 3511 Indole-3-Carbinol Reprograms Endothelial and Immune Cell Dynamics to Suppress SEB-Induced Inflammation: A Single-Cell RNA Velocity and Pathway Modeling Study

A. Marudamuthu, S. Thada, M. Palrasu, H. FNU, P. Nagarkatti, and M. Nagarkatti. University of South Carolina, Columbia, SC.

Background and Purpose: Indole-3-carbinol (I3C), a naturally occurring phytochemical derived from cruciferous vegetables, has demonstrated anti-inflammatory and immunomodulatory properties. However, its effects on cellular transcriptional dynamics and signaling pathways during toxin-induced lung inflammation remain unclear. Staphylococcal enterotoxin B (SEB), a potent superantigen, induces acute lung injury through hyperactivation of immune and vascular pathways. This study applied single-cell RNA velocity analysis integrated with PROGENy pathway modeling to define the cell-type-specific mechanisms by which I3C mitigates SEB-induced immunopathology. **Methods:** Single-cell transcriptomic data from SEB-challenged mouse lungs were analyzed across 18 major cell clusters representing immune, endothelial, and stromal lineages. RNA velocity metrics (length and confidence) and delta-velocity differentials were computed for SEB+Veh, and SEB+I3C groups. PROGENy-based signaling pathway scoring was used to infer downstream transcriptional activity changes across clusters. **Results:** I3C markedly reprogrammed transcriptional dynamics in Endothelial Cell 2 (EC2) and CD4⁺ T-cell populations. In SEB+Veh, pro-inflammatory and stress-related genes (Stk40, Tmem147, Pde3a, Il7r) were elevated, while I3C treatment upregulated regulatory and structural genes (Cav1, Itga2, Xab2, Tox). Pathway modeling revealed heightened NFκB, TNFα, and JAK-STAT signaling under SEB+Veh, contrasted by increased TGFβ, PI3K, and p53 pathway activity following I3C intervention. **Conclusions:** These findings demonstrate that I3C mitigates SEB-induced inflammation by reprogramming endothelial and immune cell transcriptional trajectories and shifting signaling balance from pro-inflammatory toward regulatory networks. This integrative single-cell systems approach highlights I3C's therapeutic potential as a molecular modulator of immune and vascular toxicities induced by bacterial superantigens. (Supported in part by NIH grants R01ES030144, P30GM154631, P20GM103641 and R01AI160896).

PS 3512 Development and Validation of a Human Pluripotent Stem Cell-derived Multicellular Alveolar Model for Toxicity Assessment and Disease Modeling

C. Hua^{1,2}, C. Ma¹, J. Zhao², P. Shang¹, X. Li², and F. Xie¹. ¹Zhengzhou Tobacco Research Institute of CNTC, Zhengzhou, China; and ²Beijing Life Science Academy, Beijing, China. Sponsor: R. Meng

Background and Purpose: The growing demand for reliable *in vitro* models for inhalation toxicity testing and respiratory systems research has driven the development of platforms that can accurately mimic the complex human alveolar microenvironment. This study aimed to develop a alveolar model with multicellular composition and pathological response capabilities. **Methods:** Human induced pluripotent stem cells (hiPSCs) were differentiated into alveolar cultures at the air-liquid interface (ALI) using a multi-stage directed differentiation protocol. The differentiation process and cellular composition were systematically characterized by immunofluorescence staining and RT-PCR. Fibrosis was induced by stimulation with 10 ng/mL TGF-β1. Epithelial barrier function was assessed by measuring transepithelial electrical resistance (TEER), and the expression of pro-fibrotic genes (ACTA2, COL1A1, FN1) was quantified by qPCR. Pharmacological response was evaluated using the anti-fibrotic drug nintedanib. **Results:** The results demonstrate the successful establishment of an alveolar model containing multiple key cell types, including alveolar epithelial cells (pro-SPC⁺, PDPN⁺), mesenchymal fibroblasts (PDGFRα⁺), and immune cells (CD68⁺). TGF-β1 treatment effectively induced epithelial barrier dysfunction and significantly upregulated the expression of pro-fibrotic genes. Furthermore, the model showed the expected pharmacological response to nintedanib, as evidenced by a significant inhibition of fibrotic marker expression. **Conclusions:** These findings highlight the model's potential for application in compound screening, pulmonary toxicity assessment, and research into the mechanisms of pulmonary fibrosis.

PS 3513 Toxicity after exposure to inhaled amorphous Silicon Dioxide Nanoparticles in Golden Syrian Hamsters

R. P. Renda, and J. M. Cerreta. St. John's University, Queens, NY.

Background and Purpose: Amorphous SiO₂ NPs are abundant in occupational settings, often used in food, cosmetics, and paint as fillers and anti-caking agents. Such particles are not as commonly studied when compared to their crystalline coun-

terpart. Amorphous SiO₂ NPs are pulmonary toxicants; however, the mechanism of toxicity is uncertain. **Methods:** In the current study, toxicity was assessed using an *in vivo* system, where Golden Syrian Hamsters were exposed by inhalation to different concentrations of amorphous SiO₂ NPs nanoparticles in a full body exposure chamber to determine a possible mechanism of cell death. Animals were divided into 4 groups: 1-room air control, 2-vehicle control, exposure to aerosolized water, 3-low concentration (6 mg/m³), and 4- high concentration (12 mg/m³). Concentrations were selected based on NIOSH's Time Weighted Average (TWA). Vehicle control exposed to distilled H₂O and treatment groups exposed to SiO₂ NPs were treated for 4 hours a day for 8 consecutive days. **Results:** Histopathological analysis found a significant increase in air space quantified by Mean Linear Intercept. The Mean Linear Intercept in the low and high concentration treated groups were increased by 1.9-fold and 1.7-fold respectively, when compared to controls. A TUNEL Assay found a significant increase in TUNEL positive cells in the high concentration group by 6.1-fold when compared to controls. SEM and TEM found structural alterations to the lung tissues including increase in the number of holes in alveolar walls, thinning of the alveolar septum and apoptotic bodies within tissue. Apoptosis markers Caspases 3 and 8 were significantly increased in the high concentration groups by 1.4-fold compared to controls. Cellular inflammation markers TNF- α and HSP70 were measured. TNF- α had a 1.5-fold increase in the high concentration treated group compared to controls and HSP70 was significantly increased by 7.5-fold in the high concentration treatment group compared to controls. **Conclusions:** Results of the study indicate exposure to SiO₂ NPs may induce an extrinsic apoptotic pathway, leading to tissue damage and significant airspace enlargement.

PS 3514 Increased living temperature alters the cardiopulmonary response of male and female mice to benzene-toluene-ethylbenzene-xylene (BTEX)

S. C. Toler¹, M. Fyle¹, L. Klein², M. Vaziri², B. Yoo², A. Lewis², C. Davis², W. Oshiro³, P. Evansky³, I. Gilmour³, A. Farraj³, and M. Hazari³. ¹University of North Carolina, Chapel Hill, Chapel Hill, NC; ²Oak Ridge Institute for Science and Education, Oak Ridge, TN; and ³Public Health and Integrated Toxicology Division, Center for Public Health and Environmental Assessment, U.S. Environmental Protection Agency, Research Triangle Park, NC.

Background and Purpose: Benzene, toluene, ethylbenzene, and xylene (BTEX) compounds are ubiquitous in the environment, originating from both natural and anthropogenic sources. Despite the broad presence of BTEX in the environment, extensive use of petroleum products and improper maintenance of underground storage tanks (USTs) have increased the risk of exposure to these compounds. Hazardous substances stored in USTs, like BTEX, may leak into groundwater, soil, and buildings and homes over time. Furthermore, higher temperatures exacerbate the release of VOCs. Therefore, the purpose of this study was to characterize the cardiopulmonary effects of inhaled BTEX in female and male C57BL/6J mice and assess the role of living temperature. **Methods:** Eight-week-old mice were housed at normal temperature (NT - 22°C) or high temperature (HT - 32°C) for five weeks. Mice were then exposed to either filtered air (FA) or BTEX (316ppm, nose-only) for four hours per day for two consecutive days. Ventilatory function was assessed via whole-body plethysmography (WBP) a week before and immediately after the first exposure. High-frequency echocardiography (HF-echo) was performed the week prior to exposure and again immediately following the second exposure. WBP and HF-echo measurements were compared from pre- to post-exposure. **Results:** When compared to NT, HT significantly increased tidal volume (TV), peak expiratory flow (PEF) peak inspiratory flow (PIF), and relaxation time (RT), and decreased enhanced pause (Penh) in female and male mice. BTEX increased frequency (f) and decreased expiratory and inspiratory times (Te and Ti, respectively) as well as Penh in female NT mice but had no effect on male NT mice. At HT, BTEX significantly decreased f and Penh and increased TV, Te, Ti, and RT in female mice, and only increased TV, PEF, PIF in males. Thus, the impact of HT and BTEX on female mice appeared to be greater than on males. Female HT-FA mice had a significant decrease in heart rate (HR) compared to NT, while BTEX caused an increase. On the other hand, male FA mice experienced an increase in HR at HT. No significant differences in cardiac output, stroke volume, fractional shortening, ejection fraction, end systolic volume, or end diastolic volume were observed between the groups. **Conclusions:** These results indicate that higher living temperature alters cardiopulmonary function in female and male mice in a differential manner. Although breathing changes seem to be largely driven by temperature, it is worth noting that HT might influence the inhaled BTEX dose, and, potentially, increase risk. Long-term exposure assessments are needed to clarify these effects further. (This abstract does not reflect EPA policy.)

PS 3515 A Low-Cost, Versatile Cigarette-Style Combustion Generator: System Development and Validation in Mice Acutely Exposed to Simulated Military Burn Pit Emissions

D. A. Herman, A. Jimenez-Chavez, E. J. Rangel, I. Hasen, A. Ting, A. De Vizcaya Ruiz, and M. T. Kleinman. University of California, Irvine, Irvine, CA.

Background and Purpose: Military personnel and civilians face increasing exposure to combustion emissions from military burn pits and wildfires, yet physiological impacts on cardiopulmonary systems remain incompletely characterized. Traditional combustion exposure systems are complex, expensive, lack versatility, and require specialized infrastructure, limiting controlled studies. We developed a novel, low-cost simulation military burn pit (MBP) exposure system utilizing cigarette-style fuel rods as standardized, reproducible combustion sources usable with conventional cigarette smoking machines. This study established and validated the system to perform acute inhalation exposure and measured immediate cardiopulmonary responses to controlled MBP emission exposure in mice. **Methods:** The MBP fuel mixture composition was based on reported U.S. military base solid waste data: plastics (27wt%), cardboard (49wt%), wood (24wt%). Materials underwent cryogenic mechanical grinding to achieve a relatively uniform size 'shredded' material which was blended, weighed and rolled into standard combustion rods using commercial rolling papers. Prior to ignition, a small amount of diesel fuel (DF2; 10wt%) was added. MBP emissions were drawn into a mixing chamber and diluted with purified air before passing through a rodent nose-only exposure/sampling manifold. All real-time measurements and sample collections occurred at the animal breathing zone. Particle size distribution, mass concentration, and CO were measured using a controlled puff duration and frequency. Metal, total organic and inorganic carbon, and select PAH concentrations were also measured in the collected samples. An acute inhalation study was conducted using male C57BL/6 mice (n=4-5 per group) exposed to either purified air or freshly generated MBP emissions (15 mg/m³) using a nose-only exposure system for 2 hours/day over 3 consecutive days. Respiratory parameters and blood pressure were measured post-final exposure using whole-body plethysmography and non-invasive tail cuff systems. **Results:** The system generated consistent, reproducible MBP emissions with controlled particle characteristics. Particle size, mass, and CO concentrations increased with puff frequency/duration. Combustion achieved 53% total organic carbon efficiency; average particle size (Dp) 0.050-0.30 μ m. MBP exposure significantly altered respiratory mechanics and cardiovascular function versus controls. Enhanced pause (Penh) decreased significantly while peak inspiratory/ expiratory flows (PIF/PEF) increased. Expiratory time (Te) reduced in exposed mice, indicating faster breathing cycles. Systolic blood pressure increased significantly; diastolic showed non-significant elevation. These validated the system's capability to generate biologically relevant emissions and provided preliminary evidence that acute high-concentration MBP exposure induces cardiopulmonary aberrations. **Conclusions:** This study established and validated a novel, low-cost cigarette-style combustion generator producing consistent, reproducible emissions for controlled animal inhalation studies. The system generates biologically relevant emissions inducing measurable physiological stress characterized by upper respiratory irritation and cardiovascular activation. Decreased Penh with elevated inspiratory/expiratory flows indicates increased nasal/upper airway resistance requiring greater respiratory effort. Reduced expiratory time reflects compensatory mechanisms maintaining ventilation despite increased airway resistance. Concurrent systolic blood pressure elevation suggests systemic cardiovascular stress likely mediated by inflammatory responses and sympathetic activation. The cigarette-style fuel rod approach adapts to most cigarette-smoking exposure systems, offering significant advantages for standardizing combustion research through improved reproducibility, reduced costs, and adaptability to various fuel compositions, enabling translatable findings across military/civilian scenarios including wildfire smoke studies. Validation through acute physiological responses confirms this as a reliable, versatile platform for investigating health impacts of diverse combustion emissions.

PS 3516 Transcriptomic characterization of metabolic competency in reconstructed human respiratory epithelium (RHRE)

A. O. Stucki¹, N. Roldan¹, A. Boos², P. Demuth³, M. Sharma¹, R. Landsiedel⁴, and A. J. Clippinger¹. ¹PETA Science Consortium International e.V., Stuttgart, Germany; ²Helmholtz Center Munich, Neuherberg, Germany; ³BASF SE, Ludwigshafen, Germany; and ⁴Free University of Berlin, Berlin, Germany.

Background and Purpose: Reconstructed human respiratory epithelium (RHRE) are differentiated *in vitro* cell cultures that replicate the *in situ* characteristics of the respiratory tract epithelium. Characterizing their metabolic competency is key to using these models to generate data for toxicological assessments of inhaled xenobiotics. Despite RHRE having been extensively studied, their metabolic competency has not yet been fully characterized. To address this, we analyzed the expression of genes relevant to xenobiotic metabolism across RHRE from different airway regions and compared them to human reference samples. **Methods:** RHRE of one to five donors for the nose, bronchi, small airways, and alveoli were purchased from Epithelix. Three tissues were used per donor. Tissues were cryopreserved at the provider, shipped and RNA was extracted for 50bp paired-end RNA sequencing (RNAseq). Sequencing data were processed, aligned to the human reference genome (GRCh38), transcripts were quantified, and read counts were normalized for library size. Bulk RHRE RNAseq data were compared with human single-cell RNAseq from the Human Lung Cell

Atlas (HLCA). Tracheobronchial and alveolar HLCA references were generated by using the pseudobulk approach, which involves aggregating raw counts of corresponding respiratory epithelial cells using and then normalizing for library size. Data analysis included Principal Component Analysis (PCA), hierarchical clustering, and linear regression on log₂-transformed data. For comparing relative gene expression, percentile (P) thresholds (25th, 50th, and 75th) were calculated separately for RHRE and HLCA datasets. Genes were classified as "Not detectable", "Very low" (<P25), "Low" (P25-50), "Moderate" (P50-P75), or "High" (>P75). All analyses were conducted in R (version 4.4.1) using the following packages: dplyr (1.1.4), ggplot2 (3.5.1), Matrix (1.7-0), pheatmap (1.0.12), Seurat (5.1.0), and viridis (0.6.5). **Results:** Tissue type explained most of the variance in the full RHRE expression profiles as observed by PCA (Principal Component (PC) 1=18.67%). Nasal, bronchial, and small airway tissues clustered closely, with nasal and bronchial samples having a larger variance than the small airway samples. While nasal, bronchial, and small airway samples showed substantial overlap, alveolar samples were more distinct, a pattern also confirmed by hierarchical clustering. This was also observed when the analysis focused on metabolic genes only, indicating that nasal and bronchial RHRE share a comparable metabolic profile, followed closely by small airway RHRE. Correlation with HLCA pseudobulk data showed a linear correlation trend for nasal, bronchial, and small airway RHRE (R²>0.6), but was lower for alveolar RHRE (R²=0.365). This is likely due to the cell composition of the alveolar RHRE, which includes endothelial cells not considered in the reference sample, and the limited data depth for alveolar epithelial cells in the HLCA dataset. Gene-level analysis showed nasal RHRE expression patterns aligned well with the human expression of a subset of lung-specific, CYP enzymes (e.g., CYP2A6 or CYP2A13). Nasal, bronchial, and small airway RHRE demonstrated alignment with the human reference sample for highly expressed, non-CYP, phase I enzymes (e.g., NQO1, CES, and aldo-keto reductases). **Conclusions:** In general, nasal, bronchial, and small airway RHRE showed similar expression profiles that largely aligned with the HLCA human reference sample. This work can assist in confirming whether a RHRE selected for xenobiotic testing based on the potential deposition site of a xenobiotic, expresses the human-relevant set of metabolism-associated genes for that region. The analysis pipeline presented in this work can also be used to characterize the metabolic gene expression for other RHRE and non-respiratory *in vitro* systems.

PS 3517 Comparative Histopathological Analyses of the Respiratory Tract in Preclinical Species Exposed to Dry Powder Vehicles in Inhalation Toxicology Studies

P. Novakovic, W. Lee, S. Groom, J. Younan, L. Kolodzieyski, and K. McNally. ITR Laboratories Canada Inc, Baie D Urfe (Montreal), QC, Canada.

Background and Purpose: Dry powder inhalation (DPI) formulations are increasingly used for local and systemic drug delivery due to enhanced stability and ease of use. Excipients such as lactose, leucine, mannitol, and trehalose are commonly employed carriers and are generally considered inert. However, repeated inhalation exposure in preclinical studies may induce local histopathological changes that can confound interpretation of test-item-related effects. To compare the incidence and severity of respiratory tract histopathological findings in control rats, dogs, and cynomolgus monkeys exposed to commonly used dry powder excipients during nonclinical inhalation toxicology studies. **Methods:** Retrospective analyses were conducted using data from studies performed at ITR Laboratories Canada between 2008 and 2024. Histopathological findings were extracted from Provantis® records and reviewed across the main respiratory tract regions (nasal cavity, larynx, trachea, carina, and lungs). Control groups included air and powder vehicle-exposed animals. **Results:** Across species, vehicle-exposed controls had a higher incidence of microscopic findings compared to air controls. In **rats** (n=1962), the overall incidence was 19% in vehicle controls versus 9% in air controls, and consisted mainly of respiratory epithelial atrophy (loss of cilia with flattening of epithelium) at the carina and eosinophilic globules in the olfactory epithelium of the nasal cavity. In **dogs** (n=473), 19% of tissues from vehicle controls versus 15% from air controls had findings consisting mainly of minimal alveolar macrophage increases and inflammatory infiltrates. In **monkeys** (n=74), the overall incidence was 27% in vehicle controls versus 10% in air controls and consisted mainly of minimal inflammatory infiltrates and mucous cell hyperplasia in lung airways. Across all species, most changes were minimal to mild in severity. **Conclusions:** Powder vehicle exposure was associated with a slight increase in minimal grade histopathological findings across species, with the rat demonstrating the greatest sensitivity. These results define species-specific background respiratory changes attributable to commonly used vehicles and provide reference data for interpretation of nonclinical inhalation toxicology studies.

PS 3518 Safe-by-Design Assessment of Aerosolized Hair-Care Products Using an *In Vitro* Inhalation Model

K. Schwarz¹, D. Ritter¹, T. Hansen¹, and H. Assaf Vandecasteele². ¹Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; and ²L'ORÉAL Research & Innovation, Clichy, France. Sponsor: S. Escher

Background and Purpose: Occupational exposure to aerosols from hair-care products may contribute to respiratory discomfort among hairdressers. To support product development under a Safe-by-Design strategy, we established an *in vitro* inhalation model enabling comparative assessment of biological effects from product-related aerosols under realistic application conditions. **Methods:** Aerosols were generated according by applying four commercial hair-care products (TM1-TM4) to human hair strands inside a custom-built plexiglass chamber, following manufacturer instructions. Aerosol exposure to air-liquid interface (ALI) cultures of A549 lung epithelial cells was performed using the P.R.I.T.® ExpoCube® system. To determine the surface-specific dose delivered to the cell cultures, aerosol characterization was performed, including measurements of particle size distribution and concentration. This enabled the establishment of dose-response relationships and facilitated comparison of biological effects across different products under standardized exposure conditions. Biological endpoints included cell viability (WST-1), mitochondrial membrane potential (JC-1), cell stress (Hoechst), and inflammatory response (IL-8). A composite Potential Effect Score (PES) was calculated from aerosol release (Exposure Factor, EF) and biological response metrics (Biological Activity Factors, BAF1 and BAF2). **Results:** Results showed high PES values for TM1 and TM3 (>30), correlating with reported respiratory symptoms in occupational settings. TM2 and TM4 yielded low PES values (<1), indicating minimal biological impact. Intensified application of TM2 (scenario TM2A) increased PES to 9, yet remained below TM1/TM3 levels, suggesting that product composition rather than aerosol quantity was the primary driver of biological effects. **Conclusions:** This approach demonstrates the utility of integrated aerosol and biological profiling for early-stage safety evaluation. By enabling product comparison under realistic exposure conditions, the method supports formulation decisions aligned with Safe-by-Design principles to minimize respiratory risks in professional use.

PS 3519 Utilizing Simultaneous Ultra-Sensitive Assessment of Diaphragmatic and Skeletal Muscle Force, Peripheral Train-of-Four Stimulation Predicts Diaphragmatic Recovery with Cisatracurium in a Non-Human Primate Model

S. Roof, Y. Ueyama, and R. Hamlin. QTest Labs, Columbus, OH.

Background and Purpose: Diaphragmatic recovery is more resistant to neuromuscular blocking agents than peripheral skeletal muscles. This has been shown by simultaneous measurement of peripheral skeletal and diaphragmatic muscle via non-invasive techniques such as an accelerometer or diaphragm ultrasonography. To determine the relationship between diaphragmatic and peripheral nerve recovery with better precision, highly sensitive strain-gauges were used and connected to the diaphragm and thumb. **Methods:** Added on to a model development study, four anesthetized (isoflurane, ketamine, and fentanyl) and mechanically-ventilated male/female rhesus macaque non-human primates were acutely instrumented to simultaneously assess systemic/left ventricular hemodynamics (via catheterization) as well as skeletal (quadriceps), diaphragmatic, and peripheral limb (train-of-four, TOF) force (via strain gauge). Data were collected both before, during cisatracurium (3 µg/kg/min for 30 min IV for 20 mins), and after the infusion stopped. **Results:** Cisatracurium elicited a precipitous decline in skeletal, diaphragmatic (respiratory), and peripheral limb (TOF) force until complete paralysis was achieved during the 20-minute infusion. Function recovered over the next 40-60 minutes. Diaphragmatic force recovered the fastest, skeletal muscle recovered the slowest, and peripheral limb train-of-four in between. The max height of the first TOF twitch (T1 Amp) and TOF ratio (TOFr) of the 1st and 4th twitch (T4/ T1) tracked very similarly (r²=0.99). A 25% and 40% TOF recovery from full paralysis correlated with a 70% and 90% recovery in diaphragmatic force. From the diaphragm's perspective, it recovered 25% before TOF recovery was present. A 50%, 75%, and 90% diaphragmatic recovery correlated to a 10%, 30%, and 50% recovery of the peripheral TOF. **Conclusions:** Thus, the use of ultra-sensitive strain gauges provided a full profile of diaphragmatic and skeletal muscle force to better understand their relationships with a non-depolarizing neuromuscular blocker. These data support the concept that adequate recovery of peripheral neuromuscular function, commonly defined as a TOFr (T4/T1) ≥ 0.9, indicates a functioning diaphragm and can be considered safe to extubate. Moreover, this study provides supportive evidence that the ratio of T4/T1 sufficiently reflects peripheral muscle contraction and can be used to infer diaphragmatic recovery.

S. B. Shaikh, and I. Rahman. University of Rochester, Rochester, NY.

Background and Purpose: Environmental toxicants, including ionizing radiation, induce persistent DNA damage and cellular stress that contribute to long-term tissue remodeling culminating in chronic lung disease. A key, yet underrecognized, mediator of this response is the cyclic GMP-AMP synthase (cGAS) pathway, a cytosolic DNA sensor that activates STING (Stimulator of Interferon Genes), triggering type I interferon signaling, senescence-associated secretory phenotype (SASP), and downstream lung remodeling. The role of the cGAS-STING axis in linking genotoxic injury to chronic inflammation and lung remodeling remains a critical gap in toxicological research. **Methods:** We investigated how the cytosolic DNA sensor cGAS activates the STING pathway in response to ionizing radiation (IR) using a human 3D airway epithelial-stromal model (MatTek tissues composed of epithelial cells and fibroblasts), with or without pharmacological STING inhibition (H-151). DNA damage was assessed via γ H2AX immunostaining, while activation of the cGAS-STING cascade and downstream interferon-stimulated genes (ISGs) was quantified using NanoString, qPCR, and immunoblotting. Senescence was measured by SA- β -gal staining, and SASP profiling was performed using ELISA and immunofluorescence. To validate *in vivo*, STING knockout (STING^{-/-}) mice were irradiated, and primary lung fibroblasts were isolated to assess senescence markers and mitochondrial respiration (Seahorse assay). **Results:** In 3D airway tissues, IR triggered persistent DNA damage, downregulated TREX1, and robustly activated cGAS-STING signaling, leading to elevated IFN- β , CXCL10, IL-6, CCL2, and senescence markers (GLB1, CDKN1A, CDKN2A, GDF15, SERPINE1). This was accompanied by epithelial barrier disruption, fibroblast-to-myofibroblast transition, and impaired fibrinolysis via PAI-1 upregulation. Additionally, IR induced fibrosis-like changes with increased TGF- β , COL1A1, ACTA2, and NF- κ B-driven SASP amplification. Notably, STING inhibition or knockout suppressed SASP release, restored TREX1 expression, dampened TBK1 and IRF3 activation, and reversed epithelial-stromal remodeling. **Conclusions:** Together, these findings show cGAS-STING as a key sensor of genotoxic stress that drives senescence, inflammation, and fibrotic reprogramming. Targeting this pathway may offer therapeutic opportunities in chronic lung injury, with downstream SASP and fibrinolytic mediators serving as candidate biomarkers of tissue remodeling and fibrosis risk.

PS 3521 Wood Smoke Particulate Attenuates Antiviral Cytokine Production Against Live Attenuated Influenza Virus in Differentiated Human Nasal Epithelial Cells

W. Soerianto, B. M. Ehrmann, C. Robinette, C. A. Brooks, I. Jaspers, and M. E. Rebuli. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Background and Purpose: Wildfires are occurring with increasing frequency, leading to greater human exposure to woodsmoke and exposure-associated adverse health effects. Epidemiological data suggest that wildfire smoke exposure is associated with worse respiratory infections, including influenza. Our human controlled exposure studies have shown that woodsmoke particles (WSP) can alter antiviral host defense responses in human volunteers inoculated with the live-attenuated influenza virus (LAIV) vaccine, which contains three circulating influenza strains and serves as a model for influenza infections. However, the impact of wood smoke on respiratory tract cell types that influence immune mediator profiles after LAIV has not been well-studied. Further, the order in which influenza and wood smoke exposures occur has not been evaluated. As wildfire season increasingly overlaps with influenza season and vaccination campaigns, this research could inform optimal vaccination timing relative to wildfire exposure and elucidate mechanisms by which wildfire smoke compromises the respiratory epithelium, a critical barrier against infection. **Methods:** We established an *in vitro* nasal epithelial cell WSP exposure infection model using the LAIV vaccine, which replicates at the temperature of the nasal passage and was previously used in our human controlled exposure studies. Primary human nasal epithelial cells (hNECs) from 6 adults (3 males, 3 females) were isolated and differentiated at air-liquid interface. Cells were exposed apically to 22 μ g/cm² of red oak WSP for 2 hours, followed by infection with 10⁶ 2024/2025 FluMist (intranasal LAIV) for 24 or 72 hours. In a reverse design, hNECs were first infected with LAIV for 24 hours before WSP exposure for 48 hours. WSP was created by burning red oak at a smoldering temperature. WSP were collected on Teflon filters throughout two-hour burn sessions utilized for our controlled exposures. WSP was extracted from filters via sonication in methanol and then solvent-exchanged into HBSS using a nitrogen dryer. WSP composition was analyzed by gas chromatography-mass spectrometry (GC-MS) and liquid chromatography-mass spectrometry (LC-MS). Barrier integrity was assessed by transepithelial electrical resistance (TEER). Viral replication was evaluated through gene expression analysis of H1N1 hemagglutinin (HA). IP-10 and IL-6 concentrations were measured by ELISA, and IFN α gene expression was evaluated by qPCR. **Results:** Chemical analysis confirmed the presence of polycyclic aromatic hydrocarbons, phenols, and other respiratory irritants in WSP. TEER measurements showed no significant differences between control, WSP-exposed, or LAIV-infected cells. Viral replication analysis showed an increase in HA counts after LAIV infection, indicating cellular infection and replication. IP-10 levels increased following LAIV infection, but this response was attenuated when cells were pre-exposed to WSP. IP-10 is a chemokine that plays a key

role in antiviral defense by recruiting activated T cells and natural killer cells to sites of infection and suppression may impair immune cell trafficking and reduce viral clearance. Infection with LAIV followed by WSP exposure did not significantly alter IP-10 compared to controls. IL-6 concentrations remained unchanged across all conditions. Gene expression analysis showed a significant decrease in IFN α expression when WSP exposure preceded LAIV infection. **Conclusions:** Woodsmoke exposure prior to LAIV infection dampens interferon-mediated antiviral responses in the hNECs, suggesting a potential for decreased effectiveness of intranasal vaccines after wood smoke exposure and potential increased infection rates. These findings suggest that wildfire smoke exposure may impair vaccine-induced immune responses and highlight the need to consider factors such as wildfire timing when planning vaccination strategies. These data also suggest that nasal epithelial cells are likely sources of impaired host defense response mechanisms. Ongoing work will expand our protein and gene expression targets to completely characterize the hNEC response to WSP and LAIV. Future studies are needed to elucidate the molecular pathways altered by woodsmoke and to identify chemical constituents mediating impaired antiviral signaling.

PS 3522 Inhalation route of administration imparts greater variability in systemic toxicokinetics dependent upon of molecular class

J. L. Jilek¹, E. Hackshaw¹, V. Chavez¹, and J. Baker². ¹Labcorp, Madison, WI; and ²Labcorp, Huntingdon, United Kingdom.

Background and Purpose: Achieved doses for inhaled drug products are calculated mostly based on assumptions, and systemic exposure is one metric for converting the human equivalent dose. Similar to nonclinical inhalation (INH) delivery, intravenous (IV) doses can be administered over short (bolus) or long (infusion) durations. In contrast to IV administration where a drug directly enters circulation, inhaled drugs must pass through the respiratory tract barriers to enter the bloodstream and different molecular classes can permeate to different extents. The purpose of this research was to determine the contributions of route of administration and molecular class to relative variability in exposure. **Methods:** Toxicokinetic (TK) data were extracted from the pharmacokinetic parameters (PP) domain of Standard for Exchange of Nonclinical Data (SEND) database within the company. Results were limited to studies conducted from 2020 to 2025 using rat, mouse, dog, and non-human primate test systems. For studies using a serial TK model, data for up to 59 INH studies, 18 IV bolus, and 20 IV infusion studies were available for analysis. For studies using a composite TK model, data for up to 28 INH and 16 IV (bolus) studies were available for analysis; due to limited data, IV infusion data were not evaluated. TK exposure data analyzed included dose normalized AUC and Cmax values (PPTSTCD=AUCINTD and PPTSTCD=CMAXD within the PP domain, respectively). Relative variability was evaluated using coefficient of variance (%CV) for combined sexes following a single administration. For studies using a serial TK model, %CV was calculated for each study using data from all animals and dose levels. For studies using a composite TK model, %CV was calculated for each study using data from separate sexes at all dose levels, due to the possibility of differences in achieved doses. Exposure data for small and large molecule test articles were also compared. **Results:** For all studies using a serial TK model, %CV values for AUC ranged from 6 to 213% for INH, from 14 to 83% for IV bolus, and from 13 to 104% for IV infusion, and %CV values for Cmax ranged from 17 to 391% for INH, from 9 to 118% for IV bolus, and from 12 to 105% for IV infusion. Distribution of %CV values was skewed to higher values for both parameters for all routes. For small molecules, %CV values for AUC ranged from 24 to 115% for INH and from 30 to 33% for IV bolus, and %CV values for Cmax ranged from 17 to 267% for INH and from 24 to 111% for IV bolus; insufficient data were available for IV infusion. For large molecules, %CV values for AUC ranged from 89 to 151% for INH, from 19 to 29% for IV bolus, and from 20 to 104% for IV infusion, and %CV values for Cmax ranged from 19 to 151% for INH, from 18 to 47% for IV bolus, and from 18 to 105% for IV infusion. For all studies using a composite TK model, %CV values for AUC ranged from 10 to 196% for INH and from 7 to 61% for IV bolus, and %CV values for Cmax ranged from 15 to 211% for INH and from 8 to 45% for IV bolus. Distribution of %CV values was skewed slightly to higher values for IV and bi-modal for INH. For small molecules, %CV values for AUC ranged from 32 to 91% for INH and from 7 to 33% for IV bolus, and %CV values for Cmax ranged from 25 to 211% for INH and from 11 to 26% for IV bolus. For large molecules, %CV values for AUC ranged from 25 to 36% for INH and from 15 to 51% for IV bolus, and %CV values for Cmax ranged from 31 to 35% for INH and from 8 to 26% for IV bolus. **Conclusions:** For studies using a serial and composite TK model, relative variability was greater for the INH route of administration compared to either IV route of administration, where relative variability was generally similar for IV bolus and infusion for serial TK profiles. For the INH route, relative variability was lower for small molecules, although this was skewed by higher %CV values for composite TK profiles. Due to SEND scope, non-linear TK could not be considered, which limits the ability to interpret exposure variability across studies. However, these data demonstrate greater variability in systemic exposure of inhaled drugs, particularly for large molecules.

C. Ingram¹, A. Noël¹, T. Cook¹, and M. Schexnayder². ¹Louisiana State University, Baton Rouge, LA; and ²Louisiana State University, Westbrook, ME.

Background and Purpose: Fetal development is a sensitive window of vulnerability to toxicant exposures, which can lead to lifelong respiratory health consequences. Electronic-cigarette (e-cig) devices are commonly used by young adults in the U.S., including pregnant women, as recent studies report that 2.2-7.0% of individuals use e-cigs during pregnancy. The mechanisms by which maternal vaping increases the risk of lung diseases in offspring are currently poorly understood. Our previous studies showed that mice exposed *in utero* to e-cig aerosols had upregulated expression of interleukin-10 (IL-10), a crucial immunoregulatory cytokine in lung homeostasis. This study aims to investigate both the impact of gestational e-cig exposure and the role of IL-10 on mouse offspring lung function. **Methods:** C57BL/6 wild type (WT) and IL-10 knockout (KO) dams (N=15-16 dams/group) were exposed to either air or honeywood tobacco-flavored e-cig aerosol (free base nicotine: 24 mg/mL). Total particulate matter (TPM) concentration of the e-cig aerosol was measured gravimetrically, and the stability of the aerosol was monitored in real-time using a Microdust Pro. Physical characterization of the e-cig aerosols included size distribution, evaluated using a scanning mobility particle sizer (SMPS), and number concentration measured with a condensation particle counter (CPC). Exposure consisted of 1.5-hour/day for 14 days prior to conception plus 20 days during gestation. Mouse offspring were sacrificed at 3 time points: at birth (N=11-14/group), at 14-16 days, and following phosphate-buffer saline (PBS) or house-dust mite (HDM) treatment to induce asthmatic responses at 7-8 weeks (N=4-6 mice/sex/group). Lung function testing was conducted in offspring utilizing the flexiVent. **Results:** Pregnant dams were exposed to e-cig aerosols at a TPM concentration of 0.2 ± 0.1 mg/puff. SMPS and CPC revealed that the e-cig aerosol particle geometric mean was 93.8 nm with a GSD of 1.7, and an average number concentration of 46,601 particles/cm³. At birth, WT mouse offspring exposed to e-cig aerosol *in utero* had a significantly reduced birth weight compared to air controls (1.28 ± 0.08 g and 1.38 ± 0.16 g, respectively). IL-10 deficiency improved birth weight with no difference observed between air and e-cig groups (1.33 ± 0.07 g and 1.36 ± 0.07 g, respectively). At 14-16 days of age, *in utero* e-cig exposure significantly ($p < 0.05$) affected the lung pressure-volume (PV) loops, measured via the area under the curve, in WT offspring, reflecting a restrictive pulmonary phenotype, primarily driven by the female offspring. IL-10 deficiency protected from this impairment returning PV loop curvature to air levels in male offspring. Also, in WT mice the *in utero* e-cig exposure significantly increased the respiratory system resistance (Rrs) and lung tissue damping compared to the air group. Removal of IL-10 in the e-cig group kept these parameters to the levels of the air-exposed offspring ($p < 0.05$). IL-10 deficiency was significantly beneficial for female offspring exposed to e-cig *in utero* ($p < 0.05$), highlighting sex-specific effects. Lung structure analysis at birth and at 14-16 days were supportive of underdeveloped lungs in both WT and IL-10 KO offspring exposed to e-cig *in utero*, correlating with the decreased lung function observed in these offspring. Exposure to HDM is commonly used to induce eosinophilic asthma. Following PBS and HDM treatment in adult WT offspring, we found that the impaired lung function parameters, including restrictive PV loop phenotypes and increased Rrs, carried over from the 14-16-day-old time point; however, HDM treated groups displayed exacerbations of those affected parameters. These lung function impairments were absent in IL-10 KO females, but not in IL-10 KO males. **Conclusions:** *In utero* e-cig exposure has significant effects on lung function in early-life in WT offspring, with lungs exhibiting reduced ability to stretch and expand, whereas IL-10 deficiency shielded from these impairments. The protective effect of IL-10 deficiency at birth and at 14-16 days of age remained in adulthood primarily with female offspring, whereas IL-10 KO male offspring were affected by the *in utero* e-cig exposure similarly to WT offspring.

PS 3524 Exceptional Emitted-to-Delivered Aerosol Efficiency of theBuxcoPre-Clinical Inhalation System: Bridging Theory and Experiment

U. Shemesh, and M. Girand. Harvard Bioscience, Holliston, MA. Sponsor: M. Girand, Safety Pharmacology Society

Background and Purpose: One of the primary obstacles in preclinical inhalation toxicology is the substantial quantity of test article required to achieve target lung doses across multiple subjects, driven predominantly by extensive aerosol losses within conventional exposure systems. These losses inflate research costs, complicate delivery of respirable aerosols under physiologically relevant conditions, and frequently deter investigators from selecting the inhalation route despite its scientific superiority for pulmonary therapeutics. The Buxco Inhalation System overcomes this limitation through a novel low-dead-space, precisely regulated whole-body exposure design that achieves >70% aerosol delivery efficiency. To substantiate this claim, we conducted a rigorous, empirically driven validation study. **Methods:** A 4-tier, 24-port Buxco system was configured at a total flow of 8 L/min and -0.5 cm H₂O negative pressure. Real-time aerosol monitoring included temperature/humidity sensors, a digital photometer, gravimetric filters, and cascade impaction for particle-size analysis. Test aerosol was generated using an Aerogen vibrating-mesh nebulizer (0.384 mL/min output) delivering 5 mL of a 9 mg/mL solution. The delivered dose at individual exposure ports was quantified gravimetrically using a high-sensitivity analytical

balance and compared with theoretical predictions. **Results:** Across eight replicate experiments, measured delivery efficiencies ranged from 71% to 76% (mean 72.8%, SD 1.9%), more than doubling the industry-standard 30% typically achieved with conventional systems. These results remained consistent across diverse exposure environments with relative humidity varying from 30% to 80%, induced by differing aerosol outputs and conditioning methods. Of particular relevance to inhalation toxicology, incorporating a diffuser dryer to mitigate high humidity altered the collected delivery dose by no more than 2% from the mean, demonstrating minimal additional material loss alongside substantial improvements in the inhalation environment. **Conclusions:** These findings confirm that the Buxco Inhalation System reduces test-article consumption, lowers study costs, and ensures reproducible, respirable aerosol delivery.

PS 3525 From Targets to Toxicity: Interpretable Machine Learning for Organ System Risk Prediction

O. Oechsle, and J. Almond-Thynne. Sable Bio, London, United Kingdom. Sponsor: N. Greene

Background and Purpose: Target-related toxicities remain a major cause of late-stage drug attrition and patient risk, yet systematic approaches for assessing these risks are limited. Current evaluations often rely on manual expert review or heterogeneous datasets whose relevance varies across organ systems. Genetic features such as protein interaction networks, loss-of-function tolerance, and genetic constraint (Razuvayevskaya et al., 2024) were found to correlate with clinical trial discontinuations, but represent only a part of the picture. Moreover, the relevance of specific factors is expected to vary across organ systems. Here, a target-centric ML (Machine Learning) framework is developed to predict toxicity risks across multiple organ systems and identify the most informative data features per system. **Methods:** By converting compound-based clinical data into a target-level representation, a training dataset for target toxicity across 12 organ systems was created, based on organ-level adverse events. Each target was labeled with a safety score per organ system based on the frequency and occurrence of adverse events (AEs), adjusted for placebo groups where available, and combined with an internal AE severity score. A series of interpretable ML models were trained individually per organ system, using input features spanning genetic, experimental, animal, and clinical data. **Results:** Some organ system toxicities can be validated externally. For example, DiCTRank (Qu et al, 2023) permitted evaluation of cardiovascular risk with an area under the curve (AUC) of 0.75, where AUC is a standard metric indicating how well a model distinguishes between high- and low-risk targets. SHAP-based feature importance analysis, which quantifies how much each input factor contributes to a model's prediction, revealed the relative influence of genetic, experimental, animal, and clinical data for each organ system. For instance, SHAP highlighted genetic evidence as a key contributor to predicted risks of pulmonary hypertension, consistent with clinical observations of myocardial damage captured by DiCTRank. Further insights indicate which data sources are most informative for evaluating target-specific safety across organ systems. **Conclusions:** This work demonstrates the feasibility of learning organ-specific safety signals from integrated, multimodal data. The resulting dataset and models provide a framework for understanding how diverse biological and clinical data contribute to target toxicity, supporting more systematic and interpretable investigations into the mechanisms underlying target-related safety risk.

PS 3526 Enhancing Drug Safety: Secondary Pharmacology Screening Interpretation through AI-based scientific literature mining

S. A. Ramirez¹, F. Tillier², and E. Desfosses². ¹DiscoveryAI, Saint-Charles, MO; and ²Eurofins Cerep, Celle-l'Évescault, France. Sponsor: Y. Zhao

Background and Purpose: Secondary pharmacology screening data plays a critical role in new drug applications by characterizing the selectivity profiles of clinical candidates and identifying off-target interactions. Interpreting target-related safety liabilities in the context of safety margins is essential for early risk assessment and successful clinical progression. Although public and commercial databases provide valuable information on target-associated safety risks, there remains a need for systems that can comprehensively mine, consolidate, and contextualize this data. Such systems can support safety teams and regulatory stakeholders by enabling more robust interpretation of secondary pharmacology data, ultimately guiding strategic decisions in the drug development process. **Methods:** We developed a dedicated AI system, *In Vitro Safety Insight*, to visualize biochemical assay results and potential safety liabilities associated with targets in secondary pharmacology screening panels. Adverse event data linked to these targets were sourced from both public and proprietary databases, as well as a novel in-house literature mining platform. Our analysis focused on 77 targets recommended by the IQ-DruSafe consortium (Brennan et al., 2024). The mining system retrieves abstracts and available full-text articles by querying multiple target name variants. Using state-of-the-art machine learning models, we segmented texts into sentences and identified mentions of chemicals and adverse events. Sentences containing (1) a drug and a target, (2) a drug and an adverse event, or (3) a target and an adverse event were further evaluated using a large language model (LLM) to confirm associations and classify the nature of the relationships. Following data aggregation,

we generated a curated list of target-adverse event associations, each supported by literature references. Adverse events were mapped to organ systems and integrated with safety screening results into a scoring framework termed the *Organ System Risk Profile* (OSRP). OSRP highlights organ-level risks based on the functional activity and potency of the tested compound at each target, relative to a predefined safety margin. **Results:** We present Organ System Risk Profiles (OSRP) for an antidepressant compound tested at multiple concentrations using the SafetyScreen™77 Functional Panel. We demonstrate how the safety margin influences the final OSRP by determining which targets are considered relevant for organ specific risks. A more nuanced interpretation is presented by resolving modulated targets according to agonist or antagonist compound activity, enabling a deeper understanding of safety liabilities in the context of pharmacological mechanisms. **Conclusions:** We introduce an AI-driven system designed to mine and prioritize potential adverse events associated with targets in secondary pharmacology screening panels. By leveraging the entirety of public literature, this system enhances the interpretability of secondary pharmacology data. Its application holds promise for improving the predictive power of *in vitro* safety assessments and ultimately reducing reliance on animal models in early-stage drug safety evaluations.

PS 3527 Comprehensive Evaluation of Clinically Discontinued Compounds Using an *In Vitro* Secondary Pharmacology Panel to Predict Safety Liabilities

V. Albert¹, D. E. Skinner¹, S. Karnwal¹, L. N. Guili¹, M. Vazquez¹, O. Ledezma¹, R. Shaffer¹, A. Celniker¹, A. De La Cruz¹, M. Caliendo¹, A. M. Hanna¹, L. Galdieri², A. J. King², N. B. Servant¹, and M. Jahic¹. ¹Eurofins DiscoverX, LLC, San Diego, CA; and ²Eurofins Discovery Services North America, LLC, St. Charles, MO. Sponsor: Y. Zhao

Background and Purpose: Clinical attrition of drug candidates is frequently driven by unforeseen safety liabilities, which are often associated with off-target pharmacological interactions. Systematic assessment of these interactions using *in vitro* pharmacological profiling in the preclinical stage may improve early detection of potential adverse effects and inform safer compound design. This study investigates the utility of a standardized *in vitro* secondary pharmacology panel to identify off-target interactions associated with clinical safety concerns in compounds that were previously discontinued during drug development. **Methods:** A set of 52 compounds previously terminated due to clinical safety issues was evaluated using the SAFETYscan®47 panel. This panel contains a wide array of molecular targets with established roles in safety pharmacology, including GPCRs, ion channels, nuclear receptors, transporters, and enzymes. Functional assays were performed to determine activity profiles (EC₅₀/IC₅₀), and selected compounds were further assessed in phenotypic follow-up assays to investigate their effects on integrated physiological systems. Off-target liabilities were analyzed by correlating *in vitro* activity with documented clinical safety outcomes. **Results:** The panel enabled the detection of diverse off-target interactions of the tested compounds across multiple receptor, enzyme, and ion channel families, providing a comprehensive pharmacological profile for each compound. The data offered a framework to connect *in vitro* activity with clinical safety outcomes, facilitating interpretation of how specific molecular interactions may contribute to observed adverse effects. Several compounds demonstrated activity at targets mechanistically linked to their documented clinical liabilities, such as hERG channel interactions correlating with cardiac liabilities, supporting the predictive value of the panel for safety assessment. **Conclusions:** Integration of *in vitro* secondary pharmacology profiling can identify off-target interactions predictive of clinical safety risks. Employing such panels in early drug development may enhance the identification of high-risk candidates, thereby reducing clinical attrition rates and informing safer chemical design.

PS 3528 InVEST44™ is a cost-effective *in vitro* safety panel that identifies off-target effects in early-stage drug discovery

J. R. Woollorton, A. M. Ahona, N. Barbacane, A. D'Andrea, J. D. Lansberry, C. Lay, P. Miller, J. Ries, J. Steffen, and P. A. Valentine. Reaction Biology Corporation, Malvern, PA.

Background and Purpose: Drug development costs across all therapeutic areas exceed \$172m and these costs increase to over half a billion dollars when clinical trial failures are taken into account (Sertkaya et al., 2024, DOI: 10.1001/jamanetworkopen.2024.15445). It can take as long as 20 years to successfully bring a drug to market so it is critical to identify any safety liabilities as early in the drug discovery process as possible to ensure valuable time and money are not invested unnecessarily in time-consuming and expensive preclinical and clinical trials. *In vitro* safety panels, such as InVEST44™, provide an opportunity to identify potential toxicities of lead compounds in a cost-effective manner and at an early stage in drug development. This is particularly relevant as, from 2006 onwards, the proportion of venture capital investments in early stage (including *in vitro* safety panels) has decreased from 50% (2006) to 16% (2023) while increasing for later stage (including clinical trials) from 20 to 54% over the same time (BIO. (2015). The Biopharma Industry Investment Report 2015. Biotechnology Innovation Organization; Larka, M. (2024). Trends in Venture Capital Funding for Biopharma Startups. GlobalData). This indicates an understandable trend towards expensive, high-risk but potentially lucrative,

clinical trials and away from early drug discovery. The goal is to demonstrate that early-stage *in vitro* safety panels are critical steps in the drug development process both fiscally and scientifically as these identify off-target effects of drug candidates before advancing to expensive and time-consuming animal testing and clinical trials. **Methods:** InVEST44™ is an *in vitro* safety panel designed to identify off-target effects of lead compounds in early-stage drug development, ensuring a more efficient path from discovery to clinical trials. It comprises 44 industry standard, high risk targets based on work by Bowes and colleagues (Bowes et al., 2012, DOI: 10.1038/nrd3845). It incorporates several target types, including GPCRs, transporters, ion channels, nuclear receptors and enzymes, which are crucial components in both core systems (central nervous, cardiovascular, respiratory) and secondary organs (gastrointestinal, renal). Various assay types are utilized, including radioligand binding, fluorescence polarization, enzymatic activity, cell reporter, calcium mobilization and electrophysiology assays. **Results:** We identified 20 drug candidates from a selection of failed clinical trials between 2001 and 2025 (clinicaltrials.org) applying the criteria that the trials were terminated because of reported severe adverse effects. These compounds were screened in the InVEST44™ panel. Testing at a concentration of 10 µM, 17 of the 20 drugs elicited >50% effect on at least 1 target in the InVEST44™ panel, including 8 with 4+ target interactions. One drug candidate interacted significantly with 15 safety targets. **Conclusions:** This study demonstrates the importance of *in vitro* safety panels, such as InVEST44™, by identifying off-targets effect of lead compounds before embarking on time-consuming and expensive animal testing and potentially failed clinical trials. In addition, data from such panels are increasingly being provided to enhance IND applications to the US FDA (Scott et al., 2022, DOI: 10.1016/j.vascn.2022.107205). In summary, by providing cost-efficient, early-stage identification of off-target effects by lead compounds, *in vitro* safety panels, such as InVEST44™, have become integral components of drug discovery and warrant increased early-stage consideration and investment in the future.

PS 3529 A Reproducible, Label-Free Platform for Real-Time Cytotoxicity and Hepatotoxicity Screening

S. Chvatal, D. Sullivan, P. Ellingson, M. Clements, and D. Millard. Axion BioSystems, Atlanta, GA.

Background and Purpose: Accurate and reproducible assessment of cell toxicity is essential for high-throughput screening in drug discovery and toxicology. The TrayZ system, a real-time, label-free impedance-based assay platform, enables continuous monitoring of cell health and cytotoxicity without the need for endpoint dyes or destructive labeling. This study demonstrates the use of the TrayZ system to measure cytotoxicity across multiple cell types, evaluate assay repeatability, and assess hepatocyte-specific toxicity, a key concern in safety pharmacology. **Methods:** Cancer cell lines (A549 and SKOV3) were seeded into TrayZ 96-well microplates with embedded electrodes for impedance-based detection of cell attachment, proliferation, and cytolysis. Cytotoxic compounds (paclitaxel, doxorubicin) and HER2-specific CAR T cells were used to induce cell death. The kinetics of cytolysis were quantified in real time, and key parameters such as EC₅₀ and KT₅₀ (time to 50% cytolysis) were calculated. Four independent assay plates were run to assess inter-plate reproducibility. To demonstrate hepatotoxicity screening, HepaRG cells were cultured to confluence for 1 week and exposed to known cytotoxic compounds (tamoxifen, nocodazole, FPL 64176) at multiple concentrations for 48 hours. Cytolysis of the HepaRG cells was calculated by comparing treated wells to no treatment control wells. **Results:** The EC50 for Paclitaxel (13.2, 13.9, 14.5, and 13.9 nM) and doxorubicin (1.02, 0.99, 1.01, and 1.09 µM) was consistent across plates with a coefficient of variation of 3.9% and 4.2%, respectively. In a separate assay, SKOV3 cells were treated with HER2-specific CAR T cells across four replicate plates at three effector-to-target cell ratios (1:5, 1:2, 2:1). A two-way ANOVA analysis was performed and found the greatest source of variation to be different treatment groups as opposed to different plates at 96 hours. Of note, the variation between plates was less than the error (or unexplained variation) in the analysis. At the highest dose (E:T = 2:1), the KT50 was 10.4 hours, with a coefficient of variation of 9.8%. HepaRG cells exhibited dose-dependent cytotoxicity in response to all compounds tested. Tamoxifen at 100 µM induced near-complete cytolysis by 48 hours, while nocodazole and FPL 64176 reached ~85% cytolysis at their highest concentrations (50 and 100 µM, respectively). **Conclusions:** The TrayZ system provides a robust, high-throughput, and label-free platform for real-time cytotoxicity assessment. Its reproducibility across multiple plates and compatibility with diverse cell types, including hepatocytes, supports its use for both compound screening and mechanistic toxicology studies. These findings highlight TrayZ as a powerful tool for evaluating hepatocyte toxicity and other cell-based toxicological endpoints in drug development workflows.

PS 3530 Off-Target Platelet Sensitisation by Therapeutic Oligonucleotides: Validation of a High-Throughput Screening Approach

W. Tomlinson, P. Cato, C. Jewell, S. Bhaker, A. Johnson, E. Rendall, and N. Dovlatova. Platelet Services Ltd., Nottingham, United Kingdom. Sponsor: N. Dovlatova, Safety Pharmacology Society

Background and Purpose: There is evidence indicating that synthetic oligonucleotides (ONs), including CpG-containing immunostimulatory sequences, can exert unintended effects on platelets. Several phosphorothioate-modified ONs have been reported to promote platelet activation, aggregation, or clearance through off-target interactions with platelet receptors, thereby posing a potential thrombotic risk. Inotersen represents a clinically relevant example where platelet liability has been implicated. Similarly, ODN2395 and ISIS120704, CpG-rich immunostimulatory ONs, have been shown to induce platelet activation. We previously demonstrated that the potency of collagen-related peptide (CRP) in washed platelet aggregation assays increases in the presence of ODN2395 and inotersen. However, the effect can become saturated, requiring the use of multiple concentrations to generate reliable potency data, limiting the assay throughput. Our aim was to establish and validate a high-throughput assay to quantify off-target platelet stimulation by ODN2395, ODN2395PO, inotersen, inotersen Neg, and ISIS120704 by using a single subthreshold concentration of CRP with increasing ONs concentrations and employing pooled donor platelets to increase throughput. **Methods:** Washed human platelets were preincubated with test ONs prior to stimulation with CRP. Aggregation was measured in a 96-well plate by light absorbance. Full CRP concentration-response curves were generated to quantify EC₅₀ shifts in the presence of 3 concentrations of ONs (up to 8 compounds can be assessed per donor sample); and compared with single-point assay using subthreshold CRP concentration with a 7-point concentration-response curve of ON (up to 40 compounds per donor sample). ODN2395 (phosphorothioate CpG ODN), ODN2395PO (phosphodiester bonds), inotersen, inotersen Neg (phosphodiester bonds), and ISIS120704 were tested. Responses from individual donors were compared with those from two-donor pooled platelet samples. **Results:** Preincubation with ODN2395 and inotersen produced a consistent leftward shift in the CRP concentration-response curve, indicating platelet stimulation and enhanced sensitivity to CRP. However, the effect observed with ODN2395 reached a saturable plateau, suggesting the need to use lower concentrations. The use of a single subthreshold CRP concentration with increasing ON concentrations, allowed for the quantification of the EC₅₀ for responses to ODN2395, inotersen and ISIS120704. In contrast, ODN2395PO and inotersen Neg had no detectable effect on CRP-induced aggregation. The results were consistent between pooled and unpooled platelet samples. **Conclusions:** Using 96-well plate-based platelet aggregation we demonstrated the off-target prothrombotic potential of ODN2395, inotersen and ISIS120704 as they enhanced platelet responsiveness to CRP, whereas ODN2395PO and inotersen Neg showed no such effect. The agreement between full CRP concentration-response data and simplified single-point assay validates the latter method as a scalable, high-throughput platform for assessing ON-induced platelet aggregation. Utilising this approach in two-donor pooled platelet samples increases the assay throughput from 8 to 80 compounds and enables integration of platelet safety screening within iterative design make test workflows to identify and mitigate thrombotic risks and support safer and more efficient development of therapeutic oligonucleotides.

PS 3531 Development and Validation of High-Throughput *In Vitro* Assays for Thrombolysis and Thrombolysis Modulation Using Human Whole Blood Clots

S. Albrecht, S. Ramsaroop, and Y. Zhao. Eurofins Discovery Services North America, LLC., St. Charles, MO.

Background and Purpose: Reliable *in vitro* models are essential for evaluating thrombolytic efficacy and potential drug interactions in the context of thromboembolic diseases. This study aimed to develop and validate high-throughput thrombolysis and thrombolysis modulation assays using human whole blood clots formed in 96-well plates. **Methods:** Thrombin-induced halo clots were treated with known thrombolytic agents (t-PA, Tenecteplase [TNK], Urokinase, Streptokinase) and inhibitors (Aminocaproic Acid, Tranexamic Acid, Aprotinin). Thrombolysis was quantified spectrophotometrically over 60 minutes. EC₅₀ and IC₅₀ values were calculated using non-linear regression. Assay reproducibility was assessed across multiple donors and time points. **Results:** All thrombolytic agents demonstrated dose-dependent clot lysis, with EC₅₀ values of 1.6 nM (t-PA), 0.55 nM (TNK), 126 U/mL (Urokinase), and 0.88 U/mL (Streptokinase). Inhibitors showed concentration-dependent inhibition of thrombolysis, with IC₅₀ values of 43.7 μM (Aminocaproic Acid), 3.0 μM (Tranexamic Acid), and 1.45 μM (Aprotinin). Flumazenil, used as a negative control, showed no thrombolytic or inhibitory activity. The assays demonstrated low inter-donor and inter-day variability. **Conclusions:** These validated assays provide a robust platform for screening thrombolytic agents and evaluating potential drug interactions. Their reproducibility and sensitivity support their use in preclinical safety and efficacy assessments relevant to toxicology and drug development.

PS 3532 Low-Input RNA Sequencing of Liver Microtissues to Study Adverse Drug Effects Across Species and Structural Analogs

M. Colombo, A. Pawlowska, and B. Filippi. InSphero AG, Schlieren, Switzerland. Sponsor: W. Tong

Background and Purpose: Drug-induced liver injury remains a critical obstacle in drug development, often appearing late in clinical trials. Moreover, hepatotoxic effects detected in nonclinical species frequently fail to predict human outcomes, complicating regulatory evaluation and risk assessment. Recent advances in comprehensive quantitative analytical methods, together with physiologically relevant and scalable *in vitro* models, provide a valuable opportunity to better understand adverse drug effects before first-in-human studies. **Methods:** Low-input bulk RNA sequencing was performed on a single liver microtissue derived from multiple species and exposed to three well-characterized drugs with differing toxicity profiles across species or structural analogues, to evaluate the ability of this approach to identify adverse liver effects. Liver microtissues are miniaturized physiologically relevant spheroid *in vitro* models composed of primary parenchymal and non-parenchymal liver cells. Human, monkey, dog or rat liver microtissues were treated for seven days with troglitazone, rosiglitazone, or fialuridine, and the corresponding effect on gene expression measured by low-input bulk-RNA transcriptomic analysis. **Results:** Troglitazone and rosiglitazone are both hepatotoxic thiazolidinediones used to treat type 2 diabetes, though they exhibit different clinical patterns of liver injury. Troglitazone was withdrawn from the market due to fatal hepatotoxicity, whereas rosiglitazone remains in use, with liver injury typically resolving upon discontinuation of the drug. Both drugs elicited peroxisome proliferator-activated receptor gamma-related transcriptional responses consistent with their pharmacological activity in human liver microtissues, yet only troglitazone triggered additional pathways associated with rug-induced liver injury such as bile acid homeostasis, oxidative stress response, and apoptosis. Fialuridine, a nucleoside analog discontinued in clinical trials due to fatal liver injury, demonstrated significantly higher cytotoxicity in human liver microtissues compared to those from animal species, consistent with *in vivo* findings. Transcriptomic profiling revealed a human-specific gene expression signature characterized by mitochondrial dysfunction, DNA damage response, altered bile acid metabolism, and impaired detoxification pathways, in line with reported pathological observations. **Conclusions:** Overall, these findings suggest that transcriptomic sequencing of liver microtissues can enhance the understanding of adverse liver effects across structural analogues and between different species. In the context of drug development, this approach can support lead compound selection, aid in interpreting discordant animal study results, and help assess whether findings in animal models are likely to translate to humans.

PS 3533 Human Intestinal Organoids and Derived Barrier Models for High-Efficiency Assessment of Drug-Induced Gastrointestinal Toxicity

Y. Wang, J. Zhang, J. Zhu, P. Pan, and F. He. Pharmaron Beijing Co., Ltd., Beijing, China. Sponsor: S. Luo

Background and Purpose: Drug-induced gastrointestinal (GI) toxicity is one of the most frequent adverse events in Phase I clinical trials, often manifesting as diarrhea, dehydration, and ulceration mainly due to damage to the intestinal epithelium, functional cells (e.g., goblet, enteroendocrine cells), and finally to the barrier integrity. This toxicity frequently leads to dose-limiting complications for chemotherapeutic and targeted agents, compromising clinical efficacy and contributing to clinical trial attrition. There is a critical need for highly physiologically relevant *in vitro* intestinal models to improve preclinical safety assessment. Compared to traditional 2D cell lines, human intestinal organoids (HIOs), which recapitulate the *in vivo* intestinal architecture, self-renewal capability, and cellular function, represent a promising model. This study demonstrates the unique advantages of HIOs and HIO-derived barrier models in predictive drug safety evaluation. **Methods:** HIOs were established from patient-derived small intestinal crypts embedded in Matrigel. An HIO-derived intestinal barrier model was further developed. Model quality was validated via immunofluorescence (IF) and single-cell RNA sequencing (scRNAseq). The predictive sensitivity of HIO and HIO-derived barrier models was systematically compared to traditional Caco-2 models using clinical reported GI-toxic drugs (e.g., 5-FU, Trametinib). We developed a comprehensive evaluation system assessing: 1) 3D cell viability (CellTiter-Glo® 3D); 2) histopathology (H&E), key cellular components (PAS/MUC2 IHC for goblet cells), and tight junctions (ZO-1 IHC); and 3) barrier integrity detection in both 24/96-Transwell systems (Trans epithelial electric resistance (TEER) reading and permeability coefficient determination). **Results:** IF/IHC staining and scRNA-seq confirmed that HIOs and derived barrier models recapitulated the crypt-villus architecture and contained all major intestinal epithelial cell lineages (stem cells, enterocytes, goblet cells, and enteroendocrine cells), whereas Caco-2 models remained monotypic. **3D HIO Toxicity:** HIOs exhibited significantly greater sensitivity to GI-toxic drugs in viability assays versus Caco-2. Pathological staining revealed that 5-FU and Trametinib impaired bud formation, suggesting disruption of stem/progenitor cell renewal. Furthermore, 5-FU depleted goblet cells, while Trametinib induced their aberrant hyperplasia, mirroring clinical GI adverse effects. **HIO-derived Barrier Model Toxicity:** The HIO-derived barrier model was more sensitive to drug-induced barrier dysfunction than the Caco-2 model at clinically relevant concentrations. Drug treatment resulted in a pronounced, dose-dependent barrier disruption, evidenced by significantly decreased TEER values and increased Lucifer-

Yellow permeability. **Conclusions:** We established a highly biomimetic HIO-based platform and multifaceted detection systems, creating a comprehensive *in vitro* framework for GI toxicity assessment. Our results validate that HIO models robustly predict drug-induced GI toxicity and elucidate underlying mechanisms (e.g., impaired stem cell function, goblet cell dysfunction) that are poorly captured by traditional models. Future integration of immune cells and microfluidic systems will further enhance physiological relevance. This platform provides a reliable and predictive tool for de-risking GI toxicity in drug development.

PS 3534 Investigating the Toxicity of Novel Cannabinoids from a Native New Zealand Liverwort

M. Howes¹, J. Powell¹, C. Billington¹, M. McCarthy², and M. Caddie³. ¹PHF Sceince, Christchurch, New Zealand; ²PHF Sceince, Wellington, New Zealand; and ³IO Ltd, Tauranga, New Zealand.

Background and Purpose: Regulatory, accessibility and safety concerns have limited the uptake of cannabis-derived medicines such as Sativex and Epidiolex in New Zealand as well as globally, despite approval as add-on treatments for multiple indications. Recently, the cannabinoid-like compounds (-)-*cis*-perrottetene (PET) and (+)-*trans*-perrottetene diol (PTD) were discovered in a liverwort native to New Zealand termed Wairuakohu (*Radula Marginata*), prompting research lead by indigenous Māori groups to explore the therapeutic potential and safety of these compounds. This study investigated the hepatotoxicity of PET and PTD and hypothesized that the Wairuakohu-derived cannabinoids would be less cytotoxic to liver cells than those derived from cannabis. **Methods:** Human HepG2 cells (2×10⁴ cells/well) were treated with cannabis-derived (Δ-9-tetrahydrocannabinol (THC), cannabidiol (CBD)) or Wairuakohu-derived (PET, PTD) cannabinoids for 72 hours. Cell viability across a range of concentrations was determined using a Sulforhodamine B protein assay. Non-linear regression was used to estimate best-fit values from three independent replicates performed in triplicate. **Results:** At a comparable concentrations*, PET and PTD reduced cell viability by 10.8% and 16.9%, respectively, compared with 45% and 93% by THC and CBD. THC and CBD were cytotoxic with IC₅₀ values of 30.2 μM and 19.7 μM, respectively. *Due to commercial sensitivity, the concentrations of PET and PTD tested cannot be reported. **Conclusions:** These early findings indicate PET and PTD may be less cytotoxic to liver cells than cannabis-derived cannabinoids *in vitro*. Due to the limited solubility of PET and PTD, IC₅₀ values could not be generated. Future experiments will utilize primary hepatocytes and a liver-on-a-chip approach to generate translatable data and inform the discovery process for PET and PTD. Furthermore, a comparison of plant-derived, and synthetic PET and PTD will aid in the understanding of any hepatotoxicity.

PS 3535 Beyond osimertinib: SGR-5573, a next generation brain-penetrant EGFR inhibitor, overcomes resistance with a favorable safety profile

L. Denluck¹, K. Amberg-Johnson², J. Xu², R. Kannan², S. Ellery³, S. Kurhade², A. Verras², J. Guo², M. Svensson², P. Hsiao³, Z. Liu², J. Vasoya², J. Bell², K. Akinsanya², K. K. Jenson², A. Gerasiuto², and M. Liu². ¹Schrödinger, Portland, OR; ²Schrödinger, New York, NY; and ³Schrödinger, San Diego, CA.

Background and Purpose: Epidermal growth factor receptor (EGFR) gene mutations are found in ~15-40% of non-small cell lung cancers (NSCLC) and several generations of EGFR inhibitors have been developed. A key to clinical safety is selectivity for mutant EGFR over wild-type (WT), as WT-EGFR inhibition is associated with adverse events including skin rash and gastrointestinal tract toxicity. Osimertinib is a third generation, irreversible tyrosine kinase inhibitor (TKI) used as a first-line treatment of NSCLC with EGFR classical mutations. Osimertinib is selective for EGFR classical mutations, but has an active metabolite with high WT-EGFR potency that may contribute to its safety profile. Post-osimertinib treatment, approximately 8-15% of patients develop EGFR on-target mutation C797S, which blocks binding of osimertinib. **Methods:** Leveraging Schrödinger's computational platform including *in silico* fragment screening, physics-based methods such as Free Energy Perturbation (FEP+) and energy of solvation (E-sol), we identified SGR-5573, a highly potent, selective, and brain-penetrant EGFR inhibitor with nanomolar potency on EGFR Del19 and EGFR L858R, as well as the osimertinib-resistant mutants EGFR Del19/C797S and EGFR L858R/C797S. **Results:** SGR-5573 has WT-EGFR selectivity *in vitro* comparable to osimertinib using various cellular models of WT-EGFR activity. Further, it lacks the potent *in vivo* WT-EGFR activity conveyed by the active metabolite of osimertinib. We conducted non-GLP repeat dose exploratory studies with SGR-5573 and established a favorable safety profile with double digit margins in rats and dogs. Adverse findings present at high efficacious margins were consistent with WT-EGFR inhibition. **Conclusions:** The margins, efficacy, and ADME properties of SGR-5573 support its development as a next-generation EGFR inhibitor for NSCLC.

PS 3536 Safety Profile Assessment for IND-enabling Studies: Bispecific Antibodies and Antibody-Drug Conjugates (ADCs)

L. Ratcliffe¹, S. Hill¹, S. de Munnik², G. van Puijvelde², B. Quist², L. Scanduzzi², K. Carr³, G. Sixsmith¹, N. Brown¹, C. Hardy³, M. Aspinall O'Dea¹, N. Jayanth², and P. I. Rac². ¹Charles River Laboratories, High Peak, United Kingdom; ²Charles River Laboratories, Leiden, Netherlands; and ³Charles River Laboratories, Saffron Walden, United Kingdom.

Background and Purpose: The development of antibody-based therapeutics, including monoclonal antibodies, bispecifics, and antibody-drug conjugates (ADCs), requires a delicate balance between potency and safety. Off-target interactions represent a significant risk, potentially leading to adverse clinical events and late-stage attrition. **Methods:** To address this challenge, we present a systematic de-risking roadmap designed to identify and mitigate off-target liabilities early in the development process, prior to IND-enabling studies. This integrated platform combines two complementary approaches: (1) Retrogenix® Cell Microarray Technology for comprehensive off-target interaction mapping, and (2) *in vitro* safety profiling using human primary tissue cells to evaluate functional liabilities in physiologically relevant systems. **Results:** The Retrogenix® platform enables high-throughput screening against thousands of human membrane and secreted proteins, providing an unbiased assessment of unintended binding events. This early detection capability reduces development risk by informing candidate selection and guiding engineering strategies to improve specificity. In parallel, *in vitro* safety profiling in healthy human cells offers critical insights into potential cytotoxicity or functional perturbations, ensuring precise target engagement and minimizing safety concerns. Together, these approaches deliver a robust framework for evaluating both on-target and off-target effects. **Conclusions:** The case studies demonstrate the value of this integrated strategy for complex modalities such as bispecific antibodies and ADCs, where structural complexity increases the likelihood of off-target interactions. By combining molecular-level screening with cell-based functional assays, the platform developed by Charles River Laboratories accelerates candidate refinement and enhances confidence in progressing to IND and clinical phases. Ultimately, this systematic de-risking approach supports safer, more effective antibody therapeutics, reducing attrition and improving the probability of clinical success.

PS 3537 Accelerating Immunotherapy Development with Bioinformatics-Driven Target Safety Evaluation

K. Jankovic¹, T. Krsmanovic¹, P. Stojakovic¹, A. Surla¹, D. Dragovic¹, G. Apic¹, and R. B. Russell². ¹Metisox, Cambridge, United Kingdom; and ²Heidelberg University, Heidelberg, Germany.

Background and Purpose: Immunotherapies are emerging as an effective cancer treatment, using the body's immune system to target tumors. Despite the effectiveness of immune checkpoint inhibitors, not all patients experience the same level of benefit, and organ-specific immune-related adverse events (irAEs) may occur that can halt trials early. The aim of this study was to predict potential toxicities of immune checkpoint drug targets before they enter the clinical trials using preexisting data. **Methods:** For this purpose, we have generated a comprehensive database and software, including internally curated and various publicly available data on proteins, biologically-active chemicals, their interactions, pathways and pathologies. We catalogued over 30 million references, supporting each database entry. Molecular interactions are hyperlinked to appropriate PubMed articles as support (over 300 million evidence links), while proteins and chemicals are hyperlinked to EntrezProtein and PubChem, respectively. In order to support data integration and capture different levels of histopathological observations, we developed toxicology ontology with over 9000 diseases and 800 pathology endpoints. We validated the system by exploring PD-1 (PDCD1, programmed cell death 1) a known immune-checkpoint drug candidate for cancer treatment. **Results:** Mapping PD-1 onto Gene Ontology (GO) cluster using Analysis function within the system, identified PD-1 biological function in regulation of tolerance induction, T cell apoptotic process, and T cell mediated immune response to tumor. Mapping PD-1 together with its **very high confidence** protein interaction network onto Diseases module within our system, associated PD-1 with several cancers, including endometrial carcinoma, clear cell renal cell carcinoma, head and neck squamous cell carcinoma, lung squamous cell carcinoma, and mucosal melanoma in which is PD-1 dysregulated, which corresponds to potential indication of PD-1 inhibitors. Indeed literature search confirms PD-1 inhibitors are effective in many of these cancers. The other group of diseases that is prominent are immune diseases including autoimmune myocarditis, autoimmune uveitis, allergic asthma and autoimmune glomerulonephritis, which correspond to potential PD-1 inhibitors' toxicity, i.e. adverse events. This is confirmed by mapping PD-1 with its protein interacting network onto adverse events cluster that reveals association with several pathologies mostly related to immune system (myocarditis, pneumonitis, hypophysitis, and colitis). In addition, it reveals potential PD-1 inhibitors toxicities related to sensory system (sudden hearing loss), urinary system (secondary adrenocortical insufficiency) and muscle (muscular weakness, myasthenia). Mapping PD-1 together with its protein interacting network onto organ and tissue pathologies showed association with T-cell apoptosis and T-cell inflammation as the most relevant, which is expected given that PD-1 is an inhibitory receptor on T cells. Mapping PD-1 with its **very high confidence** chemical interaction partners (potential inhibitors) onto adverse events cluster within our system identified lung inflammation,

colitis, myocarditis, hypothyroidism, sudden hearing loss, muscular weakness and hypercalcemia as potential toxicities following PD-1 inhibitor treatment. The results correspond to literature findings. Namely, treatment with PD-1 monoclonal antibodies nivolumab and pembrolizumab is associated with potential muscle toxicities (myasthenia gravis, myopathy, and myositis). In addition, drug-related adverse events following nivolumab treatment included pneumonitis, vitiligo, colitis, hepatitis, hypopharyngitis and thyroiditis, corresponding to irAEs that can be life-threatening or chronic, requiring immunosuppressants. **Conclusions:** On the example of PD-1 inhibition we showed that our tool can contribute to a better understanding of target role in a disease, therapeutic potential of a target inhibition and quick target toxicological assessment.

PS 3538 *In vitro* assessment of potential hematotoxicity of ADC drugs

Q. Hu, S. Zhang, X. Du, P. Gao, and F. He. Pharmaron Beijing Co., Ltd., Beijing, China. Sponsor: S. Luo

Background and Purpose: Antibody-drug conjugates (ADCs) have emerged as a transformative class of cancer therapeutics, integrating antibody-mediated target specificity with potent cytotoxic payloads. However, their clinical utility is frequently constrained by off-target toxicities, among which hematotoxicity (e.g., neutropenia, thrombocytopenia, anemia) representing a common and dose-limiting adverse effect. This phenomenon arises from unintended targeting of hematopoietic cells, either via cross-reactivity with antigens expressed on immature or mature blood cells or non-specific payload release. The objectives of this study are: 1) To evaluate the hematotoxic potential of a panel of ADCs across human CD34⁺ hematopoietic stem and progenitor cells (HSPCs), erythroid, myeloid, and megakaryocytic lineages, using assessments of cell viability and lineage-specific marker expression. 2) To identify lineage-specific vulnerabilities to ADCs, thereby providing mechanistic insights to inform safer therapeutic design and optimized clinical dosing strategies.

Methods: Primary human CD34⁺ cells were isolated from cord blood using magnetic-activated cell sorting and cultured in StemSpan™ SFEM II medium supplemented with cytokines (SCF, Flt3-L, TPO) to maintain stemness. Erythroid, Myeloid and Megakaryocytic differentiation were achieved with indicated cytokines for desired time. A panel of ADCs was administered to CD34⁺ HSPCs; alternatively, ADCs were supplemented continuously for 72 hours during erythroid, myeloid, or megakaryocytic differentiation. Toxicity assessments included: Cell viability measurement via the CellTiter-Glo® (CTG) luminescent assay, with ATP levels quantified as a surrogate for viable cells. Results are expressed as percentage viability relative to vehicle controls. Lineage-specific marker expression analysis via flow cytometry using the following antibodies: Erythroid (CD71-FITC and CD235a [GPA]-PE), myeloid (CD11b-APC and CD15-PE-Cy7), and megakaryocytic (CD41-PE and CD61-APC). Data are reported as percentage of positive cells and mean fluorescence intensity (MFI) relative to controls. **Results:** Flow cytometric analysis of lineage markers and cell viability revealed that ADCs exerted distinct viability effects across human CD34⁺ HSPCs, erythroid, myeloid, and megakaryocytic lineages, while also impairing differentiation. ADCs exhibited lineage-specific toxicity: erythroid cells were most sensitive to DM1-type ADCs, myeloid cells showed greater susceptibility to MMAE-type ADCs, and megakaryocytes displayed relative tolerance—consistent with clinical reports of mild thrombocytopenia associated with the tested ADCs. **Conclusions:** This study demonstrates that primary human CD34⁺ HSPCs and their differentiated lineages constitute a robust *in vitro* model for assessing ADC-mediated hematotoxicity. This model enables the early identification of lineage-specific risks, providing a foundation for preclinical ADC development by guiding payload selection and target validation to minimize hematotoxicity. Future work will expand the panel of ADCs evaluated and investigate payload release kinetics within lineage-specific niches.

PS 3539 Everolimus Toxicology: Tissue Concentration Effects

W. Chang, N. Chang, T. Hoque, A. Park, and C. Lee. Sapu Nano, San Diego, CA.

Background and Purpose: Common adverse events to Afinitor (oral Everolimus) include anemia (~60%), lymphopenia (~40%), and thrombocytopenia (~35%), with severe cytopenias ≤10%. Stomatitis is dose-limiting (≤70%), while rash, fatigue, and metabolic effects occur in 15-50%. Non-infectious pneumonitis occurs in ~15%, and infections in ~50%. This study examined the relationship between tissue distribution and toxicity following a single oral everolimus dose in rats. **Methods:** Sprague-Dawley rats (1 male, 1 female/group; n=4) received a single 3 mg/kg oral dose. Whole blood and major organs were collected at 0.083 h, 0.5 h, 8 h, and 24 h. Everolimus concentrations were quantified by LC-MS/MS (LLOQ: 0.30 ng/mL blood; 1.00 ng/mL tissue). Tissue concentrations (ng/g) and tissue-to-blood ratios were calculated, and PK parameters (C_{max}, T_{max}, AUC_{0-∞}) determined by noncompartmental analysis (WinNonlin® 8.5). **Results:** Everolimus was rapidly absorbed and concentrated primarily in gastrointestinal organs, liver, lung, and spleen, with no sex differences. The highest exposures occurred in the stomach, small intestine, and large intestine, detectable within 5 min post-dose. At 0.5 h, C_{max} values were 16,893.64 ng/g (stomach), 4,173.68 ng/g (small intestine), and 1,478.18 ng/g (large intestine), compared with 689.70 ng/g (liver), 266.75 ng/g (lung), and 244.42 ng/g (spleen). Whole-blood C_{max} was 2.22 ng/mL, and brain levels were below LLOQ. Everolimus concentrations declined gradually but remained detectable up to 24 h. The correlation between C_{max} and the organ toxicity reported for patients treated with Afinitor was demon-

strated. Higher C_{max} was found in the GI tract and was associated with the high incidence of stomatitis/oral ulcers (44-70%) and diarrhea (50%). In contrast, lower C_{max} was found in blood and was associated with a low incidence of thromboembolism (3%). **Conclusions:** These findings demonstrate that everolimus toxicology correlates with tissue distribution, paving the way for better therapeutic drug monitoring beyond blood levels alone.

PS 3540 Alterations of Xenobiotic ADME in a Rat Model of Heat Strain

P. A. Sample, V. Pirro, V. Samala, D. Farrera, and N. Cherrington. University of Arizona, Tucson, AZ.

Background and Purpose: The impact of temperature on chemical action has been well studied for many years. A series of publications in the late 1950s began to investigate this premise *in vivo*: the LD₅₀ of varied chemical compounds were assessed in rats housed at different temperatures—cold, control, and hot—and temperature-dependent changes to toxicity were measured. These were the last published studies to test this phenomenon. While environmental stressors are known to influence xenobiotic metabolism, the impact of thermal stress—particularly exposure to elevated temperatures—on the mechanisms underlying absorption, distribution, metabolism, and elimination (ADME) remains almost entirely unexplored. Of note are two major classes of hepatic enzymes, the members of the Cytochrome P450 superfamily (P450), which account for over 75% of drug metabolism in the human body and have implications in the metabolic pathways of many xenobiotic toxicants, and transporters, which are responsible for the distribution and elimination of many xenobiotics and their metabolites. **Methods:** In this study, we examined the effects of environmentally relevant high-temperature cyclical exposure (34°C, 12 hours/day for 7 days) on the expression and function of hepatic P450s and transporters in male Sprague-Dawley rats. Cytochrome P450 activity was evaluated using LC-MS/MS-based quantification of metabolite formation from isoform-specific probe substrates, e.g. testosterone for Cyp3a4. Protein quantification of hepatic transporters, both uptake and efflux, were assessed via a targeted LC-MS/MS method developed using surrogate peptides. **Results:** Results revealed alterations in the P450 activity of 4 of the 8 most prevalent drug metabolizing P450 isoforms, namely Cyp2b1, 2d1, 2e1, and 3a1. Further, multiple xenobiotic uptake and efflux transporters were demonstrated to change, including a decrease in uptake transporters Ntcp, Oatp2b1, and Oat2, as well as in efflux transporters Bcrp and Bsep, alongside multiple trends in other transporters. **Conclusions:** These changes, accompanied by classical heat strain physiology, including increased body temperature and significant body weight fluctuations, suggests that cyclical thermal stress can induce a transient phenotypic state resulting in altered capacity for xenobiotic disposition and metabolism.

PS 3541 MASH Impairs Renal Anion Transporter Function and Alters Cefazolin Disposition

M. M. Maloney, D. O. Farrera, L. J. Martinez-Guerrero, S. Marie, M. M. Alaaldin, P. Lindberg, K. Frost, P. A. Sample, C. S. LaMadrid, P. Lenzen-Hammerel, L. R. Radtke, S. H. Wright, and N. J. Cherrington. University of Arizona, Tucson, AZ.

Background and Purpose: Metabolic dysfunction-associated steatohepatitis (MASH), a progressive form of liver disease, affects up to 30% of the global population. While hepatic transporter alterations in MASH have been well characterized, far less is known about the effect of MASH on renal transport processes. In particular, the renal handling of organic anions remains poorly understood. Herein, we used cefazolin (CEF), an anionic antibiotic primarily used to prevent surgical site infection, as a model compound to investigate MASH-induced alterations in renal transporter function and their role in pharmacokinetics. **Methods:** MASH was induced in mice using fast food-dieted/thioacetamide (FFDTH) which has been shown to accurately model the transporter changes seen in human MASH. Using LC-MS/MS, transporter expression was evaluated via proteomics, and plasma, urine, and tissue concentrations of CEF were analyzed. **Results:** Expression of Oat3 and Oat5 were significantly reduced (50% and 80%, respectively) in MASH animals compared to controls. In response, plasma concentrations of CEF increased from 83% in MASH compared to controls, while hepatic accumulation rose ~80%. No differences in renal accumulation or excretion of CEF were observed between MASH and healthy mice. **Conclusions:** This data suggests that MASH-induced Oat transporter reduction increases both systematic CEF concentration along with the accumulation in the liver, without differences in renal or urinary excretion. Overall, these findings highlight the risk of increased systemic exposure in MASH patients, specifically those undergoing surgical procedures ultimately suggesting that it would be beneficial to explore dose adjustments in these patients.

W. Zhang¹, D. G. Muhammad¹, M. Blosi², R. Cai¹, C. Chen¹, and F. R. Cassee³.
¹CAS Key Laboratory for Biomedical Effects of Nanomaterials and Nanosafety & CAS Center for Excellence in Nanoscience, National Center for Nanoscience and Technology, Beijing, China; ²Institute of Science, Technology and Sustainability for Ceramics, National Research Council of Italy, Faenza, Italy; and ³National Institute for Public Health and the Environment Netherlands, Bilthoven, Netherlands.

Background and Purpose: With the increasing integration of nanomaterials (NMs) into daily life, their technological advantages have become evident. However, their intricate interactions with biological systems introduce complexities that can lead to unpredictable toxicological outcomes. **Methods:** This study investigated the *in vivo* toxicokinetics and toxicodynamics of single- and multi-component NMs composed of silicon carbide (SiC), titanium dioxide (TiO₂), and a SiC@TiO₂ composite, along with a physical mixture of SiC and TiO₂ in the same ratio as the composite. Rats were exposed to these materials via single intratracheal instillation, and biological responses were assessed over time (1 h to 28 days) to identify the no-observed-adverse-effect level (NOAEL). **Results:** All NMs induced minimal structural alterations in lung tissue and prompted varying degrees of inflammatory cell infiltration. Over time, translocation from the lungs to secondary organs (heart, spleen, liver, kidney) was observed, with distinct distribution patterns between Si- and Ti-containing NMs. Bronchoalveolar lavage fluid analysis revealed a minimal to mild inflammatory response that evolved in a time-dependent manner, even at NOAEL exposure levels, suggesting delayed-onset biological effects. **Conclusions:** SiC@TiO₂ demonstrated a reduced pulmonary toxicological profile relative to its single-component counterparts, likely due to antagonistic effects between its constituents. These findings highlight the need to assess multicomponent nanomaterials as distinct entities and suggest that rational material design may help mitigate adverse biological effects, supporting safer nanotechnology development.

PS 3545 Development of a long-term 3D spheroid mouse hepatocyte culture model for use in drug-induced liver injury (DILI) applications

M. Nautiyal¹, M. Cook¹, K. Grady², and A. Sharma¹. ¹Lonza Durham, Morrisville, NC; and ²Lonza Walkersville Inc., Walkersville, MD. Sponsor: K. Dunnick

Background and Purpose: Rodent models are an important tool for safety and toxicology testing. However, recent FDA guidance indicates a shift from animal models towards cell culture models to minimize the impact to and use of animals in drug safety and efficacy testing. Despite this, rodent systems will continue to play an important role in drug testing for years to come. In order to better align with FDA guidance, advanced rodent cell culture models, especially physiologically-relevant 3D models, can offer better predictivity of *in vivo* results in live animals, ultimately requiring the use of fewer animals throughout the entire testing workflow. Here, we demonstrate a protocol for long-term culturing of two strains of mouse hepatocytes (CD-1 and C57BL/6) in a 3D spheroid format for 21 days in culture. The utility of this model is validated through a DILI assessment of acetaminophen, an exemplar hepatotoxin. **Methods:** Lonza mouse hepatocytes (CD-1 or C57BL/6) were thawed in Lonza Rodent and Monkey Cryopreserved Hepatocyte Thawing Medium. Tubes were centrifuged aspirated of supernatant, and then cells were resuspended in Spheroid Formation Medium (consisting of Hepatocyte Culture Medium (HCM) Medium; Lonza) with 20% FBS and 25 mM HEPES buffer). Mouse hepatocytes were seeded at 1,500 cells / well in an ultra-low attachment 96-well plate and were incubated for 5-7 days. Spheroids formed by day 7, after which spheroids were maintained in serum-free HCM medium for another 14 days in culture (total of 21 days). Spheroid health and functionality was assessed visually using live-cell imaging and by measuring basal and rifampicin-induced (10µM; 72 hour exposure) CYP3A4 enzyme induction using a P450 luminescence assay at time points 3, 7 and 14 days post-spheroid formation (days 10, 14 and 21 in culture). Repeated drug exposure with acetaminophen (a hepatotoxic compound; 0-25 mM) began on day 7 in culture and continued for 14 days (to day 21). Cytotoxicity assessments were made at multiple time points (3, 7 and 14 days after dosing) based on total cellular ATP to generate dose response curves and EC₅₀ values. **Results:** Primary mouse hepatocytes of both strains formed spheroids with well-defined perimeters within 7 days and maintained appropriate morphology for an additional 2 weeks in culture (total of 21 days). CYP3A4 induction by rifampicin was observed across the entire 14-day spheroid culture period by both mouse strains; however, the basal CYP3A4 activity was far higher in strain CD1, resulting in an overall lower induction potential compared to the C57BL/6 strain, but much higher activity in general. Overall, both mouse strains showed robust morphology and functionality across the entire 14-day spheroid culture period - 21 total days in culture. Both mouse strains exhibited the expected dose-response to acetaminophen over time. EC₅₀ values for both mouse strains decreased significantly over time. There were also significant differences between strains. Mouse strain C57BL/6 showed significantly greater toxicity at earlier timepoints when compared with strain CD-1. By day 14 of acetaminophen exposure (21 days total in culture), EC₅₀ values had declined for both strains of mouse nearly to the 10x C_{max} value for acetaminophen in humans, indicating that both mouse strains offer predictive models of DILI toxicity for acetaminophen in humans. **Conclusions:** This study demonstrates a physiologically-relevant and user-friendly 3D spheroid culture model for two strains

of mouse hepatocytes that is validated for use in DILI toxicity testing. In this study, both strains of mouse hepatocytes maintained proper morphology and functionality over the course of a 21-day culture period (14 days of spheroid culture). This long-term culture format allows for the evaluation of acute and chronic DILI toxicity as demonstrated with the exemplar hepatotoxin, acetaminophen. This protocol provides a physiologically relevant initial screening of compounds prior to *in vivo* animal testing, reducing the overall number of live animals needed in the safety testing process.

PS 3546 Enhancing metabolic stability of beagle dog primary hepatocytes via culture optimization

B. Huang, M. Qu, and X. Li. Milecell Biotechnology Inc., Shanghai, China. Sponsor: S. Xiao

Background and Purpose: Primary hepatocytes serve as essential *in vitro* models for drug metabolism and toxicology studies. However, during culture—particularly in non-human species such as Beagle dogs and rats—the expression of drug-metabolizing enzymes declines rapidly, resulting in unstable metabolic capacity. Directly applying human-optimized culture methods to other species often yields limited improvement in metabolic activity and causes significant batch-to-batch variability. Our preliminary comparative studies revealed distinct interspecies differences in metabolic performance. Specifically, Beagle dog primary hepatocytes exhibited slower metabolic turnover, reduced CYP enzyme activity, and heightened sensitivity to culture conditions, all of which substantially restrict their utility in *in vitro* research. Therefore, this study aimed to establish a standardized culture system that systematically improves the metabolic stability of primary hepatocytes—particularly Beagle dog hepatocytes—thereby enhancing their *in vitro* metabolic performance and batch consistency, and providing a high-quality cellular model for pharmacokinetic and toxicological evaluation. **Methods:** The culture system for Beagle dog primary hepatocytes was systematically optimized in three aspects: (1) medium composition, (2) temperature regulation, and (3) physical culture conditions. Verapamil, a CYP3A substrate, was used as the metabolic validation compound. Metabolite concentrations and residual parent drug were quantified by liquid chromatography-tandem mass spectrometry (LC-MS/MS), and metabolic half-life was calculated to evaluate the effects of the optimized system on metabolic capacity. **Results:** Moderate elevation of culture temperature significantly improved the metabolic stability of Beagle dog primary hepatocytes. The addition of sodium thyroxine to the culture medium markedly enhanced CYP3A enzyme activity in Beagle dog hepatocytes, whereas its effect on CD-1 mouse primary hepatocytes was minimal. **Conclusions:** This study established a standardized culture method that systematically enhances the metabolic stability of Beagle dog primary hepatocytes, offering a new technical approach and experimental foundation for developing non-human *in vitro* models for drug metabolism evaluation.

PS 3547 Understanding Mechanisms of PFAS Absorption, Distribution, and Elimination Using a Physiologically Based Toxicokinetic Model

F. C. Fischer¹, C. Thackray², N. Ferguson¹, C. Chicoine¹, O. Skende¹, Z. Hu², Y. Zhu², A. Slitt¹, and E. Sunderland^{2,3}. ¹University of Rhode Island, Kingston, RI; ²Harvard John A. Paulson School of Engineering and Applied Sciences, Cambridge, MA; and ³Department of Earth and Planetary Sciences, Harvard University, Cambridge, MA.

Background and Purpose: Exposures to some per- and polyfluoroalkyl substances (PFAS), including perfluoroalkyl acids (PFAA), are associated with diverse adverse health effects. Physicochemical properties of PFAA are known to influence their toxicokinetics in mammals, and mechanistic models capable of identifying the key drivers of absorption, distribution, and elimination are limited. Herein, we developed and evaluated a physiologically based toxicokinetic (PBTK) model parameterized to an *in vivo* mouse model using data from *in vitro* studies, addressing the limitations of prior empirical models by incorporating mechanistic data on permeability, protein and lipid binding, and transporter interactions. **Methods:** The PBTK model quantified blood flow, binding to tissue proteins and phospholipids, membrane permeability, hepatic and renal transporters, and fecal and urinary excretion. The model was parameterized using *in vitro* transport data for nine PFAA with fluorinated carbon chain lengths ranging from 4 to 10 (n_{ptc} = 4-10). We simulated PFAA tissue concentrations in wild-type mice, and for perfluorooctanesulfonic acid in knockout mice, following intravenous and oral exposures. Model performance was evaluated by comparing simulated and experimental blood and tissue concentrations. **Results:** The PBTK model reproduced experimental blood and tissue concentrations, with R² values ≥0.67 and relative root mean square errors ≤66% for most PFAA. Model sensitivity analyses showed that permeability and phospholipid binding strongly influenced elimination and distribution of long-chain PFAA (n_{ptc} ≥ 7), while elimination for short-chain PFAA (n_{ptc} ≤ 6) was most sensitive to renal transporters and albumin binding. Blood accumulation was most sensitive to albumin binding, while tissue retention was most positively associated with phospholipid binding. **Conclusions:** This study illustrates that integration of *in vitro*-derived parameters into a PBTK model enables mechanistic evaluation of PFAS toxicokinetics across diverse compounds and physiological conditions.

D. Thomas¹, P. MacLaughlin², T. Williams², and L. Hollister². ¹Elsevier, Inc., San Diego, CA; and ²Elsevier, Inc., Philadelphia, PA. Sponsor: D. Thomas, International Society for the Study of Xenobiotics

Background and Purpose: Integrating toxicological insight into early discovery decisions remains limited despite decades of safety-driven attrition in drug development. Many clinical safety failures arise from mechanisms intrinsic to target biology or compound design—factors that could be identified earlier through systematic analysis of mechanistic data. This gap is evident for emerging modalities such as antibody-drug conjugates (ADCs), where antibody specificity, payload potency, and linker stability jointly determine efficacy and toxicity. ADCs enable targeted delivery of cytotoxic payloads but pose safety challenges. Toxicities may result from off-target binding, premature payload release, or target antigen expression in healthy tissues. These events are difficult to predict using standard models because relevant data—spanning chemical, biological, and clinical domains—are typically siloed. Mechanistic safety science provides a framework for linking molecular events to tissue and organ outcomes, yet its application in discovery has been hindered by data fragmentation and inconsistent contextual representation. To address this gap, Elsevier's Life Science Research Assistant (LSRA) was developed as a multi-agent AI framework that performs cooperative interrogation of diverse scientific information sources. Through coordinated reasoning among specialized agents, LSRA retrieves, evaluates, and synthesizes evidence spanning chemical, biological, pharmacological, and clinical data. Drawing on Elsevier content and third-party databases such as PubMed and ClinicalTrials.gov, LSRA supports hypothesis-driven exploration of mechanistic safety relationships during target identification and lead optimization. **Methods:** LSRA employs autonomous agents specialized in chemistry, biology, toxicology, and clinical science to retrieve and evaluate diverse datasets, iteratively sharing findings through consensus cycles to construct mechanistic hypotheses grounded in experimental and clinical data. LSRA incorporates natural language querying to enable intuitive question formulation and employs computational methods to interpret and connect information across structured and unstructured data sources. A hypothetical ADC program employing tubulin-inhibitor payloads was used to demonstrate the framework's capabilities. Agents examined cytotoxic mechanisms, linker chemistry, and target expression profiles in relation to hepatic and hematologic safety. Computational interrogation included toxicophore mapping and mechanistic substructure inference to identify chemical motifs associated with stress-response pathways. Integrated data encompassed curated toxicology collections, peer-reviewed literature, and clinical trial records. **Results:** The LSRA workflow established mechanistic linkages across preclinical and clinical domains, providing a coherent framework for interpreting biological processes underlying toxicity. Natural language querying enabled discovery of cross-domain relationships that might be overlooked through conventional searches. Findings revealed how linker instability and payload lipophilicity contribute to hepatocyte and bone marrow exposure. Comparison with ClinicalTrials.gov data confirmed concordance between preclinical predictions and clinical adverse event patterns in ADCs with similar design features. Iterative reasoning enhanced the biological plausibility of proposed toxicity mechanisms, refining early safety assessments and informing compound design decisions. **Conclusions:** Integrating mechanistic safety science with molecular, pharmacological, and clinical data enhances early recognition of design factors relevant to safety. The multi-agent approach exemplified by LSRA provides a structured means to integrate mechanistic data across disciplines and evidence sources. Such integration may enhance the interpretability of toxicity mechanisms in complex modalities like ADCs and inform more evidence-based decisions in target selection and lead optimization.

PS 3549 Integrating Physiologically Based Pharmacokinetic (PBPK) Modeling with Intra-Arterial Drug Delivery (I-ADD) for Brain Tumor Therapy

X. Wang, A. Canchola, H. Nandula, M. Kinra, K. R. Pequeno, H. Liu, E. Zagha, and W. Chou. University of California, Riverside, Riverside, CA.

Background and Purpose: Systemic administration of therapeutics is often hindered by the limited drug distribution in the targeted organ and substantial off-target toxicity. To address this challenge, a bioresorbable polymer-metal intra-arterial drug delivery (I-ADD) device has been developed to enable sustained and localized drug release directly into the cerebral arterial circulation. In this study, we aim to develop a physiologically based pharmacokinetic (PBPK) model to simulate intra-arterial drug delivery (I-ADD) to the brain and to optimize dosing strategies that maximize therapeutic efficacy while minimizing systemic side effects, using dexamethasone (DEX) and cisplatin (CIS) as model drug compounds. **Methods:** A whole-body PBPK model was constructed for multiple species (e.g., rats and mice) comprising blood, liver, kidney, gastrointestinal tract, and a permeability-limited brain submodel consisting of vascular and extravascular (parenchymal) spaces. Model parameters were initialized from the literature and calibrated by published intravenous and oral pharmacokinetic data. To model I-ADD, conventional drug input was replaced with a time-variant intra-arterial release function derived from *in vitro* release experiments. Drug release was described by a Weibull equation and applied as a local input to the carotid artery compartment. This approach enabled simulation of implant-specific

factors (e.g., device composition, drug loading, surface area, degradation rate) on downstream brain and systemic exposure. Sensitivity analyses were performed to identify parameters that most influence brain exposure, and model performance was evaluated against internal pharmacokinetic data. **Results:** The PBPK model successfully reproduced plasma and tissue concentration-time profiles of DEX across collected datasets. Most of the predictive values were within a twofold deviation of experimental observation (>80%), with coefficients of determination (R^2) greater than 0.73. Preliminary simulations indicated that sustained intra-arterial input markedly increased brain exposure while minimizing systemic accumulation compared with intravenous dosing, consistent with expected I-ADD performance. The model will be extended to CIS, and rat physiology is currently in progress to evaluate cross-species and compound-specific applicability. **Conclusions:** This PBPK framework provides a quantitative basis for optimizing I-ADD device design and guiding translational dose selection to maximize brain exposure while minimizing systemic toxicity. By integrating device release kinetics with physiological parameters, the model establishes a mechanistic link between implant design and properties, local hemodynamics, and therapeutic outcomes. The framework will be extended to cisplatin (CIS), rats, and ultimately extrapolated to humans to support rational dose translation and clinical application of I-ADD technologies for brain-targeted therapy.

PS 3550 Transgenerational Implications of Age-Dependent Half Life for Dioxins in Mothers and Breastfed Children

B. D. Kerger¹, and A. E. Locciano². ¹Exponent Inc, Tampa, FL; and ²Exponent Inc, Alexandria, VA.

Background and Purpose: Adult body burdens of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and other dioxin-like dibenzodioxins and dibenzofurans have been declining at an average rate of approximately 4% per year since the early 1980s. This decline correlates with US and international regulatory efforts to reduce emissions due to concerns about potential health risks to children from breastmilk transfer of maternal body burdens. However, pharmacokinetic data analysis since the late 1990s revealed that infants have a far shorter TCDD clearance half-life (e.g., 0.5 y at age 0-1) compared to adults (e.g., 7 y at age 30). Further research showed that this shorter half-life trend applied to all dioxin-like compounds with gradual increasing half-life from infancy through late adolescence, indicating that elevated body burdens acquired *in utero* and from breastfeeding were eliminated within a few years. The current study examines the magnitude of changes in maternal and child body burdens of TCDD toxicity equivalents (TEQ) across three generations of firstborn females born in 1985, 2005, and 2025. **Methods:** A pharmacokinetic model for childhood dioxin body burden was used to integrate concurrent estimates of adult body burden and breastmilk concentrations with age-specific child intake parameters for 12 months of breastfeeding followed by concurrent background dietary intake through age 7 y. All intake and output parameters were calibrated to concurrent TEQ in lipid in maternal and child tissues as well as in breastmilk and other childhood dietary intake. Published data showed an average 4% annual decline in dioxin body burdens on a lipid basis from the 1980s through 2010; this rate of decline was used to estimate child TEQ body burden at birth, maternal breastmilk TEQ, and concurrent childhood dietary TEQ in 1985, 2005, and 2025. The model estimated blood lipid TEQ concentrations monthly for the first 12 months and then annually through age 7. **Results:** The first-generation child (1985) was assumed to ingest breastmilk with 140 pg TEQ/g (lipid basis, first 6 months average) which led to peak blood level of 73 pg TEQ/g lipid at age 6 months that declined to 12 pg TEQ/g lipid at age 7 y. The second-generation child (2005) was assumed to ingest breastmilk with 78 pg TEQ/g which led to a peak blood level of 40 pg TEQ/g at age 6 months that declined to 6.5 pg TEQ/g at age 7 y. The third-generation child (2025) was assumed to ingest breastmilk with 15.5 pg TEQ/g which led to a peak blood level of 8.1 pg TEQ/g at age 6 months that declined to 1.3 pg TEQ/g at age 7 y. **Conclusions:** The childhood dioxin body burden model results illustrate that the shorter age-dependent half-life of dioxins in early childhood rapidly ameliorates the higher dose from breastfeeding and attenuates cumulative intake from background dietary sources through young adulthood. While background dietary dioxins declined in parallel with adult body burdens over time, the shorter age-dependent half-life of dioxins may also contribute to transgenerational body burden declines in reproductive age adults due to more rapid excretion of dietary dioxin intake through early adulthood.

PS 3551 Development of gestational PBK modeling to support dose selection for the developmental neurotoxicity *in vitro* battery testing

Y. Wu, B. Jackson, A. Hofstra, and A. Karmaus. Syngenta, Greensboro, NC.

Background and Purpose: Use of the Developmental Neurotoxicity *In Vitro* Battery (DNT IVB) has been endorsed by the OECD as a basis for investigating potential DNT hazard. Appropriate concentration selection is essential, as with any other *in vitro* testing, to ensure that results reflect biologically relevant exposure levels. This enables accurate interpretation of chemical effects and improves the predictive value of the DNT IVB assays at environmentally relevant concentrations. **Methods:** This study addressed challenges in incorporating species-specific and gestational factors by developing rat and human physiologically based kinetic (PBK) models to estimate

fetal exposure during gestation and guide concentration selection. This modeling approach was developed for a specific case study using a pesticide active ingredient. We first developed and evaluated a nonpregnant rat PBK model. Next, a parallel-gram approach was applied to extrapolate rat to human, enabling development of a nonpregnant human PBK model. The nonpregnant rat and human PBK models were used to derive the human equivalent doses (HED) from the doses tested in rat *in vivo* DNT study: 8.2 mg/kg bw/day (low) and 326.2 mg/kg bw/day (high). The nonpregnant human model was then extended to pregnancy by incorporating physiological changes in pregnancy to develop the gestational human PBK model. **Results:** The modelled systemic exposure to parent compound is significantly lower than main metabolite due to its rapid and extensive metabolism. The daily average concentrations of parent compound in blood and brain were predicted to be below 1 µmol/L for all exposure scenarios. For the metabolite, the estimated daily average human fetal blood and brain concentrations were predicted to be < 80 µmol/L at the high HED. In rats, predicted concentration were below 120 µmol/L in blood and under 30 µmol/L in brain at 326.2 mg/kg bw/day. Based on the predictions, a top concentration of 30 µmol/L was chosen for the parent compound in most assays, and the top dose for metabolite was 100 µmol/L (for human cell-based test systems) or 300 µmol/L (for rat-derived assays). **Conclusions:** This study highlights the value of PBK modeling in informing concentration selection for *in vitro* assays across species, particularly when *in vivo* or environmental exposure is known. By predicting fetal brain exposure using gestational human models, we identified biologically relevant concentrations that would ultimately improve the interpretation and human health relevance of DNT IVB results.

PS 3553 Toxicity and biotransformation of trans-1,2-difluoroethene (R-1132-(E))

R. H. Dekant¹, W. Dekant¹, Z. Guo², T. Nakaue², S. Tokuno², A. Mally¹, and C. Burger¹. ¹University of Wuerzburg, Wuerzburg, Germany; and ²Daikin Industries, Ltd., Osaka, Japan.

Background and Purpose: 1,2-Difluoroethene (R-1132-(E)) is a potential novel refrigerant with favorable environmental properties. Inhalation studies in rats indicate a low toxicity potential, with no observed adverse effect levels (NOAELs) exceeding 15,000 ppm in a 90-day repeat exposure study. In contrast, 28-day whole body exposure of rabbits to 500 ppm resulted in mortality (two of 10 exposed animals), demonstrating pronounced species-differences in R-1132-(E) toxicity. These species-differences may be linked to species-specific biotransformation to toxic metabolites in rabbits. To comparatively study the biotransformation of R-1132-(E) between species, fluorine-containing metabolites were monitored by ¹⁹F-NMR in urine of rats and rabbits following inhalation exposure. **Methods:** Male and female rats (n=5 per sex) were exposed to 0, 2,000, 5,000 and 15,000 ppm of R-1132-(E) for 6 h/day, 5 days/week, for up to 28 days. Male and female rabbits (n=5 per sex) were exposed to 0, 500, 1,000 and 2,000 ppm of R-1132-(E) for the same duration and schedule. Urine of rats was collected in metabolic cages for 16 hours following the 6 h exposure on days 3, 14, 17 and 27. Rabbit urine was obtained by puncture of the bladder 18 hours after the final exposure. **Results:** Besides fluoride, which was also found in urine of untreated rats at comparable levels, ¹⁹F-NMR spectra of urine from rats exposed to 15,000 ppm of R-1132-(E) did not contain any signals indicative of fluorine-containing metabolites. In contrast to rats, trace levels of 2,2-difluoroacetic acid (DFA) were identified in urine of several rabbits exposed to 500, 1,000 and 2,000 ppm of R-1132-(E), with no apparent dose-response. **Conclusions:** The absence of signals of DFA in urine of control rabbits, suggests that DFA may be a potential urinary metabolite of R-1132-(E), even though formation of DFA from R-1132(E) requiring intramolecular 1,2-fluorine migration – similar to the biotransformation of 1,2-dichloroethene – appears unexpected. The at best low levels of biotransformation of R-1132-E is further supported by *in vitro* studies in rat, rabbit and human hepatocytes exposed to 0 or 15,000 ppm of R-1132-(E) for 48 hours, in which no fluorine containing metabolites could be identified by ¹⁹F-NMR. Due to the low levels of DFA detected and the paucity of DFA toxicity data it is currently not possible to draw any conclusions on the role of DFA in R-1132-(E) toxicity in the rabbit. This work was supported by Daikin Industries, LTD.

PS 3554 Bioactivation of alkylfurans to reactive α,β-unsaturated dicarbonyls: Evidence from *in vitro* and *in vivo* studies

R. H. Dekant, J. Buchholz, L. Willi, L. Geisenfelder, C. Burger, and A. Mally. University of Wuerzburg, Wuerzburg, Germany.

Background and Purpose: Alkyl-substituted furans (alkylfurans) are present in a range of foods and are likely to contribute significantly to overall furan exposure. While furan is a well characterized hepatotoxin and rodent liver carcinogen, there is limited toxicity data on alkylfurans. Based on their structural analogy, there is concern that alkylfurans may produce similar toxicological effects as furan due to CYP450-mediated oxidation of the double bond and subsequent ring opening of the furan moiety to yield reactive dicarbonyls. However, the side-chain may influence the rate of bioactivation, and thus assumption of dose additivity may overestimate health risks. **Methods:** The overall objective of the present work was to inform risk assessment by investigating the biotransformation of selected alkylfurans with different

side-chain length in rat and human microsomes, HepaRG cells and in rats through quantitative analysis of glutathione (GSH)- and N-acetyl-lysine (NAcLys)-adducts of ring-opened metabolites of alkylfurans via stable isotope dilution LC-MS/MS. **Results:** In analogy to furan, GSH- and NAcLys-adducts were detected in incubations of rat and human liver microsomes with 2-methylfuran (2-MF), 2-ethylfuran (2-EF) and 2-pentylfuran (2-PF) in the presence of GSH and NAcLys as trapping agents, confirming CYP450-mediated bioactivation of 2-MF, 2-EF and 2-PF to the reactive α,β-unsaturated dicarbonyls 4-oxo-2-pentenal, 4-oxo-2-hexenal and 4-oxo-2-nonanal, respectively. Quantitative analysis revealed differences in the rate of formation of GSH- and NAcLys-adducts, with overall lower rates with alkylfurans compared to furan (Furan > 2-MF >> 2-EF > 2-PF). Across compounds, higher rates of GSH- and NAcLys-adduct formation were observed in rat vs. human liver microsomes, indicating species-differences. The impact of the side-chain on the extent of bioactivation of furans to reactive dicarbonyls was confirmed in HepaRG cells exposed to furan and alkylfurans (0-10 mM) for 24h and in rats. In male F344 rats administered a single oral dose of 1 mg/kg bw 2-MF, 2-EF or 2-PF, urinary 24h-excretion rates of GSH-adducts of alkylfurans were significantly lower as compared to the excretion rate of the furan derived GSH adduct after furan administration (1 mg/kg bw), with a clear trend with increasing side-chain length (Furan >> 2-MF > 2-EF > 2-PF). Similar to furan, NAcLys-adducts of alkylfurans were also detected in urine of untreated rats, suggesting a yet unknown exogenous or endogenous source. **Conclusions:** Overall, our data support the hypothesis that the rate of bioactivation of alkylfurans to a reactive intermediate is lower as compared to furan, which may suggest that alkylfurans may be of lower toxicological concern. Moreover, the species-differences observed in rat vs. human liver microsomes suggest that humans may be less susceptible to (alkyl)furan toxicity than rodents. This work was supported by Nestlé Research and the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation).

PS 3555 Machine Learning-Enabled Reconstruction of Complete Nanoparticle Biodistribution Profiles in Tumor-Bearing Mice from Incomplete Experimental Data

X. Chen, Q. Chen, and Z. Lin. University of Florida, Gainesville, FL.

Background and Purpose: Most nanomedicine studies in tumor-bearing mice report biodistribution in only 2-3 tissues, limiting cross-study comparability and slowing translation. To address this, we developed a machine-learning (ML) framework to reconstruct full biodistribution profiles across six tissues (tumor, heart, liver, spleen, lung, kidney) from incomplete datasets. Importantly, the model incorporates nanoparticle (NP) dose as a continuous input, enabling dose-aware, cross-study predictions. **Methods:** We curated 1,073 NP biodistribution profiles from tumor-bearing mouse studies, including 505 complete six-tissue datasets. To prevent data leakage, we used profile-level cross-validation and group-based train/test splits, generating 28,280 prediction scenarios with 2-5 tissue inputs. Eight algorithms were benchmarked, including linear regression, tree ensembles, and XGBoost variants. Performance metrics included R², RMSE, MAE, and overfit gap. Model interpretation identified physicochemical and biological drivers of NP fate. **Results:** The tree-based and gradient-boosted models achieved strong performance. For tissues characterized by predominantly passive distribution (tumor, heart, liver, spleen, lung), top test R² values by tissue were tumor 0.695, heart 0.583, liver 0.911, spleen 0.650, lung 0.495 (mean R² = 0.667). In contrast, kidney exhibited lower predictive performance (R² = 0.160), with feature correlations near zero (mean |r| = 0.021 vs. 0.068-0.107 for other organs), indicating renal clearance is driven by unmeasured physiological factors rather than static NP properties. Across all tissues, mean test R² was 0.558, with RMSE 6.32 %ID and MAE 1.63 %ID. Key predictors included NP dose, size, shape, core material, zeta potential, timepoint, and cross-tissue correlations. **Conclusions:** We present the first dose-aware ML framework capable of reconstructing complete 6-tissue NP biodistribution profiles in tumor-bearing mice from partial data. Our findings reveal a fundamental distinction: while static physicochemical properties reliably predict passive organ distribution (R² > 0.49), renal clearance requires additional physiological factors that remain to be determined. This platform enables standardized, cross-study analysis without requiring full experimental reporting, and identifies key physicochemical drivers of NP fate including dose, size, shape, core material, zeta potential, and timepoint. Building on this quantitative foundation, the next step is to integrate these ML predictions with physiologically based pharmacokinetic (PBPK) modeling to create an ML-enhanced PBPK framework. This integrated approach will combine the predictive power of ML with mechanistic pharmacokinetic insights, accelerating rational nanomedicine design and translation.

PS 3556 Major *in vitro* Phase I and Phase II Metabolites of Cannabichromene

A. Ward, R. McCullough, and U. Christians. University of Colorado Anschutz Medical Campus, Aurora, CO.

Background and Purpose: Cannabichromene (CBC) is considered one of the most prevalent minor cannabinoids. The U.S. minor cannabinoid market was estimated to be 11.5 billion dollars in 2023 and is expected to triple to nearly 33.3 billion dollars by 2030. The biological effects of CBC are largely uncharacterized. Anecdotal sources targeted to the public claim far-reaching medical benefits including being anti-in-

flammatory, antidepressive, antinociceptive, and having cancer-fighting properties. These broad and unspecific claims coupled with the projected popularity and lack of rigorous scientific research elucidate a critical gap in knowledge. Therefore, characterization of CBC pharmacokinetics, particularly metabolism, will aid in alleviating the current deficiency in research. Previous studies of major cannabinoids (i.e. Δ^9 -tetrahydrocannabinol and cannabidiol) indicate that their respective metabolites maintain biological activity and thus are critical to consider in terms of pharmacokinetic and pharmacodynamic relationships. To date, phase I and phase II metabolic products of CBC have yet to be determined in human *in vitro* or *in vivo* models alike. **Methods:** To study *in vitro* metabolism, CBC was incubated with HepaRG cells and human liver microsomes (HLMs). In HepaRG cells, CBC was incubated for 2 and 24 hours at various concentrations (0.5, 5.0, and 50 μ M). Both cell extract and media were collected from each sample. A semi-quantitative methodology utilizing high-performance liquid chromatography-high resolution mass spectrometry (HPLC-TripleTOF) was used to gauge metabolite generation. To determine HLM enzyme kinetics, incubation time and protein concentration were first optimized for phase I and phase II generation of metabolites. Following optimization, the dose-dependent production of CBC metabolites was calculated wherein K_m and V_{max} values were determined via Michaelis-Menten kinetics. Intrinsic clearance was calculated by the following equation: $CL_{int} = V_{max}/K_m$. **Results:** The metabolic products generated from both HepaRG cells and HLMs were chromatographically separated and analyzed via HPLC-TripleTOF. The major phase I oxidative metabolite was confirmed to be 2'-hydroxycannabicitran, and the major phase II conjugated metabolite was hypothesized to be CBC-glucuronide according to high resolution exact mass. In both HepaRG cells and HLMs, 2'-hydroxycannabicitran was rapidly generated, while CBC-glucuronide exhibited a relatively slower generation. The kinetic patterns of metabolite generation in HepaRG cells were aligned with those of the HLM incubations. In HepaRG cells, these two metabolites constituted the main metabolites detected. There was not any combinatorial oxidation-conjugation type metabolite detected from the given incubations. **Conclusions:** Identification of CBC metabolites is a critical step in elucidating the pharmacokinetics of CBC. Additional experiments characterizing which specific drug metabolizing enzymes namely CYP450s and UGTs are involved in generating 2'-hydroxycannabicitran and CBC-glucuronide, respectively, would be a fundamental step in establishing if there is potential for subsequent drug-drug interactions. Utilizing *in silico* methodologies, further work will probe the potential for biological activity of 2'-hydroxycannabicitran and CBC-glucuronide on various proteins in the endocannabinoidome.

PS 3557 Mechanistic Insights into Liposomal Doxorubicin Distribution in Mice through Physiologically Based Pharmacokinetic Modeling

C. Chen, and Z. Lin. University of Florida, Gainesville, FL.

Background and Purpose: Cancer remains a major global health challenge, with its incidence and mortality continuing to rise. Nanotechnology offers a promising strategy to improve anticancer drug delivery by enhancing pharmacokinetics (PK) and bioavailability while minimizing systemic toxicity. Liposomal doxorubicin (Doxil®), the first clinically approved nanomedicine for cancer treatment, has been widely studied, yet most preclinical investigations have focused on comparing the PK profiles of native drug versus released drug rather than characterizing the whole-body disposition of intact drug-loaded nanoparticles in tumor-bearing models. Hence, this study aims to develop a joint physiologically based pharmacokinetic (PBPK) model that simultaneously describes the biodistribution of both encapsulated and released doxorubicin in tumor-bearing mice, providing mechanistic insights into nanodrug delivery and disposition processes. **Methods:** The joint PBPK model consists of submodels for encapsulated and released doxorubicin, respectively, sharing an identical physiological structure comprising major organs (lungs, liver, spleen, kidneys, heart, muscle), tumor tissues, blood, and a rest-of-body compartment. Both submodels incorporate plasma albumin binding and excretion via bile, feces, and urine, but differ in kinetic assumptions. The released doxorubicin submodel uses perfusion-limited kinetics for most tissues (permeability-limited for muscle and rest-of-body), includes DNA and cardiolipin binding, and accounts for hepatic metabolism via glycosidase activity. In contrast, the encapsulated submodel applies permeability-limited kinetics to all compartments and includes reticuloendothelial system (RES) subcompartments in the liver, lungs, spleen, and kidneys to describe nanoparticle uptake and clearance. The two submodels are linked by nanodrug uptake and release mechanisms, allowing encapsulated doxorubicin internalized by RES cells or tumor-associated macrophages and cells to be released into the corresponding compartments of the free-drug model. PK profiles for native and released doxorubicin reported from the same studies were used for model calibration, while other available PK data served as evaluation data. Given the numerous parameters in this joint PBPK model, model development proceeded sequentially: first, native drug in healthy and tumor-bearing mouse models to characterize doxorubicin-related parameters; then, liposomal doxorubicin in healthy and tumor-bearing mouse models to characterize parameters related to drug-carrying liposomes. Sensitivity analyses were conducted both before and after parameter fitting to identify essential parameters for optimization and determine which parameters significantly impact organ dosimetry for both released and encapsulated forms. **Results:** Model calibration demonstrated excellent agreement with *in vivo* data over 48 hours, achieving a root mean square error of 13% and an adjusted R^2 of 0.87. Based on preliminary sensitivity analyses and multiple calibration trials, tissue-to-plasma partition coefficients and the Michaelis constant for fecal elimination were identified as requiring

optimization. Compared to default values adopted from previously published PBPK models for doxorubicin, the optimized partition coefficients decreased by an average of two orders of magnitude, while the Michaelis constant for fecal elimination increased 10-fold. Despite these adjustments, the model maintained strong predictive performance, suggesting that the optimized parameters more accurately represent underlying physiological processes captured by the expanded mechanistic framework. **Conclusions:** The model provides a comprehensive framework for understanding liposomal nanotherapeutic pharmacokinetics by capturing critical mechanistic aspects often overlooked in conventional PK models. This approach offers a valuable tool for optimizing liposomal formulations, predicting tissue-specific drug exposure, and enabling rational nanomedicine design. Future applications include extending the model to other nanoparticle-based drug delivery systems and supporting translational efforts to refine clinical dosing strategies.

PS 3558 Safety and Pharmacokinetic Evaluation of a Platelet inspired Hemostatic Nanotechnology in Sprague Dawley Rats and Beagle Dogs

E. Gahagan, U. Sekhon, B. Traylor, K. Aldridge, E. Quill, M. Ahmed, C. Pawlowski, and M. Bruckman. Haima Therapeutics, Cleveland, OH. Sponsor: D. Hobson

Background and Purpose: Allogeneic platelet transfusion is a mainstay therapy for bleeding complications in trauma, surgery, hematology/oncology, and congenital disorders, yet its use is limited by short shelf life, contamination risks, and logistical challenges. To address these limitations, we developed SynthoPlate (SP), a lyophilizable, shelf-stable, platelet-inspired nanoparticle that mimics primary hemostatic mechanisms to serve as a potential platelet surrogate for both in-hospital and pre-hospital use. This non-GLP study evaluated SP safety, tolerability, and pharmacokinetics (PK) following intravenous administration in Sprague Dawley rats and Beagle dogs. **Methods:** SP was manufactured using established methods with physicochemical and functional release testing. Non-GLP single ascending-dose studies were performed in healthy Sprague Dawley rats and Beagle dogs, with infusion rate and dose adjusted to assess administration limits. Tolerability was evaluated via clinical observations, hematology, clinical chemistry, cytokine profiling, coagulation panels, gross pathology, and histopathology. Plasma levels of SP were quantified by LC-MS/MS and PK parameters were determined. Lastly, biodistribution in rats was assessed over 72 hours by IVIS imaging. **Results:** As observed with other nanoparticle systems, infusion-related reactions occurred across species and increased in severity with higher doses; however, reducing the infusion rate markedly improved tolerability. In Beagle dogs, complete blood counts showed dose-dependent decrease in white blood cells (neutrophils, lymphocytes, monocytes, eosinophils) and platelets and increase in mean platelet volume (MPV), red blood cells, hemoglobin, hematocrit, and reticulocytes. In rats, a decrease in platelet counts and an increase in MPV was observed with transient dose-dependent recovery. Clinical chemistry in dogs revealed dose-dependent increase in liver enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT], alkaline phosphatase [ALP], and gamma glutamyl transferase [GGT]). Furthermore, coagulation analysis in dogs indicated prolonged partial prothrombin time (aPTT) at the highest dose tested without significant effects on prothrombin time (PT) or fibrinogen. Cytokine analysis in dogs showed slight increases in IL-6, IL-10, MCP-1, and TNF- α and decrease in IL-8, consistent with infusion-related immune response. No mechanism-based toxicity was observed; necropsy and histopathology revealed no signs of thrombosis or abnormal clot formation. PK analysis demonstrated biphasic clearance with half-lives of ~3-6 hours in dogs and 2-4 hours in rats. Biodistribution indicated primary accumulation in the liver, moderate uptake in the lungs and spleen, and minimal presence in the brain, heart, and kidneys with near complete clearance from all organs by 72 hours. **Conclusions:** SynthoPlate is a fully synthetic, platelet-mimicking nanotechnology exhibiting dose-dependent, transient, infusion-related inflammatory and hematologic responses consistent with other liposomal platforms. No on-target toxicity was observed at any of the doses tested, which exceeded 250X the effective dose range. The nanoparticles were largely cleared from circulation within 24-48 hours and from major organs by 72 hours. These data establish a favorable tolerability and PK profile and support definitive, IND-enabling GLP toxicology studies in preparation for first-in-human evaluation.

PS 3559 A Regulatory Aligned Dual-Endpoint Human Hepatocyte Platform for Mechanistic and Quantitative CYP450 Induction Assessment and Drug-Drug Interaction Risk Prediction

R. S. Sharma, M. Gibson, and A. Augello. Concept Life Sciences, Dundee, United Kingdom. Sponsor: R. Sharma, EUROTOX

Background and Purpose: Cytochrome P450 (CYP) enzyme induction is a key mechanism underlying drug-drug interactions (DDIs) that can affect systemic drug exposure and patient safety. Regulatory agencies, including the FDA and EMA, require robust *in vitro* evaluation of CYP induction potential to support safe clinical progression and regulatory submissions. Despite existing models, variability in hepatocyte responses and reliance on single-endpoint assays can limit mechanistic insight and predictive confidence. To address these gaps, we developed a regulatory aligned, dual-endpoint human hepatocyte platform that quantitatively evaluates both CYP

mRNA expression and enzymatic activity, providing mechanistic insight into induction responses and enabling early, informed decision-making in drug development programs and facilitate compliance with current regulatory guidelines. **Methods:** Cryopreserved primary human hepatocytes are used in two assay formats: a 48-hour induction assay with pooled hepatocytes for screening CYP1A2, CYP2B6, and CYP3A4; and a 72-hour induction assay with hepatocytes from at least three individual donors to assess CYP1A2, CYP2B6, CYP3A4, CYP2C8, CYP2C9, and CYP2C19, capturing donor variability. Media is refreshed every 24 hours during treatment. Following exposure to test compounds, positive controls (omeprazole for CYP1A2; phenobarbital for CYP2B6; rifampicin for CYP2C8, CYP2C9, CYP2C19, and CYP3A4), or the negative control flumazenil, cells are either harvested for gene expression analysis via qRT-PCR or washed and incubated with isoform-specific probe substrates. The substrates used include phenacetin, bupropion, midazolam, amodiaquine, diclofenac, and S-mephenytoin, with their respective metabolites acetaminophen, hydroxybupropion, 1-hydroxymidazolam, N-desethylamodiaquine, 4-hydroxydiclofenac, and 4-hydroxymephenytoin measured. A novel, highly sensitive LC-MS/MS bioanalytical method was developed to simultaneously quantify all six CYP-specific metabolites from a single sample, enabling efficient and accurate assessment of catalytic enzyme activity. Test compound dosing is guided by cytotoxicity assessment (LDH and ATP viability assays). Data are analysed to calculate fold induction relative to vehicle controls, Emax, and EC50 values using four-parameter nonlinear regression. **Results:** Positive control compounds omeprazole, phenobarbital, and rifampicin induced CYP1A2, CYP2B6, CYP3A4, CYP2C8, CYP2C9, and CYP2C19 in a dose-dependent manner at both gene expression and enzyme activity levels, demonstrating assay sensitivity and specificity. Fold inductions relative to vehicle controls ranged from 2- to 15-fold depending on the CYP isoform and inducer. EC50 and Emax values calculated using four-parameter nonlinear regression were consistent with literature and regulatory expectations. A strong positive correlation was observed between mRNA fold changes and corresponding catalytic activity measurements across tested CYPs, validating the complementary dual-endpoint readout. Induction profiles were reproducible across multiple individual donors, supporting assay robustness and the ability to capture donor variability. These results confirm the platform's ability to quantitatively assess CYP450 induction and provide mechanistic insight into potential drug-drug interaction risks, supporting confident decision-making during early and late-stage drug development. **Conclusions:** The developed regulatory-aligned dual-endpoint human hepatocyte platform enables sensitive, quantitative assessment of CYP450 induction at both gene expression and enzymatic activity levels. Leveraging pooled and individual donor hepatocytes alongside a novel multiplexed LC-MS/MS bioanalytical method for simultaneous metabolite quantification, this approach provides comprehensive mechanistic insights into drug metabolism. The platform supports early prediction and de-risking of drug-drug interaction potential, streamlines regulatory submissions aligned with FDA/EMA guidelines, and facilitates informed decision-making across drug development stages. This assay offers a robust, reproducible, and efficient solution for evaluating CYP induction, advancing the safety and efficacy assessment of new chemical entities.

PS 3560 Protecting Predators: Developing a Non-Lethal Framework for Toxicological Impacts of Mercury and PFAS in Sharks

P. C. Powell¹, M. Walker¹, G. Aniolek¹, B. Frazier², S. Kim³, and K. D. Rock¹. ¹Clemson University, Clemson, SC; ²South Carolina Department of Natural Resources, Charleston, SC; and ³University of California Merced, Merced, CA.

Background and Purpose: Sharks are apex predators critical for maintaining marine ecosystem balance, yet they face growing pressures from overfishing, habitat loss, and chemical pollution. Mercury (Hg) and per- and polyfluoroalkyl substances (PFAS) are two contaminants that bioaccumulate in marine food webs and have been shown to disrupt neurological, hepatic, and reproductive processes in vertebrates. Sharks' long lifespans, high trophic status, and slow reproduction make them particularly susceptible to such stressors. However, the distribution and physiological processing of these contaminants remain poorly characterized due to ethical and logistical limits on lethal sampling. We **hypothesize** that contaminant concentrations in non-lethal tissues, specifically blood and muscle, can reliably predict burdens in internal organs that are critical for shark health and reproduction (e.g., liver, brain, gonads). By establishing quantitative relationships among these matrices, we can describe contaminant transport and accumulation across tissues using physiologically based toxicokinetic (PBTK) modeling. This project addresses this gap by developing a way to predict tissue-specific contaminant burdens using only blood and muscle samples. Integrating contaminant data, trophic ecology, and shark-specific physiological parameters, this approach establishes a scalable and ethical framework for assessing chemical risk and informing conservation strategies for sharks. **Methods:** Blood and muscle samples were collected from finetooth (*Carcharhinus isodon*) sharks in Bulls Bay and St. Helena Sound, South Carolina, in collaboration with the South Carolina Department of Natural Resources (SCDNR). Organ tissues (liver, brain, gonads, spleen, stomach) from incidental mortalities were collected to aid model calibration. Hg concentrations were quantified by thermal decomposition-amalgamation atomic absorption spectrophotometry (EPA Method 7473), and PFAS congeners are being analyzed via high-performance liquid chromatography coupled with tandem mass spectrometry. Stable isotope analyses ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$) are being used to assess trophic position and diet. Doppler ultrasound assessments will measure total cardiac output and regional blood flow to vital organs at two physiological states (active and stabilized) to parameterize circulatory dynamics. These data,

along with tissue:blood partition coefficients, organ volumes, metabolic rates, and clearance parameters, will inform Bayesian-calibrated PBTK models developed in R and Berkeley Madonna. **Results:** Preliminary Hg data from neonate finetooth sharks show tissue-specific variability, with the highest concentrations observed in muscle, followed by liver, spleen, stomach, brain, and blood. A significant positive correlation between Hg concentrations in blood and muscle ($R^2 = 0.77$) demonstrates consistent partitioning dynamics between these two matrices. This relationship suggests that both tissues reflect integrated exposure and bioaccumulation processes and can be jointly used to estimate internal contaminant distribution. This correlation supports a core assumption of the PBTK framework, that equilibrium partitioning among vascularized tissues can be inferred from accessible compartments. Ongoing analyses are extending these relationships to PFAS congeners and incorporating stable isotope-derived trophic data to refine model parameterization. Upcoming Doppler ultrasound data will provide the first non-lethal estimates of cardiac output and organ-specific perfusion in sharks, improving prediction of contaminant transport and deposition. **Conclusions:** This research represents one of the first integrated efforts to pair empirical contaminant data with physiological modeling to enable non-lethal toxicological risk assessment in sharks. The developing PBTK model will allow prediction of organ-specific Hg and PFAS burdens from easily obtained blood and muscle samples, enhancing conservation and management for species where lethal sampling is not possible. In partnership with SCDNR and NOAA, this work will advance evidence-based risk assessment, support proactive conservation strategies, and strengthen ecosystem-based management of apex predators in coastal environments.

PS 3561 Streamlining tissue toxicokinetic analysis in dose range finding toxicology studies for small molecules

S. Mukherjee, V. Siramshetty, M. Hayes, S. Ubhayakar, X. Zhang, E. Choo, B. Dean, M. Durk, L. Salphati, Y. Zhong, and S. Kakiuchi-Kiyota. Genentech, South San Francisco, CA.

Background and Purpose: Tissue toxicokinetic (TK) analysis is typically considered at the discovery stage of small molecules, especially for those with an inherent risk to accumulate in tissues. In an effort to systematically replace ad hoc practices with a pragmatic operating model, the purpose of this analysis was to reframe tissue TK assessment from a default requirement to a case-by-case decision. **Methods:** A concise WHEN-HOW-IF framework was applied with a decision tree that triggers analysis when high drug concentrations could affect the tox profile, target tissue exposure, GLP study design, and/or target engagement only after target organ toxicity is confirmed. **Results:** Leveraging historical pilot toxicity data and robust statistical analyses, it was demonstrated that tissue-to-plasma ratios are largely dose-independent in rodents, enabling a "one-dose-only" approach that preserves scientific rigor while minimizing resources. If tissue TK is determined to add value, tissues of concern are to be collected but quantitation can be deferred until warranted. The mid-dose should be prioritized for tolerability and interpretability, and focusing on rodent TK when cross-species data is available would not change decisions. **Conclusions:** This approach accelerates the advancement of safer and more promising molecules by eliminating potentially non-informative tissue TK assessments and focusing analyses where they clarify mechanisms of toxicity, inform study design, or support target engagement. It reduces bioanalytical burden, animal use, turnaround time to obtain results, and cost, while maintaining decision confidence—"one-dose-level" rodent TK and "analyze-when-warranted" workflows streamline dose range finding studies and is an example of how lean practices can improve outcomes without sacrificing rigor, creating a sustainable model that scales across portfolios and de-risks early development.

PS 3562 Route-Specific Variation of Systemic Bioavailability of Chemical Emissions

J. F. Wambaugh¹, K. K. Isaacs¹, N. Charest¹, C. Choo², H. Clewell³, M. Linakis⁴, S. Sharma², G. Sinclair¹, C. Weitekamp¹, C. Wright², Q. Zhang², K. Paul Friedman¹, and M. Wilson². ¹ULRI Chemical Insights, Research Triangle Park, NC; ²ULRI Chemical Insights, Marietta, GA; ³Ramboll, Durham, NC; and ⁴Ramboll, Salt Lake City, UT.

Background and Purpose: Chemical systemic bioavailability, as represented by plasma concentration achieved per unit of external dose, can vary significantly depending upon route of absorption. In the extreme, chemicals might be effectively unavailable by one route but readily absorbed by another. The health risk posed by a chemical therefore depends on the plausible routes of exposure. **Methods:** In this study, we sought to predict via high throughput physiologically-based toxicokinetic (PBTK) models how systemic bioavailability of chemicals varied by route of exposure. Four scenarios were considered: 1) inhalation of fumes, 2) oral ingestion, 3) dermal exposure after eight hours of daily exposure to hands (UK Surrey permeability model), and 4) inhalation of an aerosol of particles with mean size 100 nm and standard deviation 40 nm. Chemicals of interest were compiled from public information on semi- and volatile organic compounds (VOCs) including those with known *in vivo* inhalation toxicological points of departure (PODs), Toxic Substances Control Act (TSCA) high priority substances, aldehydes, chemicals identified in emissions from a 3D printer, and a limited number of chemicals screened with air-liquid inter-

face-based new approach methods (NAMs). High throughput toxicokinetic (HTTK) modeling requires chemical-specific values for intrinsic hepatic clearance (Cl_{int}) and fraction unbound in plasma (f_{up}). Quantitative structure-property relationship (QSPR) models were used to make predictions for Cl_{int} and f_{up} . A three-compartment PBTK model was used to predict steady-state plasma concentration (C_{ss}) for oral and fume inhalation exposures. A dermal PBTK model was used to predict C_{ss} for repeated exposure to hands. An aerosol dosimetry model coupled to a gas-inhalation PBTK model was used for C_{ss} from aerosol exposure. Each PBTK model has been individually evaluated using route-specific plasma concentration vs. time data across multiple reference chemicals. Chemicals were ranked using the Toxicological Prioritization Index (ToxPI) to visualize the total and relative contributions of four potential routes of exposure to systemic bioavailability. **Results:** Out of 2776 unique chemicals of interest, *in vitro* measured HTTK model parameter values were available for 136. 2113 had representative structures. Of these, descriptors could be generated for 1892. QSPR predictions were within domain of applicability for 1479 (78%). With QSPRs, HTTK predictions could be made for a total of 1547 chemicals. The chemical that was predicted to be most bioavailable was 2-tert-butylphenol, which is predicted to be readily absorbed from oral, dermal, fume inhalation, and aerosol routes. Among chemicals with PODs, 2-methyl-4,6-dinitrophenol was the most bioavailable; it has an occupational inhalation lowest effect level (LEL) of 4.7 mg/m³ and a clinical oral lowest observed adverse effect level (LOAEL) of 0.35 mg/kg-d. Among seven chemicals that had both oral and inhalation PODs, the bioavailability predictions explained at least 39% of variation in POD by route. For dermal exposure the most bioavailable chemical was 1,2-dimethyl-3-nitrobenzene. Among the chemicals found in emissions from 3D printers, the most bioavailable from fumes was tridecane while 2,2,4-trimethyl-1,3-pentanediol diisobutylate was the most bioavailable as an aerosol. **Conclusions:** The environment is full of potential sources of chemical exposure - the extent to which these exposures result in meaningful tissue concentrations depends on both inherent chemical properties and the route of exposure. Using generic PBTK models, it is now possible to quantitatively predict how the route of exposure may impact human plasma concentrations. These predictions can help identify the most valuable exposure pathway information to measure or curate, as well as the most informative experimental designs for understanding potential toxicity from chemical exposures.

PS 3563 A Quantitative Synthesis of the Drivers and Magnitudes of Maternal-Child PFAS Transfer

Y. Zhu¹, C. Thackray¹, Z. Hu¹, J. M. Braun², E. M. Sunderland¹, and F. C. Fischer^{1,3}.

¹Harvard University, Cambridge, MA; ²Brown University, Providence, RI; and

³University of Rhode Island, Kingston, RI.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are persistent environmental pollutants that impair vaccine responses and immune function during vulnerable early-life stages. While breast milk is essential for infant nutrition, it also serves as a major PFAS exposure route, yet the toxicokinetics (TK) of transplacental PFAS transfer remain poorly characterized. We developed a maternal-child TK model to better understand the dynamics of maternal-child PFAS transfer and quantify the contribution of breastfeeding to internal exposures across from early life through adulthood (0-30 years). **Methods:** We applied the TK model to perfluorooctane sulfonic acid (PFOS), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), and perfluorohexane sulfonic acid (PFHxS) that incorporates continuous pre-pregnancy, gestational with maternal-fetal transfer, and lactational with breastfeeding transfer periods. The model was parameterized with chemical- and life-stage-specific physiological parameters and estimated PFAS exposure through drinking water, food, dust, and inhalation. Model evaluation used paired biomonitoring data from 16 cohorts with maternal, child, and breastmilk PFAS concentrations. We simulated a range of breastfeeding durations to estimate internal PFAS burdens during sensitive developmental windows. **Results:** Model predictions were broadly consistent with biomonitoring data. Predicted PFAS concentrations in breastfed infants after weaning were 2-4 times higher than those prior to breastfeeding. Sensitivity analyses suggest breastfeeding duration and drinking water PFAS concentration as key drivers of early childhood exposures. Breastfeeding was the primary driver of PFAS accumulation in children between ages 1 and 4, with each additional month of breastfeeding associated with a 1.3%-10% increase in serum PFAS concentrations at age 3. The relative contribution of breast milk increased to 34-49% during breastfeeding and declined after weaning, falling below 20% by 2-6 years of age. Compared with drinking water, breastfeeding contributed more to serum PFAS concentrations until approximately 13 years of age, with peak contributions 3.3-6.0 times higher. **Conclusions:** This quantitative synthesis advances our understanding of how maternal-child PFAS transfer shapes childhood PFAS burden. Future maternal cohort studies should integrate detailed exposure, physiological, and breastfeeding data to refine the developed TK model and enhance its applicability across diverse populations.

PS 3564 A rapid dosimetry model to investigate long-term spaceflight effects on drug disposition

S. U. Hirway^{1,2}, D. W. Cowan^{1,2}, T. Jaworek^{1,2}, T. LaLonde^{3,2}, L. M. Sweeney^{1,2}, T. R. Sterner^{3,2}, R. A. Clewell^{4,2}, and J. F. Reichard^{5,6}. ¹BlueHalo, an AV Company, Dayton, OH; ²Air Force Research Laboratory, Wright Patterson Air Force Base, OH; ³Henry M. Jackson Foundation for the Advancement of Military Medicine, Inc., Wright Patterson Air Force Base, OH; ⁴Eagle Integrated Services, Inc., Wright Patterson Air Force Base, OH; ⁵NASA Johnson Space Center, Houston, TX; and ⁶University of Cincinnati, Cincinnati, OH.

Background and Purpose: Spaceflight causes a wide range of physiological changes which have potential to affect the pharmacokinetics (PK) of drugs. As NASA seeks a more diverse astronaut corps, the combined influence of altered physiology and changing demographics could increase the risk of reduced drug efficacy or adverse effects. Age, sex and racial diversity also introduce a potential concern for genetic polymorphisms that could impact medical outcomes during long-term missions. Thus, a better understanding of how spaceflight physiology and gene polymorphisms impact the PK of drugs is needed. Although studies have tested the PK disposition of a few medications during spaceflight and under simulated microgravity environments, it is impractical to empirically test the impact of microgravity on all drugs that may be provided to astronauts. This study aims to use physiologically-based pharmacokinetic (PBPK) modeling to evaluate how the physiological changes associated with long-duration exposure to microgravity impact drug disposition of medications that may be included in medical kits for lunar and planetary space missions.

Methods: This study used the US EPA's High Throughput Toxicokinetics (httk), a PBPK model that estimates chemical exposure doses in the body for thousands of drugs simultaneously. Physiological parameters were adjusted to reflect current astronaut demographics, and spaceflight modifiers were applied to measured changes during spaceflight, including glomerular filtration rate (GFR), hepatic metabolism, body weight, hematocrit, cardiac output and fraction of drug absorbed in gut. In addition, to explore the role of genetic diversity in drug disposition, metabolic enzyme polymorphisms were introduced using published prevalence data. Model predictions were compared between terrestrial and spaceflight modified conditions for 74 drugs that were grouped into four classes defined by the Biopharmaceutical Drug Disposition Classification System (BDDCS), and the predicted blood concentrations were evaluated. **Results:** Sensitivity analyses showed that GFR, hepatic metabolism and fraction of drug absorbed in gut had the strongest effects on steady state parent-drug blood concentrations. Conversely, the impact of the cephalic shift of fluids and volume loss, which are commonly associated with microgravity, had a negligible effect. Genetic polymorphisms primarily affected Class 1 drugs, with their Oral Equivalent Doses (OEDs) exhibiting fold changes below -0.5 in 8 out of 30 drugs. High metabolism drugs from Class 1 and 2 were predicted to have a greater negative change in spaceflight, with lower OEDs compared to Earth, than Class 3 and 4 drugs. Specifically, two Class 1 drugs, diazepam and fluoxetine, as well as clobidogrel (Class 2), had the lowest fold change, with OED fold changes below -1.5. GFR spaceflight modifiers affected 13 of the 25 drugs from Classes 3 and 4. **Conclusions:** This study uses a high-throughput PBPK model to determine the effects of spaceflight and genetic polymorphisms on drug dosimetry and highlights how predictive approaches can improve personalized medicine for astronauts and the military in physiology-altering environments. The model is flexible and can be updated as impacts of long-term spaceflight on human physiology and mission parameters become clearer. PBPK modeling predictions can be used to guide medical treatment with drugs that exhibit significant PK changes in space, target drug classes for further study, and support drug provisioning for exploratory missions. The httk model enables exploration into the effect of spaceflight on drug disposition and preliminary evaluation of genetic variability in metabolism. Future steps could involve developing bespoke models which can evaluate physiological effects such as fluid shifts associated with microgravity to better characterize spaceflight PK.

PS 3565 Towards a defined approach to assess pesticides for their potential to cause parkinsonian neurodegeneration

T. Tal¹, J. Nyffeler¹, S. Schildknecht², B. Viviani³, T. Burgdorf⁴, R. Owen¹, A. E. Krishnakumar¹, M. Mohammadi¹, Q. Fu¹, I. Mangas⁵, A. Castoldi⁵, and A. Terron⁵. ¹Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany; ²Hochschule Albstadt-Sigmaringen, Sigmaringen, Germany; ³Università degli Studi di Milano, Milano, Italy; ⁴German Federal Institute for Risk Assessment (BfR), Berlin, Germany; and ⁵European Food Safety Authority, Parma, Italy.

Background and Purpose: The pathophysiology of Parkinson's Disease (PD) implicates the death of dopaminergic neurons projecting from the substantia nigra pars compacta, which contribute to the control of motor function. Epidemiological studies indicate exposure to pesticides represents a risk factor in acquiring PD. Adverse Outcome Pathway 3 (AOP3) outlines the potential of chemical exposure to inhibit complexes of the mitochondrial respiratory chain in dopaminergic neurons, triggering a cycle of cell death and neuroinflammation leading to Parkinsonian motor manifestations. We developed a test battery of New Approach Methodologies (NAMs) utilizing human cell-based and zebrafish embryo assays to potentially link exposure to pesticides used in Europe to mitochondrial complex inhibition, neurodegeneration, and ultimately Parkinsonian motor deficits. **Methods:** 143 pesticides and reference compounds were tested at a single concentration in permeabilized human dopami-

nergic cells (LUHMES) to assess their potential to inhibit individual complexes of the respiratory chain (complexes 1-3). In parallel, potential effects on neurite architecture and cell viability were evaluated in intact LUHMES cells exposed to eight concentrations of the test compounds using high-content imaging. Exploratory characterization of the zebrafish dopaminergic system at 5 days post fertilization (dpf) was carried out through high-content confocal dorsal imaging of the Tg(*slc6a3:EGFP*) line, in which neurons expressing the dopamine transporter (DAT) are labeled with green fluorescent protein (GFP) and behavior was assessed in the Visual and Acoustic Motor Response (VAMR) NAM, capturing 26 behavior-based endpoints. **Results:** NAMs were anchored to AOP3 which describes inhibition of mitochondrial complex 1 (key event; KE1), linked to mitochondrial disruption (KE2), impaired proteostasis (KE3), degeneration of dopaminergic neurons (KE4), and Parkinsonian motor defects (adverse outcome). An initial prediction model identified 24 likely AOP3 positive compounds that inhibited one or more of the mitochondrial complexes (KE1) and reduced neurite mass at lower concentrations than those necessary to provoke cell death (KE4). An additional 14 chemicals were identified to be inactive in all assays. Ten chemicals inhibited a mitochondrial complex and caused neurite loss but not cell death and were classified as potential AOP3 positives. High-content imaging of the dorsal zebrafish brain resulted in quantifiable DAT-expressing neurons, including the main dopaminergic groups within the subpallium and diencephalon. 24 h exposure to known complex I inhibitors MPTP or 6-OHDA induced widespread behavioral hypoactivity across visual motor and acoustic startle endpoints at 5 dpf, suggesting that these compounds can be used to disrupt mature signaling systems to produce bradykinesia-like behaviors rather than impairing the developmental formation of motor circuitry, a key distinction for modeling PD in larval zebrafish. **Conclusions:** This work demonstrates the ability of *in vitro* and *in vivo* NAMs to identify AOP3 positive pesticides. Compounds identified as hits in cell-based NAMs will be tested for mitochondrial respiration inhibition in intact cells. For selected compounds, experiments in zebrafish will assess whether a loss of dopaminergic neurons results in concurrent PD-like behavioral effects. Finally, an AOP-informed Integrated Approach to Testing and Assessment (IATA) will be developed for one chemical as a best practice case study for the use of NAMs to assess effects associated with Parkinsonian-type neurotoxicity.

PS 3566 Prolonged Low-Dose Paraquat Inhalation Model in Mice Reveals Sex Specific Dopaminergic Neurodegeneration and Behavioral Deficits

P. J. Reina-Gonzalez, A. Anchan, A. Abu-Salah, D. Chalupa, M. Ay, R. Strazdins, S. Sarkar, and D. A. Cory-Slechta. University of Rochester School of Medicine and Dentistry, Rochester, NY.

Background and Purpose: Paraquat (PQ) is an industrial herbicide used to kill weeds and green plant matter during harvest season. Long-term exposure to PQ has been epidemiologically associated with increased risk of Parkinson's Disease (PD) and neurodegeneration in agricultural workers and rural communities in the United States (US). While PQ is banned in many countries throughout the globe, it remains widely used in the US, partially due to its efficacy and affordability. While inhalation of PQ has been known to induce systemic organ failure at acute concentrations, prolonged low-dose inhalation from agricultural pesticide drift has not been readily evaluated for its potential to contribute to neurodegenerative diseases *in vivo*. Instead, many animal studies have relied on other routes of exposure, including ingestion and intraperitoneal injections, which do not effectively replicate the most common ways that individuals are exposed to PQ in the environment. **Methods:** Whole-body inhalation exposures were conducted in the University of Rochester Inhalation Exposure Facility. Exposures were conducted 5 days a week for 12 weeks. Animals were exposed to either filtered air or PQ aerosols for 4 hours, during which time the mice were singly housed in wire-mesh chambers inside a 30-L steel-reinforced Lexan exposure chamber. PQ aerosols were produced by adding a 0.2 mg/mL solution of PQ in ddH₂O (made fresh every day) into an ultrasonic nebulizer (Ultrasonic2000, Novag Dental and Medical Equipment). Clean, dry air (approximately 500 mL/min) was passed through the nebulizer at a frequency of 2.4 MHz to produce a PQ mist, which then passed through a heated drying tube and a cold trap to remove moisture. The subsequent PQ particles were mixed with diluting air and passed into the exposure chamber at a rate of 25-30 L/min. A condensation particle counter (CPC Model 3022 A, TSI Inc.) was used to capture real-time exposure measurements, allowing for the quantification of continuous particle count concentrations. The particle size distribution of the aerosol was measured once per day using an electrostatic classifier (SMPS Model 3071, TSI Inc.). Three filters (Pallflex Membrane Filters, Pall Life Science) were collected hourly to determine gravimetric exposure concentration by mass. The concentration of PQ on the filters was quantified chemically using a UV-Vis spectrophotometer (HP-Agilent Technologies) at an absorbance wavelength of 259 nm. Analytical standard grade PQ (PQ dichloride hydrate PESTANAL®, ≥98.0% purity) was purchased from Millipore Sigma (CAS No: 75365-73-0). **Results:** Here, we establish and characterize an environmentally relevant mouse model of low-dose PQ inhalation that captures key behavioral deficits and pathophysiological hallmarks of PD. These include mild locomotor dysfunction, anxiety, and depression-like phenotypes, significant reductions in dopamine in the striatum, along with alterations in dopamine synthesis. We validated that PQ can enter the brain, as it was detected in the olfactory bulb, cortex, and the brain stem. The highest concentration was found to be in the olfactory bulb. These findings support the hypothesis that PQ, when inhaled, can bypass the BBB through an alternative route of entry into the CNS. This

likely occurs through sensory neurons in the olfactory epithelium that innervate the olfactory bulb and are partially exposed to the surrounding environment **Conclusions:** This model can be used to more accurately replicate environmental exposure to PQ, leading to a more accurate recapitulation of its toxic effects in humans. Further research on PQ should emphasize low-dose inhalation, given the strength of the epidemiological literature associating prolonged exposure to PD.

PS 3567 Tiny messengers, big impact: EV-miRNAs induce apoptotic signaling pathways in rotenone-induced Parkinson's Disease model

F. M. Currim, J. M. Brown-Leung, and J. R. Cannon. Purdue University, West Lafayette, IN.

Background and Purpose: Parkinson's Disease (PD) is a progressive neurodegenerative disorder characterized by the selective loss of dopaminergic neurons, primarily within the nigrostriatal pathway. Rotenone, a naturally occurring insecticide and pesticide, is a potent inhibitor of mitochondrial complex I and is implicated in PD pathogenesis. *In vivo* rotenone models replicate key PD pathogenesis and neuropathology. Emerging evidence indicates that PD pathology may propagate through intercellular communication, particularly via extracellular vesicles (EVs). miRNAs enriched in the EVs, present in biofluids such as serum, have gained attention as potential early biomarkers and mechanistic mediators of PD progression. Preliminary studies demonstrated consistent downregulation of miR-30a-5p and miR-484 in serum-derived exosomes from rotenone-treated young adult and aged rats, accompanied by mitochondrial dysfunction and neuronal cell death. This consistent pattern across ages suggested that these miRNAs may regulate shared pathological mechanisms contributing to PD progression. Bioinformatic analyses predicted that miR-30a-5p and miR-484 target genes associated with mitochondrial functions and apoptotic signaling pathways. The current study aimed to elucidate how downregulation of these miRNAs contributes to neurotoxicity. We aimed to test the hypothesis that reduced expression of miR-30a-5p and miR-484 upregulates pro-apoptotic genes, BNIP3L and CASP2, respectively, leading to mitochondrial dysfunction-mediated neuronal death. **Methods:** Serum-derived EVs were isolated from 15-month old (aged) rotenone-treated rats (a single dose of 3 mg/kg, i.p.). EVs were collected 8 and 24 hours after rotenone treatment. These EVs were incubated with SH-SY5Y neuroblastoma cells. Cell viability was assessed using MTT and calcein-AM assays. BNIP3L and CASP2 were identified and validated as target genes of miR-30a-5p and miR-484, respectively by RT-qPCR. To further characterize the apoptotic response, downstream gene expression of Bax, Bak, and BCL2 was evaluated to assess pro- and anti-apoptotic signaling balance. Gene expression levels were quantified following miRNA modulation and rotenone exposure using RT-qPCR. **Results:** RT-qPCR analysis confirmed that BNIP3L and CASP2 are direct targets of miR-30a-5p and miR-484, respectively. Treatment of SH-SY5Y cells with serum-derived EVs from rotenone-exposed rats resulted in significant upregulation of BNIP3L and CASP2, indicating activation of the BNIP3L-CASP2 apoptotic pathway. Since EVs from young adult rats previously induced mitochondrial dysfunction and cell death, EVs from aged rotenone-treated rats were further evaluated and found to similarly reduce cell viability under rotenone toxicity. Downstream apoptotic profiling revealed that increased BNIP3L expression correlated with Bax and Bak upregulation and BCL2 suppression, confirming activation of the apoptotic cascade. **Conclusions:** The findings indicate that rotenone-induced downregulation of miR-30a-5p and miR-484 enhances the expression of pro-apoptotic genes BNIP3L and CASP2, leading to mitochondrial dysfunction, Bax/Bak activation, BCL2 inhibition, and subsequent neuronal death. These results provide mechanistic insight into miRNA-mediated apoptotic signaling and identify EV-miRNAs as potential therapeutic targets for mitigating neuronal cell death in PD.

PS 3568 Impact of neuromelanin formation on modeling Parkinson's Disease in rats and its implications in Parkinson's disease neurobiology

M. T. Corson, F. M. Currim, J. M. Brown-Leung, and J. R. Cannon. Purdue University, West Lafayette, IN.

Background and Purpose: Parkinson's Disease (PD) is a chronic, neurodegenerative disease characterized by the death of dopaminergic (DA) neurons in the substantia nigra of the midbrain, producing the condition's hallmark motor symptoms. While genetic and environmental risk factors have been identified, there are critical gaps in the understanding of the biochemical mechanisms at play. Heterocyclic aromatic amines (HAAs) formed during the cooking of red meats are known as dietary carcinogens. Prior studies have indicated that HAAs, specifically 2-amino-1-methyl-6-phenylimidazo[4,5-b] pyridine (PhIP), may induce mitochondrial dysfunction and neurotoxicity in DA-neurons, which are susceptible to toxicants. Neuromelanin (NM) is a unique dark pigment found in humans, specifically in dopaminergic neurons, and it is believed to play a significant role in protecting against oxidative stress induced by environmental toxicants, such as HAAs. Cellular studies show that HAAs bind to neuromelanin, and neuromelanin formation increases HAA neurotoxicity. Rodents do not express tyrosinase in dopaminergic neurons, which is the enzyme responsible for producing neuromelanin. Expression of human tyrosinase enables neuromelanin

synthesis, which is a more accurate model reflecting human neurobiology. This study aims to validate a transgenic rodent model in which human tyrosinase is expressed in a rat model, producing neuromelanin, thus allowing for an investigation into interactions between NM and HAAs that induce neuronal mitochondrial dysfunction and neurodegeneration. **Methods:** Transgenic rats expressing human tyrosinase were generated using CRISPR-mediated genome editing. Progeny was genotyped using PCR-based assays to distinguish wild-type, heterozygous, and homozygous animals and confirm tyrosinase expression. Neuromelanin formation in dopaminergic neurons was validated through histological analysis, including Fontana Masson staining. **Results:** Genotyping has confirmed successful insertion of the tyrosinase-expressing gene into the genomes of some rats. Neuromelanin production has been validated through histology in tyrosinase-expressing rodents, which show NM granules resembling those found in human substantia nigra neurons. Ongoing analysis will help determine to what degree NM formation amplifies HAA-induced oxidative stress and dopaminergic neurodegeneration. Early *in vitro* work suggests that NM expression increases intracellular PhIP concentration and cell death. **Conclusions:** The validation of the NM-forming, transgenic rat model is a major step forward in overcoming translational limitations in research aimed at neurodegenerative diseases, including Parkinson's Disease and many others. This model provides the unique opportunity to understand how environmental toxicants, like PhIP, contribute to mitochondrial and autophagic dysfunction relevant to PD. Preliminary work confirms NM production, and ongoing work aims to define how NM interacts with HAAs and results in DNA adduct formation, autophagic impairment, and PD pathogenesis. Beyond Parkinson's Disease, this model may provide a foundation for studying broader types of environmental neurotoxicants and advancing the shared understanding of environmentally induced dopaminergic neurodegeneration.

3569 Caffeic Acid Mitigates α -Synuclein Neurotoxicity by Suppressing Fyn Kinase Signaling and α Syn Aggregation

A. George, C. Janarthnam, P. Padhi, J. Thomas, H. Jin, V. Anantharam, G. Phillips, A. Kanthasamy, and A. Kanthasamy. University of Georgia, Athens, GA.

Background and Purpose: Parkinson's disease (PD) and related synucleinopathies are characterized by the accumulation of misfolded α -synuclein (α Syn) aggregates that exert neurotoxic and pro-inflammatory effects. Studies from our laboratory and others have reported that α Syn pre-formed fibrils (PFFs) act as proteinaceous neurotoxins that seed fibril propagation and activate inflammatory signaling in microglia via Fyn kinase. Caffeic acid (CA), a naturally occurring phenolic compound abundant in coffee and fruits, is well-characterized for its antioxidant, anti-inflammatory, and anti-fibrillogenic properties. Given its ability to modulate both anti-fibrillogenic activity and inflammatory signaling, CA was investigated as a dual-action modulator of α Syn-induced neurotoxicity. Thus, this study examined whether CA can mitigate α Syn-induced neurotoxicity by suppressing proinflammatory Fyn kinase activation and inhibiting α Syn seeding activity. **Methods:** Recombinant human α Syn monomers were purified and incubated under continuous agitation at 37°C for seven days to generate pre-formed fibrils (PFFs) according to the MJFF protocol. C20 human microglial cells were exposed to 1 μ M α Syn PFFs for 1-24 h, with or without co-treatment of 0-100 μ M CA. Cells were harvested at various time points for RT-qPCR analysis of cytokine expression (IL-6, pro-IL-1 β , and TNF- α) and for immunoblotting of total Fyn and phosphorylated Fyn (p-SrcY416). Immunofluorescence staining for IBA1, Fyn, and p-SrcY416 was also performed to validate CA's effect on Fyn activation. α Syn seeding reactions were initiated in different dilutions of PD brain homogenate and contained 10 μ M ThT (Thioflavin). Fluorescence kinetics were monitored for up to 50 h at 37°C with orbital shaking. Concentrations of 300 nM-100 μ M CA were tested to assess concentration-dependent inhibition of α Syn seeding activity. Reaction end-products were spotted onto nitrocellulose membranes and immunoprobed with an α Syn filament-specific antibody to assess fibril formation. **Results:** Exposing human microglial cells to 1 μ M α Syn PFFs elicited a robust proinflammatory response, evidenced by marked upregulation of TNF α , IL-6, and pro-IL-1 β mRNA levels. Co-treatment with CA significantly suppressed α Syn PFF-induced TNF α and IL-6 expression and showed a downward trend in pro-IL-1 β induction, demonstrating the anti-inflammatory properties of CA. To further elucidate the mechanisms underlying this effect, we examined CA's impact on activation of the tyrosine kinase Fyn, a critical upstream regulator of the PKC δ -NF- κ B inflammatory axis. Western blot analyses revealed that α Syn PFF exposure triggered a rapid Fyn activation (evidenced by increased p-SrcY416 phosphorylation) within 1 h that persisted for up to 24 h, whereas co-treatment with CA markedly attenuated Fyn hyperphosphorylation at all time points examined. Immunocytochemical analysis further confirmed CA-mediated inhibition of Fyn activation. Interestingly, RT-QuIC analysis demonstrated that CA addition dose-dependently inhibited α Syn seeding activity derived from human PD brain and skin samples. This reduction in α Syn fibrillization was further validated by dot-blot analysis, confirming that CA exerts both anti-aggregative and anti-inflammatory effects against α Syn pathology. **Conclusions:** Collectively, these findings identify CA as a promising small-molecule modulator that targets both cellular neuroinflammatory responses and molecular mechanisms underlying α Syn misfolding and aggregation, supporting its translational potential in PD and related synucleinopathies. Supported by NIH/NINDS R01 NS121692 and NIH/NIEHS R01 ES036241.

3570 A Trichloroethylene Metabolite Drives Microglial Aging and Inflammation: Implications for Parkinson's Disease

A. Shah, A. Anchan, A. Abu-Salah, R. Strazdins, P. Reina Gonzalez, M. Ay, and S. Sarkar. University of Rochester Medical Center, Rochester, NY.

Background and Purpose: Parkinson's Disease (PD) is a leading motor neurodegenerative disorder marked by the loss of tyrosine hydroxylase (TH)-positive neurons in the midbrain and the formation of α -synuclein-rich aggregates known as Lewy bodies. While genetics explain only about 10-15% of PD cases, environmental exposures are gaining attention as major contributors. Trichloroethylene (TCE), a common industrial solvent, has been implicated in PD and shown to induce α -synuclein aggregation, dopaminergic neuron loss, and motor dysfunction in animal models. However, the role of TCE's metabolite S-(1,2-dichlorovinyl)-cysteine (DCVC) in promoting neuroinflammation remains largely unknown. Since microglia—the brain's immune cells—are central to neuroinflammation and aging in PD, we examined how DCVC affects microglial metabolism, inflammation, and senescence. We also explored whether senolytics quercetin and dasatinib could reverse these effects. **Methods:** We first conducted an MTS assay to measure microglial metabolic activity across DCVC concentrations. A 10 μ M dose significantly reduced viability and was used for subsequent experiments. Mitochondrial function was then assessed with a Seahorse Mito Stress Test, measuring basal respiration, ATP production, and non-mitochondrial respiration. To probe inflammatory signaling, we used immunocytochemistry (ICC) and qRT-PCR to quantify interleukin-6 (IL-6) expression—a marker of the senescence-associated secretory phenotype (SASP). Cellular aging was confirmed with the senescence-associated β -galactosidase (SA- β Gal) assay. Similar experiments were performed in human astrocytes to evaluate cell-type specificity. To test for therapeutic rescue, microglial cultures were co-treated with quercetin and dasatinib, a senolytic combination known to selectively eliminate senescent cells and suppress chronic inflammation. **Results:** DCVC exposure disrupted microglial metabolism, leading to decreased basal respiration, ATP production, and non-mitochondrial respiration, indicating mitochondrial dysfunction. ICC and qRT-PCR revealed increased IL-6 expression, consistent with activation of the SASP, while the SA- β Gal assay confirmed enhanced microglial senescence. In contrast, astrocytes showed no significant changes, suggesting a microglia-specific vulnerability. Remarkably, co-treatment with quercetin and dasatinib restored mitochondrial function, reduced IL-6 levels, and diminished SA- β Gal staining. These senolytics effectively reversed several DCVC-induced phenotypes, demonstrating their potential to counteract environmentally driven microglial aging. **Conclusions:** Our findings reveal that the TCE metabolite DCVC promotes microglial mitochondrial dysfunction, inflammation, and senescence, contributing to cellular conditions associated with PD. The reversal of these effects by quercetin and dasatinib highlights the therapeutic potential of targeting microglial aging in toxin-induced neurodegeneration. Importantly, this work strengthens our understanding of gene-environment interactions in PD: environmental toxicants like TCE may accelerate neurodegenerative processes in individuals with genetic susceptibility by triggering microglial senescence and chronic inflammation. By uncovering this mechanistic link, our study bridges molecular toxicology and neurogenetics, offering a clearer view of how environmental exposures interact with cellular pathways to shape disease risk.

3571 Whole-Brain Mapping Reveals a Novel Neurogenic Role of Prokineticin-2 Signaling in the SVZ-RMS-OB During Parkinsonian Neurotoxic Stress

G. Clabaugh, H. Jin, V. Anantharam, A. Kanthasamy, and A. G. Kanthasamy. University of Georgia, Athens, GA.

Background and Purpose: Chronic exposure to manganese (Mn) from environmental and occupational settings is linked to the development of parkinsonism, including Parkinson's disease (PD). Prior to the onset of motor symptoms, parkinsonism and PD patients frequently display olfactory dysfunction, but the underlying mechanisms remain poorly understood. Emerging evidence also suggests that the subventricular zone (SVZ) neurogenic niche may be affected in PD pathology. Our lab previously discovered that prokineticin-2 (PK2) mediates a novel neuroprotective response during the early stages of parkinsonian neurotoxic stress by inducing mitochondrial biogenesis and activating anti-apoptotic signaling pathways. PK2 is a secreted neuropeptide that initiates its biological functions by activating two cognate GPCRs, PKR1 and PKR2. Intriguingly, PK2 plays a well-established role in olfactory bulb (OB) neurogenesis by serving as a chemoattractant for migratory neuroblasts in the rostral migratory stream (RMS). Building on these observations, we hypothesized that PK2 serves as an early compensatory neuropeptide against Mn-induced neurotoxic stress in the OB-RMS-SVZ neurogenic niche. A comprehensive understanding of PK2 signaling may enable the development of novel drug discovery platforms targeting non-motor dysfunctions associated with neurodegenerative diseases. **Methods:** We utilized the NIH Accelerating Medicines Partnership PD (AMP-PD) clinical and transcriptomics datasets to determine changes in PK2 mRNA expression in the blood of PD patients. For *in vivo* experiments, transgenic PK2-eGFP reporter mice were intranasally exposed to 300 μ g of MnCl₂ for 5, 10, or 30 days. Brain Mn deposition was visualized using preclinical 7T MRI, and behavioral performance was assessed via the open-field, pole, and novel-scent tests. We used iDISCO whole-brain tissue clearing, immunohistochemistry (IHC), and Western blot analyses to map the spatial distribution of PK2 in the brain of Mn-treated mice. PK2-dependent effects in

Mn neurotoxicity were tested by co-treating mice with MnCl₂ (300µg) and the PK2 receptor antagonist PKA7 (5 mg/kg) for 5 days. Additionally, mice were injected with 6-OHDA in the striatum and sacrificed after 3 days for histological analysis. **Results:** We first evaluated whether PK2 serves as a potential biomarker of PD by analyzing the AMP-PD whole-blood transcriptome and clinical datasets. A comparison of the control (n = 1,097) and PD (n = 1,624) cohorts revealed a significant upregulation of PK2 mRNA. Surprisingly, PK2 was further enriched in prodromal patient samples and was positively correlated with motor dysfunction in PD patients. Next, *in vivo*, PK2-eGFP reporter mice intranasally exposed to MnCl₂ showed increased MRI signal intensity in olfactory regions, basal ganglia, and the SVZ, accompanied by olfactory and locomotor deficits following 10 days of Mn exposure. IHC revealed strong PK2 induction in SOX2⁺/GFAP⁺ neural stem cells in the subependymal layer of the OB after a 5-day Mn exposure, coinciding with increased DCX immunostaining, a marker for migrating neuroblasts. These effects were diminished after 10- and 30-day exposure to Mn. Interestingly, we observed PK2⁺ cells in the RMS and nucleus accumbens (NAc) that were contacting neuroblasts in the SVZ and RMS. The iDISCO tissue clearing and light sheet microscopy confirmed PK2⁺ neurons projecting from the NAc to the SVZ and revealed Mn-induced architectural alterations in the SVZ-RMS-OB axis. Notably, PKA7 inhibition of PK2 receptors attenuated the increase in DCX immunostaining in the OB that was observed after 5 days of Mn exposure. Finally, using the 6-OHDA mouse model of PD, we observed a significant increase in PK2⁺/SOX⁺ cells at the lesion site, further suggesting a similar compensatory PK2 response to neurotoxic injury. **Conclusions:** Collectively, PK2 appears to facilitate a novel compensatory neuroprotective signaling response during the early stages of Mn-induced neurotoxicity in the SVZ-RMS-OB axis. These results underscore PK2 as a key mediator linking environmental neurotoxicant exposure to compensatory neurogenic mechanisms and as both a promising therapeutic target and a potential biomarker for addressing environmentally linked neurodegenerative conditions (Supported by NIH/NIEHS R01 ES034196).

PS 3572 Molecular Mechanisms of Nuclear Pore Complex Impairment in Environmental Neurotoxicity Models: Implications for Pathogenesis of Parkinson's Disease

Y. Chang¹, Z. Riaz², D. Miller¹, G. Zenitsky¹, H. Jin¹, V. Anantharam¹, A. Kanthasamy¹, and A. G. Kanthasamy¹. ¹University of Georgia, Athens, GA; and ²Emory University, Atlanta, GA.

Background and Purpose: Environmental exposure to neurotoxic chemicals like pesticides, metals, and pollutants has been implicated in the etiology of Parkinson's disease (PD). However, the mechanisms driving neurotoxicant-induced neurodegeneration remain poorly understood. The nuclear pore complex (NPC), which mediates bidirectional nucleocytoplasmic transport of proteins and RNAs, has recently emerged as a critical pathophysiological target of neurodegenerative disorders. Our recent work demonstrated that mitochondria-impairing pesticides activate protein kinase C delta (PKCδ) and induce Lamin B1 hyperphosphorylation, thereby compromising nuclear membrane integrity. Yet, the role of nucleoporins (Nups), functional unit of NPCs, in environmentally linked neurotoxicological processes has not been systematically investigated. **Methods:** Protein levels of Nups were quantified by immunocytochemistry (ICC) and Western blot (WB) in N27 dopaminergic neuronal cells (DAergic cells) exposed to rotenone (1 µM, 3-6 h) or paraquat (400 µM, 12 h) in serum-free RPMI-1640 medium. PKCδ dependence of Nup62 loss was evaluated by WB in CRISPR/Cas9-based PKCδ-knockdown (KD) cells under identical treatment conditions. In addition, nuclear fractions from DAergic cells/DAergic cells were isolated for phosphoproteomic analysis, and Nup153 phosphorylation was validated by proximity ligation assay (PLA). *In vivo*, immunohistochemistry (IHC) for Tyrosine hydroxylase (TH) and Nups was performed in MitoPark mice. Reductions in Nup153 and Nup50 levels were further confirmed by IHC in dementia with Lewy bodies (DLB) patient brain tissues obtained from the UC Davis Health Alzheimer's Disease Research Center. **Results:** Rotenone exposure in N27 DAergic neuronal cells resulted in a time-dependent reduction of the nuclear basket Nup153, the channel Nup62, and the scaffold Nup107 within 3-6 h, without overt cytotoxicity, as confirmed by ICC and WB analyses. Treatment of N27 cells with the redox-cycling pesticide paraquat resulted in a convergent phenotype, characterized by pronounced reductions of Nup62 and 153, increased Lamin B1 phosphorylation, and fragmented perinuclear organization of Nup62 and 153 as revealed by 3D confocal reconstruction, consistent with nuclear envelope destabilization and loss of NPC structural integrity. Further WB analysis identified PKCδ as a key mediator of mitochondrial stress-induced Nup dysregulation, as CRISPR/Cas9-mediated PKCδ-KD significantly rescued Nup62 from rotenone-induced downregulation. Phosphoproteomic profiling of nuclear fractions from rotenone-treated N27 cells identified hyperphosphorylation of Nup153, which was validated by PLA, showing enhanced Nup153-phosphoserine interactions following rotenone treatment. Notably, our transgenic MitoPark mouse model of PD exhibited a drastic decrease in nuclear Nup153, 62, and 107 and accumulation of cytoplasmic Nup62 puncta in intact TH⁺ nigral neurons, accompanied by nuclear membrane invaginations. Human post-mortem brains from DLB patients similarly showed diminished levels of Nup62 and 50, as well as disorganized nuclear morphology, validating clinical relevance. **Conclusions:** Taken together, our findings identify Nup/NPC dysregulation as a major neurotoxicological mechanism mediated by PKCδ activation during pesticide-induced mitochondrial/oxidative stress, provid-

ing a mechanistic link between neurotoxic chemical exposure and selective neuronal loss in environmentally linked PD. Supported by NIH R01 Grants: NS121692 and ES034196.

PS 3573 CeMbio Gut Microbiota Influences the Neuroprotective Effects of Tea Catechins in a Transgenic C. elegans Parkinson's Disease Model

A. Rehman, J. Wang, and L. Tang. University of Georgia, Athens, GA.

Background and Purpose: The gut microbiota has a direct influence on the metabolism and neuroprotective potential of dietary polyphenols such as tea catechins (TCs). The study conducted has investigated how defined gut microbial communities (CeMbio consortium) exerts a modulating TC-mediated neuroprotection in the *Caenorhabditis elegans* Parkinson's disease (PD) model UA44, which expresses human α-synuclein in dopaminergic neurons. **Methods:** Twelve bacterial strains from the CeMbio community were tested individually and as a pooled mixture against the standard laboratory diet *E. coli* OP50. L4-stage UA44 worms were exposed to 0-200 µg/mL TCs for seven days at 25 °C. Dopaminergic neuron integrity was assessed by fluorescence microscopy using a neuronal damage scoring scale (0-3), where 0 = all six head neurons intact and 3 = all six neurons degenerated (n = 30 worms × 3 replicates). Dopamine-linked behaviors—area-restricted search (ARS) and basal slowing response (BSR)—were quantified under food and no-food conditions using video-based analysis. **Results:** TC treatment significantly reduced neuronal degeneration in a **dose- and strain-dependent** manner (two-way ANOVA, p < 0.001). In OP50-fed worms, the mean degeneration score decreased from **2.4 ± 0.3 (control)** to **1.6 ± 0.2 at 200 µg/mL TC** (33 % improvement). CeMbio-mix-fed worms showed greater protection, with scores of **1.1 ± 0.2 at 100 µg/mL** and **0.8 ± 0.1 at 200 µg/mL**, corresponding to ~65 % less degeneration than OP50-fed worms (p < 0.001). Among individual strains, *Lelliottia amnigena* (JUB 66) and *Stenotrophomonas maltophilia* (JUB 19) exhibited the lowest damage scores (**0.9 ± 0.2** and **1.0 ± 0.2**, respectively), whereas *Pseudomonas lurida* (MYb11) remained highly susceptible (**2.3 ± 0.3**). Behavioral assays mirrored the neuronal trends: CeMbio-fed worms displayed a **higher basal slowing index (0.68 ± 0.04)** compared with **0.42 ± 0.05 in OP50-fed controls** (p < 0.01) and recovered ARS turning frequency to **14.6 ± 1.2 turns/min** versus **9.5 ± 1.5 turns/min** (p < 0.05). **Conclusions:** CeMbio-associated microbes significantly potentiate the neuroprotective effects of TCs by reducing dopaminergic neuronal degeneration and improving dopamine-regulated behaviors. The protection is strain-specific, with *Lelliottia amnigena* and *Stenotrophomonas maltophilia* providing the most pronounced benefit. These results suggest that microbial enzymatic conversion of catechins into bioactive metabolites (e.g., phenolic acids, valerolactones) underlies the observed reduction in α-synuclein-associated neurotoxicity in the *C. elegans* PD model.

PS 3574 Trichloroethylene metabolites in Parkinson's Disease-related toxicity in C. elegans and mice

J. Dient¹, M. L. Bucher¹, C. V. Duarte-Hospital¹, N. M. Ilieva², B. R. De Miranda², R. R. Singh¹, and G. W. Miller¹. ¹Columbia University, New York, NY; and ²University of Alabama at Birmingham, Birmingham, AL.

Background and Purpose: Trichloroethylene (TCE) is an industrial solvent associated with Parkinson's Disease (PD) onset in humans. Studies characterizing TCE metabolism in humans indicate that 40-75% of the absorbed dose is metabolized, suggesting that TCE's toxic effects may be attributed to these metabolites. However, there is limited knowledge of TCE metabolites and their neurotoxicity in PD. We performed TCE inhalation studies in mice and then conducted high-resolution mass spectrometry (HRMS) on multiple organs, including the brain, to determine which TCE metabolites are present in the system post-acute exposure to occupationally and environmentally relevant exposures to TCE. We then used *Caenorhabditis elegans* (*C. elegans*) to study how these metabolites disrupt dopamine-dependent behaviors, such as movement and fecundity, and dopamine neuron viability. **Methods:** Mice were exposed to 100 ppm of TCE for 4 hours. Blood, brain, lungs, and liver were collected from each animal at 0, 1, 2, 4, 8, and 24 hours after exposure or 0 hours after no exposure. Using the Thermo Orbitrap IQ-X system, a liquid chromatography-based mass spectrometry system (LC-MS/MS), brain tissue, liver tissue, and plasma from TCE-exposed mice were analyzed for the presence of TCE metabolites. A follow-up untargeted analysis was conducted using brain and liver tissue. In *C. elegans*, wild-type (N2), pdat-1::GFP (BZ555), and pdat-1::α-syn, pdat-1::GFP (UA44) strains were exposed to 5 mM trichloroethanol (TCEOH), 10 mM trichloroacetic acid (TCA), or control doses. Worms were exposed to these compounds at L4 stage and the dose was refreshed every 48 hours until assay completion. Fecundity assay and behavioral assays were conducted using all strains. Area-restricted searching (ARS) assay was conducted, as well as general measures of movement, using the WormLab Behavioral Analysis Software. Using the fluorescent reporter strains, dopaminergic neuron viability was assessed in both the neuron cell bodies and the dendrites. **Results:** HRMS-analysis of TCE-exposed mouse brain, liver, and plasma identified three TCE metabolites, TCA, trichloroethanol glucuronide (TCEOH-gluc), and dichloroacetic acid (DCA). Untargeted analysis of the TCE-exposed mouse brain and liver revealed that the greatest amount of significantly different features occurred at 4

hours post-exposure, when compared to the untreated control. In *C. elegans*, we observed that TCEOH led to the most notable differences across the assays. In particular, the UA44 strain that was treated with 5 mM TCEOH exhibited a significant increase in omega bends and pirouettes, markers of altered dopamine function, as compared to the control-treated worms on day 1, followed by a significant decrease in both by day 5. Additionally, the UA44 strain exhibited more pronounced neurodegeneration as compared to the other doses or strains. **Conclusions:** Together, these findings indicate that TCA, DCA, and TCEOH-gluc are the most prevalent TCE metabolites in the brains of mice exposed to TCE by inhalation. Disruption of metabolic pathways was most dramatic at 4 hours post-exposure. Administration of the metabolites identified in mouse brain to *C. elegans* model indicates that TCEOH can lead to changes in behavioral outcomes, as well as dopamine neuron degeneration. Given that many of the significant results were from a strain that also expresses human α -synuclein, it is possible that TCEOH may exert these significant changes through an interaction with α -synuclein. Additionally, these findings indicate that *C. elegans*-based assays can be used to identify changes in PD-relevant outcomes from TCE metabolite exposure, providing a complement to the mouse studies and enabling the systematic analysis of TCE metabolites.

PS 3575 Inhibition of Mitochondrial Complex III Causes Dopaminergic Neurodegeneration by Redox Stress in *Caenorhabditis elegans*

J. Huayta, and J. N. Meyer. Duke University, Durham, NC.

Background and Purpose: Environmental factors including chemical exposures are important contributors to Parkinson's disease (PD). Nearly all well-validated chemicals involved in PD also affect mitochondria. However, it is not feasible to test all the chemicals that induce mitochondrial dysfunction. Moreover, most of the chemicals connected to PD inhibit complex I of the mitochondrial electron transport chain, leading to oxidative stress and ATP depletion. We are working to define if other forms of mitochondrial dysfunction result in dopaminergic neurodegeneration, as well as whether oxidative stress and ATP depletion, are required for dopaminergic neurodegeneration. This information should help narrow the focus of efforts to identify chemicals that could contribute to PD. Here, we report results from inhibition of complex III. **Methods:** We are using the model organism *C. elegans* to evaluate the *in vivo* effects of toxic mitochondrial exposures on dopaminergic neurodegeneration (based on morphological changes), ATP levels, and redox state. We exposed *C. elegans* from the embryo stage until the L4 larval stage to complex III inhibitors antimycin A and pyraclostrobin, which are environmentally relevant pesticides. We acquired images of the animals' heads using fluorescence microscopy, capturing the 4 cephalic dopaminergic neurons. Neurodegeneration was quantified by assigning a score of 0 to 6 to each neuron, depending on the type and extent of damage. We used pharmacological (N-acetylcysteine, S3QEL-2, and others) and genetic (superoxide dismutase *sod-2* overexpression, and others) antioxidant interventions to rescue neurodegeneration. We used an optogenetic approach to generate reactive oxygen species (ROS) at complex III to test if this would cause neurodegeneration independent of chemical exposure. **Results:** Complex III inhibitors antimycin A and pyraclostrobin caused dopaminergic neurodegeneration in a dose dependent manner, and significant neurodegeneration was observed for concentrations of 500 nM and 50 μ M respectively. Complex III inhibitors did not induce neurodegeneration in glutamatergic, cholinergic, serotonergic, or GABAergic neurons, nor in neuronal sheath cells. Additionally, antimycin A increased the ratio of oxidized to reduced roGFP, a reporter of redox state in dopaminergic neurons. Rescue experiments with an antioxidant (N-acetylcysteine), and a blocker of ROS specific to Complex III (S3QEL-2) indicated that neurodegeneration linked to complex III inhibitor exposure is caused by an increased production of mitochondrial ROS. Additional rescue experiments with a superoxide dismutase and catalase mimetic (EUK-134) and exposure using a *C. elegans* strain overexpressing the mitochondrial superoxide dismutase gene *sod-2*, strongly confirmed the role of superoxide anion in neurodegeneration driven by complex III inhibition. Finally, artificial production of superoxide anion specifically at the complex III site using an optogenetic approach caused dopaminergic neurodegeneration. This confirmed, in a manner independent of chemical exposure, that ROS generation at the complex III site can cause dopaminergic neurodegeneration. **Conclusions:** PD is the second most common neurodegenerative disease and the most common movement disorder, affecting approximately 10 million people worldwide globally as of 2021. Exposure to environmental pollutants such as pesticides and heavy metals has been linked to the onset of PD, but epidemiological evidence is scarce and causality often unclear. Mitochondrial toxicity is a mode of action for these toxicants, with strong evidence for complex I inhibition as causative of parkinsonism and dopaminergic neurodegeneration. Our work provides robust confirmation that 1) complex III inhibition causes dopaminergic neurodegeneration *in vivo*, and 2) that this is caused by generation of mitochondrial ROS in complex III, providing mechanistic insights on this specific mode of mitochondrial dysfunction. This is important from a regulatory perspective because complex III inhibitors are common in nature, frequently used as pesticides, and increasingly pursued for drug development. From a mechanistic perspective, the knowledge that mitochondrial ROS, in particular superoxide anion, is at the center of dopaminergic dysfunction will be helpful in the development of preventive and therapeutic approaches.

PS 3576 Synaptic and Neurotransmitter Alterations in Canine Cognitive Dysfunction: A Translational Model for Alzheimer's Disease

P. Shirley^{1,2}, A. Alsulami^{1,2}, K. Kawai-Puaa^{1,2}, S. Boland^{1,2}, A. Lessard¹, K. Crozier¹, S. McGrath^{2,3}, and J. A. Moreno^{1,2}. ¹Department of Environmental and Radiological Health Services, Fort Collins, CO; ²Brain Research Center, Fort Collins, CO; and ³Department of Clinical Sciences, Fort Collins, CO.

Background and Purpose: Alzheimer's disease (AD) is the leading cause of dementia, accounting for 83.6% of cases globally in 2019. Despite its prevalence, effective treatments remain limited underscoring the need for translational models that capture key aspects of human pathology. Canine cognitive dysfunction (CCD) syndrome is a naturally occurring neurodegenerative disorder in aged dogs that mimics AD through shared clinical signs including disorientation, altered social interactions, and neuropathological features including gliosis and protein misfolding. **Methods:** This study examines neurotransmitter and synaptic protein alterations in aged canines with and without presumed CCD to evaluate the presence of synaptic dysfunction and its parallels to AD pathology. Hypothesizing that aged canines with presumed CCD will show similar etiology to Alzheimer's patients, revealing pathological changes at the synaptic and neuronal level. Canines were evaluated using the Canine Dementia Scale (CADES) and divided into CCD- and CCD+ groups, with further subdivision based on amyloid beta pathology. Neurotransmitter concentrations including glutamate, acetylcholine, GABA, dopamine, DOPAC, HVA, serotonin, 5-HIAA, norepinephrine, and epinephrine were quantified across frontal cortex, hippocampus, striatum, and cerebellum using LC-MS/MS. Quantification of pre- and postsynaptic proteins SNAP25, VAMP2, PSD95, and HOMER1, key regulators of neurotransmitter release and postsynaptic signaling, through Western blot analysis. **Results:** Our results show that synaptic proteins are modulated in presumed CCD+ dogs, with region-specific changes across cortical and subcortical areas when compared to aging dogs without CCD. Neurotransmitter analysis revealed slight decreases in glutamate, GABA, and acetylcholine within cortical regions, suggesting early disruption of excitatory and inhibitory balance. **Conclusions:** Together, these findings indicate that CCD involves both biochemical and structural synaptic alterations that parallel AD pathology.

PS 3577 Drug Repurposing of Rapamycin Mitigates Alzheimer's Disease Associated Proteotoxicity in *Caenorhabditis elegans*

S. Alkhudaydi, and J. Moreno. Colorado State University, Fort Collins, CO.

Background and Purpose: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by the accumulation of misfolded proteins, including amyloid- β ($A\beta_{1-42}$), which disrupt neuronal function and lead to cognitive decline and reduced lifespan. The mechanistic target of rapamycin (mTOR) pathway is a central regulator of aging, proteostasis, and neuronal survival. Its inhibition by rapamycin has demonstrated protective effects against neurodegeneration in several species. Given these findings, rapamycin (RAP), an FDA-approved compound, is being repurposed for Alzheimer's disease therapy due to its ability to attenuate proteotoxicity in multiple model systems. **Methods:** The transgenic *Caenorhabditis elegans* strains expressing human $A\beta_{1-42}$ were used as a model to study Alzheimer's-like proteotoxic stress. Rapamycin was administered across a range of doses to evaluate its neuroprotective potential. Paralysis assays were conducted to measure behavioral outcomes associated with $A\beta$ -induced toxicity, and the timing of paralysis onset was used as the main endpoint for treatment efficacy. **Results:** Rapamycin treatment significantly delayed the onset of paralysis in the transgenic *C. elegans* strains expressing $A\beta_{1-42}$ compared with vehicle-treated controls. This delay indicates a reduction in $A\beta$ -induced proteotoxicity. Dose-response analysis revealed that the neuroprotective effect of rapamycin varied with concentration, providing insight into its optimal therapeutic range. **Conclusions:** These findings demonstrate that rapamycin exerts a neuroprotective effect in a *C. elegans* model of Alzheimer's disease by mitigating $A\beta$ -induced paralysis. The study is among the first to systematically assess rapamycin across multiple doses in this model, offering new insights into its dose-dependent effects on proteostasis and neuroprotection. This work supports further exploration of rapamycin as a candidate for Alzheimer's therapy and highlights the potential for combination treatments and validation in higher model organisms.

PS 3578 Effects of prophylactic tirzepatide treatment in a mouse model of Alzheimer's disease

C. Shillito, S. Ba, M. Lang, A. Stevenson, and D. L. Graham. Florida State University College of Medicine, Tallahassee, FL.

Background and Purpose: Glucagon-like peptide-1 receptor (GLP-1R) agonists have been used to treat neurodegenerative diseases such as Alzheimer's disease with overall positive results. This neuroprotection is achieved at least to some extent by GLP-1R's actions on decreasing neuroinflammation, amyloid-beta deposits, and tau hyperphosphorylation, while improving brain energy metabolism and neurogenesis. However, treatment is not often initiated until after diagnosis, when symptoms are already present. Given the neuroprotective value of GLP-1R activity on brain health, we hypothesized that initiating treatment prior to symptom onset may slow disease

progression. **Methods:** Male and female 5XFAD (wild-type and transgenic) mice were administered either saline or tirzepatide (10 nmol/kg) twice daily from postnatal day (P)21-P60. Tirzepatide is a more efficacious formulation, targeting both the GLP-1 and GIP receptors. Mice then underwent a behavioral battery assessing mood-like behaviors, motor coordination, and cognition. **Results:** There were significant differences in anxiety-like behavior (light/dark task, open field test, elevated zero maze) and motor coordination (rotarod) between transgenic and wild-type mice. Prior exposure to tirzepatide did not significantly alter any of these outcomes. These tasks, however, are best suited at detecting gross behavioral deficits and not more subtle changes. To that end, we used a touchscreen-based operant task to assess location discrimination, a hippocampal-based form of episodic memory. Preliminary data suggest that while there were no significant differences in performance between wild-type and transgenic mice, early tirzepatide treatment significantly enhanced performance in the more difficult probe trials. **Conclusions:** Prophylactic treatment with tirzepatide did not significantly alter motor- or mood-related outcomes in 5XFAD mice. However, earlier exposure to the drug enhanced cognitive function in older mice, regardless of disease status. We will next use histology to determine if pretreatment with tirzepatide altered neuroinflammation or beta-amyloid plaques at the neuroanatomical level.

PS 3579 Leveraging Telmisartan to Assess TGFβ's Role in Mediating Traffic Related Air Pollution Effects on Alzheimer's Relevant Neuropathology

N. Nasim, A. Bhusal, A. Valenzuela, K. J. Bein, A. Wexler, and P. J. Lein. UC Davis, Davis, CA.

Background and Purpose: Alzheimer's disease (AD) is a complex neurodegenerative disease linked to numerous environmental risk factors. Epidemiological and experimental animal studies have identified traffic related air pollution (TRAP) as an environmental factor that increases AD risk and severity. TRAP is a heterogeneous mixture of particulate matter (PM), volatile organic compounds, and gases from vehicular emissions generated by fuel combustion, brake and tire wear, and resuspension of road dust. Despite TRAP's association with AD, the mechanism(s) by which it promotes AD are unknown. TRAP exposure is associated with fibrosis in the lung, which is promoted by TGFβ. In the brain, TGFβ is known to promote endothelial to mesenchymal transition (EndoMT), a pathological process in which endothelial cells of the blood brain barrier (BBB) dedifferentiate leading to BBB dysfunction. BBB impairment is a key characteristic of AD, which can exacerbate AD-relevant pathology and inflammation. Based on these observations, we hypothesize that pharmacological inhibition of TGFβ signaling will mitigate TRAP-induced AD-relevant pathology. **Methods:** Male and female TgF344-AD rats, which express two human AD risk genes, were exposed to ambient TRAP drawn from a heavily trafficked tunnel and delivered in real-time to exposure chambers adjacent to the tunnel. Controls housed in the same facility were exposed to filtered air (FA). TRAP and FA groups were fed either telmisartan-containing or control chow. Telmisartan, an angiotensin receptor blocker, is a well-established inhibitor of TGFβ signaling. The rats were transported to the tunnel at 1 month of age, telmisartan treatment was initiated at 3 months of age, and animals were euthanized when they were 4, 9, or 15 months old to collect tissues. Neuronal cell loss and amyloid fibrils were assessed using quantitative immunohistochemical (qIHC) analyses of NeuN and OC immunoreactivity, respectively, in AD-impacted brain regions, specifically the hippocampus and entorhinal cortex. Aβ42:40 ratios and phosphorylated tau levels were quantified in the blood and brain via bead-based multiplex immunoassay. **Results:** The Aβ42:40 ratio is used clinically to assess AD progression. Telmisartan decreased Aβ42:40 ratios in both the plasma and cortex from TRAP and FA, with the most robust effects observed at the 15-month timepoint. Phosphorylated tau, another AD biomarker, was increased and decreased by TRAP and telmisartan, respectively. A significant exposure effect was observed in 4-month males, while a significant drug x exposure interaction was found in the 9-month females. IHC indicated that telmisartan decreased neuronal cell count at 4 months in FA and TRAP groups. Neither telmisartan nor TRAP had a significant effect on amyloid deposition in the hippocampus measured by OC immunopositive area. **Conclusions:** These results suggest that telmisartan affects AD pathology with TRAP exposure, and that these effects are age dependent, with ameliorative effects occurring in later stages of the disease. Changes in Aβ42:40 ratios, which we observed precede the accumulation of plaques in the brain measured via IHC, further support a role for TGFβ in promoting the progression of AD phenotypes. Further investigation into the effect of TGFβ inhibition on additional markers of AD and EndoMT will inform the role of TGFβ in mediating TRAP effects on AD-relevant neuropathology.

PS 3580 Neuroinflammation drives CNS metal accumulation: a new perspective on metals, inflammation, and neurodegeneration

A. T. Kramer¹, K. A. Shapiro¹, and F. E. Harrison^{2,1}. ¹Vanderbilt University, Nashville, TN; and ²Vanderbilt University Medical Center, Nashville, TN.

Background and Purpose: Metals play a key role in maintaining homeostasis within the Central Nervous System (CNS), contributing to neurotransmitter synthesis, antioxidant defense, and myelination. Environmental exposure to metal toxicants

is a known risk factor for the development of several neurodegenerative diseases, including Alzheimer's disease (AD). Amyloid-β plaques, tau-neurofibrillary tangles, and reactive glia have increased metal content, contributing to the CNS accumulation of iron (Fe) and manganese (Mn) seen in AD. Previous work has emphasized the role of metal exposure in AD, identifying increased oxidative damage, neurotransmitter disruption, and neuroinflammation as key mechanisms of toxicity. Far fewer studies have directly assessed how AD-related pathology may, in turn, increase susceptibility to adverse effects from environmental metal exposures. This work assesses the effects of neuroinflammation on metal homeostasis in the CNS, and the potential for Mn exposure to exacerbate disease-related changes. **Methods:** Male and female C57BL/6J mice were placed on a control (70 ppm) or high-Mn (2400 ppm) diet from 5- to 11-weeks of age. Following the 6-week exposure, mice received an intraperitoneal (IP) injection of lipopolysaccharide (LPS) (3.5 mg/kg body weight) or saline (0.9% NaCl). Health scores, body temperature, and body weight were recorded over 24 hours. Hippocampal and cortical tissue were collected 24 hours post-injection for biochemical analysis. Bulk RNA was extracted from the hippocampus for use in a Mouse Neuroinflammation Panel on the NanoString nCounter platform. Bulk RNA from both the hippocampus and cortex was converted to cDNA for RT-qPCR experiments. The housekeeping genes for RT-qPCR were 18S and GAPDH. The genes of interest in the RT-qPCR experiments assessed metal import (DMT1, ZIP8, ZIP14, Tfr1), metal storage (H-ferritin, L-ferritin), metal export (FPN1, ZNT10), and cellular stress (NRF2, NQO1, HO-1). Protein homogenate from the hippocampus and cortex were used for Western blot analysis of metal transport and storage proteins and for ICP-MS quantification of metal content. **Results:** LPS treatment resulted in significant changes to sickness behavior, as seen by decreased health scores, body temperature, and body weight. Importantly, the high-Mn diet did not impact the effects of LPS on sickness behavior. There was a robust glial-driven neuroinflammatory response in both the control and high-Mn diets following LPS; however, high-Mn mice exhibited a much more pronounced response. Differential gene expression and pathway analyses revealed greater neuroinflammation in mice on the high-Mn diet, reflected in astrocyte function, inflammatory signaling, and microglial function gene sets. LPS treatment increased expression of metal importer (DMT1, ZIP8, ZIP14, Tfr1) and storage genes (H- and L-ferritin), while decreasing expression of exporters (FPN1, ZNT10). Altered metal transport dynamics following LPS treatment were reflected in Western blot experiments. ICP-MS analysis indicated that Mn and Fe accumulation in the CNS was also increased by LPS treatment. Cellular stress gene expression showed a sex-specific response to LPS; males on the high-Mn diet exhibited the most severe changes compared with control diet males, and females under the same exposure. **Conclusions:** We identified that an inflammatory insult was sufficient to disrupt metal transport in a coordinated manner, with increased metal import and storage, and decreased metal export. These changes reflect an increased capacity for intracellular uptake of metal ions from the systemic circulation and surrounding interstitial fluid. We further confirm that inflammation-induced changes to metal transport do increase the concentration of Mn and Fe in the CNS. We also showed that exposure to Mn exacerbates neuroinflammation and inflammation-induced metal transport changes, ultimately driving an LPS-induced increase in cellular stress. This study highlights an unexplored relationship between inflammation and metal exposure within the CNS, one in which inflammation drives metal accumulation. This relationship has the potential to be further explored in the context of neurodegeneration, to identify how neuroinflammatory changes to metal transport increase susceptibility to environmental exposures throughout the course of disease.

PS 3581 Cholinergic transmission dysregulation and neurodegeneration induced by thyroid signaling disruption following butylparaben single and repeated treatment

P. Moyano¹, A. Flores¹, J. Sanjuan¹, J. C. Plaza¹, L. Guerra-Menendez², L. Abascal¹, O. Mateo¹, and J. Del Pino¹. ¹Complutense University of Madrid, Madrid, Spain; and ²San Pablo CEU University, Madrid, Spain.

Background and Purpose: Butylparaben (BP), a widely used preservative, was implicated in cognitive impairment, though its neurotoxic mechanisms remain elusive. Basal forebrain cholinergic neurons (BFCN) are selectively lost in dementias, contributing to cognitive decline. **Methods:** To explore different mechanisms related with BFCN loss, we employed BF SN56 cholinergic wildtype or silenced cells for Tau, amyloid-beta precursor protein (βAPP), acetylcholinesterase (AChE), or glycogen synthase kinase-3 beta (GSK3β) genes, exposing them to BP (0.1-80 μM) for 1 or 14 days alongside triiodothyronine (T3; 15 nM), N-acetylcysteine (NAC; 1 mM), or recombinant heat shock protein 70 (rHSP70; 30 μM). **Results:** BP disrupted cholinergic transmission by AChE inhibition, and provoked cell death, through thyroid hormones (THs) pathway disruption, Aβ/p-Tau protein accumulation, AChE-S overexpression and oxidative stress (OS). Aβ/p-Tau accumulation was correlated with HSP70 downregulation, OS exacerbation, and GSK3β hyperactivation (for p-Tau). BP-induced OS was mediated by reactive oxygen species (ROS) overproduction and nuclear factor erythroid 2-related factor 2 (NRF2) pathway disruption. All observed effects were contingent upon TH signaling impairment. **Conclusions:** These findings uncover novel mechanistic links between BP exposure and BFCN neurodegeneration, providing a framework for therapeutic strategies.

H. Zhao, J. Xie, S. Wu, X. Zhao, S. Yu, J. L. Freeman, and C. Yuan. Purdue University, West Lafayette, IN.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are widely used in daily consumer and industrial products, and human exposure to PFAS has been associated with various neuronal disorders, including Alzheimer's disease (AD), although the underlying mechanisms remain poorly understood. **Methods:** In this study, we investigated the neurotoxic effects of PFOA, a legacy PFAS, and GenX, its proposed "safer" alternative, using human induced pluripotent stem cell (hiPSC)-derived cortical neurons. To assess persistent neurotoxicity, neurons were assessed immediately after exposure and after a 7-day relaxation. Neuronal resilience was evaluated using a secondary challenge assay targeting organelle-specific stressors. **Results:** We identified distinct neurotoxic effects of PFOA and GenX, leading to increased risk of developing AD. PFOA exposure induced transient alteration in neuronal activity, neuron network morphology and synaptic density, but with persistent damage in mitochondria function, further corroborated with increased vulnerability towards mitochondria stress. GenX exposed neurons showed persistent alteration in neuronal network morphology and synaptic density, accompanied by persistent increase in vulnerability towards autolysosomal stress. Both PFOA and GenX triggered transient changes in AT8 and tau expression and conferred persistent vulnerability to tau-preformed fibrils (tau-PFF), implicating impaired proteostasis. Transcriptomic profiling further supported our findings. **Conclusions:** Collectively, our findings reveal divergent neurotoxic mechanisms of PFOA and GenX—mitochondrial damage versus autolysosomal stress—that converge on tau pathology, highlighting increased AD risk induced by PFAS exposure.

PS 3583 Assessing Lead Levels in Human Bone with Portable XRF and Benchtop XRF Technology to Explore Links to Cognitive Performance and Neuropathology

G. A. Kowis, and L. H. Nie. Purdue University, West Lafayette, IN. Sponsor: J. Shannahan

Background and Purpose: This study investigates the role of cumulative metal exposure—specifically lead (Pb)—in relation to neurodegeneration in an elderly population, focusing on Alzheimer's disease (AD). Lead is a well-established neurotoxin associated with cognitive decline. While animal studies suggest associations between heavy metal exposure and AD-related neuropathology, human studies are limited. This research aims to quantify bone Pb concentrations in elderly donors and assess their relationship with cognitive function, neuropathological markers, and APOE genotype. **Methods:** Skull bone samples from 191 elderly donors, including individuals diagnosed with Alzheimer's disease (AD), were scanned using portable (pXRF, 12 min) and benchtop (7 min) X-ray fluorescence systems. Pb concentrations were processed in MATLAB and analyzed in R using ANOVA, Kruskal-Wallis, Wilcoxon rank-sum, and Spearman correlation tests. Pb levels were compared across sex and APOE genotype, and associations with cognitive diagnoses and neuropathological markers were examined. Longitudinal cognitive data were analyzed using a Linear Mixed Model (SPSS) to evaluate the effect of Pb on cognitive decline over time, adjusting for age and sex. **Results:** Males had significantly higher bone Pb concentrations than females (mean $\pm$ SD: females = 3.37 ± 2.41 μ g/g; males = 5.50 ± 3.26 μ g/g; t-test $p = 0.0016$; Wilcoxon $p = 0.00065$). When stratified by APOE genotype, significant sex differences were observed within APOE3 ($p = 0.0043$) and APOE4 ($p = 0.0007$) groups, but not among APOE2 carriers ($p > 0.05$). APOE genotype was significant in the longitudinal model ($p < 0.05$), indicating an interaction between genetic susceptibility and Pb exposure on cognitive decline. Longitudinal analysis preliminary results revealed a significant $f_{u\_year} \times$ concentration interaction ($F(1, 28.92) = 8.39$, $p = 0.007$), suggesting greater cognitive decline over time among individuals with higher bone Pb levels. **Conclusions:** Preliminary findings suggest potential associations between cumulative bone lead (Pb) exposure, cognitive decline, and modifying effects of sex and APOE genotype. Males showed higher bone Pb concentrations than females, particularly among APOE3 and APOE4 carriers, indicating that biological and genetic factors may influence Pb accumulation and related outcomes. The observed interaction between Pb concentration and follow-up year suggests a possible link between higher Pb levels and greater cognitive decline over time. Further analyses are needed to confirm these trends and clarify the role of genetic and sex-specific factors in Pb-related neurotoxicity.

PS 3584 Investigating the effect of Bisphenol A-induced neurotoxicity in a striatal cell model of Huntington's disease

W. F. Muliawan, M. Moon, E. Astafiev-Holmes, and G. F. Kwakye. Oberlin College, Oberlin, OH.

Background and Purpose: Exposure to environmental factors such as heavy metals and pesticides can induce neurotoxicity and cell death in Huntington's disease (HD), exacerbating disease severity and age of onset. Bisphenol A (BPA) is a commonly used chemical in the production of numerous widely-used plastics and has been

found at detectable levels in over 90% of the U.S. population's urine. BPA has been shown to cause neurotoxicity and cell death through oxidative stress and mitochondrial disruption in models of Parkinson's disease (PD) and cause a PD-like phenotype in drosophila. Given that similar pathophysiological mechanisms exist between PD and HD, and BPA's demonstrated effect in models of PD, we hypothesize that expression of mutant huntingtin coupled with chronic exposure to BPA will increase neurotoxicity and neurodegeneration through mitochondrial disruption, oxidative stress, and protein aggregation-related pathways. **Methods:** We are using an established immortalized striatal cell model of HD (WT - STHdhQ7/Q7, HD - STHdhQ111/Q111), and exposing cells for 24 and 48 hours, separately. To measure cell viability and death, we use the MTT and SYTOX Green assays, respectively. We measured mitochondrial membrane potential through the use of the TMRE assay. **Results:** We report that 48-hour exposure to BPA resulted in a dose-dependent increase in cell death which trended towards greater susceptibility of the mutant cells in both cell death and mitochondrial capacity assays, with no significant difference at 24 hour exposure. Further investigation into mitochondrial health showed a reduction in mitochondrial membrane potential at both 24 and 48 hour timepoints, with a greater reduction in membrane potential in mutant HD cells. **Conclusions:** Ongoing studies are investigating the impact of BPA exposure on mitochondria biogenesis, oxidative stress signaling pathways, and examining differentially expressed genes via RNA sequencing. Understanding the gene-environment interaction between BPA and HD will elucidate striatal specific effects associated with BPA and help educate at risk-populations.

PS 3585 Investigating cellular mechanisms of prion disease in a primary cervid fibroblast model

C. F. Dobkins¹, K. Popichak¹, L. Parrie², P. Smith², J. Malmberg², and J. A. Moreno¹. ¹Colorado State University, Fort Collins, CO; and ²National Wildlife Research Center, USDA, Fort Collins, CO.

Background and Purpose: The United States is known for a robust cervid population throughout all fifty states. Hunting culture is well established, and the proximity of these wild populations is getting closer to human civilization. Chronic Wasting Disease or CWD was first discovered in captive deer in Colorado State. Since then, it has spread throughout the United States and has traveled to both Europe and Asia via importation of diseased cervid species. CWD is a prion disease characterized by the misfolding of the PrP protein found throughout the central nervous system and surrounding peripheral tissues. This misfolding can happen via contact with an already misfolded PrP protein (PrP^{Sc}) or spontaneously for unknown reasons. Accumulation of PrP^{Sc} in cervids leads to neurological symptoms such as tremors, difficulty walking, drooling and altered behavior like loss of aggressive and fearful tendencies. **Methods:** In this project we use primary fibroblasts isolated from the cheek and ear of White Tail and Mule deer. As this is a primary deer cell line, we needed to optimize the cells maintenance and growth conditions prior to undergoing experimentation. To do this, we tested the growth and death of the cells using various ratios of new to conditioned media. We tested 100:0, 90:10, 75:25, 50:50, 25:75, and 0:100, new to conditioned media for ten days in dishes with normal confluency and low confluency starting with 50,000 and 10,000 cells, respectively. Morphological analysis was performed on day 1, 5, 7 and 10 to determine any changes in the cells with the various ratios of media. On day 11, the cells were trypsinized and percentages of live vs. dead cells we quantified using both trypan blue and flow cytometry to assess quantitative changes in cell viability. **Results:** Based on our morphologic data we found that 100:0 maintained fibroblast morphology however, the 50:50 ratio had the highest percentage of cells that did not undergo cell death and maintained expected morphology in both the low and normal confluency. **Conclusions:** Through these optimization assays we conclude that 50:50 is the best concentration for growth and overall viability in our primary deer fibroblasts. This optimization of cell conditions will allow us to move forward to characterize our primary cell lines and to use them as a tool to understand the cellular mechanisms of prion diseases like chronic wasting disease.

PS 3586 Mechanistic profiling of new potential Parkinsonian toxicants Identified through qHigh-Throughput Screening of MT1G expression in a model of differentiated LUHMES cells

M. D. Garcia-Aguilar, Z. Tong, S. Sakamuru, X. Menghang, R. Huang, and D. Gerhold. National Institutes of Health, Rockville, MD.

Background and Purpose: The etiology of Parkinson's disease (PD) remains unresolved; however, cumulative evidence implicates environmental chemical exposure as a major contributor to disease risk. To identify previously unrecognized environmental factors, we developed a quantitative high-throughput screening (qHTS) assay to identify chemicals toxic to dopaminergic neurons. To increase assay sensitivity, a reporter gene was identified, *MT1G*, which was dynamically up-regulated following chemical exposure to seven examples Parkinsonian neurotoxicants. *MT1G* encodes Metallothionein-1, a small protein that sequesters toxic labile metals such as iron and copper, as well as scavenging reactive oxygen species, processes commonly associated with the development of PD. Consequently, LUHMES cells were engineered to express luciferase under the control of endogenous *MT1G* regulatory

elements, enabling a sensitive 3D MT1G-Luciferase reporter assay optimized for qHTS in 1536-well microplates. Screening of the LOPAC library and Tox21 10K library yielded 28 active chemicals, selected for mechanistic characterization of neurotoxicity associated with MT1G induction. **Methods:** To dissect the pathways potentially contributing to neurodegeneration, we employed differentiated LUHMES dopaminergic neurons (dLUHMES) and we plan to evaluate five different mechanistic pathways: (1) Mitochondrial dysfunction, assessed by measuring mitochondrial membrane potential via TMRE fluorescence using flow cytometry at 30 minutes and 3 hours post-exposure, as well as by evaluating cell viability (CellTiter-Glo assay) under glucose- and galactose-based culture conditions at 24 hours; (2) Oxidative stress, determined through quantification of reactive oxygen species and cuproptosis/ferroptosis-associated lipid peroxidation, using viability assays in the presence of pathway inhibitors such as Ferrostatin-1 and metal chelators such as deferoxamine at 24 hours. (3) Dopamine transporter interference, evaluated using functional DAT activity assays; (4) Autophagy and proteasome impairment, assessed by quantification of autophagosomes via flow cytometry and analysis of LC3-II levels by Western blot; (5) Excitotoxicity, examined through intracellular calcium measurements (Fura-2 calcium flux assay), apoptosis analysis using Annexin V assays, and viability assessments in the presence of calcium channel blockers and glutamate transporter antagonists. **Results:** In galactose conditions, dLUHMES cells became more dependent on mitochondrial function. We observed that mitotoxins elicited responses that were approximately three orders of magnitude more sensitive than under glucose conditions, whereas compounds whose primary mechanism of toxicity does not involve mitochondrial dysfunction showed no significant changes in ATP levels. In addition, our preliminary findings after TMRE fluorescence assay indicate that these compounds can be classified into two groups: (i) uncoupling agents that create an alternative pathway for protons and induce mitochondrial membrane depolarization within 30 minutes, and (ii) inhibitors of electron transport chain complexes that lead to mitochondrial depolarization over approximately 3 hours. After standardization of the experimental strategy with the use of known parkinsonian neurotoxins, we observe that some of the compounds do not induce ferroptosis; however, we observed significant differences in cell viability following treatment with iron-chelating agents, indicating that iron availability could modulate the cellular response to these compounds. This finding suggests that iron-dependent processes may still contribute to the observed cytotoxicity. **Conclusions:** Together, these findings underscore the multifactorial nature of environmentally induced dopaminergic neurodegeneration and highlight the value of MT1G-based screening coupled with targeted pathway analyses for uncovering mechanistic liabilities of environmental chemicals relevant to Parkinson's disease risk and even identify potential therapeutic targets.

PS 3587 Evaluation of neurotoxicity of 21 organophosphorus pesticide binary mixtures using rapid behavioral screening in the planarian *Dugesia japonica*

D. Ireland¹, R. Wang¹, S. G. Fuselier¹, C. Rabeler¹, R. T. Somach¹, R. J. Richardson², and E. S. Collins¹. ¹Swarthmore College, Swarthmore, PA; and ²University of Michigan, Ann Arbor, MI.

Background and Purpose: Organophosphorus pesticides (OPs) are a chemically diverse class of compounds that exert their acute toxicity through acetylcholinesterase (AChE) inhibition. However, chronic low-dose exposure to OPs has been shown to cause neurotoxicity and developmental neurotoxicity through other mechanisms besides AChE inhibition. Given the large number of OPs and their frequent use in mixtures, high throughput screening (HTS) methods are needed for comparative OP mixture studies to better understand potential interactions. Because many OPs require bioactivation, HTS-amenable organismal models with human-relevant metabolism are required. Here, we utilized the planarian *Dugesia japonica*, which is well-suited for comparative studies of OP toxicity and amenable to behavioral HTS in developing and adult specimen, to evaluate whether the adverse outcomes of binary mixtures of OPs can be recapitulated by a concentration addition model that assumes a shared mode of action. **Methods:** We screened 21 binary mixtures of 7 OPs (acephate, chlorpyrifos (CPF), diazinon, dichlorvos (DDVP), malathion, parathion, and profenofos) in equimolar ratios across at least 5 concentrations up to 10 μ M in adult and regenerating *D. japonica* planarians using an automated screening platform. We evaluated 22 readouts, quantifying effects on lethality, stickiness, locomotion and responses to light and temperature on days 7 and 12 post-exposure. Using published planarian data on the individual OPs, we determined whether a Loewe concentration addition model describes the experimental OP mixture data. Four OP mixtures were also tested for AChE inhibition, to contextualize the behavioral screening results. **Results:** We found that binary interactions between these OPs can be non-additive and identified both synergistic and antagonistic interactions depending on the OP mixture, readout and developmental stage (adult vs regenerating planarians). For example, in regenerating planarians, except for the binary mixture of DDVP and CPF, all DDVP-containing mixtures showed antagonistic effects on stickiness at day 12. CPF- or profenofos-containing mixtures showed either additive or synergistic effects on stickiness. Regarding AChE inhibition, CPF-malathion and CPF-parathion mixtures showed additive effects, mixtures of diazinon-DDVP showed antagonistic effects, and diazinon-profenofos mixtures showed synergistic effects. These data agree with our previous findings that increased stickiness is correlated with increased cholinergic signaling. In contrast, other readouts did not correlate with AChE inhibition. **Conclusions:** Our results suggest that OP binary mixtures can have both additive and non-additive interactions and that these can vary between the

adult and developing nervous system. Due to the conservation of key enzymes in OP toxicokinetics/toxicodynamics between planarians and humans, the insights gained here are likely to be relevant to human health and can be further verified in targeted mechanistic studies in human cells.

PS 3588 Acute organophosphate intoxication activates the TGF β signaling pathway

B. Davis, Y. Tsai, T. Teodoro, C. Unkel, D. Bruun, M. Muñoz, A. Gelli, and P. Lein. University of California, Davis, Davis, CA.

Background and Purpose: Intentional and accidental poisonings with organophosphate (OP) cholinesterase inhibitors can trigger an acute cholinergic toxidrome that includes not only peripheral cholinergic symptoms, but also acute seizures that can rapidly progress to life-threatening status epilepticus (SE). Human and preclinical studies have demonstrated that individuals who survive the acute OP-induced SE have a high risk of developing spontaneous recurrent seizures (SRS) as well as persistent blood-brain barrier (BBB) impairment, neurodegeneration, and neuroinflammation. Other research groups have shown that BBB disruption and the consequential albumin leakage into the brain parenchyma can activate the transforming growth factor β (TGF β) signaling cascade. Data from our lab have shown plasminogen activator inhibitor-1 (PAI-1), a TGF β -responsive gene, is increased following acute OP intoxication and persistently expressed in astrocytes. Phosphorylation of the transcription factors SMAD2/3 (pSMAD2/3) is the signaling molecule that links TGF β receptor activation to upregulation of PAI-1. Our overall goal is to evaluate TGF β signaling as a therapeutic target for mitigating the adverse neurological effects of acute OP intoxication. As a first step towards this goal, we assessed the spatiotemporal expression of PAI-1 and pSMAD2/3 relative to total SMAD2/3 following acute OP intoxication. **Methods:** Adult female Sprague Dawley rats were injected with the OP diisopropylfluorophosphate (DFP, 4 mg/kg, SC; n=36) or PBS (n=22) followed by atropine sulfate (2 mg/kg; IM), 2-pralidoxime (25 mg/kg; IM), and two doses of midazolam (0.65 mg/kg; IM), to improve survival rate. Seizure behavior was scored using a modified Racine Scale (0-5) to monitor the progression and severity of seizures. Animals that had an average behavioral score of 2.5 within the first 40 min (a score that has been shown previously to correspond with electrographic SE) were included in the study. At 3, 6, 12, 24, 72, 168, and 336 h post-exposure, brain tissue was collected for biochemical analysis. The cortex, piriform cortex, and hippocampus were dissected, flash-frozen, and stored at -80°C prior to lysate preparation using a lysis buffer that contained protease and phosphatase inhibitors. PAI-1, pSMAD2/3, and total SMAD2/3 were quantified in 3 technical replicates of each sample using commercially available enzyme-linked immunosorbent assays (ELISAs); values were normalized to total protein concentration. Tests for normality indicated the data were not normally distributed, so Kruskal-Wallis with Bonferroni adjustment was used to assess group differences in target molecule expression. **Results:** Preliminary results indicate that PAI-1 expression was increased in the cortex, hippocampus, and piriform cortex from 12 h through 72 h following DFP intoxication (p<0.05). The ratio of phosphorylated to total SMAD2/3 was increased in all brain regions at 6, 12, and 24 hours post-DFP intoxication (p<0.05) with significant differences persisting at 72 h post-exposure in the piriform cortex and hippocampus (p<0.05). **Conclusions:** Our findings demonstrate that the TGF β signaling pathway is activated following acute DFP intoxication, with the highest activity observed in brain regions previously shown to exhibit severe BBB disruption, neuroinflammation, and neurodegeneration. Converging evidence from multiple studies supports a link between activation of TGF β signaling, BBB disruption, and subsequent epileptiform activity and cognitive deficits. Characterizing the spatiotemporal dynamics of TGF β signaling after acute OP exposure supports further studies evaluating TGF β signaling as a potential therapeutic target for mitigating the adverse neurological sequelae of acute OP intoxication.

PS 3589 Single-nuclei transcriptomics reveal significant glial cell expansion and selective neurotoxicity during the epileptogenic period following organophosphate-induced status epilepticus

M. J. Armstrong, A. Izadi, M. A. Muñoz, D. A. Bruun, G. G. Gurkoff, and P. J. Lein. University of California, Davis, Davis, CA.

Background and Purpose: Acute intoxication with organophosphate (OP) pesticides or nerve agents inhibits acetylcholinesterase, causing neuronal hyperexcitability that can progress to acute status epilepticus, persistent brain damage, and spontaneous recurrent seizures (SRS). While current standard of care can mitigate acute symptoms, they fail to prevent persistent neurological effects, and 70-80% of intoxicated individuals that experience status epilepticus (SE) develop SRS. Currently, we do not understand the molecular mechanism(s) underlying the development of SRS following acute DFP intoxication, the cell types involved, or why a subset of individuals (20-30%) do not develop SRS despite experiencing acute DFP-induced SE. **Methods:** To address these data gaps, we leveraged a well-characterized rat model of acute intoxication with the OP diisopropylfluorophosphate (DFP). Electrographic profiles predictive of SRS development were used to identify adult male Sprague Dawley rats highly likely to develop SRS (referred to as the SRS group) and which were not (non-SRS group) following DFP-induced SE. snRNA-Seq was performed on nuclei

isolated from the piriform cortex of control animals not intoxicated with DFP (n = 4, 19,165 nuclei), non-SRS DFP animals (n = 4, 29,453 nuclei) and SRS DFP animals (n=4, 25,389 nuclei). Single nuclei analysis showed bidirectional changes in expression of genes regulating neuronal excitability that tracked with seizure outcome. **Results:** Relative to SRS, the glutamatergic neurons of control and non-SRS animals displayed elevated expression of potentially protective genes, *Scn1a* (NAV1.1), *Kcnk2* (TREK-1), *Gabra1/Gabrb2* (GABAA $\alpha 1/\beta 2$ subunits), cell polarity genes *Prickle1/2*, and *Gria3* which encodes an AMPA receptor subunit, which may aid in reducing neuronal excitability. Additionally, we identified increased expansion of glial cell populations in SRS vs. non-SRS DFP rats, including proliferative subpopulations of astrocytes, microglia, and oligodendrocyte precursors cells, with elevated expression of proliferation markers, *Mki67*, *Top2a*, *Cenpe*, *Cenpf*, and *Kif4a*. **Conclusions:** This is the first study to apply single-cell transcriptomic technologies to characterize the impact of acute OP intoxication on individual cell types and subpopulations. The results demonstrate that increased risk of developing SRS was associated with significantly reduced neuronal cell populations and expanded glial cells, including highly proliferative and inflammatory glial subpopulations that were largely absent under homeostatic conditions. Importantly, only glutamatergic neurons showed significant transcriptional shifts between non-SRS and SRS animals. Together, these results suggest that a multipronged treatment strategy that targets both glutamatergic signaling and neuroinflammation during the epileptogenic period is likely necessary to prevent SRS development.

PS 3590 Dose-Dependent Effects of Chlorpyrifos on Embryonic Cortical Neuronal Network

S. Schumann, R. Tanwar, K. Namburi, and J. Cannon. Purdue University, West Lafayette, IN.

Background and Purpose: Chlorpyrifos (CPF), a widely used organophosphate pesticide, has been linked to neurotoxic effects in children exposed prenatally, including brain anomalies, behavioral changes, and structural deficits. Previous research has shown disturbance in neuronal networks of postnatal cortical neurons. However, there remains a gap in knowledge regarding the effects of CPF on the embryonic cortical neuronal network. Research has also suggested that embryonic cortical neurons are more vulnerable to CPF exposure than postnatal cortical neurons. Given this previous research, we hypothesize that the embryonic cortical neuronal network is more sensitive to CPF. **Methods:** Primary cortical neurons were prepared from embryonic day 17 (E17) Sprague-Dawley rat embryos. Cells were plated onto multi-well MEA plates, which contain 48 wells per plate, with each well consisting of an array of 16 individual embedded nanotextured microelectrodes. Cells were plated at a density of 120,000 cells/well and cultured in Neurobasal medium. The culture medium was switched to BrainPhys at DIV5, and a full media change was performed at DIV11 to establish baseline activity. At DIV13, a full media change was performed again with increasing concentrations of CPF (0.1 μ M, 1 μ M, 3 μ M, 5 μ M, and 10 μ M). **Results:** We observed a decrease in the number of spikes, number of (network) bursts, (network) burst duration, number of spikes per (network) burst, mean ISI within network bursts and synchronicity in all CPF concentrations in embryonic cortical neurons. **Conclusions:** In contrast to previous studies, which found these effects only occurring at the highest dose in postnatal cortical neurons, our results suggest that embryonic neurons are more vulnerable to the neurotoxic effects of chlorpyrifos. Future work will aim to elucidate the mechanisms underlying CPF-induced neurotoxicity in embryonic cortical neurons.

PS 3591 Substance P Mediates Chlorpyrifos-Induced Airway Hyperreactivity While Neurokinin A and Calcitonin Gene-Related Product Mediate Chlorpyrifos-Induced Lung Tissue Stiffness

A. C. Grodzki, E. Schelegle, and P. J. Lein. University of California Davis, Davis, CA.

Background and Purpose: Occupational and environmental exposures to organophosphorus pesticides (OP) are associated with increased asthma incidence. The canonical mechanism of OP neurotoxicity is acetylcholinesterase (AChE) inhibition; however, we previously demonstrated that the OP chlorpyrifos (CPF) causes airway hyperreactivity (AHR) in adult rats 24 h and 7 days after exposure at levels that do not significantly inhibit AChE. Neurogenic inflammation has been suggested to play a role in AHR; therefore, we tested the hypothesis that substance P, neurokinin A and calcitonin gene-related peptide (CGRP) contribute to CPF-induced AHR. **Methods:** Eight-week-old male Sprague Dawley rats were administered 30 mg/kg CPF subcutaneously, and airway responsiveness to electrical stimulation of the vagus nerve was assessed at 24 h or 7 d post-exposure using a Flexivent mechanical ventilator. Atropine was administered IP during mechanical ventilation and electrical stimulation to confirm the role of muscarinic receptors in CPF-induced AHR in rats. To test potential contributions of substance P, neurokinin A and CGRP, we determined whether pharmacological antagonism of the receptors activated by these neuropeptides were effective in attenuating CPF-induced AHR. SR140333 (1 mg/kg, IP), which antagonizes the NK1 receptor activated by substance P; olcegepant (1 mg/kg, IP), which blocks the CGRP receptor; and GR159897 (0.2 mg/kg, IP), an NK2 receptor antagonist that blocks signaling by neurokinin A, were injected 1 h before physiological measurements. **Results:** As previously demonstrated, CPF significantly increased

airway resistance and elastance at 24 h and 7 d post-exposure. Atropine, which binds to and inhibits muscarinic receptors, abolished CPF-induced AHR, confirming airway responsiveness was due to activation of the parasympathetic nerves that control contraction of airway smooth muscle. NK1 receptor inhibition significantly decreased vagally-stimulated bronchoconstriction in CPF-exposed animals to levels observed in vehicle controls at 24 h and 7 d post-CPF exposure. Neurokinin A receptor inhibition decreased pressure-volume loops at 24 h and 7 d post-CPF exposure, and CGRP receptor antagonist decreased the pressure-volume loop at 7 d post-CPF exposure, but neither neurokinin A or CGRP receptors antagonists decreased vagally-stimulated bronchoconstriction in CPF-exposed animals. **Conclusions:** These data suggest that substance P signaling contributes to both acute and persistent CPF-induced AHR, which is mediated at the level of the conducting airways, while neurokinin A and CGRP contribute to CPF effects on the elastic properties of the lung tissue, the surface tension of the alveoli, and the compliance of the lung. These findings identify substance P and its receptor as a new therapeutic target for mitigating OP-induced AHR in exposed individuals and further characterize the sites of overall effects of CPF on the mechanics of breathing. This work was supported by the NIH (grant R01 ES017592 and P30 ES023513).

PS 3592 Chlorpyrifos-induced motor deficits are exacerbated in Pon1(-/-) vs wild type.

R. Tanwar, F. Currim, S. Schumann, K. Namburi, T. Syeda, S. Sammi, and J. Cannon. Purdue University, West Lafayette, IN.

Background and Purpose: Chlorpyrifos (CPF) is an organophosphate pesticide widely used in agriculture despite its adverse impacts on human health through acetylcholinesterase inhibition, causing cholinergic effects. Epidemiological and laboratory research has linked environmental exposures, such as CPF, to Parkinson's Disease (PD). However, the impact of genetic variations in PD-related genes, specifically on dopaminergic neurotoxicity, is not well understood. Paraoxonase 1 (Pon1) has a key role in detoxifying neurotoxic CPF Oxon, and genetic polymorphisms in Pon1 may increase susceptibility to PD from CPF exposure. We tested the hypothesis that Pon1 knockout and CPF exposure would represent a PD-relevant gene-environment interaction. **Methods:** We conducted this study on male and female Pon1-knockout (KO) and wild-type Sprague-Dawley rats, aged 3 months. The rats were divided into groups based on their genotype, treatment, and sex, and CPF was administered at a dose of 2.0 mg/kg or a control treatment (Corn oil) for 8 weeks. Behavior was assessed prior to exposures and weekly after exposures began. **Results:** Results from the study revealed that Pon1 KO rats treated with 2 mg/kg CPF demonstrated a decrease in neurobehavioral assessments, including postural instability, vibrissae-elicited forelimb placing, compared to wild-type rats treated with the same CPF dose. These findings suggest that the absence of Pon1 exacerbates the neurotoxic effects of CPF. **Conclusions:** This study highlights the potential for genetic predisposition (Pon1 deficiency) to increase vulnerability to CPF-induced neurobehavioral alterations associated with PD. Future work will involve molecular and neurochemical analyses of isolated brain and liver tissues to elucidate further the mechanisms underlying these effects.

PS 3593 Epigenetic Histone Modifications and Synaptic Plasticity Alterations associated with Chronic Neurobehavioral Deficit Following Repeated Chlorpyrifos Exposure in Adult Rats

S. Kulkarni, Y. Paudel, A. Ribeiro-Davis, E. Hawkins, J. McClay, and L. Deshpande. Virginia Commonwealth University, Richmond, VA.

Background and Purpose: Chlorpyrifos (CPF) is one of the most widely used organophosphate (OP) worldwide. Epidemiological studies report long-term depression and cognitive impairments, in OP-exposed individuals. We recently demonstrated that occupational-like CPF exposure in adult rats was associated with significant chronic anxiety and depression. Epigenetic modifications to chromatin are regulatory mechanisms that can adaptively or maladaptively respond to external stimuli. Our previous research identified epigenetic alterations in a rat model of OP DFP-induced depression. In this study we investigated whether occupational-like CPF exposures affect epigenetic pathways that ultimately alter neuronal plasticity mechanisms leading to chronic depression in adult rats. **Methods:** CPF (5 mg/kg, SC, 1x daily for 21-days) was delivered to adult male Sprague-Dawley rats. Following a 12-week washout period, anxiety and depressive outcome were assessed using a battery of rat neurobehavioral assays. Subsequently rats were euthanized and hippocampus was dissected, flash-frozen and used for molecular studies. Another cohort of rats were perfused with paraformaldehyde and brains post-fixed in sucrose for histology. To evaluate CPF-induced changes on histone modifications, antibody-specific western blotting and chromatin immunoprecipitation assays were conducted. Gene expression studies were conducted using RNAseq. Hippocampal spine density was assessed using Dil staining and synapse number was determined by assessing colocalization of PSD95 and synaptophysin using immunohistochemistry. **Results:** CPF exposures in adult rats produced signs of anhedonia, higher anxiety, and increased despair on rodent behavioral tests. These signs were associated significant increase in hippocampal expression of histone deacetylase proteins (HDAC3 and HDAC5) and a decrease in global levels of histone 3 lysine 27 acetylation (H3K27ac). RNA-seq

identified 100 differentially expressed genes (DEGs). Gene Ontology analysis found that these DEGs were enriched in several pathways including regulation of neuronal plasticity. Using Western blotting, we found a significant decrease in BDNF protein expression in the hippocampus of CPF rats and ChIP showed a significant reduction in H3K9ac occupancy at Bdnf promoter IV in CPF rats. Dil staining showed a significant decrease in spine density in CPF-5 rats along with significant reductions in immunohistochemical staining for synaptophysin and PSD-95 in the hippocampal CA1 and dentate gyrus regions **Conclusions:** CPF exposures that mimic human occupational exposures produce chronic depression associated with dysregulations in histone acetylation pathways, a decrease in expression of brain neurotrophic factors, and a reduction in dendritic spine density along with a decrease in synaptic marker proteins indicative of synapse loss. These observations led us to hypothesize that repeated, low-dose OP CPF exposure induces sustained upregulation of HDACs that reduce expression of key genes and proteins involved in the growth and integrity of synapses, manifesting as reduced synaptic plasticity and signs of chronic depression in rats. This study will provide new data on CPF's effects on the brain and deepen our mechanistic understanding of how OPs affect the risk for depression.

PS 3594 Using rodent MRI to assess changes in brain morphology of adult C57BL/6 mice following prenatal chlorpyrifos exposure

D. Kendrick¹, L. Aksu¹, G. Johnson², K. Hornburg², J. Cook², D. Tokarz³, E. Singletary³, Z. Howe², R. Herbert¹, C. McPherson¹, R. Sills¹, and J. Cushman¹. ¹National Institute of Environmental Health Science, Research Triangle Park, NC; ²Duke University, Durham, NC; and ³Experimental Pathology Laboratories, Morrisville, NC.

Background and Purpose: Early developmental exposure to the organophosphate pesticide, chlorpyrifos, impairs activity of acetylcholine, disrupts social and motor behavior, and causes heightened oxidative damage in humans and rodent models. Such early life exposure also impacts brain development both in human children and in rodent models. Human children exposed to chlorpyrifos have disrupted white and gray matter density that co-occur with impairment in motor function. In rodent models of exposure, locomotor impairments have been reported, but whether these changes are also met with changes in white and gray matter microstructure has yet to be determined. **Methods:** The current study utilized magnetic resonance histology, i.e. MR microscopy of postmortem specimens to assess changes in brain morphology of C57BL/6J mice exposed prenatally to chlorpyrifos. A total of 42 male and female mice were exposed to 0, 0.5, or 5 mg/kg/day chlorpyrifos from gestational days 6-17. Locomotor behavior was assessed in early adulthood. At 7 months of age, brains were perfused with ProHance and imaged using diffusion tensor images (DTI) acquired on an Agilent 7T scanner. Images were acquired at 35 μ m isotropic resolution (~180,000 times that of clinical DTI). Difference in volume and fractional anisotropy from chlorpyrifos exposure were quantified using multiple ANOVA across control and exposed groups in 231 different regions of interest (ROI). **Results:** Chlorpyrifos exposure resulted in reduced fractional anisotropy in eight ROI, including the sensory regions of the midbrain, regions within the inferior and superior colliculi, the pontine reticular formation, and cochlear nuclei. Volume fraction, i.e. the percentage of volume of a region normalized to total brain volume, increased in 11 ROI including the midbrain reticular formation, subthalamic nucleus, and red nucleus. Exposure also resulted in reduced volume fraction in 8 ROI, including the infralimbic cortex, cerebellum, and orbital cortex. As expected, there were significant differences in fractional anisotropy and volume fraction between males and females, regardless of exposure. **Conclusions:** Alterations seen in this rodent model of prenatal exposure are similar to those reported in humans exposed early in life, showing the potential use of rodent MR microscopy to detect human-relevant changes in neurological endpoints. The observed changes seen with chlorpyrifos exposure are also suggestive of a potential target driving long-term behavioral differences seen in exposed animals. These findings raise potential concern about neurodegeneration occurring due to early life pesticide toxicity that require additional study.

PS 3595 APOE Genotype and Sex Modify the Effects of Organochlorine Pesticide DDT in Humanized APOE Mice

A. J. Barahona¹, I. Mhatre-Winters¹, J. J. Zhan², A. Eid³, R. P. Hart⁴, V. Tran², Y. Han¹, Y. Go², D. P. Jones², and J. R. Richardson¹. ¹University of Georgia, Athens, GA; ²Emory University, Atlanta, GA; ³Florida International University, Miami, FL; and ⁴Rutgers University, Piscataway, NJ.

Background and Purpose: Alzheimer's disease (AD) is the most common neurodegenerative disease in the US with substantial health, social, and economic implications. There is extensive epidemiological data that suggests the environment plays a considerable role in the etiology of the disease. The organochlorine pesticide dichlorodiphenyltrichloroethane (DDT) was used extensively to combat insect-borne diseases in the US until its ban in 1972. Nevertheless, existing dumpsites and DDT's long half-life contribute to persistent trace levels in the environment and food chain. There is limited data on how environmental exposure to DDT is influenced by non-modifiable risk factors. The Apolipoprotein (APOE) ϵ 4 genotype is known to be the strongest genetic risk factor for late-onset AD. Different APOE genotypes have revealed unique effects on lipid metabolism, inflammation, and neuronal function.

Moreover, two-thirds of all AD cases in the US are reported in women, emphasizing the role sex plays as a risk factor. Previous work from our lab suggests that age, sex, and APOE interact to influence basal neuroinflammation and synaptic function. We have also previously demonstrated that DDT-exposed E4 females exhibit the greatest synaptic impairment compared to all groups, as evidenced by immunofluorescence staining and western blot analysis. DDT-exposed E4 females also have the highest levels of serum NFL, a prognostic biomarker of neurodegeneration, compared to all groups. In this study, we sought to investigate the mechanisms behind these findings by investigating how sex and APOE genotype mediate DDT-induced transcriptional and metabolomic changes in humanized targeted replacement (TR) APOE3 (E3) and APOE4 (E4) mice. **Methods:** Male and female, 3-month-old humanized TR mice were exposed to 3 mg/kg of DDT or corn oil every 3 days for 5 months by oral gavage. Brain tissue was dissected and snap frozen following saline perfusion. Hippocampal samples were analyzed using RNA sequencing for transcriptomics and untargeted metabolomics by mass spectrometry. **Results:** Transcriptomics analysis revealed APOE genotype and sex were major drivers of differential gene expression across groups. Interestingly, there was minimal correlation between significantly differentially expressed genes (DEGs) in E4 vs. E3 DDT-exposed males and E4 vs. E3 DDT females, suggesting sex modifies APOE-dependent transcriptional changes under DDT exposure. Functional analysis showed that E4 vs. E3 DDT-exposed males exhibited dysregulation of membrane potential and ion transport, whereas E4 vs. E3 DDT-exposed females displayed alterations in RNA splicing, providing further evidence for a sex-by-genotype interaction in DDT-exposed mice. Furthermore, metabolomics pathway analysis revealed distinct APOE genotype-dependent effects in DDT-exposed mice, where differences in E4 vs. E3 DDT males were primarily associated with inflammatory signaling and energy metabolism, indicating altered mitochondrial function and lipid signaling. In contrast, differentially expressed metabolites in E4 vs. E3 DDT females were enriched for vitamin metabolism and lipid synthesis, reflecting genotype-dependent metabolic differences. **Conclusions:** Overall, these findings suggest that DDT exposure has a multifaceted impact across biological systems, elucidating a complex gene-by-environment interaction modulated by sex. These data identify potential mechanisms by which DDT exposure may interact with the APOE genotype and sex, potentially contributing to Alzheimer's disease risk.

PS 3596 DDT Alters Amyloid β Oligomerization and Synaptic Density in Humanized Amyloid β Mouse Model

A. N. Harriman¹, A. J. Barahona¹, F. M. Sammoura², I. Mhatre-Winters¹, Y. Han¹, and J. R. Richardson¹. ¹Isakson Center for Neurological Disease Research, University of Georgia, Athens, GA; and ²Florida International University, Miami, FL.

Background and Purpose: Alzheimer's disease (AD) is a neurodegenerative disease characterized by a decline in memory and function. Environmental factors are increasingly recognized as major contributing factors to the onset of Alzheimer's disease and related dementias (ADRD). Dichlorodiphenyltrichloroethane (DDT) is a highly persistent organochlorine pesticide used widely between the 1940s and the 1970s to combat insect-borne diseases. Since the ban in the United States in 1972, DDT levels have been steadily declining, however the persistent metabolite, dichloro-diphenyl-dichloroethylene (DDE) is still detectable. We've previously reported that DDT exacerbates amyloid beta ($A\beta$) plaque pathology and synaptic impairment in the 3xTG-AD mouse model, which overexpresses rare, causal AD genes. Here, we investigated the ability of DDT on $A\beta$ pathology in hA β mice, a humanized $A\beta$ knock-in model (hA β). This model uses a Cre-lox system to humanize the site in mouse amyloid precursor protein to generate human $A\beta$ at physiological levels. This model also produces amyloid burden and related pathologies comparable to those in human late-onset Alzheimer's disease (LOAD) compared to traditional mouse models that overexpress rare, causal genes. **Methods:** Male and female hA β knock-in mice (aged 3 months) were exposed to 3 mg/kg DDT or corn oil (control) by oral gavage every 3 days for 30 days (N=5-7 males and females per treatment). One day after completion of exposure, a Y-maze behavioral test was conducted. The mice were sacrificed 2 days after the final dose. The brains were dissected following saline perfusion. The left hemispheres were fixed in 10% formalin and sectioned at 40 μ m using a microtome. Sections were stained with anti-MOAB (Biosensis, M-1586-100) to visualize oligomeric $A\beta$ and anti-SV2A (Abcam, Ab32942) to assess synaptic loss. Fluorescent images were captured using BZ-X800 and the fluorescence intensity was quantified using BZ-X800 Analyzer. Data were analyzed using a two-way ANOVA followed by Tukey's for multiple comparisons. **Results:** The disruption of working memory was investigated by calculating spontaneous alternations in the Y-maze. Our results revealed that female hA β mice exposed to DDT performed significantly worse compared to control females and fell below chance level (50%) ($p < 0.05$) (Control: 66%; DDT: 51%; $p = 0.026$). Although not statistically significant, DDT decreased percent alternation in males (Control: 62%; DDT: 53%; $p = 0.2398$). The total number of arm entries across groups did not change, suggesting the difference observed in alternations was not due to differences in activity. To assess whether DDT altered synaptic density, immunofluorescence staining was performed for SV2A and the brightness was quantified. DDT exposure decreased synaptic density in the hippocampus (39% in CA3, 27% in CA1, and 38% in the dentate gyrus) and entorhinal cortex (33% decrease) of males compared to the control, indicating reduced connectivity between neurons and thus a potential for cognitive dysfunction. In females, DDT exposure decreased synaptic density in the CA1 (10%) and dentate gyrus (12%), although these differences were not statistically significant. Preliminary

qualitative immunofluorescence images for oligomeric A β suggests that exposure to DDT exacerbates oligomeric A β in hippocampal and cortical regions in male and female hA β mice compared to vehicle-treated mice. However, no plaque pathology was observed. **Conclusions:** These findings demonstrate that DDT exposure induces cognitive deficits and increases oligomeric A β , accompanied by reduced SV2A levels. This evidence highlights the critical role of environmental exposures in altering mechanisms related to AD risk.

PS 3597 Association of Prenatal Pesticide Exposure with Plasma A β -42/40 and Cognitive Function in Midlife is Modified by APOE Genotype: Evidence from the CHDS cohort

I. Mhatre-Winters¹, P. M. Cirillo², Y. Han¹, N. Krigbaum², P. Factor-Litvak³, B. G. Link⁴, Y. Go⁵, D. P. Jones⁵, B. Cohn², and J. R. Richardson¹. ¹Isakson Center for Neurological Disease Research, University of Georgia, Athens, GA; ²Child Health and Development Studies, Public Health Institute, Oakland, CA; ³Columbia University Medical Center, New York, NY; ⁴University of California, Riverside, CA; and ⁵Department of Medicine, Emory University, Atlanta, GA.

Background and Purpose: Complex gene-environment interactions across the lifespan are increasingly recognized as key contributors to Alzheimer's disease (AD) and related dementias, with studies linking pesticide exposure to a decline in cognitive performance. Dichlorodiphenyltrichloroethane (DDT), an organochlorine pesticide used extensively in the US to combat insect-borne diseases until its ban in 1972, persists in trace amounts due to its long half-life, bioaccumulation, and legacy dumpsites. Although environmental DDT levels have steadily declined, its persistent metabolite, dichlorodiphenyldichloroethylene (DDE), remains ubiquitously detectable and is considered non-neurotoxic. Further, Apolipoprotein ϵ 4 (APOE4) is the strongest genetic risk factor for late-onset AD (LOAD), but it is not entirely predictive. This exemplifies the need to investigate legacy exposures as people highly exposed to DDT between the 1940s and 1970s face a significantly increased risk of developing late-onset AD (≥ 65 years). We have previously reported nearly four times higher serum DDE levels in AD patients compared to healthy individuals, where the APOE genotype modified mini-mental state exam scores and contributed a ~4-fold increase in AD risk. Additionally, we demonstrated that DDE exacerbates amyloid (A β) pathology in cell culture and animal models, and disrupts cognitive function. However, little is known about the effects of DDE exposure on plasma A β -42/40 ratio, a reliable biomarker for prodromal AD and cognitive dysfunction in humans. Here, we sought to assess (i) the effects of human prenatal DDE exposure on cognition and plasma A β -42/40 ratio in mid-life and (ii) the impact of APOE4 genotype on plasma A β -42/40 ratio. **Methods:** To assess the effects of prenatal *p,p'*-DDE exposure, offspring from the Child Health and Development Studies (CHDS) pregnancy cohort (1960-1963) in Oakland, California, were recruited in 2010 for a follow-up study. Participants (mean age: 49.3y) completed cognitive function assessments, including the Wechsler Digit Symbol Substitution Test (DSST), and provided blood samples. A total of 179 individuals were included in this study (56% females and 44% males; 26% black and 74% non-black). Quanterix N3PA kit was used to measure plasma A β -42/40 in mid-life. Genomic DNA was extracted from the buffy coat, and the APOE genotype was determined using PCR-based SNP genotyping. Matched prenatal *p,p'*-DDE, measured in archived maternal pregnancy serum, was available. Associations were estimated in linear, binomial, and multinomial logistic regression models, adjusted for sex, race, and education. **Results:** Higher prenatal DDE levels were associated with lower mid-life DSST scores ($\beta = -0.0219$, 95% CI [-0.0401, -0.0038]; $p = 0.0178$). Associations were robust to multiple alternative modeling approaches. Adjusting for achieved education in mid-life did not alter results. Higher prenatal DDE levels were also associated with lower plasma A β -42/40 ratio in mid-life, where higher prenatal DDE was associated with increased odds of being in the lowest tertile of A β -42/40 ratio (Tertile 3: $\beta = -1.0176$; 95% CI [-2.0212, -0.0140], $p = 0.046$). The test for trend across DDE tertiles was significant ($p = 0.04$). Furthermore, poor cognitive performance in mid-life was associated with lower A β -42/40 ratios ($\beta = 0.0005$; 95% CI: [0.0001, 0.0008]; $p = 0.0069$). Lastly, APOE4 carriers also showed lower A β -42/40 levels ($\beta = -0.62$; 95% CI: [-1.15, -0.08]; $p = 0.02$), with an interaction between DDE and APOE4 ($\beta = 0.01$; $p = 0.04$), suggesting that APOE4 status modifies the relationship between early-life DDE exposure and mid-life amyloid pathology. **Conclusions:** Overall, these data indicate that DDE exposure has a long-lasting neurological impact on amyloid processing and cognitive function. Our translational findings in humans provide evidence that prenatal and early-life environmental exposures increase AD risk, advancing opportunities for early mid-life interventions to prevent disease progression.

PS 3598 Rotenone induced Parkinsonian neurotoxicity in fish alters central catecholamine metabolism in the brain

M. Badruzzaman¹, T. Chakraborty², and A. H. Shanto³. ¹Gazipur Agricultural University, Gazipur, Bangladesh; ²Kyushu University, Fukuoka, Japan; and ³Sylhet Agricultural University, Sylhet, Bangladesh.

Background and Purpose: Rotenone, widely used as an agricultural pesticide and piscicide in aquaculture, is highly toxic to aquatic life and can induce Parkinsonism by causing selective loss of dopaminergic neurons and disrupting catecholamine

metabolism in the brain. This study examines rotenone-induced neurotoxicity and its disruption of central catecholamine metabolism in the fish brain, developing a vertebrate model for Parkinson's-like neurodegeneration. **Methods:** Adult Indian freshwater catfish, (*Mystus cavasius*) were exposed either to a vehicle or water containing mitochondrial complex-1 inhibitor rotenone at 250 μ g/L for three days to induce dopaminergic neurodegeneration. The brain was collected, and catecholamines along with their metabolites were measured using high-performance liquid chromatography (HPLC). **Results:** Neurochemical analysis revealed decreased levels of dopamine (DA), its metabolite 3,4-dihydroxyphenylacetic acid (DOPAC), the vesicular storage index (DOPAC/DA), catecholamines (epinephrine and norepinephrine) and aldehyde dehydrogenase (ALDH) activity (DOPAC/DOPAL) with elevated levels of 3,4-dihydroxyphenylacetaldehyde (DOPAL) in the whole brain, indicating disrupted catecholamine metabolism. These alterations were associated with changes in the activities of key enzymes involved in catecholamine synthesis and degradation, including tyrosine hydroxylase (TH) and monoamine oxidase (MAO). Compared to controls, rotenone-treated fish exhibited reduced locomotor activity along with increased anxiety and aggressiveness. Immunohistochemically analysis further confirmed neuronal damages in brain areas controlling movement. **Conclusions:** These findings indicate that rotenone neurotoxicity profoundly disrupts brain catecholamine homeostasis, closely mimicking the neurochemical deficits observed in both mammalian models and human Parkinson's disease. Therefore, the rotenone-treated fish provide a useful model for studying Parkinsonian mechanisms and for screening potential neuroprotective agents targeting catecholaminergic dysfunction.

PS 3599 STING ablation attenuates rotenone-induced astrocytic activation and sex-dependent dopaminergic, motor deficits.

O. A. Yanouri, A. J. Schuller, A. M. Bibb, A. M. Briggs, M. R. Hager, N. E. Yates, and R. B. Tjalkens. Colorado State University, Fort Collins, CO.

Background and Purpose: Parkinson's disease (PD) is the fastest growing neurodegenerative disorder. Exposure to environmental toxins has been associated with an increased risk of disease-relevant pathology. A growing body of evidence shows glia are crucial in PD pathogenesis, illustrated by findings that abrogation of glia-mediated inflammation protects against PD-like pathology across various models. In recent years the antiviral cGAS-STING pathway has emerged as a potential target for disease-modifying therapies. A cytosolic dsDNA sensing and IFN-I stimulating system, post-mortem examination of PD patients has associated STING activation with PD pathology. Microglia, considered the primary immune cell of the brain, has been the focus of much of this work. However, astrocytes are crucial partners in responding to neurotropic viral infection and modulating immune responses. This work examines the effects of STING disruption on locomotor functioning utilizing the murine rotenone PD model in addition to interrogating the effect of rotenone exposure on astrocytic cGAS-STING signaling, both utilizing wild-type (WT) and STING-deficient mice. **Methods:** Primary astrocyte-enriched mixed glial cultures were established from neonatal C56BL/6 and golden-ticket STING truncation (Tmem173⁹⁹; GT) strains. We established the IC₅₀[Rotenone] = 78.90nM via dose-response viability assays in WT cultures following 12-hour exposure. Cell survival was again examined at doses at or below the IC₅₀ in GT, WT, and WT cultures co-treated with a STING modulator. Oxidative DNA damage and dsDNA breaks were assessed in DNA isolated from mitochondrial and nuclear fractions using commercially available 8-OHdG and p- γ H2A.X assays, respectively. Proinflammatory signaling was assessed longitudinally using NF κ B-GFP and IFN- β -YFP reporter lines. High-content immunofluorescence microscopy coupled with automated AI-based image analysis was performed against cGAS-STING signaling components. Transcriptomic analysis was performed on RNA extracted from WT and GT cultures following rotenone treatment. To further interrogate STING involvement in glia-mediated neurotoxicity, the viability of primary neuron cultures was determined after exposed to glia-conditioned media (GCM). Locomotor functioning was assessed in male and female WT and GT mice ($n = 5$ /sex/group) administered rotenone (2.5mg/kg/day) or vehicle intraperitoneally for 14 days, followed by a 14 day post-lesioning period. Vehicle-treated mitochondrial polG mutator mice ($n = 4$ /sex/group) served as a positive control. Baseline behavior measures were collected prior to rotenone insult, and every week for 28 days using open-field behavior assessment and automated gait system. Mice were then anaesthetized with isoflurane prior to euthanasia and striatal tissue was isolated for the quantification of catecholamines and monoamines commonly disrupted in PD using HPLC-ECD. **Results:** Rotenone treatment induced significant cytotoxicity in WT astrocytic cultures, which was blunted by both pharmacological and genetic STING disruption, as well robust oxidative damage and double-stranded breaks in both nuclear and mitochondrial DNA. Immunofluorescence microscopy reveals an increase in perinuclear p-STING⁺ puncta in GFAP⁺ and ALDH1L1⁺ astrocytes, and p-IRF3⁺ nuclear area in dual-labeled GFAP⁺/ALDH1L1⁺ astrocytes. Induction of downstream STING signaling partners was attenuated by STING ablation. Notably, co-treatment with the VDAC1 inhibitor DIDS blunted NF κ B-GFP and IFN- β -YFP induction. Further mechanistic interrogation revealed a STING-dependent enrichment of MAPK signaling and ECM remodeling via transcriptomics, as well as the secretion of TNF- α , IFN- β , VEGF, and IL-6 into the supernatant of WT cultures. Locomotor assessment reveal time-, treatment-, and genotype-dependent changes in behavioral parameters in male, but not female, WT mice. Moreover, changes were attenuated in GT mice and neurochemical assessment reveals sex-, treatment-, and genotype-specific alterations in dopamine and dopamine metabolites. **Conclusions:** This data demon-

strates the involvement of cGAS-STING in astrocyte reactivity *in vitro* and protection against locomotor changes *in vivo* following rotenone administration. Future work will assess the contribution of astrocytic cGAS-STING to PD-like pathology *in vivo*.

PS 3600 APOE4 Genotype Modifies Paraquat Effects on α -Synuclein Levels and Ventricular Volume in Aged Humanized Mouse Models

J. R. Boos, C. Kim, I. Mhatre-Winters, Y. Han, A. J. Barahona, and J. R. Richardson. University of Georgia, Athens, GA.

Background and Purpose: There is increasing concern over the rise of Parkinson's Disease with dementia (PDD) and Dementia with Lewy Bodies (DLB), which collectively form the second most common form of dementia in the United States behind Alzheimer's disease. While age is the most common risk factor for PDD/DLB, presence of the Apolipoprotein E (APOE) 4 allele is one of the most well-established genetic risk factors for PDD/DLB. Studies have shown the APOE4 allele contributes to alterations in synaptic function, lipid and glucose metabolism, mitochondrial dysfunction, and increased neuroinflammation in the brain. Previous studies using transgenic knock-in mouse models containing the humanized targeted replacement APOE3 (TR-APOE3) and APOE4 (TR-APOE4) alleles have shown TR-APOE4 mice have increased PDD/DLB-associated cognitive and motor deficits and α -synuclein aggregation compared to TR-APOE3 mice after AAV-mediated overexpression of α -synuclein or injection of α -synuclein fibrils. While research studying the associations and risks of APOE4 on PDD/DLB pathogenesis has been conducted, there is a gap in the field evaluating the link(s) between APOE4 allele and environmental exposures, such as pesticides. Therefore, this study aims to expand the knowledge in that gap to understand the effects of paraquat (PQ), a widely used herbicide known to cause dopaminergic neuron loss and increase α -synuclein deposition and aggregation, on PDD/DLB-associated pathology and its interaction with APOE genotype. **Methods:** 12- to 14-month-old male TR-APOE3 and TR-APOE4 mice were administered 2 doses, 7 days apart, of either 10 mg/kg PQ or saline (control) via intraperitoneal injections for a total exposure time of 14 days. Following saline perfusion, brains were extracted, divided into hemispheres, and the left hemispheres were coronally sectioned. Fluorescence microscopy was used to assess α -synuclein pathology via immunofluorescence staining in the substantia nigra and striatum using the α -synuclein [MJFR1] antibody and co-localized with dopamine neurons and projections using a tyrosine hydroxylase antibody. Total ventricle volume was calculated by measuring the ventricle area of every 12th nissl-stained section between Bregma +1.44 mm through Bregma -3.84 mm, multiplied by the section thickness and summed. **Results:** In the dopaminergic neurons of the substantia nigra, we observed increased α -synuclein immunofluorescence in saline-administered TR-APOE4 mice compared to TR-APOE3 mice. Furthermore, we observed α -synuclein pathology in dopaminergic neurons of PQ-exposed TR-APOE3 and TR-APOE4 groups compared to saline controls, with TR-APOE4 groups showing the highest synuclein levels. Similar results were also observed in the striatum. In saline controls, TR-APOE4 mice showed increased α -synuclein immunofluorescence compared to TR-APOE3 mice. Additionally, PQ exposure increased striatal α -synuclein immunofluorescence in both TR-APOE3 and TR-APOE4 mice, with the TR-APOE4 mice presenting the highest levels of α -synuclein immunofluorescence. In addition to elevated synuclein deposition, clinical cases of PDD/DLB often present increased lateral ventricle volume. We first examined the effects of APOE4 genotype on lateral ventricle volume in saline-administered controls. In saline-administered controls, TR-APOE4 mice presented 106% increase in ventricle volume compared to TR-APOE3 mice. Next, we evaluated the effects of PQ on ventricle volume. Compared to saline controls, PQ exposure increased ventricle volume by 57% and 69% in TR-APOE3 mice and TR-APOE4 mice, respectively. **Conclusions:** Overall, our results demonstrate that the combination of PQ exposure and APOE4 genotype affect multiple pathologies associated with PDD/DLB. These findings suggest a potential link between APOE4 genotype and PQ exposure with PDD/DLB pathology.

PS 3601 Humanized APOE4 genotype exacerbates paraquat-induced tau pathology and NLRP3 inflammasome activation

C. Kim, Y. Han, J. Boos, I. Mhatre-Winters, and J. Richardson. Center for Neurological Disease Research, Department of Physiology and Pharmacology, College of Veterinary Medicine, University of Georgia, Athens, GA.

Background and Purpose: Neurodegenerative diseases involve neuronal loss and dysfunction caused by proteotoxic and oxidative stress and neuroinflammation, leading to progressive deficits in memory, movement, cognition, and sensory functions. Their main pathological features include misfolded protein aggregates, such as α -synuclein in Parkinson's disease (PD) and amyloid- β and hyperphosphorylated Tau in Alzheimer's disease (AD). PD is marked by dopaminergic neuron loss in the substantia nigra and Lewy bodies composed of α -synuclein, which are also observed in PD with dementia (PDD) and dementia with Lewy bodies (DLB). Tau pathology is a hallmark of AD, but can be observed in PD and DLB and PDD. APOE4 is the strongest genetic risk factor for late-onset AD, promoting A β and Tau accumulation more than other APOE isoforms and is also associated with Lewy body pathology in DLB and PDD. Studies using P301S tau mice with humanized APOE knock-in alleles

showed that APOE4 significantly increases tau accumulation and phosphorylation in the hippocampus compared to APOE2 or APOE3. However, the mechanism has not been well established. Paraquat (PQ), a herbicide linked to PD, induces dopaminergic neuron loss, α -synuclein aggregation, and neuroinflammation, while also activating the NLRP3 inflammasome. Recently, we have found that APOE4 genotype results in increased NLRP3 inflammasome activation. However, the interaction between PQ exposure and APOE4 genotype in tau pathology and inflammasome activation remains unclear. Here, we examined whether exposure of humanized APOE mice to PQ affected Tau pathology and the NLRP3 inflammasome. **Methods:** Humanized APOE3 or APOE4 (TR-APOE3/4) mice from Dr. Patrick Sullivan (Duke University) were bred in-house. Male and female mice (22-25 weeks old and 12-14 months old) received intraperitoneal injections of paraquat (10 mg/kg) or saline once weekly for two weeks and were sacrificed seven days later. After isoflurane anesthesia, blood was collected, and brains were perfused with PBS, fixed in 4% paraformaldehyde, and cryoprotected in 30% sucrose. Coronal brain sections (30 μ m) were immunostained for total Tau, phospho-Tau (AT8 (Ser202/Thr205), AT180(Thr231)), NeuN, and tyrosine hydroxylase (TH), imaged with a BZ-X810 microscope, and quantified using a BZ-X800 analyzer. **Results:** We examined total Tau levels in the cortex and striatum of TR-APOE4 and APOE3 mice after paraquat (PQ) treatment. Total Tau was markedly increased in both regions of TR-ApoE4 mice compared to TR-APOE4/Saline, TR-APOE3/Saline, or TR-APOE3/PQ groups, whereas TR-APOE3 mice showed only mild to moderate increases after PQ exposure. Tau hyperphosphorylation (p-Tau AT8, AT180) was significantly elevated in the cortex of TR-ApoE4 mice after PQ treatment, with slight increases in TR-APOE3 mice. In the substantia nigra (SN), p-Tau (AT8) levels were higher in TR-APOE4/PQ mice than in other groups and moderately increased even in TR-APOE4/Saline mice relative to TR-ApoE3/Saline. PQ treatment also modestly elevated p-Tau (AT8) in TR-APOE3 mice. Notably, p-Tau (AT8) levels in the cortex and SN were significantly higher in male than in female TR-APOE4 mice after PQ treatment. NLRP3 expression colocalized with Iba-1 was significantly elevated in the striatum of TR-APOE4/PQ group and moderately increased in TR-APOE3/PQ group, indicating enhanced inflammasome activation in APOE4 backgrounds. **Conclusions:** Taken together, these findings demonstrate that PQ exposure increases total Tau protein levels and Tau hyperphosphorylation, specifically p-Tau AT8 and p-Tau AT180, in neurons of the cortex, striatum, and substantia nigra. These effects are further exacerbated by the APOE4 genotype, and NLRP3 appears to play a key role in mediating Tau alterations in PQ-treated mice. Overall, this study highlights a critical gene-environment interaction that may potentiate Tau pathology and neuroinflammation, key features of multiple neurodegenerative diseases. This work was supported by National Institutes of Health grant R01ES033892.

PS 3602 Paraquat Exposure Increases Alpha-Synuclein and Phosphorylated Tau Levels in Rat Dopaminergic Neuron Cells

S. Bhatia, C. Kim, J. R. Boos, and J. R. Richardson. University of Georgia, Athens, GA.

Background and Purpose: Exposure to environmental toxins, such as pesticides, has been implicated as a risk factor for Parkinson's disease (PD) in many epidemiological studies. Paraquat (PQ), a widely used herbicide, is the best-known environmental risk factor for PD, due to its role in promoting oxidative damage, neuroinflammation, and triggering the accumulation of pathological proteins associated with neuronal dysfunction. PD-pathology is characterized by the accumulation of misfolded and aggregated proteins, particularly α -synuclein (α -syn) and phosphorylated-tau (pTau). Given PQ's ability to drive oxidative damage and protein aggregation, its exposure may contribute to PD pathogenesis by exacerbating neuroinflammation and neuronal degeneration through the upregulation of these pathogenic proteins. Here, we investigated the effects of PQ-exposure on α -syn and pTau protein expression levels in N27 dopaminergic cells to further elucidate PQ's role in protein aggregation and neuronal toxicity. **Methods:** N27 rat dopaminergic neuron cells were treated with PQ at varying concentrations (10 μ M, 20 μ M, 50 μ M, and 100 μ M) for 24 hours (n=6). Immunofluorescent staining was used to visualize and measure α -syn [MJFR1], phospho-synuclein (pS129), pTau Ser202/Thr205 (AT8), and pTau Thr231 (AT180) proteins in the treated cells. Fluorescent images were captured using a BZ-X fluorescence microscope. Quantification of fluorescence intensity was completed on the BZ-X800 Analysis software. Results were analyzed via one-way ANOVA followed by Tukey's post-hoc test, with p<0.05 considered statistically significant. **Results:** PQ exposure induced dose-dependent increases in PD-related pathological proteins in N27 cells. Data analyses revealed a 57% increase in total α -syn expression following 100 μ M PQ treatment compared to controls (p < 0.0001). pS129 demonstrated similar concentration-dependent results, showing significant increases of 62% and 57% at 50 μ M (p = 0.005) and 100 μ M (p = 0.0003) PQ indicating enhanced α -synuclein aggregation following PQ exposure. Tau phosphorylation was also significantly upregulated with increasing PQ concentrations. pTau (Ser202/Thr205) was increased, indicated by 70% increased AT8 fluorescence intensity at 100 μ M PQ compared to controls (p = 0.003). Likewise, pTau (Thr231) was similarly elevated as observed by a 72% increase in AT180 fluorescence at 100 μ M PQ relative to untreated cells (p = 0.005). **Conclusions:** These findings suggest that PQ not only exacerbates α -syn aggregation but also promotes tau phosphorylation, which has recently been shown to occur before α -syn pathology in PD brains. Additionally, these results further elucidate PQ's role as a neurotoxicant capable of inducing multiple hallmark features of PD pathology. Collectively, these findings demonstrate that

paraquat induces a dose dependent accumulation of pathological α -syn, p-syn, and pTau species in dopaminergic neurons, consistent with neurotoxic mechanisms implicated in Parkinson's Disease pathology.

PS 3603 Developmental PFOS exposure increases pancreatic β -cell sensitivity to secondary ROS-driven stress in zebrafish (*Danio rerio*) embryos

K. Wong, M. Graham, and A. Timme-Laragy. University of Massachusetts Amherst, Amherst, MA.

Background and Purpose: Perfluorooctane sulfonate (PFOS), a ubiquitous and persistent environmental pollutant, has been detected in human tissues, including the pancreas, and cord blood, evidencing the ability of PFOS to expose developing fetuses during gestation. PFOS exposure has been shown to disrupt pancreatic function, resulting in dysregulated insulin signaling pathways and impaired glucose homeostasis, and induce oxidative stress via accumulation of reactive oxygen species (ROS)-driven damage, a critical factor in pancreatic β -cell dysfunction. We have previously demonstrated in zebrafish that developmental PFOS exposure negatively impacts pancreatic development and islet morphology. Whether these early structural alterations make pancreatic β -cells more susceptible to secondary insults remains unknown. With the rise of chronic diseases in the U.S., understanding how PFOS exposure, particularly early in life, contributes to long-term health outcomes, such as diabetes, is needed. Therefore, the primary goal of this investigation is to test the hypothesis that developmental exposures to PFOS alter pancreatic β -cell capacity to counter secondary redox stressors. **Methods:** We employed a transgenic zebrafish line with the bacterial nitroreductase (NTR) enzyme expressed under the insulin promoter (*Tg(Ins:NTR-mCherry)*), enabling us to selectively induce redox-active byproducts in pancreatic β -cells upon activation with the pro-drug metronidazole (MTZ). At high concentrations, MTZ is used to selectively ablate cells carrying the NTR enzyme, but at low concentrations, has been shown to selectively induce ROS. To confirm MTZ generates ROS and to optimize detection, *Tg(Ins:NTR-mCherry)* zebrafish embryos were challenged at 72 hours post-fertilization (hpf) with 0 (0.1% DMSO), 2.5, 5, 7.5, or 10 mM MTZ for 6 hrs, then incubated with 10 μ M CellROX Green for 15 or 60 mins. Samples were fixed with 4% paraformaldehyde (PFA) and principal islets imaged via confocal microscopy for β -cell mass volume (i.e. ablation) and CellROX fluorescence intensity (i.e. ROS). To examine β -cell resilience in PFOS-exposed embryos to a secondary redox stressor, *Tg(Ins:NTR-mCherry, Ins:GFP)* embryos were exposed to 0 (0.01% DMSO), 1, or 2 μ M PFOS, concentrations below the LOAEL found to impact islet size and morphology, from 3 to 72 hpf. At 72 hpf, larvae were washed, then challenged with either 0.1% DMSO or 5 mM MTZ for 6 or 18 hrs. Half of each treatment group was either fixed in 4% PFA or raised to 9 dpf in clean conditions. In fixed larvae, pancreatic islets were imaged via confocal microscopy, with images blinded prior to analysis. In samples challenged with MTZ, β -cell damage was scored as mild, moderate, or severe ablation, and islet volume was measured. To assess later-life health outcomes, fish were live-imaged at 9 dpf using brightfield and fluorescence microscopy to assess primary islet morphology, number of secondary islets, and overall growth (i.e. body length). **Results:** Findings following an MTZ challenge and a 60 minute CellROX incubation revealed a dose-dependent increase in CellROX fluorescence intensity, indicative of ROS generation in β -cells. Here, 5 mM MTZ was selected as an optimal concentration that generated significant ROS detection without leading to significant cell ablation. Exposure to 1 or 2 μ M PFOS or 5 mM MTZ alone did not significantly alter islet volume; however, developmental PFOS exposure followed by a 6 hr MTZ challenge yielded a dose-dependent increase in ablation severity, reflected by 6% and 22% decreases in islet volume in the 1 μ M and 2 μ M PFOS groups, respectively. At 9 dpf, preliminary results show no significant changes in growth across PFOS or MTZ groups; however, a significant difference in positional distribution of insulin-expressing cells along the whole pancreas was observed in the 1 μ M PFOS group challenged with MTZ compared to the control. **Conclusions:** These findings support the hypothesis and demonstrate that developmental PFOS exposure impairs β -cell capacity to counter ROS-driven secondary stressors. Future work will interrogate PFOS impacts on β -cell recovery and function at later-life stages, potentially informing pharmaceutical interventions. Overall, this research highlights how developmental contaminant exposure can impair cellular resilience, contributing to metabolic disorders later in life.

PS 3604 Individual phthalate or phthalate mixture alters metabolic health and microbiome via Sirtuin regulation

S. Venkatesgowda, S. Meruvu, N. Shree, A. U. Ufondo, A. Jayaraman, and M. Choudhury. Texas A&M, College Station, TX.

Background and Purpose: Phthalates exposure has been linked to an increased risk of diabetes. Our previous studies have shown that individual phthalates are capable of disrupting metabolic health. While human exposure involves a mixture of phthalates (MIX), and not one specific, the effect of individual phthalate or MIX in adipose tissues has not yet been explored. Specifically, regulation of sirtuins under these exposures are virtually unknown. Here, we investigated the effect of Benzyl butyl phthalate (BBP) individually and in combination with other environmentally relevant phthalates namely diisobutyl phthalate, diisononyl phthalate, dibutyl phthalate,

di(2-ethylhexyl) phthalate, and diethyl phthalate on metabolic dysregulation via sirtuin-mediated pathways along with alterations in gut microbiome composition.

Methods: To investigate the effect of individual phthalates, we exposed 8-week-old male and female mice to BBP with and without High fat diet (HFD) for 16 weeks. Sirtuin3 (Sirt3) gene expression analysis was performed in subcutaneous (SAT), visceral (VAT), and brown (BAT) adipose tissue. Additionally, to understand the mechanistic connection, 3T3L1 cells were treated with 100 μ M palmitic acid (PA) and BBP ranging from 0.1-50 μ M differentiated until Day 8. Adipogenic, Sirt3, and mitochondrial gene expression analysis as well as Oil Red O staining was performed on Day 8 of differentiation. Furthermore, to understand the chronic effect of MIX, mice were exposed to either MIX (200 μ g/kg, 5mg/kg, 200mg/kg) or VC on CD (4 kcal% fat, set1) or HFD (60 kcal% fat, set2) for 14 weeks. We examined weekly body weight, fasting glucose, glucose tolerance, insulin resistance (IR), serum insulin, triglyceride, and cholesterol levels in both sets of mice. Additionally, composition and diversity of the gut microbiome in the mice exposed to HFD and 200mg/kg of MIX using MiSeq platform were analyzed. We also carried out Ingenuity Pathway Analysis (IPA) to understand the effect of phthalates on the downstream targets specifically Sirt3 contributing to disease condition. *In silico* analysis are being carried out to connect microbiome regulation with sirtuin pathways. **Results:** Male mice exposed to BBP showed significant downregulation ($p < 0.05$) of Sirt3 in SAT along with decreasing trend in VAT and BAT. In contrast, female mice showed significant downregulation ($p < 0.05$) of Sirt3 in BAT. In our mechanistic study, BBP treatment with PA showed a dose dependent increase in adipogenic genes, PPAR γ and aP2 expression and Oil Red O staining with a concomitant decrease in Sirt3 expression and glucose uptake. Moreover, both the treatment groups showed a significant decrease in mitochondrial markers; NRF1, NRF2, and PGC-1 α . Furthermore, in set 1 mice, chronic exposure at 5mg/kg showed an increasing trend in body weight compared to VC. At week 8, 5mg/kg showed increasing trend in fasting glucose and 200mg/kg group showed significant increase in fasting blood glucose and IR. Additionally, in set 2 mice, 200 μ g/kg and 200mg/kg doses showed significant increases in body weight compared to VC. Both 200 μ g/kg ($p < 0.05$) and 5mg/kg ($p < 0.05$) showed increase in fasting blood glucose at week 10. Additionally, at week 14, an increase in fasting glucose level was observed at 5mg/kg ($p < 0.001$). Glucose intolerance was evident at all doses, with IR at only 5mg/kg ($p < 0.01$). Interestingly, 5mg/kg MIX displayed more inflamed, hypertrophied adipocytes in both SAT and VAT compared to VC or the 200mg/kg dose. Microbiome analysis revealed that the MIX significantly altered the alpha and beta diversity and reduced the abundance of beneficial bacterial species. The alpha diversity was increased in the MIX treated group at both the phylum ($p < 0.05$) and genus level ($p < 0.05$). The beta diversity exhibited non-significant differences. However, at the phylum level, Firmicutes increased and Bacteroidetes decreased after the treatment. Our IPA analysis showed that all six phthalates can directly and indirectly modulate Sirt3 and contribute to mitochondrial dysfunction. Finally, our *in-silico* analysis reveals that sirtuin regulates the microbiome. **Conclusions:** Phthalates may disrupt metabolic dysfunction via sirtuin 3 pathway. Therefore, we predict that an early epigenetic therapeutic strategy to treat phthalate induced metabolic disruption will significantly advance the field of environmental health.

PS 3605 Regulatory Effects of ZCE on 3T3-L1 Adipocytes differentiation and High-Fat Diet induced Obesity in Mice

S. Heo^{1,2}, H. Lee^{1,2}, S. Cho³, D. Choi², and C. Choi^{1,2,3}. ¹Department of Integrative Biological Sciences & BK21 FOUR Educational Research Group for Age-Associated Disorder Control Technology, Chosun University, Gwangju, Korea, Republic of; ²Institute of Well-Aging Medicare & Chosun University G-LAMP Project Group, Chosun University, Gwangju, Korea, Republic of; and ³Department of Biomedical Science, Chosun University, Gwangju, Korea, Republic of.

Background and Purpose: With the global rise in obesity prevalence, various anti-obesity drugs are being developed. However, many currently available treatments are expensive and associated with significant side effects. *Zephyranthes carinata* is a naturalized plant species native to South America. It is primarily cultivated as an ornamental plant in gardens and pots. In South Korea, it has been observed in limited areas, particularly on Jeju Island. We will investigate the anti-obesity effects of extracts from *Z. carinata* leaves (ZCE). This study aimed to investigate the anti-obesity effects and pharmaceutical potential of ZCE, a natural extract, using 3T3-L1 cells and high-fat diet induced obesity mice. **Methods:** Differentiation of 3T3-L1 preadipocytes was induced using an IBMX, Dexamethasone, Insulin (MDI cocktail) in the presence of ZCE. Cell viability was evaluated via MTT assay. Intracellular lipid accumulation was assessed using Oil Red O staining. Expression levels of proteins and genes related with lipid metabolism were analyzed by Western blotting and RT-PCR, respectively. ICR mice were fed with high-fat-diet for 6 weeks to induce obesity. Serum and epididymal adipose tissues were collected for further analysis. The effects of ZCE administration were evaluated by measuring body weight and serum biochemical parameters. Epididymal adipose tissues were analyzed by Western blotting and RT-PCR to examine the expression of lipid metabolism-related markers. **Results:** ZCE inhibited the differentiation of 3T3-L1 cells as the concentration increased. Analysis of gene and protein expression revealed a significant reduction in the expression levels of lipid metabolism-related markers. Consistently, quantitative analysis of Oil Red O staining demonstrated that intracellular lipid accumulation was also suppressed in a dose-dependent manner following ZCE treatment. In the *in vivo* study, ZCE administration reduced the body weight of obese mice compared to the untreated obese group. ZCE exerts anti-obesity effects by regulating adipogenic and lipogenic signaling path-

ways. **Conclusions:** These findings suggest that ZCE has potential as a natural therapeutic candidate for obesity treatment. Further studies will be conducted to explore other potential mechanisms involved in its anti-obesity activity.

PS 3606 Perfluorooctanesulfonic acid (PFOS) and glucose exposures alter pancreatic islet vascularization during development in zebrafish (*Danio rerio*)

A. K. Sobo¹, M. C. Tompach², and A. R. Timme-Laragy¹. ¹University of Massachusetts Amherst, Amherst, MA; and ²Eli Lilly and Company, Boston, MA.

Background and Purpose: Vascularization of the islets of Langerhans provides essential contact for pancreatic β -cells to monitor blood glucose and secrete insulin to maintain normal glucose levels. However, this vascularization also renders islets vulnerable to toxicants that can enter systemic circulation. One such toxicant is perfluorooctanesulfonic acid (PFOS), a ubiquitous environmental contaminant found in >98% of human serum samples tested. Previous studies have shown that exposure of zebrafish embryos to PFOS increased aberrant islet morphology and disrupted pancreatic organogenesis, although the mechanisms that underlie these changes are not understood. In our recent study using single-cell RNA-Seq to measure gene expression changes in PFOS-exposed zebrafish eleutheroembryos, we found reduced expression of cell-cell adhesion genes including integrins that are essential cell surface proteins connecting cells to the extracellular matrix. In islets, activation of integrins at contact points between vascular endothelial cells and β -cells can drive both β -cell proliferation and polarization, with critical implications for the proper release of insulin to the vasculature. Thus, we hypothesized that the abnormal arrangements of β -cells in PFOS-exposed embryos co-occur with alterations in islet vascularization. **Methods:** To establish the pliability of islet vasculature in zebrafish embryos and larvae, we used a prolonged nutrient challenge and confocal microscopy to map and measure changes in islet size, structure, and vascularization. To examine the vasculature in combination with pancreatic β -cells, *Tg(fli1:GFP)* x *Tg(ins:mCherry)* fish were used allowing for visualization of the vasculature endothelial cells and pancreatic β -cells respectively. Embryos were exposed to glucose (0, 15, 30, or 50 mM), or PFOS (4, 8, and 16 μ M) or both starting at 24 hpf, fixed and imaged at 96 hpf. Fish were imaged using confocal microscopy to visualize contact between vasculature and Nikon NIS Elements software was used to measure the surface area of contact points between vasculature and β -cells in embryos exposed to glucose, PFOS or co-treatment. **Results:** Results showed no significant changes in β -cell volume at 15, 30, and 50 mM glucose concentrations at 96 hpf. However, β -cell volume was significantly reduced compared to controls with exposure to 4 and 8 μ M PFOS. In zebrafish that were exposed to PFOS and glucose, there were concentration dependent increases in volume compared to PFOS only groups with no significant differences compared to controls. Embryos exposed to glucose only had no significant changes in the total contact point surface area between β -cells and blood vessels although there was a trend of increase in total contact point surface area in the 15 and 50 mM groups compared to the controls. In contrast, embryos exposed to 16 μ M PFOS had a reduction in the total contact surface area between β -cells and blood vessels at 96 hpf. Results also showed a trend of reduction in total contact surface area for both PFOS and glucose exposed groups although not significant. **Conclusions:** These results show that a glucose enriched environment increases β -cell mass and the contact between vasculature and β -cells, which agrees with evidence that vascular endothelial cells and β -cells coordinate growth and interact to respond to an increased need for insulin. Exposure to PFOS during development seems to disrupt this interaction raising concerns for how fetal islet growth may occur in cases of gestation diabetes. Ongoing studies are looking at how exposure of embryos to integrin inhibitors will affect vascularization of the islet and insulin production as well as the potential of offspring developing diabetes in later life time-points. Comparative RNA-sequencing analyses from prior PFOS exposure studies across species will also be performed to assess the concordance of potential mechanisms through which PFOS may influence islet vascularization.

PS 3607 Concurrent Iron Supplementation Prevents Cardiomegaly and Metabolic Dysfunction-Associated Steatotic Liver Disease in Mice with Perinatal Cadmium Exposure

M. Cowley, R. Lichtler, N. Smith, and C. Hoyo. North Carolina State University, Raleigh, NC.

Background and Purpose: Despite regulations and guidelines designed to minimize public contact with heavy metals, cadmium exposure through food, water, or tobacco remains prevalent during pregnancy and affects many organ systems of the developing fetus, including the nervous, cardiovascular, and hepatobiliary systems. Pregnancy is a particularly vulnerable time for cadmium exposure due to a programmed increase in uptake of divalent metals, and both pregnancy and cadmium exposure increase the risk of iron deficiency anemia. We have previously demonstrated that perinatal exposure to cadmium induces growth restriction, cardiomegaly, and juvenile metabolic dysfunction-associated steatotic liver disease (MASLD). Because iron is an essential element required for proper growth and organogenesis, we hypothesized that providing dams with supplemental iron concurrently with cadmium exposure will preclude iron deficiency and anemia onset and, in turn,

rescue the morphometric, cardiac, and hepatic outcomes in offspring. **Methods:** To test this hypothesis, virgin C57BL6/J dams were treated with cadmium in the form of 30 mg/L cadmium chloride in water. Dams were provided with treated drinking water from five weeks prior to mating and throughout gestation, until ten days post-partum. Two levels of iron supplementation, "low-dose" amounting to double the amount of ferric citrate in standard chow, or "high-dose" amounting to five-times the amount in standard chow were provided to dams. Embryos and dams were collected at embryonic day 18.5 (e18.5) or alternatively, pups were collected at postnatal day 21 (PND21), and body and organ weights were observed. Cadmium absorption and iron deficiency status were determined via inductively coupled plasma mass spectrometry (ICP-MS), and anemia status was evaluated by quantifying hemoglobin levels. Biochemical, molecular, and histological signatures of MASLD were evaluated in offspring at PND21. **Results:** The protective effects of iron supplementation depended on the subject and timepoint. In dams, the high-dose regimen effectively improved the iron deficiency and anemia outcomes that resulted from cadmium exposure, and levels of hepatic stored cadmium were reduced. However, stored iron levels remained low due to cadmium. In e18.5 embryos, low-dose iron treatment partially rescued cadmium-induced cardiomegaly, and the high-dose regimen fully returned heart size to normal. High-dose iron induced growth restriction and placental insufficiency at e18.5, signs of overt toxicity, however these outcomes disappeared by PND21. At this later timepoint, low-dose iron supplementation partially rescued cadmium-induced cardiomegaly, and high-dose iron fully ameliorated the condition, following the trend observed in embryos. Iron deficiency and anemia statuses were largely returned to normal by the low-dose regimen. Males did remain slightly anemic, but high-dose iron raised hemoglobin levels to normal. Iron supplementation was also sufficient to prevent cadmium-induced juvenile MASLD. Perinatal cadmium exposure upregulated hepatic transcription of several genes linked to steatosis and fibrosis, including genes related to fatty acid transport (*Pparg*, *Fabp4*, *Cd36*), accumulation of triacylglycerides (*Fsp27*) and collagen biosynthesis (*Tgfb1*, *Col1a1*, *Col5a2*, *Col6a1*). Low-dose iron treatment returned expression levels to control levels in males and moderated the expression profile in females. Signs of cadmium-induced hepatic steatosis disappeared with low-dose iron supplementation in both male and female offspring. **Conclusions:** The developmental toxicity of cadmium exposure can be ameliorated by dietary iron supplementation, though there are some limitations to consider. Because the high-dose iron group exhibited growth restriction and placental insufficiency in embryos near birth, a regimen containing five-times the standard iron levels in chow exceeds the appropriate level of treatment. However, these detrimental effects did not persist at PND21, and the lower iron dose was sufficient to reduce the majority of cadmium-induced effects on growth, cardiac, and hepatic presentations. Our findings highlight the potential for oral iron supplementation as a therapeutic intervention in populations with high risk for cadmium exposure.

PS 3608 Impact of Pancreatic Sweet Receptors on Beta Cell Function and Pathobiology throughout Development

K. M. Polemi¹, C. S. Cho², A. J. Torres-Berrios¹, L. K. Harrison², F. Rubens², and K. E. Sant¹. ¹Michigan State University, East Lansing, MI; and ²San Diego State University, San Diego, CA.

Background and Purpose: Diabetes is a public health issue affecting over 38 million Americans, with 90-95% being Type 2 Diabetes (T2D), a chronic condition marked by insulin resistance and impaired insulin secretion, causing dangerously high blood sugar levels without management. Though most often observed in adults over 45, children and teens increasingly develop both obesity and T2D. The pancreas regulates metabolic processes by maintaining glucose homeostasis through insulin and glucagon secretion. During pancreatic organogenesis, disruptions from genetic, epigenetic, or environmental factors can lead to long-term issues like T2D. Non-nutritive sweeteners (NNS) are substances that provide sweetness to foods and beverages without adding significant calories or nutrients. NNSs are extensively used in Western human diets and are environmentally prevalent due to excretion with minimal degradation. Sweet receptors (TSR) are primarily known for their role in taste perception; however, they are also expressed in pancreatic β -cells. Research has suggested that activation of the sweet receptor heterodimer, T1R2 and T1R3, can trigger insulin secretion—even in the absence of glucose. Here, we hypothesize that TSR activity is sufficient for insulin secretion and that exposure to TSR activators, such as NNS, may result in transcriptional and morphological changes in pancreatic islets during organogenesis and juvenile development. **Methods:** A well-established beta cell line, INS-1s, were exposed to biologically relevant concentrations (0.1, 1, 10, 100 μ g/mL) of glucose and several common NNSs, including Sucralose, Saccharin, and Acesulfame Potassium (AceK). Co-treatment with Lactisole (1 mM), an inhibitor of the sweet taste receptor heterodimer, determined whether actions were mediated through the sweet receptor. Cell viability and proliferation were measured using microscopy, and RNAseq was performed. *Tg(insulin::GFP)* zebrafish (*Danio rerio*) embryos were collected at 1 hour post fertilization (hpf), screened for viability, and dechorionated at 24 hpf. Embryos were exposed to NNS at either a high (1 mg/L) or a low concentration (10 μ g/L) from 24-96 hpf. Embryos were immobilized and imaged individually on a Nikon Eclipse Ti-2 microscope using NIS imaging software. Larvae that exposed from 24-216 hpf to glucose and/or Lactisole were also examined for islet size and number of secondary islets, and RNAseq was performed. For all endpoints, 1- or 2-way ANOVAs were performed after assessment of normality and variance. A confidence level of 95% ($\alpha = 0.05$) was used. **Results:** Our *in vitro*

results show that our NNSs and glucose cause concentration-dependent proliferation in INS-1 cells. Cells co-treated with Lactisole experienced lower rates of proliferation. We observed no change in cell viability due to biologically relevant concentrations of glucose or NNS. Our *in vivo* results included morphology changes in primary islets size and number of secondary islets in the presence of Glucose. However, islets sizes decrease whenever exposed to Lactisole, regardless of glucose availability. When Lactisole was co-administered with glucose, transcriptomic analyses revealed that Lactisole administration reduced the number of significantly changed metabolic pathways. Finally, embryos exposed to the NNS AceK have larger β cell areas, while sucralose and aspartame exposures did not induce islet expansion in larvae. **Conclusions:** Our *in vitro* findings suggest that NNS and glucose promote INS-1 cell proliferation in a concentration dependent manner, while co-exposure with the TSR inhibitor Lactisole suppresses this effect. Importantly, these exposures did not compromise the cells viability, indicating that the observed changes reflect altered proliferation rather than cytotoxicity. Our *in vivo* findings suggest that glucose exposure promotes pancreatic islet growth and metabolic activity, while Lactisole suppresses these effects. This indicates that TSR signaling contributes to islet development. Among the tested NNS exposures, only AceK increase β -cell area, suggesting distinct compound-specific impacts on pancreatic function. Further work is necessary to examine the TSR as a potential mechanism of insulin secretion through pancreatic β cells and to determine if NNS use during development may impact metabolic health.

PS 3609 Developmental exposure to polychlorinated biphenyls (PCBs) impacts expression of potassium ion channels and steroid hormone receptors in the bladder and brain of adult mice

M. Ridlon, C. L. Kennedy, A. Lentine, T. Jordan, J. Tlapa, K. Wang, L. Felth Tanaka, and K. K. Stietz. University of Wisconsin - Madison, Madison, WI.

Background and Purpose: Polychlorinated biphenyls (PCBs) are anthropogenic, ubiquitous, persistent organic pollutants produced over the last century. Mice with *in utero* and lactational exposure to human-relevant PCBs develop signs of lower urinary tract dysfunction with weaker bladder muscle contraction as adults. PCB effects in this exposure model are sex- and dose-dependent, therefore, we hypothesize PCBs effects arise through increasing expression of the BK channel (large-conductance Ca^{2+} -activated K^{+} channel) which regulates bladder relaxation and is important in neuronal excitability, and/or endocrine disruption through steroid hormone signaling. PCBs are also known neurotoxicants, given that central nervous system control of the bladder is essential for proper function it is important to understand effects of PCBs at the level of the bladder and the brain. Therefore, we also test whether changes in BK channel and hormone receptors occur in the bladder, brain or both and whether these changes occur embryonically or only as adults. **Methods:** PCB exposure of mice mimicked human-relevant developmental exposure where PCBs from the maternal source were transferred *in utero* and through lactation. Female nulliparous mice (C57BL/6) were dosed with MARBLES PCBs (serum PCB profile of pregnant women enrolled in Markers of Autism Risk in Babies - Learning Early Signs) at 0, 0.1, 1, or 6 mg/kg/d 2 week prior to mating. Dam dosing continued until fetal tissue collection (E18) or until weaning (P21). Aged offspring (~P42) were euthanized with bladders and brains immediately collected. qPCR was performed to quantify RNA abundance of BK channel subunits (*Kcna1*, *Kcnmb1-Kcnmb4*), estrogen receptors (*Esr1*, *Esr2*), and progesterone receptor (*Ppr*) in the different tissues and time points. Blood was collected at P42 for a serum steroid hormone panel (progesterone, testosterone, estradiol, and estrone). **Results:** PCB exposed mice had sex- and dose-dependent impacts on transcriptional expression of genes related to bladder smooth muscle relaxation and steroid hormone signaling. At P42, PCB effects in the bladder were primarily observed in the 1 mg/kg/d PCB males with increased RNA abundance of BK channel subunits and trending increases in estrogen and progesterone receptors compared to the vehicle control. In the brain, these PCB effects were not observed, and PCBs decreased estrogen receptor alpha expression in male mice. Conversely, female mice did not display any PCB effects on expression of these genes in the bladder, however with 1 and 6 mg/kg/d PCB exposure had decreased RNA abundances of BK channel subunits, estrogen receptors, and the progesterone receptor compared to the vehicle control in the brain. Quantification of the urogenital sinus at E18 was limited to markers observed changed at P42, with no observed PCB effects. No PCB effect was observed on serum levels of testosterone or estradiol in the P42 male mice with results pending in the female mice. **Conclusions:** Human-relevant PCBs impact murine urinary voiding physiology and bladder contractility. These sex- and dose-dependent adverse outcomes may in part be influenced through PCB effects on expression of ion channels important to intracellular calcium dynamics in nerves and bladder smooth muscle, and impacts on steroid hormone receptor expression. Our results highlight that PCBs uniquely impact transcript levels of genes important for contractility/nerve activity and hormone signaling in the bladder versus the brain and do so in a sex-dependent manner. Further, adult changes in bladder gene expression were not observed embryonically, suggesting a temporal component of these effects on bladder. These differences help to understand the complex effects of developmental PCB exposure on bladder health. Adverse health outcomes of PCB exposure and influence on neurodevelopment, urological impacts including bladder smooth muscle over/underactivity, and endocrine disruption of steroid hormone signaling are clinically relevant yet the impacts of environmental chemicals on the molecular underpinnings of these disorders require further study.

PS 3610 Persistent impacts of parental BaP-exposure on adult male behavior and brain transcriptome in Japanese medaka (*Oryzias latipes*)

N. E. Cook¹, Y. Lu², and F. Seemann¹. ¹Texas A&M University-Corpus Christi, Corpus Christi, TX; and ²Texas State University, San Marcos, TX.

Background and Purpose: Benzo[a]pyrene (BaP) has previously been shown to affect neurobehavioral responses in *F₁* *Oryzias latipes* larvae upon parental exposure. However, little is known about the persistence of these behavioral changes throughout the life span. Therefore, the present study aims to investigate differences in behavior and gene expression in brain tissue between exposed and unexposed *O. latipes* to determine whether neurological processes could contribute to downstream behavioral effects. **Methods:** Ten pairs of adult medaka (n=5) were exposed to solvent control or 1 $\mu\text{g/L}$ BaP for 21 days. Eggs were collected after the exposures ended and offspring raised to 4 months old. Male and female fish were introduced to three different experimental set-ups for 10-minute increments and recorded for software-based behavioral analysis. Lateral and diving swimming patterns as well as light/dark preference were assessed. Subsequently, brain tissue from control and BaP-exposed group male *F₁* medaka was extracted. Gene expression was analyzed using single-nuclei RNA sequencing (3DGenomics; scRNA-seq). For both control and exposed groups, 14 cell clusters were identified. Major cell types were assigned using the most significantly expressed genes in each cluster. These cell type assignments were confirmed by the presence of their respective key marker genes in previously published literature. Differentially expressed genes (DEGs) between the control and exposed groups were identified by analyzing the fold change difference in expression. Enriched pathways were identified for each cluster using gProfiler. **Results:** The data from the behavioral experiments indicate an increased affinity for darker environments and display increased patterns of lethargy in adult male fish with a parental exposure history. This is consistent with patterns previously observed in the larvae and is indicative of an increased stress response in the parentally exposed fish. The snRNA-seq allowed for identification of glycinergic neurons, GABAergic interneurons, cortical pyramidal neurons, midbrain glutamatergic neurons, endothelial cells, pallium cells, Purkinje neurons, pineal gland cells, glial cells, endoderm cells, taste bud cells, olfactory bulb neurons, oligodendrocyte progenitor cells (OPCs), and vascular smooth muscle cells. Genes most differentially expressed between the exposed and control groups were identified. Few changes were observed in the glycinergic neurons, the endothelial cells and the olfactory bulb cell cluster (<7 DEGs). Less than 20 DEGs were measured in the cortical pyramidal neurons, the pallium cells, the glial cells, the endoderm cells and the taste bud cells. Major expression changes were identified in the GABAergic interneuron cluster (16 downregulated, 4 upregulated), the midbrain glutamatergic neuron cluster (3 downregulated, 53 upregulated), the Purkinje neuron cluster (4 gene downregulated, 26 upregulated) and the pineal gland cell cluster (30 downregulated, 7 upregulated). Thus, the data indicate cell population-specific impacts of parental BaP exposure on the adult male brain. **Conclusions:** The findings of this study demonstrate that parental BaP exposure causes persistent and cross-generational neurobehavioral alterations that remain detectable in adulthood and are accompanied by cell type-specific transcriptional disruptions in the *F₁* brain. The lethargy and dark-preference behaviors in exposed males align with DEG patterns involved in inhibitory-excitatory balance, sensorimotor processing, and stress-axis regulation. Downregulation in GABAergic interneurons and cortical pyramidal neurons, coupled with large clusters of upregulated genes in midbrain glutamatergic and Purkinje neurons suggest that BaP may imbalance inhibitory and excitatory signaling pathways. Altered expression in pineal and glial cell clusters suggests impacts on circadian regulation and neuroinflammation, processes known to modulate stress responsiveness and activity levels. Since many neurological processes are conserved among vertebrates, this study may predict effects of BaP on ecosystem and human health and can inform environmental risk assessments.

PS 3611 Maternal Metabolic Health Alters Infant Adipocyte Differentiation and Inflammatory Signaling via Human Milk Lipids

C. Thomas, M. Rabotnick, and B. Gregg. University of Michigan, Ann Arbor, MI.

Background and Purpose: Despite extensive research on the influence of *in utero* exposures on offspring metabolic health, there remains a gap in understanding the influence of lactation on metabolic programming, particularly among women living with obesity or diagnosed with gestational diabetes (GDM). As infant metabolic programming extends beyond parturition, exposures during lactation likely contribute to downstream metabolic dysfunction; however, little is known about molecular mechanisms driving any such changes in offspring. The rates of pediatric and adult obesity and metabolic disease continue to rise worldwide, highlighting the need to investigate early-life intervention points. Identifying the impact of maternal health-status on early childhood metabolic risk parameters provides a unique opportunity to evaluate potential windows of intervention whereby changes in maternal diet may successfully reduce the burden of disease in future generations. Our proposed research aims to better understand how variation in human milk (HM) composition impacts offspring metabolism using a model of infant preadipocytes. Based on our previous work linking HM fatty acid profiles and infant adiposity, we hypothesize that infant adipocyte maturation and inflammatory states differ following HM lipid exposure from moms with varying health statuses. **Methods:** A non-immortalized,

diploid human infant preadipocyte strain derived from subcutaneous adipose tissue of a 3-month-old male donor with Simpson-Golabi-Behmel Syndrome (SGBS) was differentiated. HM underwent an *in vitro* digestion and lipid extraction protocol after which conjugated HM lipids from mothers with varying health-statuses, defined as healthy, obese, and gestational diabetes (GDM), were used to treat the SGBS cells. A lipid depleted bovine serum albumin (BSA) at 0.67% was used as the control. Differentiation was initiated on day 0 (D0) when the cells reached 80-90% confluence. To mimic circulating levels of serum free fatty acids (FFAs) in infants, SGBS preadipocytes were treated with 200µM of lipids isolated from either the healthy, obese, or GDM group on D6-8, D6-10, D6-12, or D6-14 during adipocyte maturation. After each treatment window, RNA was isolated and analyzed via RT-qPCR for PPAR γ , GLUT4, FABP4, UCP1, GATA6, METRN1, PREF1, AMPK α 1 (differentiation/browning), and CCL2, CXCL6, IL-6, IL-12 (inflammation). Statistical significance was defined as $p < 0.05$ following a two-way ANOVA with Tukey's post-hoc for multiple comparisons. **Results:** Expression of differentiation/browning (UCP1) and inflammatory markers (CCL2, CXCL6, IL-12) varied by exposure duration and maternal health status. After D6-10, UCP1 increased in GDM compared to healthy followed by a decrease in expression with extended treatment, D6-12 and D6-14 ($p = 0.006$). Following D6-8, CCL2 and CXCL6 trended towards increased expression in GDM treated groups compared to healthy ($p < 0.1$). This increase recovered during the next treatment window; however, following D6-14, CCL2 and CXCL6 significantly increased in GDM treated groups compared to healthy, aligning with a biphasic increase in inflammatory signaling ($p < 0.0001$). IL-12 increased in GDM compared to healthy from the beginning of treatment (D6), a trend which then increased in severity through the end of treatment period (D14) (p -values ranging from 0.0483 to < 0.0001). **Conclusions:** From D6-8 to D6-10, the increase in UCP1 observed in the GDM groups, together with elevations in the chemokines CCL2 and CXCL6 (innate-immune signaling), may indicate a browning phenotype: potentially a protective or compensatory response to lipid/fatty-acid exposure in which cells enhance oxidative capacity and immune-like signaling for homeostasis. As treatment continued, UCP1 drops while IL-12 increases significantly and stays elevated which suggests a shift toward chronic inflammatory signaling and possible loss of metabolic flexibility. This may reflect the breakdown of the compensatory browning program toward a dysfunctional phenotype. The second increase in CCL2 and CXCL6 and sustained increase of IL-12 reinforces a pro-inflammatory, metabolically stressed adipocyte phenotype. These preliminary findings suggest that maternal health status may significantly influence infant adipocyte development and downstream metabolic risk via exposures occurring during lactation.

PS 3612 Green-engineered montmorillonite clays for the adsorption and detoxification of polychlorinated biphenyls

J. O. Oladele, X. Xenophontos, P. Tamamis, S. H. Safe, and T. D. Phillips. Texas A&M University, College Station, TX.

Background and Purpose: The prevalence of polychlorinated biphenyls (PCBs) in the environment has been linked to a broad range of adverse toxicological effects in both animals and humans. These include carcinogenicity, immunosuppression, neurotoxicity, obesity, diabetes, and endocrine disruption. In this study, *in vitro*, *in silico*, and *in vivo* models were used to investigate the surface interactions of PCBs with green-engineered hydrophobic clays. In earlier work, we showed that these green clays tightly adsorbed benzene and significantly reduced its toxicity. Our objective for this study was to show that green clays could also sorb PCBs and decrease the toxicity of a commercial PCB mixture. **Methods:** Green-engineered clays (GECs) were synthesized by amending montmorillonite clays with chlorophyll and chlorophyllin to increase their binding proficiency. Gastrointestinal pH and temperature were simulated *in vitro*, and the clay surface binding interactions of six PCB congeners (PCB 77, PCB 126, PCB 153, PCB 154, PCB 155, and PCB 157) were characterized using isothermal analyses. Binding parameters and thermodynamics, including sorption capacity, enthalpy of sorption, free energy of sorption, affinity, and capacity of the GECs for the six PCB congeners, were investigated. The *in vitro* data was validated while *in silico*, and molecular dynamics simulations were used to explore the amendments of the clay and provide atomistic insights into PCB congener binding to both the parent and green-engineered clays. To confirm the ability of the GECs to protect a living organism, a commercial mixture of PCBs, Aroclor 1260, was investigated using a well-established hydra assay. **Results:** The results for both the parent clays and GECs demonstrated that all the PCB congeners fit the Langmuir model, indicating saturable binding sites with high capacities and affinities at both acidic and neutral conditions. The GECs had increased capacities for the PCBs at acidic and neutral conditions. For instance, chlorophyll amendment markedly increased the clay's binding capacity for PCB 153 ($0.19 \rightarrow 0.46 \text{ mol kg}^{-1}$), PCB 154 ($0.26 \rightarrow 0.54 \text{ mol kg}^{-1}$), PCB 155 ($0.15 \rightarrow 0.27 \text{ mol kg}^{-1}$), PCB 157 ($0.12 \rightarrow 0.22 \text{ mol kg}^{-1}$) and PCB 77 ($0.36 \rightarrow 0.70 \text{ mol kg}^{-1}$). Similarly, chlorophyllin amendment enhanced the GEC's adsorption capacity for PCB 153 ($0.19 \rightarrow 0.54 \text{ mol kg}^{-1}$), PCB 154 ($0.26 \rightarrow 0.55 \text{ mol kg}^{-1}$), PCB 155 ($0.15 \rightarrow 0.25 \text{ mol kg}^{-1}$), PCB 157 ($0.12 \rightarrow 0.22 \text{ mol kg}^{-1}$) and PCB 77 (from 0.36 to 0.66 mol kg^{-1}). This finding was corroborated by independent molecular dynamics (MD) simulation, which revealed that PCB molecules capable of adapting co-planar configurations (PCB77, PCB126, and partly PCB157) were able to align both rings in the same plane, enabling the molecules to bind to clay surfaces and maximizing interactions across both aromatic rings and the clay surface. PCB molecules interacted mainly with both the head (chlorin ring) and tail (aliphatic) groups of chlorophyll simultaneously or only the tail of chlorophyll, and to a lesser extent, the head

of the chlorophyll only. The MD simulation showed that chlorophyll amendments enhanced the binding of PCBs. Moreover, isotherms of adsorption for all the PCBs were thermodynamically favorable with ΔG values ranging from -19.00 to -32 kJ/mol . **Conclusions:** The findings of this study indicate that edible green organoclays adsorb PCBs with the highest sorption associated with co-planar congeners. The mechanism for this adsorption to chlorophyll-amended surfaces may involve van der Waals attraction of PCBs to the hydrophobic tail on chlorophyll and/or pi-to-pi and cation to pi interactions from benzene rings in PCBs to aromatic chlorin rings in chlorophyll. Further studies are warranted to study the application of these "edible" clays as potential supplements in the diet to reduce the bioavailability of PCBs from contaminated food and water, especially following disasters and emergencies.

PS 3613 Integrating Behavioral, Morphological, and Transcriptomic Endpoints to Define PCB Developmental Toxicity in Zebrafish

N. M. Breese¹, L. Truong², R. L. Tanguay², and H. Lehmler¹. ¹University of Iowa, Coralville, IA; and ²Oregon State University, Corvallis, OR.

Background and Purpose: Polychlorinated biphenyls (PCBs) are neurotoxic, persistent organic pollutants; however, the mechanisms underlying their developmental neurotoxicity remain incompletely defined. Zebrafish (*Danio rerio*) provide a high-throughput, mechanistic model to assess chemical bioactivity across behavioral, morphological, and molecular endpoints. This study aimed to systematically evaluate the developmental effects of 28 PCB congeners, metabolites, and mixtures in zebrafish, identify morphological and behavioral phenotypes associated with exposure, and characterize transcriptional pathways responsive to representative PCBs. **Methods:** Wild-type (Tropical 5D) and transgenic *cyp1a* reporter zebrafish were bred and maintained at the Sinnhuber Aquatic Research Laboratory (Oregon State University). At 6 hpf, enzymatically dechlorinated embryos were placed into 96-well plates and exposed to PCBs ($0-100 \text{ }\mu\text{M}$) in DMSO. Developmental (neuro)toxicity was assessed using a suite of high-throughput assays: embryonic photomotor response (EPR, 24 hpf), larval photomotor response (LPR, 120 hpf), and morphological scoring at 24 and 120 hpf. A benchmark dose (BMD10) was calculated for behavioral effects. A set of 10 PCBs that spanned diverse activity profiles in EPR, LPR, and morphology were selected for further testing in *cyp1a* reporter zebrafish. Another set of 10 PCBs that included parent compounds and their metabolites, as well as 2 mixtures, was selected for transcriptomic profiling in wild-type larvae at 120 hpf to identify KEGG pathways altered by PCB exposure using gene set enrichment analysis (GSEA). **Results:** Among the 28 PCB congeners, metabolites, and mixtures tested, distinct patterns of (neuro)developmental toxicity were observed across behavioral and morphological endpoints. Eight compounds produced effects in morphology, EPR, and LPR. Fourteen compounds elicited responses in morphology and EPR only. One compound affected both EPR and LPR without morphological change. The remaining five compounds altered either morphology or EPR alone. In *cyp1a* reporter zebrafish, only PCB126 induced measurable *cyp1a* activation, consistent with its known aryl hydrocarbon receptor agonist activity. Principal component analysis (PCA) of transcriptomic data revealed that 5-OH-PCB11 elicited a transcriptional profile distinct from both controls and other test compounds, indicating a unique mechanism of action. The two PCB mixtures tested also produced transcriptomic signatures distinct from those of individual congeners or metabolites. GSEA identified enrichment of multiple signaling and metabolic pathways across treatments. Eight compounds or mixtures significantly altered cytokine-cytokine receptor interaction pathways. Another eight PCBs affected neuroactive ligand-receptor interaction pathways, consistent with the observed behavioral disruption. Six PCBs showed mixed activation of ATP-dependent chromatin remodeling and ribosome biogenesis pathways, suggesting potential impacts on transcriptional regulation and protein synthesis. **Conclusions:** This integrative analysis reveals that specific PCB congeners, metabolites, and mixtures elicit distinct patterns of (neuro)developmental toxicity across behavioral and morphological endpoints. These patterns are associated with distinct transcriptomic effects. These results offer novel insights into how PCBs or their metabolites disrupt neurodevelopmental processes in a translational zebrafish model.

PS 3614 Acute PCB126 exposure alters cell type specific transcriptional profiles in the adult zebrafish brain

N. Aluru, and C. S. Murray. Woods Hole Oceanographic Institution, Woods Hole, MA.

Background and Purpose: Neuropsychiatric disorders such as anxiety, depression, and schizophrenia are major public health concerns, and growing evidence suggests that environmental chemical exposures contribute to their etiology by altering neuro-immune signaling. The aryl hydrocarbon receptor (AHR) is a ligand-activated transcription factor that mediates responses to environmental contaminants and also plays essential roles in neurodevelopment and immune regulation. Our previous work demonstrated that developmental exposure to the dioxin-like polychlorinated biphenyl congener PCB126 disrupted microglial abundance and morphology in zebrafish, implicating AHR-mediated interference with primitive macrophage development. The present study examined whether acute AHR activation in the adult brain induces cell type-specific transcriptional alterations that could contribute to neuroimmune dysregulation. **Methods:** Adult male zebrafish (9 month old) were exposed to either

control (DMSO; solvent control) or 10 nM PCB126, a potent AHR agonist, for 24 hours. Brains were collected immediately following exposure for single-nuclei RNA sequencing (snRNA-seq) using the 10x Genomics Chromium platform to characterize acute, cell type-specific transcriptional responses. Approximately 10,000 nuclei per sample were sequenced at an average depth of 20,000 reads per nucleus, with four biological replicates per treatment. Cell clustering, annotation, and differential expression analyses will be performed to identify transcriptional changes across neuronal and glial populations. **Results:** Previous work from our group demonstrated that early-life exposure to PCB126 alters microglial development in zebrafish. Specifically, exposure at 4 hours post-fertilization (hpf) caused a reduction in microglial abundance without affecting morphology, suggesting impaired proliferation of primitive macrophages originating from the rostral blood island. In contrast, exposures at 2 and 3 days post-fertilization (dpf) did not change microglial numbers but produced pronounced morphological alterations consistent with microglial activation and a potential response to PCB-induced neuronal apoptosis. These findings indicate that the timing of AHR activation during development determines distinct neuroimmune outcomes. Building on these observations, we are now characterizing the transcriptional consequences of acute AHR activation in the adult zebrafish brain. snRNA-seq data generation and quality assessment are complete, encompassing approximately 10,000 nuclei per sample at high sequencing depth. Ongoing analyses will define major neuronal and glial cell clusters and evaluate transcriptional responses to 24-hour PCB126 exposure. We will present detailed cell type-specific gene expression profiles and identify molecular pathways responsive to AHR activation in the adult brain. Together, these developmental and adult datasets will provide a comprehensive framework for understanding how PCB126 perturbs neuro-immune function and neuronal signaling across life stages. **Conclusions:** This study is designed to determine how acute AHR activation in the adult brain influences cell type-specific transcriptional regulation. The results will provide insight into how environmentally relevant contaminants rapidly alter molecular processes governing brain homeostasis and immune function. This work extends previous findings on developmental neurotoxicity to the adult stage and contributes to understanding AHR-mediated mechanisms underlying the neurobiological effects of environmental exposures linked to neuropsychiatric outcomes. This research is supported by the National Institute of Environmental Health Sciences (1R21ES034839-01) and Woods Hole Center for Oceans and Human Health (NIEHS P01 ES028938; NSF OCE-2418297)

PS 3615 The bladder as a target for PCB toxicity: Evidence from PCB levels, phase I metabolite levels, and cytochrome P450 expression following developmental exposure to a human-relevant PCB mixture in mice

H. Wang¹, E. Schumacher², A. Spiegelhoff², C. L. Kennedy², M. M. Ridlon², R. F. Marek³, K. P. Keil Stietz², and H. J. Lehmler¹. ¹Department of Occupational and Environmental Health, University of Iowa, Iowa City, IA; ²Department of Comparative Biosciences, University of Wisconsin-Madison, Madison, WI; and ³Department of Civil and Environmental Engineering, University of Iowa, Iowa City, IA.

Background and Purpose: Lower urinary tract dysfunction is multifactorial, yet the role of environmental exposures is not well understood. Developmental exposure to polychlorinated biphenyls (PCBs) has been linked to altered voiding in mice; however, the disposition of PCBs in the bladder, their bioactivation, and the effects on cytochrome P450 (CYP) expression remain unclear. **Methods:** We exposed mice to an environmentally relevant PCB mixture via maternal diet during gestation and lactation (vehicle, 0.1, 1, or 6 mg/kg/day). Offspring were euthanized at 6 to 7 weeks of age. PCBs and hydroxylated PCBs (OH-PCBs) levels were quantified in bladder, liver, blood, and urine. CYP expression was measured in bladder and liver. **Results:** PCBs and OH-PCBs accumulated in all tissues in a dose- and sex-dependent manner, with higher-chlorinated congeners (e.g., PCB118, PCB138, PCB153, and PCB180) preferentially retained. Females exhibited greater hepatic accumulation, reduced urinary elimination, and distinct CYP regulation, characterized by increased hepatic and decreased bladder expression. **Conclusions:** These findings, for the first time, define the signature of PCBs and OH-PCBs in the bladder and reveal sex-specific PCB disposition and CYP responses. Our results provide new mechanistic insight into developmental PCB exposure and its potential contribution to voiding dysfunction relevant to wildlife, domestic animals, and humans.

PS 3616 Sex-dependent Hepatotoxicity of an Environmentally Relevant Dioxin Mixture in a Humanized AHR Mouse Model

O. E. Bolatimi¹, Y. Hua¹, S. Singh², P. Brizendine-Ames¹, A. Ekuban¹, G. J. Phillips³, F. A. Ekuban¹, W. H. Watson¹, and B. Wahlang¹. ¹University of Louisville School of Medicine, Louisville, KY; ²Rocky Vista University College of Osteopathic Medicine, Ivins, UT; and ³University of Louisville College of Arts and Sciences, Louisville, KY.

Background and Purpose: Legacy persistent organic pollutants like dioxins and dioxin-like compounds (DLCs) remain present in our environment in relatively low yet significant levels and are associated with metabolic disruptions that initiate or drive the progression of steatotic liver disease. Dioxins and DLCs are potent aryl hydrocarbon receptor (AHR) activators and have been reported to induce hepatotoxicity

via this pathway. However, the majority of studies utilize murine models (mAHR), which have higher affinity and responsiveness to these pollutants compared to the human AHR (hAHR). Knowledge on how dioxins act through the hAHR to promote liver and metabolic dysregulation is still limited. Thus, this study aims to investigate the translational relevance of acute exposure to an environmentally relevant dioxin mixture namely 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD), 2,3,4,7,8-Pentachlorodibenzofuran (PeCDF) and Polychlorinated biphenyl 126 (PCB 126), in the context of liver disease and underlying sex differences, using a humanized AHR mouse model. **Methods:** 6-8-week-old male and female hAHR-C57BL/6 mice were fed a low-fat diet and administered a weekly dose of either TCDD (10ng/kg) + PeCDF (80ng/kg) + PCB 126 (140ng/kg) or vehicle control (corn oil) over a 2-week period. Body weight and food consumption were recorded weekly, and body composition measured using Echo-MRI. At euthanasia, plasma and tissues were collected for downstream analyses. Statistical tests were performed using two-way ANOVA or Kruskal Wallis followed by post-hoc tests with correction for multiple testing ($p \leq 0.05$). **Results:** Body composition analyses revealed that compared to males, females had higher fat mass but lower lean mass. Females also exhibited elevated hepatic triglyceride and cholesterol levels than males. Plasma glucose and glucose uptake levels were increased by dioxin exposure in males but decreased in females. This was accompanied by a dioxin-driven reduction in insulin resistance and pancreatic insulin production in the male group, while exposed females displayed increased levels of these measurements. Furthermore, the dioxin mixture did not appear to activate hepatic hAHR in this model as canonical target genes (*Cyp1a1* and *Cyp1a2*) were not induced with exposure in both sexes. This lack of classic AHR target gene induction with exposure was also observed in extra-hepatic tissue including the ileum. Notably, transcription of the hepatic *hAhr* gene which had higher expression in females was reduced by dioxin exposure in this group alone. Additionally, hepatic gene expression of xenobiotic receptors *Car* and *Pxr*, as well as endobiotic receptors *Lxr* and *Ppara* were also selectively decreased with dioxin exposure in females only. Further, exposure of primary hAHR-C57BL/6 hepatocytes to individual components of the dioxin mixture at relatively higher concentrations (0.5nM TCDD, 10nM PeCDF, 100nM PCB 126) led to induction of AHR targets, *Cyp1a1* and *Cyp1a2*, with the magnitude of induction differing by sex and chemical. Importantly, for males, induction of AHR targets was more robust in wildtype C57BL6 mouse hepatocytes expressing mAHR, compared with hAHR-C57BL/6 hepatocytes. **Conclusions:** Phenotypic changes including body composition, glucose and lipid disruption patterns were consistent with our previous findings in the mAHR model, yet classic AHR activation was absent *in vivo*, suggesting off-target effects and mechanisms. While primary hepatocyte exposures confirmed that the hAHR is activated by these dioxin chemicals, this was only observed at relatively higher concentrations and is sex dependent. The current data also demonstrated sex-specific dioxin alterations of liver transcriptional machinery, highlighting sex-specific mechanistic differences between mAHR and hAHR in its role in mediating dioxin-induced hepatotoxicity and metabolic dysregulation. Comprehensive evaluation of canonical and non-canonical AHR mechanisms, extrahepatic responses, and chronic outcomes in this human-relevant model, will better assess how dioxins, particularly at current environmental levels, drive sex-specific liver and metabolic toxicity in humans.

PS 3617 Sex- and Diet-Specific Disruption of the Adipose-Liver Axis with Subchronic Exposure to a Dioxin Mixture

K. D. Stewart¹, O. E. Bolatimi², G. J. Phillips¹, Y. Hua², and B. Wahlang². ¹University of Louisville College of Arts and Sciences, Louisville, KY; and ²University of Louisville School of Medicine, Louisville, KY.

Background and Purpose: Persistent organic pollutants (POPs), including "dioxin and dioxin-like" compounds, are linked to metabolic disorders such as diabetes, obesity and steatotic liver disease. However, the combined effects of mixtures of dioxins and dioxin-like compounds on the adipose-liver axis, and how these effects contribute to metabolic outcomes, remain unclear. Studies investigating the longer-term effects from exposures to these environmentally relevant mixtures are also currently lacking. Thus, the objective of this study is to examine the impact of subchronic exposures to a dioxin mixture in male and female mice in the context of a hypercaloric diet, with focus on adipose, liver and systemic metabolic outcomes. **Methods:** Male and female C57BL/6 mice were fed a low-fat diet (LFD) or a high-fat diet (HFD) and administered a vehicle control (corn oil) or defined mixture of dioxin and dioxin-like compounds, namely TCDD (10ng/kg) + PeCDF (80ng/kg) + PCB 126 (140 ng/kg) weekly over a 12-week period. Body weight was recorded weekly. Body composition was assessed using Echo-MRI and glucose tolerance tests were performed at the mid-study period and prior to study termination. At study completion, liver, adipose tissue, and plasma were collected. White adipose tissue (WAT) morphology and liver sections were assessed histologically, while hepatic and circulating lipids were quantified by biochemical assays. Hepatic gene expression was measured by RT-PCR. Statistical analysis was performed using Three-Way ANOVA followed by post-hoc test with Holm-Sidak correction ($p < 0.05$). **Results:** Males generally exhibited higher body weight and total fat mass compared to females. Male mice also had greater adipose tissue weights relative to body weight. In terms of adipose morphology, males displayed larger adipocyte area than females, while crown-like structure (CLS) burden showed modest sex differences. Diet exerted strong effects on metabolic endpoints. HFD significantly increased body weight, adiposity, adipocyte hypertrophy, and CLS burden compared to low-fat diet (LFD), regardless of sex. HFD also elevated plasma triglycerides, hepatic lipid accumulation, and markers of liver injury

(ALT and AST), confirming its role as a primary driver of metabolic disruption. Dioxin exposure did not exacerbate these HFD-driven adipose parameters but led to altered adipocyte morphology only in the LFD-fed mice. This was mirrored by increased body fat composition (Echo-MRI at 12 weeks) with dioxin exposure in LFD-fed females. Moreover, LFD-fed females exposed to the dioxin mixture displayed elevated hepatic triglyceride levels, alongside increased circulating ALT levels, and upregulation of the hepatic fatty acid transport gene *Cd36*. This observation was absent in diet-matched males. Instead, dioxin exposed LFD-fed males showed suppressed liver *de novo* lipogenic gene expression (*Fasn*, *Scd1*) coupled with resistance to glucose uptake. Activation of hepatic xenobiotic receptors differed by context: AHR was activated across all exposed groups as seen by *Cyp1a1* and *Cyp1a2* induction, although HFD feeding decreased AHR target gene induction in male livers. Notably, exposure to the dioxin mixture also resulted in CAR activation (*iCyp2b10*, *Cyp2c29*), specifically in LFD-fed males but not females. **Conclusions:** Taken together, the results suggest that exposure to the dioxin mixture produced sex- and diet-specific metabolic effects, along the adipose-liver axis. Sex-specific toxicant responses observed included dioxin-mediated steatotic liver phenotype and altered fat composition in females and glucose perturbation in males, highlighting the negative impact of these chemicals on liver and metabolic outcomes even at low doses. Intriguingly, the dioxin mixture did not exacerbate HFD effects with regards to liver and adipose endpoints. Overall, these findings demonstrate that both biological sex and dietary context critically shape toxicant responses and may better inform risk assessment of these chemical mixtures.

PS 3618 Exposure to polychlorinated biphenyls (PCBs) alters endothelial-pericyte crosstalk at the blood brain barrier

K. Kumar¹, X. Li², H. Lehmler², and M. Toborek¹. ¹Department of Biochemistry and Molecular Biology, University of Miami Miller School of Medicine, Miami, FL; and ²Department of Occupational and Environmental Health, University of Iowa, Iowa City, IA.

Background and Purpose: Polychlorinated biphenyls (PCBs) are stable, environmental toxicants that are widely found in the environment. Once used for industrial purposes, PCBs have since been banned but are still found in the environment today. PCBs have been associated with neurotoxicity, with one potential mechanism being disruption of the blood brain barrier (BBB). The BBB is a semi-permeable barrier that separates the central nervous system from the cerebral vasculature. The BBB's semi-permeable properties are maintained by tight junctions between endothelial cells that form the main vascular barrier, in concert with pericytes and astrocytes that regulate its integrity and function. PCBs have been shown to dysregulate tight junction integrity, but little is known about how PCBs affect endothelial cell-pericyte intercellular communication, which is essential for proper functioning of the BBB. **Methods:** Primary human BBB pericytes were cultured with or without human brain microvascular endothelial cells. For pericyte monocultures, pericyte medium was treated with 5µM of PCB mix, reflecting the PCB concentration found in postmortem human brain samples or with a vehicle (0.1% DMSO). To evaluate endothelial-pericyte communication, a co-culture model was established using transwell inserts, with pericytes seeded on the basolateral surface of the membrane and endothelial cells on the apical surface. To mimic *in vivo* conditions in co-culture, only endothelial cell medium was treated with PCBs, as described above. RT-qPCR was used to assess the mRNA expression of several signaling molecules, while Western Blotting was used to assess the protein expression of gap junction proteins. **Results:** In pericyte monocultures, there was a decrease in the mRNA expression of the signaling molecule Angiopoietin 1 (*Angpt1*) 6 hours after treatment, and an increase in the expression of matrix metalloproteinase 9 (*MMP9*) and vascular endothelial growth factor A (*VEGFA*) at 6 hours after treatment. In endothelial cells cultured with pericytes, there was an increase in the mRNA expression of the inflammatory chemokine *CCL2* and *VEGFA*, and a decrease in *Angpt1* at 6 hours after treatment. Also, there was a decrease in the protein expression of Cx43 after 12 hours of treatment. Finally, there was an increase in the mRNA expression of *Angpt1* in co-cultured pericytes. **Conclusions:** Our results indicate that PCBs alter the expression of signaling molecules and inflammatory cytokines in both pericyte monocultures and endothelial-pericyte co-cultures. Thus, our findings suggest that exposure to PCBs may disrupt endothelial-pericyte crosstalk which is essential for BBB maintenance. Additionally, we show that direct intercellular communication between endothelial cells and pericytes may be compromised due to decreased expression of Cx43 in co-cultured endothelial cells. Taken together, our findings provide unique implications into the mechanisms by which PCBs may lead to BBB dysfunction, which may inform strategies to mediate the effects PCB-induced neurotoxicity.

PS 3619 Developmental risks of PBDE exposure through altered miRNA signaling in human placenta and breastmilk

R. Khan¹, M. Kong², A. Salamova², X. Lin³, N. Hanna⁴, and J. T. Zelikoff¹. ¹New York University, New York, NY; ²Emory University, Atlanta, GA; ³NYU Langone Hospital Long Island, Mineola, NY; and ⁴NYU Langone Hospital Long Island, New York, NY.

Background and Purpose: Polybrominated diphenyl ethers are persistent organic pollutants linked to preterm birth and adverse neurodevelopmental outcomes. Preterm infants may face compounded risks due to dual PBDE exposure via the placenta and breast milk. While *in vitro* studies suggest that PBDE disrupts extracellular vesicle (EV) miRNA packaging, its effects on placental immune tolerance (mediated by EV-miR-519c) or its impact on the composition of neuroprotective milk EV-miRNAs remain unknown. We hypothesize that elevated PBDE levels reduce protective placental EV-miR-519c, increasing the risk of preterm birth, and that higher PBDE concentrations in breast milk will negatively correlate with neuroprotective miRNAs in milk EVs, potentially impacting preterm infant neurodevelopmental outcomes. **Methods:** Human placental explants (n=11) were exposed to repeated doses of LPS to model infection-mediated preterm birth, with or without PBDE-47. EVs were isolated from culture media to assess whether PBDE-47 alters EV-miR-519c secretion following repeated LPS exposure. Additionally, breast milk PBDE levels from preterm (n=55), full-term (n=15), and donor (n=12) milk were quantified via gas chromatography-mass spectrometry (GC-MS). EVs were also isolated from breast milk samples and neuroprotective miRNAs (miR-22-3p, miR-30b-5p, and miR-146a-5p) were quantified using the LNA miRCURY miRNA assay on droplet digital PCR (ddPCR). Placental miR-519c levels were compared between treatment groups and controls by two-way ANOVA. PBDE concentrations in preterm and full-term milk were compared by Mann-Whitney U-test. Milk samples were also sorted into "high" (n=14) and "low" (n=68) PBDE categories with high samples defined as those with cumulative PBDE levels greater than 4 standard deviations above the average of healthy milk donors in the NY area. Correlation between PBDE-47, -99, and -153 concentrations and protective miRNAs was assessed by Spearman correlation and simple linear regression. Data were analyzed in GraphPad Prism v10.4.1 **Results:** PBDE-47 co-treatment in placental explants decreases protective EV-miR-519c expression in response to LPS (p<0.0001). GC-MS demonstrates that ~20% of all samples have high cumulative PBDE level, with 93% of high PBDE samples collected from preterm delivery mothers. Significant inverse correlations are evident between BDE-99 concentration and miR-22-3p (p<0.0001), miR-30b-5p (p<0.001), and miR-146a-5p (p<0.001). Cumulative PBDE burden is also inversely associated with miR-146a-5p (p<0.01) and miR-22-3p (p<0.05). **Conclusions:** These data suggest that PBDEs may alter EV-miRNA content in both human placenta and breast milk with serious implications for preterm infant health. Maternal PBDE exposure may impact infant neurodevelopment through multiple pathways. First, alterations in placental immune tolerance EV-miR-519c could increase the risk of preterm birth, which is independently linked to poor neurodevelopmental outcomes. Second, there may be direct PBDE ingestion through breast milk by preterm infants. Third, disruptions in neuroprotective milk EV-miRNAs may adversely affect infant neurodevelopment. This highlights a novel mechanism by which PBDEs may contribute to both preterm birth and neurodevelopmental delays in preterm infants.

PS 3620 In vitro mixtures toxicity testing to address wildfire smoke exposures and individual chemical components contributing to human health risk

S. L. Miller¹, J. R. Chappel¹, E. Hickman¹, Y. Kim², C. Rider³, D. M. Reif³, S. Auerbach³, I. Jaspers¹, M. E. Rebuli¹, and J. E. Rager¹. ¹UNC Chapel Hill, Chapel Hill, NC; ²US EPA, Research Triangle Park, NC; and ³NIEHS, Research Triangle Park, NC.

Background and Purpose: Wildfire incidence and severity have steadily increased in recent decades, leading to increases in smoke emissions that pose risks to public health. Due to the wide variety of chemical mixtures in smoke from wildfires, there is a need to couple high-throughput toxicity screening approaches with computational methods to assess wildfire-relevant mixtures toxicity. This study sought to evaluate transcriptomic responses of respiratory epithelial cells to individual components, defined mixtures, and complex woodsmoke mixtures with two goals: (1) identifying potential modes of action that are shared versus distinct between wildfire components, and (2) quantifying relative impacts across these various mixtures and mixtures components to inform human health risk estimates. **Methods:** The six chemicals prioritized for this study frequently co-occur across ten different wildfire-relevant burn scenarios (eucalyptus, pine, pine needles, peat, and red oak burned under flaming or smoldering conditions) and were previously positively or negatively correlated with toxicity endpoints in exposed mice through mixtures modeling. Spanning polyaromatic hydrocarbon, methoxyphenol, and metal chemical classes, they included: benzo(a)pyrene, benz(a)anthracene, coniferyl aldehyde, vanillin, sodium dichromate, and copper sulfate. Human bronchial epithelial (16HBE) cells in 12-well plates were exposed at 5 different exposure-relevant concentrations to these single chemicals, equimolar binary mixtures, an equimolar defined mixture of all 6 candidate chemicals, and 4 complex biomass mixtures (flaming or smoldering eucalyptus and flaming or smoldering pine). Bulk RNA sequencing was performed in samples collected at 4 hours post-exposure. Differentially expressed genes (DEGs), gene set enrichment, benchmark concentration (BMC) modeling, transcriptomic point of departure (tPOD) derivation, and concentration addition mixtures modeling (CAM)

analyses were performed to evaluate transcriptomic response. **Results:** Patterns in DEGs, significantly enriched pathways, BMCs, and tPODs were shared between the complex biomass mixtures, defined mixture, sodium dichromate alone, and sodium dichromate in binary mixture with copper sulfate. Ras/ERK and Ras/PI3K signaling were identified as top ranking enriched pathways highly shared across these exposure conditions, suggesting a shared mode of action involved in response to these wildfire-relevant mixtures perhaps driven by sodium dichromate. Comparisons of observed versus CAM-predicted tPODs revealed that the metals binary mixture and defined mixture exhibited synergistic effects (e.g. 0.120 μ M observed versus 0.265 μ M predicted for metals, and 0.006 μ M observed versus 0.05 μ M predicted for the defined mixture). Notably, relative potencies of the complex biomass mixtures mirrored results obtained from mice exposed to those same mixtures, providing rare *in vivo* anchoring towards this *in vitro*-based mixtures testing paradigm. **Conclusions:** Altogether, these results suggest that metals and metal mixtures may be a particular chemical class and/or mixture of public health concern when considering the respiratory health effects of wildfire smoke exposure. However, the nearly 10-fold difference in observed versus predicted tPODs in the defined mixture indicates that interactions with other co-occurring chemical classes must also be considered when determining wildfire smoke exposure risk. These results highlight the importance of variable mixtures-based approaches to assess wildfire smoke toxicity and contribute a novel dataset of risk assessment relevance.

PS 3621 Developmental Toxicity of Metal Mixture Exposures in Zebrafish Embryos

O. D. Ahmad, K. R. Siegel, and C. D. Kassotis. Wayne State University, Detroit, MI.

Background and Purpose: HF operations rely on the injection of large volumes of water, sand, and chemicals under high pressure to extract oil and natural gas. Hydraulic fracturing (HF) releases heavy metals into the environment through leaks, spills, and incomplete fluid recovery, raising concerns for communities near drilling sites. Metals such as barium (Ba), strontium (Sr), aluminum (Al), manganese (Mn), cobalt (Co), arsenic (As), and iron (Fe) are often enriched in affected water sources and have been associated with developmental toxicity. Populations living near HF sites may therefore face repeated or chronic exposures through drinking water. Epidemiology studies suggest relationships between increased birth defect risks in children born to mothers living near HF operations, raising concerns about the developmental effects of such exposures. Given these findings, it remains unclear whether metal exposures contribute directly to the birth outcomes reported near hydraulic fracturing sites. To address this, we are modeling environmentally relevant metal mixtures in the laboratory using zebrafish embryos to assess their potential to disrupt early development. **Methods:** Metals were obtained as inorganic salts, prepared in ultrapure water, and formulated into three equimolar mixtures to reflect regional differences in North American geology (5MMAs: As+Al+Ba+Mn+Sr; 5MMCo: Co+Al+Ba+Mn+Sr; 5MMFe: Fe+Al+Ba+Mn+Sr). Adult wild-type AB zebrafish were set up in breeding tanks (3 females: 2 males), and spawning occurred the following morning after gate pulls. Embryos were collected, sorted, and cleaned. At 24 hours post-fertilization (hpf), embryos were staged and seeded into 6-well tissue culture plates, with 20 embryos in each well. Treatments included embryo media (negative control), dimethyl sulfoxide (DMSO) control, 10 μ M β -naphthoflavone (BNF), and exposures to our mixtures at concentrations of 1 nM, 10 nM, 100 nM, and 1 μ M. Embryos were exposed starting at 24 hpf. At 48 hpf, survival was assessed, any dead animals were removed, and treatments were renewed after embryo media change. At 72 hpf, survival was recorded, and embryos were switched into fresh media without test chemicals prior to developmental measurements. The larvae were anesthetized and imaged, and video recorded using a Leica S91 microscope. Images were analyzed for differences in body length, yolk sac size, and pericardial edema size. Videos were analyzed to measure heart rate (HR) in each treatment group. Heart rate was determined from 5-second intervals. **Results:** Neither metal mixtures nor positive controls significantly decreased survival at 48 hpf or 72 hpf compared to negative controls. As expected, 10 μ M BNF significantly increased yolk sac and pericardial edema size (both +26% compared to negative control), decreasing overall body length (-26%), and reducing heart rate (-15%), confirming effective positive control activity. Only 500 nM 5MMAs slightly, but significantly, decreased larvae body length (-3%). Significant decreases, but not increases, in yolk sac size were observed with 5 μ M 5MMAs (-5%) and 5 nM 5MMFe (-6%) treatment. No significant changes in pericardial edema size were noted following mixture exposure. HR analysis showed that 100 nM (+5.5%) and 1 μ M (+6.0%) 5MMAs exposure significantly increased HR. **Conclusions:** The results indicate that environmentally relevant metal mixtures cause only subtle developmental effects in zebrafish embryos under the tested conditions, including small changes in body length and yolk sac size. While survival was similar between treated and untreated animals, these findings suggest that early-life exposures may still contribute to developmental disruption. The HR data indicate that the As-containing exposure increased HR at 72 hpf, suggesting potential functional changes. Future work will assess different exposure windows (earlier and later than 24 hpf) and extend observations beyond 72 hpf to allow us to observe any delayed or progressive effects. Future work will use video analysis to assess other hemodynamic endpoints, focusing on As-containing mixtures to understand their effects on cardiac function and development.

PS 3622 From Pixels to Potency: Image-Based Modeling of Component Contributions to PFAS Mixture Effects

K. M. Eccles¹, E. Cho¹, and S. Baird². ¹Health Canada, Ottawa, ON, Canada; and ²Children's Hospital of Eastern Ontario Research Institute, Ottawa, ON, Canada.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are widespread environmental contaminants with diverse chemical structures and biological activities. Since humans are typically exposed to PFAS mixtures rather than individual compounds, quantitative approaches that integrate mechanistic bioassays with mixture modeling are needed to improve risk assessment of PFAS mixtures. This study applied a component-based concentration-addition framework to predict the biological activity of PFAS mixtures using high-content image data, commonly referred to as Cell Painting, linking morphological bioactivity profiles to mixture potency and mechanistic interpretation. **Methods:** Seven PFAS (perfluorobutanesulfonic acid (PFBS), perfluorodecanoic acid (PFDA), perfluorooctanesulfonic acid (PFOS), perfluorohexanoic acid (PFHxA), perfluorononanoic acid (PFNA), perfluorooctanoic acid (PFOA), and perfluorohexanesulfonic acid (PFHxS)) were evaluated in human U2-OS cells using the Cell Painting assay. Cells were cultured in 96-well plates and exposed for 24 hours to each compound individually or to two defined mixtures: an equimolar mixture and an environmentally relevant mixture reflecting plasma concentrations from the Canadian Health Measures Survey (CHMS). Following exposure, cells were stained with six fluorescent dyes to visualize diverse organelles and morphological features and imaged using the Opera Phenix high-content screening platform. Images were processed through the Columbus image analysis software and a validated Cell Painting analysis pipeline in R to extract quantitative morphological features and aggregate cell-level values to normalized well-level medians for each treatment condition. Benchmark concentration (BMC) values and their lower (BMCL) and upper (BMCU) confidence limits were derived from concentration-response modeling for each feature and chemical. Mixture potencies were predicted using a concentration-addition model that integrated individual-chemical BMCs according to their respective proportions in each mixture (equimolar or environmental). Predictions were generated using both feature-median and feature-weighted median (1/BMC-weighted) approaches to account for differences in feature sensitivity across chemicals. Predicted mixture BMCs and confidence intervals were compared with experimentally measured mixture responses to evaluate additivity and identify dominant chemical contributors to overall mixture potency. **Results:** Predicted mixture potencies spanned several orders of magnitude across morphological features. The environmentally weighted mixture exhibited greater overall potency (lower BMCs) than the equimolar mixture, primarily driven by the high-potency and high-abundance constituents PFOS and PFOA. PFOS accounted for up to 60% of total mixture activity in the most sensitive morphological features, particularly those describing cytoplasmic texture, nuclear intensity, and granularity. Both the feature-median and feature-weighted median mixture predictions aligned closely with the measured mixture potencies, supporting additive effects among the PFAS components at this level of biological organization. Overall, predicted mixture potencies mirrored single-chemical potency rankings, underscoring consistent feature-level sensitivities and dominant chemical drivers. **Conclusions:** Component-based mixture modeling effectively captured additive PFAS responses in high-content imaging data and identified key contributors under realistic exposure scenarios. Integrating Cell Painting bioactivity with concentration-addition modeling provides a mechanistic, quantitative framework for evaluating PFAS mixture toxicity. By linking cellular phenotypes to potential modes of action, this approach advances mechanistic-based risk assessment and supports data-driven prioritization of PFAS and other complex environmental mixtures.

PS 3623 In vitro endocrine and adipogenic effects of oil and gas-associated metal mixtures: intersections with glucocorticoid signaling

K. R. Siegel, and C. D. Kassotis. Wayne State University, Detroit, MI.

Background and Purpose: Hydraulic fracturing (HF) operations inject complex chemical mixtures underground to retrieve previously inaccessible energy reserves. Metals such as barium (Ba), strontium (Sr), aluminum (Al), and cobalt (Co) are common components of HF fluid used to keep fractures open ("proppants"). HF sites can increase environmental concentrations of proppant metals, and endemic metals such as arsenic (As), iron (Fe), and manganese (Mn), via incomplete fluid recovery, wastewater mishandling, and metal aerosolization. Pregnant women residing closer to HF sites have higher hair and urinary metal levels than those living further away, constituting potential early life exposures. Metal exposure can result in metabolic dysfunction, including increased adiposity, through activation of key nuclear receptors (NRs). Epidemiologic and *in vivo* relationships between single metals and metabolism are complex, particularly those driven by NRs. Interplay between environmentally relevant HF metal mixtures, NR signaling, and adipogenesis remains poorly characterized and requires empirical assessment. **Methods:** Inorganic metals salts were prepared in ultrapure water individually and formulated into 3 equimolar mixtures to model regional differences in North American HF site geology (5MMAs: Al+Ba+Mn+Sr+As; 5MCo: Al+Ba+Mn+Sr+Co; and 5MFe: Al+Ba+Mn+Sr+Fe). Mixtures and individual metals were tested in transiently transfected luminescence reporter gene bioassays for human retinoid X receptor α (RXR α), peroxisome proliferator activated receptor γ (PPAR γ), and glucocorticoid receptor (GR). Transfected cells

were exposed to increasing, environmentally-relevant concentrations of metals (5 nM - 5 μ M for mixtures, 1 nM - 1 μ M for individual metals) or positive control chemicals for NR activation (only test chemicals) or modulation (EC₅₀ agonist co-exposure). Mixture-GR interactions were assessed by 5 μ M mixture co-exposure with mifepristone (GR competitive antagonist), Dexamethasone (DEX; GR agonist), or dithiothreitol (DTT; thiol-sparing reductant). Adipogenic effects were measured by triglyceride accumulation (lipogenesis) and DNA levels using a standardized human mesenchymal stem cell (hMSC; 6 year old female donor) differentiation protocol following exposure to metals or positive controls, with or without EC₅₀ DEX for GR-mediated lipogenesis modulation assessment. **Results:** None of the mixtures activated RXR α or PPAR γ . 5 μ M mixtures weakly activated GR (5MAs: 10% relative to positive control; 5MCo: 7%; 5MFe: 16%). Individual 1 μ M Ba significantly activated GR at greater-than-mixtures levels (24%), potentially driving mixture effects. Individual Fe activated (8-13%) and Mn inhibited (-11-6%) GR across tested concentrations. Individual Al, As, and Co did not activate GR. 5 μ M 5MCo and 5MFe enhanced EC50 DEX-mediated GR activity (+350% and +30%, respectively), as did individual 1 μ M Ba (+340%) and Sr (+240%). Nanomolar concentrations of Co, Al, and Mn inhibited GR (-100% - -71%). As and Fe did not affect DEX-mediated GR activity. Mifepristone blocked GR activity for each 5 μ M mixture. DTT increased only 5MAs-induced activity (+30%), suggesting mixture-specific interactions with GR thiol groups that could limit mixture efficacy. This was corroborated by varying magnitudes of full DEX concentration-response curves with 5 μ M mixture co-exposures (As < Co < Fe), suggesting mixture-specific non-competitive regulation of GR. 5 μ M mixtures increased hMSC lipogenesis (5MAs: 31%; 5MCo: 20%; 5MFe: 29%). DEX-mediated lipogenesis was enhanced by 5 μ M 5MAs (+117%) and 5MFe (+25%), but not 5MMCo. Individual 1 μ M Sr, As, and Ba increased lipogenesis (17%, 22%, and 16%, respectively), indicating these metals might drive mixture effects. The remaining metals did not affect lipogenesis. 1 μ M Al and Mn inhibited DEX-mediated lipogenesis (-76% and -78%, respectively) while 1 μ M As strongly enhanced (+170%). Individual Co, Sr, and Ba did not affect DEX-induced lipogenesis. **Conclusions:** Our results suggest that HF-related metal mixtures specifically activated and enhanced GR activity, potentially driven by Ba and through non-competitive receptor regulation. Some metal mixtures induced and enhanced hMSC lipogenesis. On-going mixture-exposed hMSC transcriptome analyses will help determine how mixtures mechanistically intersect with GR signaling and spur lipid deposition.

PS 3624 Assessment of Bisphenol Mixture Toxicity Using Zebrafish Larvae and HepG2 Cells

R. Chen, B. Bauer, and H. Hintzsche. University of Bonn, Department of Food Safety, Bonn, Germany.

Background and Purpose: Bisphenol analogues (BPs), extensively used in polycarbonate plastics and epoxy resins, are ubiquitous in consumer products and the environment, raising concerns regarding human and ecological health. While most toxicological studies address single compounds, real-world exposures involve complex mixtures, and the cumulative toxicity and mechanisms of BPs remain poorly understood. This study examined the toxicological effects and interactions of four bisphenol analogues—BPA, BPE, BPF, and BPS—using zebrafish larvae and HepG2 cells. **Methods:** Acute toxicity was assessed in zebrafish larvae over 48 h for individual compounds and binary, ternary, and quaternary mixtures, with mortality as the endpoint. Cytotoxicity in HepG2 cells was determined via MTT assays after 4 h and 24 h exposures, and genotoxicity of single compounds was evaluated using the comet assay. Mixture toxicity was predicted using the concentration addition (CA) and independent action (IA) models and verified by comparing experimental data with model predictions through the model deviation ratio (MDR). **Results:** All four BPs induced concentration-dependent mortality and cytotoxicity, with potency ranked as BPA > BPE > BPF > BPS. Mixture exposures in zebrafish showed composition-dependent effects, where certain binary and ternary combinations (e.g., BPF + BPS, BPA + BPF + BPS) enhanced mortality. In HepG2 cells, extended exposure (24 h vs. 4 h) significantly increased cytotoxicity. Mixtures containing BPA were generally more toxic, whereas BPE- or BPS-dominant mixtures exhibited lower toxicity. **Conclusions:** Bisphenol analogues differ markedly in potency, and their mixtures display complex, composition-dependent interactions deviating from simple dose-response behavior. Statistical analyses based on the IA and CA models revealed additive, synergistic, and antagonistic effects. These results underscore the importance of incorporating mixture toxicity into consumer product risk assessments, which may otherwise underestimate potential hazards.

PS 3625 Inhalation exposure risks from resin 3D printing used in dental fields

Q. Zhang¹, I. Sanchez², M. Maroun², B. Welmaker², C. Bell-Huff¹, and M. Wilson¹. ¹UL Research Institutes, Marietta, GA; and ²Nova Southeastern University, Davie, FL.

Background and Purpose: Vat photopolymerization 3D printing cures a photopolymer resin with a light source selectively to form an object from a digital model. Due to its cost-effectiveness, high accuracy and the smooth surface finish of printed objects, resin 3D printing is widely used in dental and medical fields, such as dental schools and clinics. However, liquid resins typically contain ingredients that are irri-

tating and/or sensitizing, which could off gas during normal use and pose inhalation risks to the users and occupants. Therefore, it is important to understand the potential exposure risks associated with resin 3D printing. **Methods:** We developed and validated methods to evaluate volatile organic compound (VOC) emissions from resin 3D printing using specialized exposure chamber setups. A full-scale chamber was used for evaluating emissions from the printing and post-printing processes; a micro-scale chamber was used for characterizing off gas from resin materials without operations. VOCs were collected on Tenax® TA tubes and analyzed by gas chromatography-mass spectrometry; low-molecular-weight aldehydes were collected on 2,4-dinitrophenylhydrazine cartridges and analyzed by high performance liquid chromatography, both followed EPA methods. Based on exposure chamber conditions, emission factors were calculated following standard methods and were applied to an indoor exposure model to estimate exposure potentials in different environments. **Results:** Resin 3D printing showed a total VOC emission rate of over 4 mg/h. Even without operation, total VOC level was over 10 times higher than the empty chamber background, indicating off gassing from resins happened in normal room conditions. The most abundantly emitted VOCs during printing included 2-hydroxypropyl methacrylate, propylene glycol, and 2-hydroxyethyl methacrylate, which were associated with the resin compositions. The printing process emitted much higher VOCs than the post-printing wash and cure processes, except for the wash solvent. Various esters, hydrocarbons, alcohols, aldehydes and ketones were detected during the operation processes. Resin off gas tests showed complex mixtures of VOCs were released at room temperature from various resin types commonly used in the dental fields. In addition to the specified ingredients listed on safety data sheets, typically acrylates and methacrylates, more compounds were released from resin off gas, which could be associated with undisclosed additives, polymer degradation, or chemical reactions. Our emission tests identified some hazardous VOCs with potential health concerns, such as 2-methoxyethyl acetate, formaldehyde, naphthalene, acetaldehyde, and toluene. These included carcinogens, reproductive and developmental toxicants, irritants and sensitizers, exposure to which could result in adverse health effects, especially at non-industrial indoor environments such as dental offices. For example, estimated personal exposure to some VOCs with health concern, such as toluene and formaldehyde, may exceed the recommended indoor levels. **Conclusions:** Resin 3D printing emitted a complex mixture of acrylates, aldehydes, alcohols, ketones, and hydrocarbons during normal use or even without operation. The emissions contain irritating, carcinogenic, and/or toxic compounds. Users and occupants are potentially exposed to hazardous mixtures when resins are present indoors, which may result in acute irritation or long-term effects. In addition, manufacturer safety data sheets may not be sufficient for assessing exposure hazards, especially inhalation risks that can be associated with byproducts from materials and processing.

PS 3626 Modeling Female Reproductive Toxicity of Endocrine Disruptor Mixtures: Insights from Targeted Chemicals

X. Jia¹, T. Zhan², S. Xiao², and H. Zhu¹. ¹Tulane University, New Orleans, LA; and ²Rutgers University, Piscataway, NJ.

Background and Purpose: The ovaries are central to female reproduction as sites of hormone synthesis and maturation and ovulation of oocytes within follicles, the functional unit of the ovary. Follicle development, steroidogenesis, and ovulation are highly susceptible to endocrine disruptors (EDCs). Most of previous research focuses on a single compound; however, humans are exposed to complex EDC mixtures which may target multiple signaling transduction pathways and their interactions. This study applied novel machine learning frameworks to evaluate the effects of real-world waterborne EDC mixtures on ovarian follicular development and ovulation, and to identify potential driving chemicals and toxicity mechanisms. **Methods:** Eight water samples were collected from the Delaware, Passaic, and Raritan Rivers in New Jersey and tested for their effects on ovarian follicular outcomes. Concentrations of over 70 organic chemicals—including PFAS, herbicides, pharmaceuticals, phthalates, and other contaminants, were quantified. Biological activity data were retrieved from PubChem, and assays representing molecular initiating events (MIEs) and key events (KEs) relevant to ovarian follicular outcomes were selected. Machine learning classification models were trained to predict untested chemical activities, and regression models were developed to predict mixture-level ovarian disruption, defined as the ratio of mixture-treated to control values, by integrating bioactivity profiles, exposure concentrations, and chemical descriptors. Model interpretation was used to identify mixture-specific toxicity-driving chemicals and mechanisms. **Results:** Chemical composition and concentrations varied across rivers, with Passaic River mixtures showing the greatest chemical diversity and strongest inhibitory effects on hormone secretion, follicle growth and ovulation. Machine learning models were developed for assays including nuclear receptor signaling (e.g., ER, AR, PPAR), mitochondrial dysfunction, p53 activation, and oxidative stress, representing plausible MIEs and KEs, with most models achieving balanced accuracy above 0.7. Regression models to predict different ovarian follicular outcomes achieved R² of 0.6-0.8. Key driving chemicals such as dibutyl phthalate, bisphenol S, and triclosan were found at elevated concentrations in Passaic River samples and predicted to modulate multiple MIEs and KEs. **Conclusions:** This study demonstrates the utility of machine learning-based mixture modeling for assessing female reproductive toxicity of complex environmental EDC mixtures. The integration of multimodal data, including exposure

levels, chemical descriptors, and bioactivity information, enables accurate prediction and mechanistic interpretation of how co-occurring environmental chemicals may jointly contribute to adverse ovarian outcomes.

PS 3627 Mixtures at the intersection of toxicology and epidemiology: Single index models and Relative Potency Factors

T. F. Webster. Boston University School of Public Health, Boston, MA.

Background and Purpose: Single index models express the outcome as a function of weighted sums of exposures. Several such models have been proposed for analyzing mixtures in epidemiology, including weighted quantile sum regression (wqs), quantile g-computation (qgcomp) and the Bayesian multiple index model (BMIM). The single index model is related to the relative potency factor (RPF) model used in toxicology. However, it is not clear how well the epidemiologic models reflect toxicologic principles. The objective of this paper is to compare and apply ideas from toxicology to epidemiology. **Methods:** We review the assumptions and generalizations of the RPF model. We mathematically examine the implications of these toxicologic ideas for the three mixtures epidemiology models. **Results:** The RPF model is perhaps best known for its application to dioxin-like compounds and saxitoxins. It assumes that all included compounds have the same dose-response curve (same shape and efficacy), differing only in potency. RPFs are computed using a reference compound, e.g., 2,3,7,8-TCDD for dioxin-like compounds. The RPFs are multiplied by the concentrations or doses (which may alter RPFs) and summed; the dose-response curve of the reference compound is applied to the sum. The RPFs can be mathematically converted into positive weights that sum to one, converting it to a typical single index model. BMIM is consistent with this toxicologic RPF model; wqs and qgcomp differ by using quantiles, which can distort dose-response curves. The RPF model is a special case of concentration addition, one of the standard toxicologic definitions of non-interaction. Generalized concentration addition (GCA) extends this concept to compounds with different efficacies, including competitive antagonists. GCA has a firm foundation in the kinetics of receptor activation by ligands. Application of a dose-response function to the result of GCA is not a single index model over the entire dose range. However, we show that at low doses, GCA is closely approximated by a single index model, allowing application to a broader range of compounds than those differing only in potency. When compounds differ in maximal effects, the weights depend on both the relative potencies and the relative efficacies. Competitive antagonists have negative weights, providing a rationale for weights of different sign in both qgcomp and BMIM. The toxicologic and epidemiologic definitions of interaction may not agree when dose-response curves are non-linear. **Conclusions:** Single index models applied to concentrations or doses have a biological basis in the toxicologic relative potency model. Related toxicology mixtures models such as GCA generalize these ideas at low concentrations, allowing for negative weights and application to compounds differing in efficacy. Appropriate single index models can be used to estimate RPFs using epidemiologic or toxicologic data.

PS 3628 Interpretable Dose-Response Modeling for Chemical Mixtures Using Symbolic Regression: A Case Study with Wildfire Smoke In Vitro Testing

J. R. Chappel, S. L. Miller, T. M. Weigand, and J. E. Rager. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Background and Purpose: Characterizing chemical exposures is complicated by the fact that individuals are rarely exposed to a single chemical at a time, but rather to mixtures that can interact in synergistic, antagonistic, or additive ways. To address this challenge, computational mixture modeling has focused on characterizing individual dose-response relationships and then combining them to predict mixture effects under frameworks such as concentration addition (CA) and independent action (IA). Traditionally, dose-response curves use predefined models (Hill, log-logistic, etc.), but real chemical responses often deviate from the suite of specified models. Model averaging can improve fits by blending models, yet reduces interpretability and complicates mechanistic insight and integration into mixture-prediction workflows. Here, we examine symbolic regression, which generates equations from input data using combinations of mathematical operators, as an alternative approach to model fitting. This method returns interpretable equations that can be directly used in CA and IA frameworks, offering a scalable, mechanistically transparent strategy for mixture toxicology. **Methods:** We evaluated dose-response modeling approaches using transcriptomic profiles from human bronchial epithelial (16HBE) cells exposed to wildfire-relevant chemicals and mixtures. Cells were treated with five concentrations of six chemicals across three classes: polycyclic aromatic hydrocarbons (benzo(a)pyrene, benz(a)anthracene), methoxyphenols (coniferyl aldehyde, vanillin), and metals (sodium dichromate, copper sulfate). In addition to single-chemical exposures, we included equimolar binary mixtures within classes, a six-chemical mixture, and four complex biomass mixtures from flaming and smoldering eucalyptus and pine combustion. Dose-response curves for each gene-exposure pair were modeled using: (i) Hill, exponential, polynomial, and power functions via *tcplfit2*; (ii) Bayesian model averaging of the same model families via *ToxicR*; and (iii) symbolic regression via *pysr*, allowing arithmetic, logarithmic, exponential, and power operations. Model performance was compared using Akaike Information Criterion (AIC),

Bayesian Information Criterion (BIC), and root mean squared error (RMSE) to assess fit quality. Fitted models were also used to predict mixture responses under CA and IA assumptions, and predictions were compared to observed mixture transcriptomic responses. **Results:** Across all genes and exposure conditions, single-model parametric fits (Hill, exponential, polynomial, power) performed poorest, particularly for non-monotonic responses or subtle inflections where rigid curves could not capture complex biology. Bayesian model averaging and symbolic regression demonstrated/exhibited similar overall fit quality, with comparable distributions of goodness-of-fit metrics. However, symbolic regression offered a key advantage by yielding compact, closed-form equations rather than weighted ensembles, thereby improving interpretability and enabling more direct integration into mixture-evaluation and risk-assessment workflows. Performance trends were consistent when models were used to predict mixture responses. Results also indicated that the optimal mixture-prediction framework varies by chemical class and mixture composition, highlighting the complexity of chemical interactions and the need for more refined predictive approaches. **Conclusions:** Together, these findings highlight symbolic regression as a promising approach for mechanistically informed dose-response modeling in the context of multi-stressor toxicity, including complex chemical mixtures.

PS 3629 Combined Arsenic and Uranium Exposure Drives Tissue-Specific Molecular Responses

J. Schilz, K. A. Torczynski, G. A. Picha, L. G. Hudson, E. J. Dashner-Titus, and S. Medina. University of New Mexico, Albuquerque, NM.

Background and Purpose: Legacy mining operations have left uranium (U) and arsenic (As) as persistent co-contaminants in groundwater and soils across the Southwestern United States. These metals, though naturally present in the environment, continue to expose rural and tribal populations. Chronic exposure has been linked to renal, pulmonary, and gastrointestinal (GI) injury, yet the mechanisms driving their individual and combined toxic actions are still not well understood. We hypothesize that differences in metal accumulation and activity across tissues give rise to unique transcriptional signatures that reveal pathways underlying tissue-selective toxicity. **Methods:** To test this, female C57BL/6J mice were exposed to 50 ppm uranyl acetate (UA), 500 ppb arsenite (AsIII), or both in drinking water for 60 days. Tissues critical for xenobiotic absorption and elimination, including kidney, lung, and GI tract, were analyzed for metal accumulation using inductively coupled plasma mass spectrometry (ICP-MS). Transcriptional responses were characterized by RNA sequencing (RNA-seq) to identify differentially expressed genes (DEGs) and enriched biological pathways. **Results:** ICP-MS revealed that the GI tract is the primary site of U accumulation, with levels reaching or exceeding administered doses. U levels were lower in kidney and lung compared to the GI tract, while As accumulated most prominently in kidney and lung following AsIII exposure. In kidney, UA induced 36 DEGs and UA + AsIII co-exposure elicited 539 DEGs, with minimal overlap in differentially expressed genes between UA and UA + AsIII exposure groups. Pathway analysis of kidney treated with UA revealed enriched metabolic and mitochondrial function pathways. In lung tissue, AsIII, UA, and UA + AsIII co-exposure produced 70, 244, and 194 DEGs. Enrichment of angiogenesis and cell junction pathways was observed in UA-treated lung tissue, whereas transcriptional and immune-related pathways were predominant in As-exposed lung tissue, reflecting distinct tissue-specific mechanisms of response and susceptibility. **Conclusions:** These findings suggest that patterns of metal distribution shape organ-selective transcriptomic responses that may underlie tissue-specific sensitivity under co-exposure conditions. Ongoing RNA-seq of intestinal tissues, combined with spatial metal imaging and speciation analyses, will further define spatial and molecular determinants of co-exposure toxicity.

PS 3630 Combined Effects of Metal Mixtures Toxicity in C. elegans

E. Lewis, S. Sierzenga, S. Pandiri, B. Lawrence, M. O'Banion, and J. Onukwufor. University of Rochester Medical Center, Rochester, NY.

Background and Purpose: Exposure to non-essential heavy metals such as cadmium (Cd) and lead (Pb) is a continued public health concern in the United States as heavy metals are naturally occurring elements found ubiquitously in the environment and are used in many parts of manufacturing and consumer products. Both elements produce pronounced toxic effects on multiple organ systems and in different windows of susceptibility and are listed as top ten agents of concern on the ATSDR. Given the heterogeneity of exposures that humans experience, it is crucial to understand how these exposures to mixtures differ from single exposures to better understand the complex interactions of the body and the environment. Thus, it is critical to explore the interactive effects of these heavy metals on the body. **Methods:** Using *C. elegans*, we investigated the acute and chronic impact of individual and/or combined effects of Cd and Pb on worm pharyngeal pumping rate (Feeding rate), metal body burden, brood size, and mitochondrial enzyme activity. We carried out an acute (24 h) dose-response for Cd (0, 0.1, 1, 10, 50 and 100 μ M) and Pb (0, 0.1, 1, 10, 50, and 100 μ M) on worm pumping rate. We then selected a No Observable Adverse Effect Level (NOAEL) dose (1 μ M) and a Lowest Observable Adverse Effect Level (LOAEL) dose (10 μ M) for both Cd and Pb, we used these conditions in our subsequent studies. A chronic(5-day) study of NOAEL, LOAEL, and mixtures was carried out to determine the long-term toxicity profile. Coincubation with either Ethylenediaminetetraacetic acid

(EDTA), a broad metal chelator, Ferristatin II, a Divalent metal transporter (DMT)-1 inhibitor, DMT 1 KO, or N-acetylcysteine (NAC), an antioxidant and glutathione precursor, was performed to investigate mechanisms of intervention. Worm body burden of heavy metals was measured to analyze metal homeostasis dysregulation after acute exposure. In addition to these readouts, we examined the brood size of worms after acute exposure as well as the enzyme activity of TCA and electron transport chain enzymes of isolated mitochondria. **Results:** We observed that acute exposure of NOAEL of Pb or Cd had no effect on the pumping rate. However, when combined, the mixtures reduced worm pumping rate. Chronic (5-days) exposure of NOAEL to Cd or Pb reduced the pumping rate, with the mixtures potentiating their individual effect on worm pumping rate. Both acute and chronic exposure to LOAEL of Pb or Cd impacted worm pumping rate. We noted that the removal of the metals after initial impact did not reverse the reduced pumping rate. We also observed reduced brood size for Pb or Cd exposure to LOAEL for individual metals or NOAEL for mixtures. The use of the broad metal chelator Ethylenediaminetetraacetic acid (EDTA) abolished both Pb or Cd induced toxicity. Like EDTA, N-acetylcysteine (NAC), an antioxidant and glutathione precursor and Ferristatin II, a Divalent metal transporter (DMT)-1 inhibitor, mitigated against Pb and/or Cd toxicity in both NOAEL and LOAEL. Genetic ablation of DMT1 proffered similar protection as those observed with pharmacologic inhibition of DMT1. Worm tissue burden revealed an increase in Pb or Cd accumulation with no impact on other resident metal homeostasis. Further, co-incubation of the metals with EDTA, NAC or DMT1 inhibitor or genetic ablation of DMT1 reduced Pb or Cd tissue burden. We observed reduced mitochondrial citrate synthase enzyme activity following exposure to Pb and Cd. **Conclusions:** Overall, our data demonstrates the critical nature of mixtures studies because we observed a synergistic interactive effect of physiologically relevant doses of Cd and Pb exposure, which can persist chronically after the removal of the exposure. We showed DMT-1 is an entry mechanism for Pb and Cd and NOAEL of the metal mixtures impacted brood size, pumping rate and mitochondrial function and could be mediated through oxidative damage.

PS 3631 Strain-Dependent Effects of Trichloroethylene Exposure and Western Diet in Wild Type and Humanized PPAR α Mice

P. M. Brizendine-Ames, A. Ekuban, M. Cave, and W. Watson. University of Louisville, Louisville, KY.

Background and Purpose: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects nearly one-third of US adults. MASLD diagnosis requires the presence of excessive hepatic fat and at least one component of metabolic syndrome of which consumption of a western diet (WD) is a major risk factor. Environmental toxicants can also cause liver injury, as seen in toxicant-associated steatohepatitis (TASH). Our research combines the concepts of MASLD and TASH focusing on an environmentally relevant, hepatotoxic chemical: trichloroethylene (TCE). TCE was the main contaminant in the water at U.S.M.C. Base Camp Lejeune, North Carolina, where as many as 1,000,000 individuals were exposed to contaminated drinking water. The TCE metabolites trichloroacetic acid (TCA) and dichloroacetic acid (DCA) are agonists of peroxisome proliferator-activated receptor α (PPAR α), a nuclear receptor with a critical role in maintaining lipid homeostasis and thus steatotic development and overall MASLD progression. PPAR α displays notable species differences; therefore, mice may not be good models to study human health effects of PPAR α agonists. **Methods:** The guiding hypothesis is that TCE exposure alters the expression of PPAR α dependent genes and predisposes the liver to fat accumulation in a sex and strain dependent manner. To elucidate these potential differences, male and female wildtype (WT) and transgenic humanized PPAR α mice (hPPAR α) were subjected to a 12-week exposure to TCE (0.5 mg/mL), WD, or their combination (n=10-12). Two-way ANOVA with the Tukey's post hoc test was performed to determine statistical significance with a predetermined p value of 0.05. **Results:** Regardless of strain, male mice displayed little response to TCE exposure but were susceptible to WD-induced liver injury as evidenced by elevated serum enzymes, increased liver weight, and decreased glucose tolerance. Both WT and hPPAR α female mice responded similarly to WD but displayed differential response to TCE exposure. Like in the males, TCE exposure did not affect WT female mice; however, in the female hPPAR α mice TCE protected against WD-induced injury as evidenced by a return to control values of white adipose tissue weight, relative fat mass, true lean mass, and percentage body weight change. **Conclusions:** These results demonstrate a sex and strain specific response to TCE exposure in which TCE exposure did not affect the male mice of either strain or the female WT mice but protected against the injury of WD in the female hPPAR α mice. This effect may involve differential PPAR α activation thereby altering the hepatic response to WD and inducing protection from WD-induced injury. These results highlight the importance of considering sex and strain specific factors when evaluating environmental exposures alongside dietary factors.

PS 3632 Liver Injury in the U.S. Population: The Combined Impact of PFAS and VOC Mixtures

N. E. Gentile¹, E. Costello², S. Li³, Y. Jung¹, J. A. Goodrich¹, Z. Li¹, S. E. Fenton⁴, D. V. Conti¹, S. P. Eckel¹, R. McConnell¹, M. Aung¹, and L. Chatzi¹. ¹University of Southern California, Los Angeles, CA; ²Brown University, Providence, RI; ³University of Hawai'i at Mānoa, Honolulu, HI; and ⁴North Carolina State University, Raleigh, NC.

Background and Purpose: Adults in the United States face a growing burden of liver disease, with an estimated one in four adults affected by metabolic dysfunction-associated steatotic liver disease (MASLD). Exposure to environmental chemicals is one contributor to MASLD, with industrial emissions, consumer product degradation, and contaminated drinking water supplies leading to joint contamination of per- and polyfluoroalkyl substances (PFAS) and volatile organic compounds (VOCs). Because these chemicals frequently co-occur across air, water, and household environments, exposure is ubiquitous. Given this widespread co-exposure, this study examined combined associations between PFAS and VOC mixtures and markers of liver injury. **Methods:** We analyzed nationally representative dataset of adults aged ≥ 20 years participating in the National Health and Nutrition Examination Survey (NHANES) cycles 2003-2012. Exposures included four serum PFAS (PFOA, PFOS, PFHxS, PFNA) and three VOCs (bromomethane, xylene, chloroform) with detection frequencies $\geq 70\%$. We utilized covariate-adjusted multiple linear regression with the R Survey Package to assess associations between PFAS (log_e-transformed), VOCs (ln-transformed), and alanine-aminotransferase (ALT; ln-transformed), a biomarker of hepatocellular injury. Liver injury was defined using established clinical thresholds of ALT ≥ 33 U/L in males and ≥ 25 U/L in females for both single-pollutant and mixture analyses. Quantile g-computation models were then applied to evaluate the joint associations of PFAS and VOC mixtures, modeled on their original (untransformed) scale following quantile g-computation recommendations, with ALT (ln-transformed) and liver injury prevalence. **Results:** Across individual PFAS, higher serum concentrations were consistently associated with elevated ALT. Perfluorononanoic acid (PFNA) showed the strongest association, with each doubling in PFNA concentration corresponding to a 3.0% increase in ALT levels (95% CI: 1.4%-4.6%) and a 20.5% higher odds of liver injury (95% CI: 7.3%-35.4%). Each tertile increase in the PFAS mixture was associated with a 6.8% higher ALT (95% CI: 2.7%-11.0%) and a 34.9% higher odds of liver injury (95% CI: 13.8%-60.1%). In contrast, the VOC mixture was not significantly associated with ALT (1.7%; 95% CI: -2.7%-6.2%) or liver injury (15%; 95% CI: -9.1%-45.0%). The combined PFAS+VOC mixture showed the strongest association, with each tertile increase corresponding to a 7.1% higher ALT (95% CI: 0.7%-13.9%) and a 42.5% higher odds of liver injury (95% CI: 7.3%-89.3%). Within the combined mixture, chloroform contributed most inversely, while bromomethane, PFNA, and PFOA contributed most positively to both outcomes. **Conclusions:** Combined PFAS and VOC mixtures were more strongly associated with elevated ALT and increased risk of liver injury than PFAS mixtures alone. These findings suggest that co-exposure to PFAS and VOCs may amplify liver injury risk beyond that observed for PFAS exposure alone.

PS 3633 Increased levels of interindividual variation in dose reduces population risks from synergistic interactions

P. Price. Risk Sciences International, Cedar Rapids, IA.

Background and Purpose: Synergistic interactions between chemicals are a concern in mixture risk assessments since they can generate responses that would not occur if the chemicals were administered separately. Synergistic interactions are also a concern since they may produce risks that exceed the risks predicted by the dose-addition models that are typically used to assess combined exposures. In this project, we analyzed the impact of different levels of interindividual variation of doses on mixture risks in a population that received doses of two chemicals that have a synergistic interaction and determined if higher levels of variation resulted in reduced risks. Higher levels of interindividual variation in dose have previously been shown to reduce risks from combined exposures that follow dose addition models but the impact of increases in variation on chemicals that have synergistic interactions has not been investigated. **Methods:** The goal of the assessment is to measure mixture risk which is here defined as the increase in the fraction of the population that receive unsafe combined exposures that is caused by a synergistic interaction. The model used in this analysis is based on an interaction between two chemicals. The analysis assumes that both chemicals are regulated and the fraction of the population receiving doses of concern are limited to a small fraction of the population (e.g., 0.01 or 0.001). The impact of the synergistic interaction is assumed to result in a reduction of the safe dose of both chemicals by either a factor of ten or three (co-synergy). The synergistic interaction is also assumed to be dose dependent and to occur only when the dose of the other chemical exceeds 0.1 of the chemical's original permitted dose (e.g., synergy is assumed to occur at doses ten-fold below doses that cause adverse effects). The interindividual variations in the doses of the two chemicals received by the population are assumed to be independent and to follow log normal distributions. For simplicity, the doses of the chemicals are assumed to have the same distribution. The model does not consider temporal variation in doses and can be viewed as a model of acute toxicity with exposures occurring on a single day. A probabilistic model is created that assigns each individual a dose of the two chemicals by randomly sampling the dose distributions. The parameters for the distributions were derived based on the geometric standard deviation (GSD) and the level of residual

risk permitted under the regulations. Decision rules are created for determining if the combined exposures are safe based on the assumptions described above. Separate analyses were performed for 1) log-normal distributions with different GSDs (1.77, 3.16, and 5.6), 2) different levels of synergy (three-fold and ten-fold reduction in safe levels), and 3) different levels of residual risk (0.01 and 0.001). The three GSD values used correspond to ratios of 10, 100, and 1,000 for the doses received by the 98th and 2nd percentiles of the population. **Results:** The results of the analysis found that increases in interindividual variation in dose reduced the mixture risks for all of the combinations of synergy and residual risk assessed. At a residual risk of 0.01 and a synergy based reduction of ten, the mixture risks declined from 0.91 to 0.026. At a residual risk of 0.001 and a synergy based reduction of three, the mixture risks declined from 0.18 to 0.0005. These reductions occurred because individuals received lower doses of one or both chemicals when the upper bound is fixed by the permitted doses of the individual chemicals and the interindividual variation in dose is increased. **Conclusions:** The implication of this work is that when a population has high levels of interindividual variation in dose and the upper bounds of the dose distributions are protective, then the potential for synergistic interactions to cause population risks is small. This suggests that synergy may be a greater concern for sources of exposure that produce similar doses across large portions of the exposed population.

PS 3634 Western Diet and Environmental Chemical Exposures: A Transcriptomic Approach

Z. Zimmerman, S. Yuan, R. Harris, N. Price, J. Beier, and A. P. Sanders. University of Pittsburgh, Pittsburgh, PA.

Background and Purpose: Populations living in areas of the Rust Belt in the north-eastern US may face unique environmental chemical exposures due to a history of industrial activities, followed by economic decline, then reinvestment. Prior work suggests that there may be increased risk of exposure to environmental chemical mixtures such as metals and per-/poly-fluoroalkyl substances (PFAS). Alongside chemical mixture exposures, a Western diet (WD) consisting of excess dietary fat is associated with a substantial burden of major cardiometabolic and chronic diseases. While adverse cardiac effects of Western diet consumption are understood, specific cardiotoxic pathways that may be altered due to co-exposure with real-world environmental chemical mixtures are not well studied. In this study, we examined the transcriptomic effects of chronic Western diet and environmental chemical mixture co-exposure in heart tissue. **Methods:** We previously defined the 'R2R' chemical mixture derived from biomonitoring metal and PFAS exposures among pregnant women in southwestern Pennsylvania. The mixture comprises 20.1% cadmium, 10.5% arsenic(III), 15.1% lead, 19.5% perfluorooctanesulfonic acid (PFOS), and 34.8% perfluorooctanoic acid (PFOA). Groups of 6-8 week-old C57Bl/6J mice received either a 13% fat control diet (CD) or a 43% fat Western diet (WD). Mice were then exposed to vehicle control, R2R mixture at 1x (R2R₁) and 100x (R2R₁₀₀) concentrations, or arsenic positive control via drinking water for 12 weeks. Hearts were collected and total RNA was extracted. Bulk RNAseq was performed followed by differential gene expression and pathway enrichment analyses. Differentially expressed genes (DEGs) were identified using a log2fold-change threshold of ± 0.5 and Benjamini-Hochberg adjusted p-value of < 0.05 . Pathway enrichment analysis was performed with a z-score threshold of $|z| > 2$. **Results:** We identified a greater number of significant DEGs in cardiac tissue associated with co-exposure to WD and R2R mixture than with individual diet or mixture exposure alone. We identified 2107 DEGs among co-exposed hearts (WD + R2R₁₀₀) compared to 1769 for high fat diet (WD) exposure alone or 107 for mixture (R2R₁₀₀) exposure alone. Further, we observed a trend for downregulated DEGs which represented 71% of co-exposure (WD+R2R₁₀₀) DEGs, 82% of Western diet DEGs, and 98% of R2R₁₀₀-associated DEGs. Pathway enrichment analysis of high fat diet (WD) identified activation of cardiotoxicity pathways involved in heart failure, congestive heart failure, dilated cardiomyopathy, and arrhythmia. Under mixture stress alone (R2R₁₀₀), pathways identified include activation of genes enriched for cardiomyopathy and cardiac enlargement. Consistent with individual high fat diet (WD) and mixture (R2R₁₀₀) exposure samples, co-exposure (WD+R2R₁₀₀) showed pathway activation of genes involved congestive heart failure, necrosis of cardiac muscle, and cell death. **Conclusions:** We observed evidence that Western diet and population-relevant co-exposure to common metal and PFAS toxicants resulted in dysregulation of cardiac gene expression. Pathway analysis suggests that co-exposure to a high fat diet and environmental chemical mixtures affects genes critical for heart health with pathways distinctly enriched for cardiac cell death that were not associated with either diet or mixture exposure alone. Our findings suggest that chronic exposure to low-level environmental chemical mixtures, combined with a typical Western diet, likely compound and contribute to poorer heart health.

PS 3635 Mitochondria-enriched extracellular vesicles as mediators and biomarkers of endothelial stress induced by polycyclic aromatic hydrocarbon mixtures

C. Chauvin¹, J. Guilloze¹, V. Genet¹, E. Vidal², H. Amessird², A. Burel³, N. Soler³, F. Barathon¹, O. Sergent¹, N. Podechard¹, C. Cloteau⁴, J. Froger^{5,6}, S. Le Lay^{5,6}, C. Elie-Caille², B. Brunel², W. Boireau², L. Sparfel¹, and É. Le Ferrec¹. ¹Univ Rennes, Irset INSERM UMR_S 1085, Rennes, France; ²Université Marie et Louis Pasteur, CNRS, Institut FEMTO-ST, Besançon, France; ³MRic Cell Imaging Platform, BIOSIT, Univ Rennes, Rennes, France; ⁴Nantes Université, Mshark, Biocore, Nantes, France; ⁵Nantes Université, CNRS, INSERM, Institut du Thorax, Nantes, France; and ⁶Université Angers, SFR ICAT, Angers, France. Sponsor: M. BURBANK

Background and Purpose: Chronic exposure to polycyclic aromatic hydrocarbons (PAHs), persistent environmental pollutants commonly found in food, is associated with mitochondrial dysfunction, leading to oxidative stress, impaired energy metabolism, and activation of apoptotic pathways. Mitochondria are thus emerging as key targets of PAH toxicity. Endothelial cells, located at the blood-tissue interface, are also sensitive to circulating PAHs and respond by increasing the production of extracellular vesicles (EVs). These EVs may carry mitochondrial components (Mito-EVs), which could reflect mitochondrial status and mediate intercellular communication. This study aimed to (i) assess how PAH mixtures influence the release of EVs and their mitochondrial cargo by human endothelial cells, (ii) characterize EV subpopulations and their biochemical signatures using an integrated workflow, and (iii) investigate the biological effects of EVs derived from endothelial cells exposed to PAHs on immune recipient cells. **Methods:** Human microvascular endothelial cells (HMEC-1) were exposed for 24 h to 100nM of benzo[a]pyrene, of a 4-PAH regulatory mixture, or of a complex 18-PAH mixture representative of human dietary exposure. EVs were isolated by ultracentrifugation and fractionated by density-gradient centrifugation. This fractionation, combined with a multi-approach characterization pipeline - nanoparticle tracking analysis, transmission electron microscopy, flow cytometry, Western blot, Raman spectroscopy, Surface Plasmon Resonance imaging (SPRi), lipidomics, proteomics, and mitochondrial DNA (mtDNA) quantification by digital PCR - allows identification of biochemical fingerprints of EVs derived from HMEC-1 cells exposed to PAHs alone or in mixture. **Results:** All PAH exposures significantly increased the total release of EVs and Mito-EVs, with the strongest effects observed with the 18-PAH mixture. Density-gradient fractionation revealed the presence of distinct EV subpopulations, including Mito-EVs and mitochondria-depleted EV fractions. The intravesicular presence of intact mitochondria - either polarized or depolarized - as well as their mitochondrial protein, lipid, and mtDNA content, was subsequently evaluated after PAH exposure. Raman spectroscopy analyses highlighted modifications in both quantity and secondary structure of vesicular proteins, allowing discrimination between the PAH exposure conditions. The interaction of EVs from crude-conditioned media with multiple ligands was then monitored using a SPRi approach. These studies revealed distinct response patterns for potential EV surface markers, including CD36 and ATP synthase. The biological impact of Mito-EVs and mitochondria-depleted EV subpopulations was further investigated on the immune recipient cells, using primary human peripheral blood mononuclear cells. Cell viability, oxidative stress, mitochondrial transfer, and bioenergetic alterations were assessed to characterize the functional consequences of exposure to the different EV fractions. **Conclusions:** This integrated workflow, combining density-gradient fractionation with multi-omics and biophysical profiling, enables detailed characterization of EV subpopulations and analysis of the influence of PAH exposure under realistic conditions. Overall, this approach could reveal EV exposure fingerprints associated with environmental pollutants, including mitochondrial signatures, and thus offer a non-invasive tool for monitoring environmental exposure.

PS 3636 Metal Mixtures and Parkinsonism: From Weighted Quantile Sum Regression to Exposure Risk Score-Guided Autoantibody Profiling

F. C. Lewis¹, N. Goulett¹, S. Azmoun¹, D. Sholeb², R. Marquez¹, V. Sundar¹, M. Ali¹, L. Pitta¹, H. Krishnamurthy³, E. Colicino⁴, L. Lambertini⁴, S. Renzetti⁵, D. Placidi², and R. G. Lucchini¹. ¹Florida International University, Miami, FL; ²Università degli Studi di Brescia, Province of Brescia, Italy; ³Vibrant Sciences LLC, Santa Clara, CA; ⁴Icahn School of Medicine at Mount Sinai, New York, NY; and ⁵Università degli Studi di Parma, Province of Parma, Italy.

Background and Purpose: Chronic manganese (Mn) exposure from industrial activities, particularly ferroalloy production in Brescia, Italy, has long been linked to parkinsonian motor symptoms. Yet Mn rarely acts alone. Individuals in industrial regions are often co-exposed to other metals, such as copper, aluminum, chromium, lead and zinc, that may amplify or counteract Mn's neurotoxic effects, complicating single-metal inference. Because these metals are highly correlated and elicit diverse biological responses, mixture-based approaches are needed to capture their joint contribution to Parkinsonism (PD). This question carries growing public health importance as global demand for Mn and other industrial metals used in electric vehicle lithium-ion batteries and alternative green technologies increases the likelihood of chronic environmental exposure. Our previous metabolomic and lipidomic findings suggested that oxidative and immune pathways underlie Mn-associated neurotoxicity (Lewis *et al.*, 2025). To test this further, we performed multiplexed neural autoantibody profiling to examine whether immune reactivity to neurological

antigens mediate metal mixture toxicity. **Methods:** A matched case-control study (N = 97) quantified whole-blood metals by inductively coupled plasma mass spectrometry and neural autoantibodies (IgG/IgA/IgM) by multiplexed chemiluminescent immunoassay. Metals were log-transformed, winsorized (1st-99th percentile), and z-standardized. Conditional logistic regression (CLR) matched on age and sex estimated odds ratios (ORs) and 95% confidence intervals (CIs). Mixture effects were evaluated using two-index weighted quantile sum regression (2iWQS; $q = 3$, 100 bootstraps, 100 repeated holdouts) and adaptive elastic net (AENET) modeling with 10-fold pair-aware cross-validation. The AENET-derived exposure risk score (ERS), computed as the weighted sum of standardized metal concentrations, was assessed using conditional and standard logistic models to estimate odds ratios per SD and evaluate discrimination by ROC area (AUC). ERS-antibody associations were tested using robust linear models adjusted for age and sex with FDR correction. **Results:** Elevated Mn (OR = 2.20, 95% CI 1.27-3.83, $q = 0.039$) and Cu (OR = 2.05, 95% CI 1.15-3.64, $q = 0.039$) were associated with higher odds of PD in univariate CLR. In multivariate models adjusting for co-exposures, Mn remained significant (OR = 3.05, 95% CI 1.12-8.27, $q = 0.087$) and Al showed a positive trend (OR = 2.75, 95% CI 0.89-8.49). The positive WQS mixture (PWQS per 0.5 unit = 3.14, 95% CI 1.47-6.70) was driven by Mn (weight = 0.33), Al (0.28), and Cu (0.25), while the negative index was nonsignificant. The ERS, representing a standardized composite of weighted metals, showed strong associations with PD: conditional logit OR = 8.44 per SD (95% CI 2.19-32.45) and logistic OR = 7.12 (95% CI 3.13-16.18). These larger estimates are appropriate for an index summarizing multiple correlated exposures. The ERS model demonstrated excellent classification (AUC = 0.878, 95% CI 0.80-0.95). Higher ERS values were linked to increased autoantibody reactivity toward dopaminergic and neuronal proteins, including α -synuclein ($\beta = 0.40$, FDR = 0.001), D2 receptor ($\beta = 0.63$, FDR < 0.001), GAD65 ($\beta = 0.41$, FDR = 0.001), Amphiphysin ($\beta = 0.61$, FDR < 0.001), and dopamine β -hydroxylase ($\beta = 0.37$, FDR = 0.003), consistent with immune activation and dopaminergic injury. **Conclusions:** Across conditional and mixture models, Mn and Cu consistently emerged as key contributors to Parkinsonism risk, with Al also playing a role. Both WQS and ERS approaches demonstrated that higher metal co-exposure burdens markedly increased disease odds. While ERS odds ratios appear large, they appropriately reflect cumulative, standardized mixture effects rather than single-metal changes. The accompanying elevation in neural autoantibodies linked to dopaminergic and astroglial pathways suggests that Mn-Cu-Al mixtures may promote neuroimmune activation and early parkinsonian processes.

PS 3637 *In vitro* to *in vivo* Translation of Developmental and Adult Models to assess Neurotoxic Mechanisms of Metal Mixtures

F. C. Sillé¹, B. Karimi¹, N. Chandra¹, B. Kincaid¹, S. Pagadala¹, A. Bhohe¹, S. S. Sanchez¹, B. Yeung-Luk¹, E. Rivera², M. Kohr¹, B. Riess¹, K. Nachman¹, L. Smirnova¹, A. Graves², and S. Biswal¹. ¹Department of Environmental Health and Engineering, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; and ²Department of Biomedical Engineering, Whiting School of Engineering, Johns Hopkins University, Baltimore, MD.

Background and Purpose: Heavy metals such as lead (Pb), arsenic (As), cadmium (Cd), and hexavalent chromium (Cr(VI)) frequently co-occur in contaminated environments, such as Superfund sites, yet their combined neurotoxic effects remain poorly understood. The Neurotoxicity due to Environmental Metal Mixture Exposure (NEMMEX) study investigates developmental and adult exposure to this "PACC" metal mixture, representing U.S. EPA drinking water standards, to uncover shared and age-specific mechanisms of neurotoxicity. Our findings inform risk assessment for how metal mixtures contribute to neurodevelopmental disorders such as Autism, and neurodegenerative diseases such as Alzheimer's Disease and Alzheimer's related Dementia (AD/ADRD). **Methods:** C57BL/6J mice exposed perinatally (2 weeks preconception through weaning), or chronically in adulthood (6wks to 6.5 months of age) to environmentally relevant PACC concentrations or individual metals [at the maximum contaminant levels (MCL) for As (10 ppb), Cd (5 ppb), and Cr(VI) (100 ppb), or maximum action level (ACL) for Pb (15 ppb)]. Behavioral tests assessed memory, anxiety, and locomotion, while electrophysiology (mPFC and CA1) characterized neuronal excitability and synaptic function. Complementary *in vitro* human neural organoids were exposed to the same conditions to examine neuronal differentiation, oxidative stress and synaptic functions. Molecular correlates were further assessed via transcriptomic profiling. We also quantified biomarkers of neurotoxicity and neuroinflammation. **Results:** Perinatal PACC metal mixture exposure caused impaired short-term memory and increased anxiety-like behavior in both sexes without affecting locomotion or working memory. Patch-clamp recordings revealed increased intrinsic excitability and larger spontaneous EPSC amplitudes in mPFC neurons, indicating enhanced postsynaptic responsiveness. Principal component analysis integrating behavioral and electrophysiological features identified distinct neurobehavioral signatures separating mixture-exposed and control mice. Chronic adult exposure similarly impaired memory and anxiety behavior, coupled with increased neuronal injury markers. Human organoids recapitulated key findings, showing oxidative stress, reduced synaptic and progenitor markers, and diminished neural differentiation. Ongoing RNAseq data analyses will identify molecular pathways driving the observed neurobehavioral phenotypes and cross-validate conserved mechanisms between animal and organoid systems. **Conclusions:** Our comparative findings demonstrate that environmentally relevant metal mixtures elicit persistent, sex-dependent neurobehavioral and physiological alterations across life stages. The convergent results across models highlight oxidative stress, neuroinflammation, and

disrupted synaptic signaling as shared adverse outcome pathways (AOPs). These insights support mixture-based risk assessment frameworks and regulatory efforts to protect neurodevelopmental and cognitive health from cumulative metal exposures.

PS 3638 Behavioral Effects and Bioaccumulation of Tire-Derived Compounds in Zebrafish: Unraveling the Chemical Drivers of Acute Sensorimotor Disruption

D. Leuthold, B. Seiwert, D. Zahn, N. Schweiger, M. Zieseniß, R. Owen, and T. Tal. Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany.

Background and Purpose: Tire wear particles (TWP) are an emerging class of environmental contaminants released into surface waters via roadway runoff. Particles leach numerous organic and inorganic constituents, including 6PPD-quinone, a compound linked to acute mortality in Coho salmon. The nervous system has been implicated as a potential target of TWP exposure, though the underlying mechanisms remain poorly understood. This study aimed to identify the chemical components and mechanistic pathways responsible for acute sensorimotor disruption induced by tire tread leachates in zebrafish larvae. **Methods:** Five-day-post-fertilization zebrafish larvae were acutely exposed (1 h) to cryo-milled tire tread (CMTT) leachates (0.1-31.6 g/L, leached for 3 d at 20 °C). Motor behavior was assessed using an automated, video-based assay battery that sequentially evaluated responses to infrared, visible-light, and acoustic stimuli. Organic compounds in leachates and larvae were analyzed by LC-MS, while metals were quantified by ICP-MS. Bioconcentration factors (BCFs) were derived from measured internal and external concentrations. *In-silico* target predictions were performed to identify molecular targets of detected compounds. **Results:** CMTT leachate exposure induced a biphasic increase in total swimming activity (EC50 = 1.2 g/L), peaking at 3.2-10 g/L where larvae were ~2-fold more active than the control ($n = 64$). The effect persisted for ≥ 5 h, with partial recovery 3 h after leachate removal. Behavioral changes were stimulus-specific, affecting responses to infrared and acoustic cues but not visible light responses, suggesting selective disruption of sensorimotor processing. LC-MS analysis of 25 organic compounds revealed a mixture dominated by benzothiazoles (43%), para-phenylenediamines (PPDs; 25%), and phenylguanidines (21%). Several PPDs accumulated in larvae with BCFs up to ~1000 and correlated with compound hydrophobicity (LogD). A synthetic mixture comprising all 25 detected organic compounds failed to reproduce the overall hyperactivity phenotype observed with CMTT leachate, although it specifically altered habituation behavior to repeated acoustic stimuli. ICP-MS revealed zinc (Zn; 0.3-8.6 μ M) as the predominant metal in CMTT leachates. Acute Zn exposure largely recapitulated hyperactivity (EC50 = 10.2 μ M) observed with CMTT-exposed zebrafish, consistent with reported Zn-mediated inhibition of GABA_A receptors. Co-exposure with the GABA_A agonist propofol rescued the CMTT-induced behavioral phenotype, implicating Zn-driven inhibition of GABAergic signaling. However, Zn alone did not account for the complete spectrum of behavioral alterations. Given the distinct, yet notable effect of the synthetic mixture on sensorimotor processing, *in-silico* predictions identified Kv12.2 potassium channels (kcnh3) as a shared target for all eleven detected PPDs. The Kv12.2 inhibitor ASP2905 phenocopied the habituation deficit induced by the synthetic mixture. High phenotypic similarity with both the mixture and ASP2905 was also found with 6PPD, a representative PPD from the mixture. These findings support the contribution of PPD-driven Kv12.2 modulation to the observed behavioral effects. **Conclusions:** These findings demonstrate that acute exposure to tire-derived mixtures rapidly disrupts zebrafish sensorimotor behavior through multi-mechanistic interactions involving both inorganic and organic constituents. Zn and PPDs emerge as co-drivers of GABAergic and potassium channel modulation, likely converging on the observed behavioral phenotype. The identification of Kv12.2 as a novel, previously unrecognized PPD target expands mechanistic understanding of TWP toxicity and may aid in elucidating the mode of action of related compounds such as 6PPD-quinone. This mechanistic insight underscores the need for mixture-specific, mechanistically informed approaches in the environmental toxicology and risk assessment of tire wear emissions to accurately capture the real-world implications of mixture toxicity.

PS 3639 Exploring Synergistic Toxicity Between Açai Extracts and Methotrexate in Human Breast and Vascular Cell Lines

D. Thornton¹, K. Heck¹, M. Patrick², S. R. Pondugula¹, J. Shen¹, and A. I. Calderón¹. ¹Auburn University, Auburn, AL; and ²Florida State University, Tallahassee, FL.

Background and Purpose: Breast cancer is the most common and deadly cancer in women worldwide, leading many survivors to use botanical dietary supplements (BDS) like açai to improve quality of life and ease treatment symptoms. Açai has antioxidant, anti-inflammatory, and antiproliferative effects, but its use alongside anticancer drugs raises toxicological concerns. FDA reports show increased cardiovascular events, such as chest pain and pulmonary thrombosis, linked to açai combined with certain chemotherapies not metabolized by CYP3A4. These suggest possible drug-supplement interactions that may worsen toxicities or affect drug metabolism, yet no mechanistic studies exist. Therefore, thorough toxicological research is urgently needed to understand how açai impacts the safety and effectiveness of these anticancer drugs. **Methods:** Açai fruit powder extracts from a trusted

Brazilian supplier, along with two commercial açai BDS brands, were standardized for cyanidin-3-O-glucoside (C3G) content. These extracts were tested on three breast cell lines: MCF-7 (ER-positive breast cancer), MDA-MB-231 (triple-negative breast cancer), and non-tumorigenic MCF-10A cells. Cell viability was measured by MTT assay after exposure to açai extracts alone and combined with methotrexate (MTX). SynergyFinder Plus visualized cell viability to identify synergistic, antagonistic, or additive effects. Apoptosis from the most synergistic combinations was assessed using Annexin V and NucFix viability dyes with fluorescence microscopy to explore toxicity mechanisms. Açai extracts were fractionated by liquid-liquid extraction with solvents of varying polarity. These fractions were tested on the breast cell lines and analyzed via biochemometrics to pinpoint toxic compounds. Human umbilical vein endothelial cells (HUVECs) will be tested with extracts and fractions to assess the direct impact of açai-methotrexate interaction on cardiovascular health. **Results:** The single treatments of açai fruit powder and açai BDS extracts showed no significant toxicity when administered alone for the two breast cancer cell lines, MCF-7 and MDA-MB-231. The açai BDS extract showed slight toxicity towards the non-tumorigenic breast cell line, MCF-10A. When combined with MTX, all açai extracts produced at least an additive response, as reported via SynergyFinder Plus for the two breast cancer cells. For MCF-10A cells, there was reported synergistic activity from MTX with açai BDS extracts and the açai fruit powder extract. The combinations with MTX were the highest synergy reported across all cell lines, indicating specific toxicity towards non-cancerous cells with non-CYP3A4 interactive anticancer drugs and açai. No antagonistic interactions were observed. The preliminary fluorescence apoptosis analysis showed a high signal of necrosis from the combination for MCF-10A cells. Subsequently, the three most synergistic açai extracts were fractionated and tested on all 3 cell lines, with the hexane and ethyl acetate fractions showing the most toxicity toward all cells. The fractions were analyzed via LC-MS to produce the top 10 compounds specific to those fractions that may contribute to the toxicity of the whole extract. HUVECs will be subjected to the same analysis of the breast cells to determine whether the toxicity translates to the cardiovascular system, confirming the reports of the adverse events. **Conclusions:** Açai extracts enhance MTX toxicity in both cancerous and normal breast epithelial cells. The increased sensitivity of normal cells raises concerns about potential side effects during combined treatments. Including endothelial cell data will improve understanding of vascular effects, such as impacts on endothelial viability and function, which are vital for drug delivery and tumor microenvironment interactions. This study lays the groundwork for mechanistic research to identify the active compounds in açai responsible for these effects and their influence on endothelial cells, ultimately supporting safer combination cancer therapies.

PS 3640 The therapeutic effects of nobiletin treatment on hypertensive nephropathy via ferroptosis-associated axis

S. Lin¹, H. Kuo¹, S. L², and C. Wu¹. ¹China Medical University, Taichung, Taiwan; and ²National Taiwan University, Taipei, Taiwan.

Background and Purpose: Taiwan is rapidly transitioning into a super-aged society, accompanied by a marked increase in chronic diseases such as hypertension and kidney disease. According to the 2022 report from Taiwan's Ministry of Health and Welfare, mortality related to hypertension—particularly hypertensive nephropathy—has risen from ninth to seventh place over the past decade. *Citrus depressa*, a member of the Rutaceae family, possesses a peel rich in bioactive compounds such as nobiletin, which exhibit antioxidative, anti-inflammatory, and antitumor activities. However, its potential role in attenuating hypertension-induced chronic kidney injury remains insufficiently explored. **Methods:** In this study, molecular docking and a dipeptidyl-peptidase-4 (DPP-4) enzymatic activity assay were performed to evaluate the binding affinity and specificity of nobiletin in renal proximal tubular cells. A uninephrectomized, deoxycorticosterone acetate (DOCA)-salt-induced hypertensive nephropathy (1K/DOCA/salt) mouse model was employed to assess the renoprotective effects of nobiletin and to delineate the associated signaling mechanisms. **Results:** Our findings demonstrate that nobiletin isolated from *Citrus depressa* peel effectively ameliorates renal damage and modulates the ferroptosis signaling network. Molecular docking analysis revealed that nobiletin exhibits a strong binding affinity for the catalytic subunit of dipeptidyl peptidase-4 (DPP-4; PDB ID: 4FFW). Subsequent enzymatic assays confirmed that nobiletin inhibits DPP-4 activity, suggesting its potential to mitigate hypertension-induced renal injury in proximal tubular cells. Moreover, treatment with *Citrus depressa* peel extract or purified nobiletin suppressed ferroptosis-related signaling, as evidenced by reduced expression of DPP4, GPX4, and XCT in a mouse model of hypertensive nephropathy induced by uninephrectomy, deoxycorticosterone acetate (DOCA), and salt loading (1K/DOCA/salt model). **Conclusions:** Collectively, these results indicate that nobiletin exerts renoprotective effects against hypertension-induced kidney injury, potentially through modulation of the DPP-4-ferroptosis axis. This pathway may represent a promising therapeutic target for the prevention and treatment of hypertensive nephropathy.

PS 3641 The study on the safety of cannabidiol isolated from *Cannabis sativa* cultivated in Korea

J. Lee¹, M. Kwon¹, G. Kim¹, Y. Kwon¹, T. Kwak², J. Park², S. Nam³, K. Lim⁴, and B. Park¹. ¹Kolmar Korea Co., Ltd, Seoul, Korea, Republic of; ²Gyeongbuk Technopark, Gyeongsan-si, Korea, Republic of; ³Biototextech Co., Ltd, Cheongju-si, Korea, Republic of; and ⁴Ewha Womans University, Seoul, Korea, Republic of.

Background and Purpose: Cannabidiol (CBD) is a major compound derived from *Cannabis sativa* (*C. sativa*), known as a hemp. CBD has been known for its anti-inflammatory, antioxidant and anti-acne effects, and has been utilized and permitted research for medical purposes in hemp regulation-free zone in Korea. However, the adverse effects and safety of CBD associated with its topical exposure are not fully established, highlighting the need for further research. This study aims to evaluate the acute and local toxicity of CBD and its topical formulations, an ointment. **Methods:** An active pharmaceutical ingredient (API) grade cannabidiol (CBD) powder with a purity of ≥99.5% was manufactured from *Cannabis sativa* cultivated in a smart farm. For acute oral and dermal toxicity tests, CBD isolates were administered orally or topically to Sprague-Dawley (SD) rats at doses up to 2,000 mg/kg. To evaluate the skin and eye irritancy of CBD and its topical formulations, CBD isolate and various concentrations of CBD ointments were applied to New Zealand white (NZW) rabbits. Additionally, *in vitro* reconstructed human epidermis (RhE) test method (OECD TG 439) and cornea-like epithelium (RhCE) test method (OECD TG 492) were conducted. Finally, skin absorption tests for CBD isolate and CBD ointments were performed using a skin-like synthetic membrane, Strat-M, with Franz diffusion cell system. Quantification of CBD in collected samples was performed using high-performance liquid chromatography (HPLC). **Results:** The oral and dermal lethal dose (LD50) was determined to be greater than 2,000 mg/kg body weight for both males and females. In the skin irritation test, the CBD ointment was classified as non-irritating *in vitro* but slightly irritating *in vivo*. All test materials were classified as non-irritating to the eyes or not affecting serious eye damage *in vitro*. Additionally, no eye irritation was observed in any of the animals during the observation period (M.I.O.I and I.A.O.I scores were both 0). In the skin absorption test, CBD exhibited moderate percutaneous penetration in a dose-dependent manner. The absorbed amount of CBD was 9,981.24±147.00 µg/cm² for the 1% CBD solution, and 8,256.86±588.07 µg/cm² (1%), 15,788.58±270.06 µg/cm² (2%) to 56,536.43±8,111.47 µg/cm² (4%) for the CBD ointments. **Conclusions:** These results suggest that CBD is considered a topically safe active ingredient in its raw form and topical formulations.

PS 3642 PIPERINE ATTENUATES CISPLATIN-INDUCED TOXICITIES IN RATS: IN VIVO STUDY

K. M. Alharthy. Prince Sattam Bin Abdulaziz University, Alkharij, Saudi Arabia.

Background and Purpose: Piperine, a natural alkaloid compound, was shown to have anti-cancer, anti-depression and anti-diarrhea effects along with its known hepatoprotective and nephroprotective activities. On the other hand, chemotherapeutic agents, such as cisplatin, are known to be associated with various side effects including depression, anxiety, anorexia, congestive heart failure and nephrotoxicity. Moreover, cisplatin and Piperine co-treatment has been showed a synergetic effect against multiple cancer types. Thus, this study was conducted to investigate the ability of Piperine co-treatment to alleviate cisplatin-induced toxicities. **Methods:** Albino male rats (average weight = 250.54 ± 25.3 g) were randomly divided into four treatment groups (n= 5). These groups were vehicle (control), cisplatin (CDDP), piperine (PIP), and cisplatin with piperine co-treatment (CDDP + PIP). All treatments were administered as intraperitoneal injection. PIP (10 mg/ kg) was given for five consecutive days, whereas a single dose of CDDP (6 mg/ kg) was given on the 3rd day of PIP treatment. Splash test was conducted to evaluate depression effects, also body and organs weight were recorded. Moreover, blood brain tissue samples were collected for further biochemical and cellular assessments such as Serotonergic, CREB, BDNF and MAPK pathways. **Results:** Results showed that CDDP treatment significantly increased the grooming latency time (250 ± 38.02 sec.), decreased grooming frequency (1.4 ± 1.02 times/ 5 min.) and grooming duration (13.4 ± 13.47 sec./ 5 min.) compared to control treatment. However, PIP significantly reversed cisplatin-induced depression in CDDP + PIP treatment group (120.25 ± 105.76 sec., 3.25 ± 1.79 times/ 5 min., 34.4 ± 17.11 sec./ 5 min. for grooming latency time, frequency, and grooming duration, respectively with p < 0.05). In addition, blind observational assessment showed that PIP significantly reduced cisplatin-induced diarrhea in CDDP + PIP group by 70% (p < 0.05). **Conclusions:** In conclusion, these findings suggest that adding PIP + CDDP co-treatment may not only increase cisplatin potency as a chemotherapy, but also reduce cisplatin toxicities.

PS 3643 Safety findings for *Cordyceps militaris* fruiting body through USP Admission Evaluation process

A. L. Roe, J. Brooks, R. Ko, J. Barnes, I. Koturbash, and N. Akhtar. USP, Rockville, MD.

Background and Purpose: *Cordyceps militaris* and *Cordyceps sinensis*, are considered valuable edible fungi; they are widely used as functional foods and for medicinal properties in East Asia and, increasingly, in Western countries. *C. militaris* is

the main source of cultivated *Cordyceps* fruiting bodies in international trade. This material is cultivated successfully and available as an ingredient of dietary supplements in the US and Europe. *C. sinensis*, is a TCM made from caterpillar fungus that is used to treat chronic kidney disease. However, due to market unavailability and concerns about heavy metal contamination, *C. sinensis* has been substituted by *C. militaris* and is now incorporated into dietary supplements. Admission evaluations for *C. militaris* and *C. sinensis* were conducted in May 2025 by the United States Pharmacopeia (USP) Dietary Supplement Admission Evaluation and Labeling Expert Committee (DSAE EC). The primary objective of USP admission evaluations is to assess whether ingredients proposed for monograph development present serious risk to human health. Since neither applicable NDIN nor GRAS notices to the FDA were identified at the time of review for either species, comprehensive reviews were conducted. The primary focus of the work presented is on *C. militaris*, with reference to *C. sinensis* for comparative purposes. **Methods:** The admission evaluation was conducted according to USP Guidelines. This process includes a thorough review of clinical and toxicological studies, clinical case reports, and adverse event data. Other important components of an admission evaluation include other pharmacopeial monographs, regulatory standards, chemistry, adulterants and contaminants, intended uses, intake levels, and interactions. The admission evaluation process concludes with ingredients admitted (Class A) or not admitted (Class B) to the USP compendial monograph development process. The DSAEL EC can recommend that articles admitted under Class A include cautionary labeling. Articles are determined to be Class B if the available evidence indicates they present a serious risk to health, or public health concern, that precludes development of a monograph that could be approved for inclusion in the compendia. **Results:** *C. militaris* has not been the subject of GRAS or NDI notifications and is not listed in the US CFR for any food uses, and its use as a dietary supplement under DSHEA has not been confirmed. Results from *in vitro* and *in vivo* genotoxicity studies are negative for *C. militaris*. Although several sub-chronic, repeat-dose oral toxicology studies in rodents did not indicate concerns about *C. militaris*, other rodent toxicology studies indicated potential toxicities, particularly to the kidney. Furthermore, 11 documented cases of acute kidney injury associated with the consumption of legal products containing *C. militaris* in Thailand were identified. Several reports of suspected kidney and liver toxicity were identified among several national pharmacovigilance databases, albeit for '*Cordyceps*' (not further specified). *C. militaris* has been studied in several clinical trials involving healthy and diseased participants, including individuals with chronic kidney disease. These trials included monitoring of basic safety parameters, and no adverse events were reported. However, many of these clinical trials may not have been sufficiently powered to identify specific organ risks, were short in duration to detect adverse events, or relied on self-reporting of adverse effects. **Conclusions:** Clinical trials conducted with *C. militaris* at dosages similar to those recommended by marketed products did not show adverse effects across diverse study populations and treatment durations. However, several animal toxicology studies revealed significant kidney effects, including histopathological alterations at higher doses. Furthermore, documented acute kidney injury in elderly individuals with prolonged use (3 months) of *C. militaris* has been reported. After reviewing these data, along with potential kidney-related signals, the USP DSAEL EC determined that high doses and prolonged exposure to *C. militaris* may pose risks to kidney health, warranting further research to confirm safety. Thus, *C. militaris* was determined to be Class B and not admitted for monograph development at this time. Concerns were not raised for *C. sinensis*, which was admitted as Class A.

PS 3644 Defining the typical composition of spearmint (*Mentha spicata*) aerial parts essential oil: A GC/MS and controlled vocabulary-based approach

D. T. Carter¹, J. T. Dawson¹, A. Poudel², P. Satyal², and C. Bascoul¹. ¹Product Safety, doTERRA, Pleasant Grove, UT; and ²Essential Oil Science, doTERRA, Pleasant Grove, UT. Sponsor: C. Mitchell

Background and Purpose: Essential oils (EOs) are natural complex substances typically composed of dozens of chemically distinct constituents, each with a unique molecular structure. Constituents are commonly characterized and quantified by gas chromatography mass spectrometry (GC/MS). However, the naming consistency of constituents has often lacked reproducibility across literature and within the essential oil industry. This inconsistency complicates rapid data integration and reduces ease of comparison across studies. Establishing unified nomenclature through development of a controlled vocabulary (CV) for essential oil constituents, together with standardized reporting of their relative abundances, would define a typical composition for an essential oil. This typical composition could then be linked with constituent and whole-oil toxicological data and inform essential oil safety assessments. GC/MS data on spearmint (*Mentha spicata*) aerial parts EO was collected, and a typical composition was generated. **Methods:** 21 GC/MS reports, analyzed from 2018-2025, on spearmint EO were gathered and integrated into a database. The EO data analyzed was on Indian sourced, steam distilled, and re-distilled spearmint (*Mentha spicata*) aerial parts EO. Compound names were unified into a CV by evaluation of the chemical structure of constituents, and sorted by criteria such as stereochemistry, bond constitution, known synonyms, shared CAS number, and other metrics. Descriptive statistics were derived by evaluating each chromatographic peak in the chromatogram, summing the corresponding values for the constituents in each compound group, and calculating the mean, median, minimum, maximum, and standard deviation values for each. Frequency of constituent appearance was

also evaluated, and histograms were generated for each compound to assess distribution. The 25 most abundant constituents in the material, as detected by GC/MS, are included in the typical composition. **Results:** In the 21 GC/MS reports analyzing spearmint EO, carvone was found to be the primary constituent, with a median abundance of 58.03%. Other constituents $\geq 1\%$ include limonene (21.28%), dihydrocarvone (2.45%), myrcene (2.17%), 1,8-cineole (2.14%), bourbonene (1.49%), β -caryophyllene (1.09%), menthol (1.06%), and β -pinene (1.06%). The constituents with the most variation in nomenclature in this GC/MS dataset were found to be β -caryophyllene and carveol, each with 7 different variations of their respective names. In the top 25 compounds reported, an average of 3.32 name variations per constituent were found. **Conclusions:** Developing typical compositions based on standardized nomenclature and quantitative profiling can inform the safety assessment of essential oils. Having the expected range and average relative abundance of key constituents also allows for the compositional comparison of an EO standard to compositions in whole-oil toxicology studies in order to weigh relevance. In cases where compositions vary greatly, the established CV enables direct linkage between compositional data and constituent-specific toxicological information, and a constituent-based assessment approach can be taken. The spearmint EO typical composition illustrates how defining compositional baselines allows constituent variability to be systematically unified and can be used to inform its safety assessment. This approach facilitates cross-study comparability, providing a robust foundation for establishing relevance and informing safety assessment. Additionally, typical compositions may increase interoperability, influencing and supporting other important toxicological approaches and industry demands. These may include quantitative comparison for quality evaluation, efficacy studies including clinical trials and mechanistic *in silico* or *in vitro* studies, exposure surveys, regulatory reviews, and many other applications.

PS 3645 Chemical Profile and In Vitro Evaluation of Hydroalcoholic Extracts from *Hyptis lantanifolia* and *Ageratina popayanensis* Obtained from Plants Grown in Colombia

C. Valdelamar-Caballero¹, J. Olivero-Verbel², P. Quintero-Rincón^{1,3}, and K. Caballero-Gallardo^{1,4}. ¹Functional Toxicology Group. School of Pharmaceutical Sciences, Zaragocilla Campus. University of Cartagena, Cartagena, Colombia; ²Environmental and Computational Chemistry Group. School of Pharmaceutical Sciences, Zaragocilla Campus. University of Cartagena, Cartagena, Colombia; ³Research Group Design and Formulation of Medicines, Cosmetics, and Related, Faculty of Pharmaceutical and Food Sciences, Universidad de Antioquia, Medellín, Colombia; and ⁴Environmental and Computational Chemistry Group. School of Pharmaceutical Sciences, Zaragocilla Campus. University of Cartagena., Cartagena, Colombia.

Background and Purpose: The use of medicinal plants is a deeply rooted component of traditional knowledge in many human communities. For centuries, diverse plant species have been employed to address a wide range of health conditions. In many developing countries, phytomedicine remains the first line of treatment for various signs and symptoms. However, numerous plant species have not yet been scientifically investigated, and much of the ancestral knowledge preserved by traditional healers continues to be largely unexplored. In this context, the present study aims to evaluate the chemical composition, and flavonoid, phenolic, and tannin contents, as well as the *in vitro* UV-protective, antioxidant, and cytotoxic activities of *Hyptis lantanifolia* and *Ageratina popayanensis* obtained from plants grown in Colombia. **Methods:** The chemical composition of two extracts was analyzed using UHPLC/ESI-Q-Orbitrap-HRMS, the total phenolic, flavonoid, and condensed tannins contents were determined using the AlCl₃, Folin-Ciocalteu, and vanillin-H₂SO₄ methods, respectively. The antioxidant activity and photoprotective capacity were evaluated by spectrophotometry. The cytotoxicity of the extracts was measured over a concentration range of 4-250 µg/mL in Calu-1 and HepG2 cells using the MTT assay, and intracellular ROS production was monitored using the H₂-DCFDA probe. **Results:** UHPLC/ESI-Q-Orbitrap-HRMS analysis revealed that the hydroalcoholic extract of *H. lantanifolia* is characterized by methoxylated and glycosylated flavonoids, together with phenolic acids such as caffeic and rosmarinic acids. In contrast, *A. popayanensis* is dominated by hydroxycinnamic acids, particularly caffeoylquinic and dicaffeoylquinic acids, as well as glycosylated flavonoids including rutin and kaempferol-3-rutinoside. The hydroalcoholic extract of *H. lantanifolia* exhibited the highest flavonoid content (>170 mg RE/g DT), whereas *A. popayanensis* had the highest phenolic (>190 mg GAE/g DT) and condensed tannins (>40 mg CE/g DT) contents. *A. popayanensis* showed good DPPH radical scavenging activity with a concentration-dependent relationship. Both extracts showed photoprotective properties (SPF_{in vitro}: >30) and long-wavelength UVA protection (λ_c > 370 nm). In the cytotoxicity assays, *H. lantanifolia* showed a dose-dependent reduction in cell viability, with IC₅₀ values of 116 µg/mL in Calu-1 cells and 216 µg/mL in HepG2 cells. In contrast, *A. popayanensis* exhibited minimal cytotoxicity, with markedly higher IC₅₀ values (>250 µg/mL for both cell lines), maintaining viability close to control levels across most concentrations. At 15.63 µg/mL, neither *H. lantanifolia* nor *A. popayanensis* induced increases in intracellular ROS levels in either cell line. **Conclusions:** The distinct phytochemical signatures and bioactivities of these two Colombian species reveal their potential as valuable sources of bioactive metabolites. Their strong *in vitro* photoprotective and antioxidant effects, together with moderate-to-low cytotoxicity and absence of ROS induction, support further bioprospecting and functional characterization for pharmaceutical and cosmeceutical applications. Minciencias - University of Cartagena (Grant: 116688, call 969-2025).

J. L. Newell-Caito¹, S. Kovacs¹, S. Caito², and T. Fasulo². ¹University of Maine, Orono, ME; and ²Husson University, Bangor, ME.

Background and Purpose: The development of therapeutics for the prevention of life-threatening diseases such as neurological disease, heart disease, and cancer is becoming more urgent every day. Currently, over one in three people are affected by neurological conditions which are the leading cause of human illness and disability. Natural remedies to cure illness have been utilized throughout history due to their abundance of polyphenols. Polyphenols are a diverse group of natural compounds found exclusively in plants that are studied for their antioxidant effects. The polyphenols found in the seaweed *Fucus vesiculosus* (bladderwrack) could contribute to bioactivity and have therapeutic effects. Research suggests that polyphenols can help combat oxidative stress, which is linked to various chronic diseases, including neurodegenerative conditions, cardiovascular disorders, and cancers. MnCl₂ is known to cause neurodegenerative diseases including Parkinson's disease and Alzheimer's disease. *Caenorhabditis elegans* has been used to examine the neurotoxicity of MnCl₂ due to its conserved pathways related to oxidative stress, making it a suitable model for human research. We hypothesize that polyphenols extracted from bladderwrack algae extract (BAE) will exhibit antioxidant properties in the nematode worm, *C. elegans*, when exposed to the oxidant manganese (II) chloride (MnCl₂). **Methods:** Total phenolic content was determined using the Folin-Ciocalteu method using gallic acid as the standard and reading the absorbance at 750 nm. Dose response-survival curves were created using L1 stage worm pretreated with increasing concentrations of BAE for 30 minutes in survival assays to determine the lethal dose in *C. elegans*. For survival curves with MnCl₂, worms were pre-treated with BAE for 30 minutes followed by treatment with varying MnCl₂ concentrations for 30 minutes. The lifespan of *C. elegans* when pre-treated with 7.5% BAE +/- 5 mM MnCl₂ was determined. DCFDA fluorescence was used to quantify reactive oxygen species (ROS) after exposure to MnCl₂ in presence or absence of BAE. Activation of the oxidative stress response genes was measured using the fluorescent reporter worm strain VP596. **Results:** Three separate extracts of the bladderwrack algae were created, and the total phenolic content of the BAE was determined to be 360 +/- 85 mg gallic acid equivalents per mg of dry material. The dose-response survival curve determined the LD₅₀, LD₂₀, and LD₁₀ values of BAE to be 40%, 7.5%, and 1%, respectively. Since oxidative stress decreases lifespan of *C. elegans*, worms were pre-treated with BAE prior to MnCl₂. Treated worms had a 2-day increase in median survival increased in the presence of BAE. Total reactive oxygen species (ROS) were measured in the presence of BAE and MnCl₂, revealing a two-fold, dose-dependent decrease in ROS with BAE pre-treatment. The oxidative stress reporter assay showed a two-fold decrease in MnCl₂-treated *C. elegans* pre-treated with 7.5%, and 1% BAE. **Conclusions:** Taken together BAE contains polyphenols which can effectively prevented oxidative damage as seen by a decrease in ROS, increase in lifespan, and decrease in activation of the antioxidant stress pathway. These results suggest that BAE reduces oxidative stress through multiple mechanisms, supporting its potential as a natural therapeutic agent for promoting cellular health and stress resistance.

PS 3647 Mechanisms of action of four major constituent cannabinoids in hemp extract

X. Gao, M. R. Yourick, K. Campasino, Y. Zhao, E. Sepehr, C. Vaught, R. L. Sprando, and J. J. Yourick. Division of Toxicology, Office of Chemistry and Toxicology, Human Foods Program, US FDA, Laurel, MD.

Background and Purpose: Hemp and hemp extracts may contain a variety of different cannabinoids, such as cannabidiol (CBD) cannabichromene (CBC), cannabigerol (CBG), and cannabinol (CBN). CBD has been extensively studied and reported to cause hepatotoxicity in clinical trials and research studies, little is known about the safety of other cannabinoids. In the current study, we set out to understand the mechanism(s) of action of these cannabinoids, beneficial or adverse, through a comprehensive functional analysis of a recently published transcriptomic dataset. **Methods:** iPSC-derived hepatocytes were exposed to 40 µM CBC, 20 µM CBD, 40 µM CBG, and 10 µM CBN, respectively, for 24 h. Gene expression changes were profiled using Affymetrix GeneChip PrimeView Human Gene Expression Arrays. Functional analysis was conducted using Ingenuity Pathway Analysis (IPA). **Results:** Each compound impacted a unique list of canonical pathways, upstream regulators, diseases and biological functions, toxicity functions, and gene interaction networks with distinctive activation/inhibition patterns. Based on the overall IPA outcome, the cannabinoids were predicted to affect metabolism and to possibly have some beneficial effects on cardiovascular disease but adverse effects on the neural system. In addition, CBC and CBN, similar to but more potently than CBD, displayed liver toxicity and cancer-inducing potential while CBG protected from these adverse effects. **Conclusions:** This study provides a comprehensive comparison across the four cannabinoids on the health effects and potential toxicities associated with their use. Further studies are needed to clarify the effects on cardiovascular disease and the oncogenic potential of these compounds.

C. Ji¹, Y. Liu², A. L. Roe³, M. Lawless⁴, J. Hsieh⁵, and M. Chen⁶. ¹Office of Innovation and Analytics, Agency for Toxic Substances and Disease Registry (ATSDR), Centers for Disease Control and Prevention (CDC), Atlanta, GA; ²Division of Toxicology, Office of Chemistry and Toxicology, Office of Laboratory Operations and Applied Science, Human Foods Program, U.S. Food and Drug Administration, Laurel, MD; ³The Procter & Gamble Co., Cincinnati, OH; ⁴Simulations Plus, Lancaster, CA; ⁵Biomolecular Screening Branch, Division of the National Toxicology Program, National Institute of Environmental Health Sciences, Research Triangle Park, NC; and ⁶Division of Bioinformatics and Biostatistics, National Center for Toxicological Research, U.S. Food and Drug Administration, Jefferson, AR.

Background and Purpose: The global use of botanical dietary supplements highlights the need for cost-effective and mechanistically informative approaches to ensure consumer safety. To address these gaps, the Botanical Safety Consortium was established to advance botanical safety assessment by integrating new approach methodologies (NAMs) into the evaluation of botanicals. Thirteen botanicals: aristolochia, ashwagandha, Asian ginseng, blue cohosh, comfrey, ephedra, goldenseal, green tea extract, kava, kratom, milk thistle, usnea lichen, and yohimbe were selected to represent cases with either known hepatotoxicity or established safety data from the literature. This study aims to 1) develop and apply a multi-tiered *in silico* screening approach to assess potential hepatotoxicity of botanicals, and 2) evaluate the performance of available *in silico* tools for predicting hepatotoxicity in botanicals. **Methods:** In this study, we developed and applied a three-tiered *in silico* screening approach. In Tier 1, several quantitative structure-activity relationship (QSAR) models, including ones in ADMET Predictor, Case Ultra, and Leadscape, were used to predict hepatotoxicity endpoints for 103 constituents in thirteen botanicals, categorized as (1) hepatocellular, (2) biliary, and (3) general liver toxicity. Predictions within the applicability domain were included. Consensus predictions were defined as those with ≥ 50% agreement, representing the majority-vote predictions among the QSAR models for each category. In Tier 2, physiologically based pharmacokinetic (PBPK) models, ADMET Predictor v10.4, were used to estimate maximum plasma concentration (C_{max}) of each constituent. The estimated oral dose for each constituent was derived from the maximum recommended consumer daily intake of the botanical, combined with quantitative chemical analysis of constituent concentrations. A threshold of 1 µM for predicted C_{max} was applied to identify potential hepatotoxic botanical constituents. Constituents with both positive QSAR predictions and C_{max} ≥ 1 µM were classified as positive for human hepatotoxicity. In Tier 3, a botanical was classified as potentially hepatotoxic if at least one of its constituents had a positive prediction in Tier 2. Finally, concordance between the model predictions and the established human hepatotoxicity of the botanicals was used to evaluate the model's predictive performance. **Results:** Of the 13 botanicals evaluated, seven have reported evidence of human liver toxicity: ashwagandha, comfrey, ephedra, green tea extract, kava, kratom, and usnea, whereas the rest have not. In Tier 1, QSAR models predicted that at least one constituent in all 13 botanicals was positive for hepatocellular endpoints, 9 botanicals were positive for biliary endpoints, and 10 botanicals were positive for general liver toxicity. In Tier 2, predicted C_{max} values of all constituents in six botanicals (including ashwagandha, Asian ginseng, and yohimbe) were below 1 µM, indicating that these constituents are either present at low concentrations in the botanicals or have limited bioavailability to reach systemic circulation, making them unlikely to cause liver toxicity. In Tier 3, the hepatocellular endpoint performed best among the three categories, yielding 5 true positives, 4 true negatives, 2 false positives, and 2 false negatives. **Conclusions:** The developed tiered *in silico* approach provides valuable insights for initial screening of liver toxicity of botanicals and their constituents. **Disclaimer:** The findings & conclusions in this presentation have not been formally disseminated by the Centers for Disease Control and Prevention/ Agency for Toxic Substances and Disease Registry and should not be construed to represent any agency determination or policy.

PS 3649 A User-Friendly iPBPK Platform for Predicting Florfenicol and Florfenicol Amine Residues in Sheep and Goats

X. Wu^{1,2}, R. H. Mahbubul^{1,2}, L. A. Tell³, R. E. Baynes⁴, J. L. Davis⁵, F. P. Maunsell⁶, J. E. Riviere⁴, and Z. Lin^{1,2}. ¹Department of Environmental and Global Health, College of Public Health and Health Professions, University of Florida, Gainesville, FL; ²Center for Environmental and Human Toxicology, University of Florida, Gainesville, FL; ³Department of Medicine and Epidemiology, University of California-Davis, Davis, CA; ⁴Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC; ⁵Department of Biomedical Sciences and Pathobiology, Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA; and ⁶Department of Large Animal Clinical Sciences, University of Florida, Gainesville, FL.

Background and Purpose: Florfenicol (FF) is an antimicrobial approved for use in cattle and swine to treat respiratory infections, but it is not approved for use in small ruminants, such as sheep and goats. Extralabel use of FF in these species can lead to violative residues of FF and its metabolite, florfenicol amine (FFA), in edible tissues, posing potential risks to human health. Scientifically based extralabel withdrawal intervals (WDIs) are essential to ensure safety of meat products derived from sheep and goats treated with FF. This study aimed to develop physiologically based pharmacokinetic (PBPK) models for FF and FFA in sheep and goats to predict tissue

concentrations and determine safe WDLs following extralabel FF use. **Methods:** Two flow-limited submodels were constructed for FF and FFA, each consisting of seven compartments (plasma, liver, kidney, lung, muscle, fat, and the rest of the body). The sheep model was calibrated using plasma FF data from intravenous (IV), intramuscular (IM), and subcutaneous (SC) administrations, along with tissue FFA data (liver, muscle, kidney, and fat) from SC exposure. Model evaluation was performed using independent datasets from the Food Animal Residue Avoidance Databank (FARAD). The goat model was calibrated separately using FF and FFA plasma and tissue data from multiple routes of administration and evaluated via independent plasma datasets. Monte Carlo simulations were conducted to characterize parameter uncertainty and population variability. The final model was implemented as a web-based interactive PBPK tool using the R Shiny package to estimate WDLs under various regulatory standards. **Results:** Model validation using independent datasets demonstrated strong predictive performance, with R^2 values of 0.94 and 0.99 for sheep and goats during calibration, and 0.97 and 0.98 during evaluation. Population-based simulations predicted the longest WDL of 42.71 days for a single 20 mg/kg IM dose in sheep based on an operating tolerance of 0.3 ppm in kidney. The predicted WDL for two repeated 40 mg/kg SC doses in goats based on an operating tolerance of 3.7 ppm in liver is 91.21 days. **Conclusions:** The developed PBPK models provide a robust, quantitative framework for predicting FF and FFA residues in sheep and goats. This work advances efforts to establish science-based WDLs, enhances veterinary and regulatory decision-making, and offers a practical, user-friendly web-based tool for estimating WDLs across diverse exposure scenarios.

PS 3650 Cannabinoid and Sensory Evaluation of Cannabidiol and Baby Leaf Hemp in Yuma, Arizona

H. Ha¹, M. C. Leung², and R. N. Masson³. ¹Arizona State University, Phoenix, AZ; ²Arizona State University, Glendale, AZ; and ³University of Arizona, Yuma, AZ.

Background and Purpose: Hemp (*Cannabis sativa*) has been legalized for production and sale in the U.S. since the passage of the Farm Bill in 2018. However, there is a legal cutoff of 0.3% delta-9 tetrahydrocannabinol (THC, by weight) for hemp and hemp-derived products, including cannabidiol (CBD). Additionally, only hulled hemp seed, hemp seed protein powder, and hemp seed oil are considered Generally Recognized as Safe (GRAS) by the U.S. Food and Drug Administration. In this study, we aim to examine the cannabinoid content and sensory properties of CBD hemp and baby leaf hemp (a novel use of the crop) in Yuma, Arizona. **Methods:** In the first part of this study, we conducted a field trial to investigate flowering dates, CBD concentration, and crop limitations across different grow environments. In the second part, we examined growing baby leaf hemp, a novel commodity that was harvested earlier than CBD hemp and unlikely to exceed the legal cutoff of 0.3% THC. **Results:** A total of 17 varieties of CBD hemp (3 auto-flower and 14 day length-dependent) were cultivated at the Yuma Valley and Mesa Stations. The first site represented the alluvial valley soil (Holtville Clay: 18% sand, 46% silt, 36% clay), and the second site represented the sandy mesa soils typical of the region (82% sand, 6% silt, 12% clay). At the Yuma Valley Station, CBD levels tended to be lower. The maximum observed CBD levels per variety ranged from 2.1% to 14.4% with an overall average of 6.1%. The average maximum THC concentration was 0.38%, also lower than in Mesa. At the Yuma Mesa Station, CBD levels were higher, ranging from 4.9% to 14.5% across varieties. The average maximum CBD content per variety was 10.4%, while the average maximum THC content was 0.60%. Notably, some varieties such as Early Spectrum and Z-5 reached CBD levels above 14%. Certain varieties such as Early Spectrum and Z-5 exceeded 14% CBD under Mesa conditions, highlighting the influence of the environment on cannabinoid content. The THC to CBD ratio remained constant over time, suggesting that this measure may serve as a reliable indicator of identifying high-risk candidates with elevated THC levels. Next, two 'drive-thru tasting' events were conducted 18 and 25 days after the planting of baby leaf hemp, and survey data were collected from 86 respondents. Hemp varieties were consistently rated higher in fuzziness compared with traditional leafy greens. The means of hemp varieties ranged between 3.0-3.3 on the scale of 1 (weakest) to 5 (strongest). These were compared to leafy greens such as romaine, kale, and spinach, with the means ranging between 2.3-2.5. Among the hemp samples, Santhica 70 received the highest fuzziness score (3.3), suggesting that textural perception differed between hemp and other leafy greens. Hemp varieties were rated lower in crispiness (means = 2.4-2.7) than leafy greens (means = 2.8-4.0). Both romaine and hemp were perceived as more floral (means = 2.5-3.2), which may be related to romaine consistently being the first sample presented to participants. Additionally, leafy greens are often bred for neutral flavor, which may have accentuated the relative perception of floral notes. Hemp samples were generally considered fruitier (means = 2.3-2.8) than kale (1.6) and more minty (means = 2.3-3.0) than other leafy greens (means = 1.7-1.8). **Conclusions:** Results from the field trial demonstrated clear differences in cannabinoid accumulation between sites. It also demonstrated the influence of environmental factors on cannabinoid content. Grown as baby leaf, hemp varieties were perceived as less bitter and with higher likability than kale. Further studies are needed to characterize such factors and the sensory attributes of hemp varieties, thereby developing hemp as an alternative leafy greens with distinct sensory attributes.

PS 3651 Safety Evaluation of a Sugar Replacement (Honey Truffle Sweet Protein) Derived from Nature

D. B. Mayfield¹, S. Potter², D. Zhao², A. Roberts³, R. Peterson², M. Lloyd⁴, T. Martin⁴, S. Papineni¹, and G. Tosi⁴. ¹Labcorp, Greenfield, IN; ²MycotoTechnology, Inc., Aurora, CO; ³AR Toxicology Inc., Oakville, ON, Canada; and ⁴Labcorp, Harrogate, United Kingdom.

Background and Purpose: Identification of sweetener alternatives has been the subject of intense research to provide a lower calorie substitute for sugar in the diet. Honey truffles (*Mattirolomyces terfezioides*) contain a sweet natural protein referred to as Honey Truffle Sweet Protein (HTSP), which exhibits intense sweetness. HTSP was expressed in *Komagataella phaffii* (formerly *Pichia pastoris*) and produced via precision fermentation. A safety and risk assessment was undertaken for its use as a sweetener in food and beverages. **Methods:** Genotoxicity tests (Ames and micronucleus assays) and a 13-week oral repeated dose study in rats were conducted (according to OECD test guidelines) to assess the safety of Honey Truffle Sweetener Protein (HTSP). **Results:** The results of the *in vitro* bacterial mutagenicity and mammalian cell micronucleus tests demonstrated a lack of genotoxic effects. In the 13-week oral exposure study, male and female Wistar Han rats were dosed by gavage to provide 1800, 3600, and 5400 mg/kg/day of HTSP (equivalent to approximately 500, 1000 and 1500 mg/kg/day of the honey truffle sweet protein active component). Treatment was well tolerated with neither mortality nor HTSP-related adverse clinical pathology findings, organ weight effects, or macroscopic or microscopic observations. **Conclusions:** The no observed adverse effect level (NOAEL) was 5400 mg/kg/day (1500 mg/kg/day honey truffle sweet protein active component). The NOAEL in association with estimated daily human intake (EDI) supports the conclusion that HTSP may be considered safe for use as a dietary sweetener.

PS 3652 Sensitive Detection of Emerging *Alternaria* Mycotoxins with Novel Aptamer- and Antibody-Based Strategies

S. Wu¹, Y. Hsieh², Y. Lin², and F. Yu². ¹Graduate Institute of Toxicology, National Taiwan University, Taichung, Taiwan; and ²Chung Shan Medical University, Taichung, Taiwan. Sponsor: S. Liu

Background and Purpose: Alternariol (AOH) and tenuazonic acid (TeA) are emerging mycotoxins produced by *Alternaria* fungal species that frequently contaminate cereals, oilseeds, spices, and various fruits and vegetables. Chronic dietary exposure to these emerging mycotoxins has been linked to hepatic and renal dysfunction, and potential carcinogenicity, highlighting their importance as food safety hazards. To enable sensitive and specific detection of AOH and TeA residues, this study aimed to develop antibody- and aptamer-based analytical tools, supported by chromatographic validation, for rapid and reliable monitoring of these toxins in food and feed matrices. **Methods:** Polyclonal antibodies specific to AOH and TeA were generated in corresponding New Zealand White rabbits and used to establish competitive direct enzyme-linked immunosorbent assays (cdELISAs). The half-maximal inhibitory concentrations (IC_{50}) were determined to be 46 ng/mL for AOH and 10 ng/mL for TeA, respectively. In parallel, eight single-stranded DNA aptamers—four for AOH and four for TeA—were selected through the SELEX process. Molecular docking simulations identified AOH Apt #4 and TeA Apt #2 as the highest-affinity sequences, which were subsequently validated by noncompetitive enzyme-linked aptamer assays (ELAAs). Complementary HPLC-FLD methods for AOH and TeA quantification were also developed to serve as reference standards. **Results:** The developed cdELISAs demonstrated high specificity and sensitivity, enabling quantitative detection of AOH and TeA within low nanogram per milliliter ranges. Aptamer-based assays constructed using AOH Apt #4 and TeA Apt #2 achieved measurable responses, although their IC_{50} values exceeded 100 ng/mL, indicating relatively lower affinity compared with antibody-based systems. The HPLC-FLD methods achieved detection limits of 0.1 ng for AOH and 20 ng for TeA, with excellent linear correlations ($R^2 = 0.999$). Collectively, these results confirm the successful generation of functional antibodies and aptamers for both mycotoxins and establish reliable immunochemical and chromatographic platforms for their detection. **Conclusions:** This study provides a comprehensive set of analytical tools for monitoring AOH and TeA contamination in food and feed. The developed antibody-based cdELISAs offer high sensitivity and specificity, while the aptamer systems present a promising alternative for future biosensor integration. Together with the validated HPLC-FLD methods, these assays support regulatory surveillance and contribute to enhanced food safety management strategies against *Alternaria* mycotoxin contamination.

PS 3653 Approach for systematically assessing study reliability and relevance in evaluations of monosodium glutamate safety

W. D. Klaren¹, B. N. Rivera¹, A. M. Sheppard², K. Franke¹, and D. S. Wikoff¹. ¹ToxStrategies, LLC, Asheville, NC; and ²ToxStrategies, LLC, Cincinnati, OH.

Background and Purpose: Monosodium glutamate (MSG) is a well-studied food additive. In addition to numerous authoritative assessments of safety, a substantial volume of research is ongoing with MSG; this includes a growing volume of research assessing the ameliorating potential of various substances against purported MSG-induced toxicity. This work set out to develop a framework for evaluating the

combined reliability and relevance of these types of investigations as part of ingredient safety assessments, and subsequently, to apply such to a case study of MSG publications involving co-exposures with other substances. **Methods:** For the development of the framework, key aspects related to internal, external, construct and biological validity were considered with particular focus on the safety of food ingredients. As the evidence base for some food ingredients often contains non-guideline studies, SciRAP was chosen to assess reliability (internal and construct validity) due to its specific development to focus on such studies. To assess the relevance (external and biological validity) study attributes that are fundamental for a food safety risk assessment were considered to ensure the most relevant studies were found. The study attributes included the study design (ensuring relevant and meaningful results), route of exposure (potentially allows for more relevant food exposures), outcomes assessed (apical or complex responses often considered when setting an ADI), and dosing regimen (chronic studies and those at levels below understood NOAELs often provide more insight than high dose acute studies). A categorization scheme was developed for both the reliability and relevance evaluation as well as an aggregate study quality categorization. After development of the framework, a case study was conducted on a unique set of publications related to MSG. Specifically, these studies involved a co-exposure investigating a potential ameliorating effect for a wide range of chemicals. **Results:** The approach assesses the reliability of the studies utilizing SciRAP, and the relevance in context of study design, dose relevance, and biological validity, resulting in an overall categorization of the informativeness of an individual study, or study quality. In a case study application to 39 studies assessing MSG toxicity and ameliorative properties of a variety of substances, no publications were deemed of 'high' study quality for the purpose of assessing safety, due primarily to low relevance to human safety (e.g., use of an acute high dose during neonatal lifestages) and limited reliability in study conduct and reporting. Consideration of the biological plausibility of the reported endpoints further determined the limited informativeness of the studies in understanding MSG safety. **Conclusions:** In all, this work developed an approach for evaluating the combined reliability and relevance of these types of investigations as part of ingredient safety assessments, and subsequently, was applied to a case study of MSG publications involving co-exposures with other substances. Such a framework has applicability to a wide range of food ingredients and offers an approach to thoroughly and reproducibly evaluate the scientific literature. Additionally, the case study did not determine any studies to be of "high" quality indicating limited utility in informing MSG safety.

PS 3654 Cell-Type-Dependent Mechanisms of Patulin Toxicity: Insights from SH-SY5Y and Caco-2 Cell Models

C. Moyano-López¹, P. Llorens¹, J. Olivero-Verbe², C. Juan¹, and A. Juan-García¹.
¹University of Valencia, Burjassot, Spain; and ²University of Cartagena, Cartagena de Indias, Colombia.

Background and Purpose: Patulin (PAT) is a mycotoxin produced by *Penicillium*, *Aspergillus*, and *Byssoschlamys* species, frequently found in apple-derived products. Its exposure poses a risk to human health due to its cytotoxic, genotoxic, and neurotoxic properties (Malir et al., 2023; Zhong et al., 2018). This study compared the toxic effects of PAT on human neuroblastoma (SH-SY5Y) and human colon adenocarcinoma (Caco-2) cell lines, aiming to evaluate its cytotoxicity, alterations in the cell cycle, and cell death mechanisms. **Methods:** Cytotoxicity was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay after 24 and 48 h of exposure to concentrations ranging from 0 to 3 µM. In parallel, cell cycle phases and cell death were analyzed by flow cytometry. **Results:** Results revealed a higher sensitivity of SH-SY5Y cells, showing a significant reduction in viability from 0.19 µM, with IC₅₀ values of 2.5 µM (24 h) and 1.5 µM (48 h). In contrast, Caco-2 cells exhibited a more stable response and even a slight increase in viability after 48 h, with no IC₅₀ values reached at either exposure time. Cell cycle analysis showed that PAT induced marked alterations in SH-SY5Y cells, including M-phase arrest at higher exposure concentrations and a decrease in all cell cycle populations after prolonged exposure. Conversely, in Caco-2 cells, the alterations were mild and transient. Regarding cell death, PAT triggered early necrosis in both lines, followed by apoptotic activation in SH-SY5Y cells and predominant necrosis in Caco-2 cells at intermediate concentrations after prolonged exposure. **Conclusions:** In conclusion, PAT exerts time- and concentration-dependent toxic effects, with significantly greater susceptibility observed in neuronal cells. These differences reflect cell type-specific response mechanisms and highlight the need to consider cellular vulnerability when assessing the toxic risk associated with this mycotoxin. **Acknowledgments:** This work has been funded by the Ministry of Science and Innovation PID2020-115871RB-I00 and by project CIAICO2022/199 of the Ministry of Education, Universities and Employment of the Generalitat Valenciana. CML would like to thank the Generalitat Valenciana and the Conselleria d'Educació, Universitats i Ocupació for the contract associated with the CIAICO/2022/199 project. **References:** Malir, F., Pickova, D., Toman, J., et al. PS 3655 Multiorgan Toxicity of Microbiome-Derived Delta-Valerobetaine in Aged Mice Occurs Through Disruption of Lipid and Lipid-Soluble Vitamin Metabolism

H. Lee, G. Lim, Z. R. Jarrell, J. Jeon, C. Lee, V. Tran, M. L. Orr, Y. Go, and D. P. Jones. Emory University, Atlanta, GA.

Background and Purpose: Toxicologic mechanisms of low dose exposures that contribute to age-related disease remain poorly understood. Declining capacity to maintain homeostatic balance heightens susceptibility to both endogenous and exogenous stressors. Metabolism—an interdependent, multi-organ process—often becomes dysregulated with age, contributing to a wide-array of adverse health outcomes. Recently, the concept of microbiome-derived metabolites as modulators of host metabolism has gained much interest. We previously showed that microbiome-derived δ-valerobetaine (VB), a metabolite enriched in ruminant meat/dairy and produced by gut microbes, promotes weight gain and adiposity in young mice on Western diet. Significant alterations to carnitine shuttle pathway, critical in energy production and fatty acid metabolism, highlighted VB-induced metabolic disruption, providing evidence of a microbiome-derived effect on host metabolism. However, toxicities resulting from microbiome metabolites remain poorly established. Moreover, because such factors may rapidly enter circulation and can act across organs, there is a need to map coordinated, multiorgan metabolic responses. Here, we investigated how dietary exposure to VB affects adiposity and lipid-related metabolism in aged mice, with attention to observable sex differences. **Methods:** 21-month-old C57BL/6J mice on standard mouse diet received drinking water *ad libitum* without (vehicle control) or with 1.62mM VB infused for 12 weeks. Body weight and diet/water intakes were monitored weekly. Perigonadal white adipose tissue (WAT) and interscapular brown adipose tissue (BAT) were collected to assess adiposity. Plasma, liver, kidney, and heart tissues were extracted and analyzed by high-resolution metabolomics. MS features with significantly altered abundance (*limma* analysis, *p* < 0.05) were used for metabolic pathway enrichment analysis with *metformin* 2.2. Abundance of hepatic transcripts for cytochrome P450 enzymes relevant to lipid and vitamin metabolism (CYP2R1, CYP27B1, CYP27A1, CYP3A11) was assessed. Hepatic and plasma lipid contents were evaluated by Oil Red O staining and colorimetric assays for plasma triglycerides and cholesterol, respectively. **Results:** VB increased body weight and WAT:BAT ratio in aged female mice but not in aged male mice. Despite increased adiposity, hepatic steatosis and systemic triglycerides remained unchanged. Interestingly, VB levels were 65% (plasma), 41% (liver), 75% (kidney) higher in aged female mice than in male counterparts despite very similar weekly water intake. Untargeted metabolomics across plasma, liver, kidney, and heart revealed sex- and exposure-dependent metabolic differences. VB predominantly perturbed lipid pathways, including the carnitine shuttle, bile acid biosynthesis, glycosphingolipid metabolism, arachidonic acid metabolism, and fat-soluble vitamin (A, D, E) pathways. Aged females consistently showed perturbation of vitamin D3 metabolism across all organs examined, whereas aged males showed more consistent alteration in vitamin A metabolism. Targeted analyses showed decreases in metabolites related to vitamins A, D, and E, while levels of the parent vitamin forms were largely unchanged. Hepatic mRNA levels of CYP2R1, CYP27B1, CYP27A1, and CYP3A11 were unchanged, suggesting that VB negatively impacts vitamin bioavailability of these vitamins independent of canonical hydroxylase gene regulation. **Conclusions:** Collectively, VB exposure perturbs lipid-associated metabolic networks across multiple major organ systems in both aged male and female mice. VB differentially impacted females, however, by inducing weight gain and altering adipose tissue composition. VB also had more pronounced effects on vitamin D metabolism than observed in males. Vitamin D decrease is one of the hallmarks of aging in women with implication in loss of bone density and osteoporosis, which is far more prominent in women than in men. VB was more impactful in males on vitamin A metabolism. Vitamin A decrease is associated with decreased sperm development, which is also one of the hallmarks of aging in older men. These results identify VB as a microbiome-derived metabolite with a potential for contributing to age-related metabolic dysfunction in a sex-dependent manner.

PS 3656 Dose optimization of tilmicosin against *P. multocida* in swine by physiologically-based pharmacokinetic - pharmacodynamic Model

L. Sun^{1,2}, K. Mi³, Y. Chen^{1,2}, and L. Huang^{1,2,4}. ¹Department of Veterinary Medicine Science, College of Veterinary Medicine, Huazhong Agricultural University, Wuhan, China; ²National Reference Laboratory of Veterinary Drug Residues (HZAU), Wuhan, China; ³Department of Environmental and Global Health, College of Public Health and Health Professions, University of Florida, Gainesville, FL; and ⁴MOA Key Laboratory for Detection of Veterinary Drug Residues, Wuhan, China.

Background and Purpose: Porcine respiratory disease complex causes substantial economic losses in intensive farming, with *Pasteurella multocida* as a key bacterial pathogen. While tilmicosin, a veterinary macrolide antibiotic, has been used to control these infections, its efficacy is increasingly compromised by antimicrobial resistance. This study aims to develop a physiologically based pharmacokinetic-pharmacodynamic (PBPK-PD) model to optimize tilmicosin dosing regimens against *P. multocida*, with the objective of restoring clinical efficacy and extending its clinical lifespan. **Methods:** A physiologically based pharmacokinetic (PBPK) model for tilmicosin in pigs was developed and validated using visual predictive

checks and mean absolute percentage error (MAPE). The model incorporated key tissues such as pulmonary interstitial fluid, liver, muscle, kidneys, and plasma. Using a hollow-fiber infection model, *ex vivo* PK-PD studies were conducted with a highly virulent strain of *P. multocida* selected at the MIC₉₀ level. These studies established PK-PD targets for bacteriostatic, bactericidal, and eradication effects based on drug exposure in plasma and pulmonary interstitial fluid. Corresponding dosing regimens were optimized for each therapeutic endpoint, and a Monte Carlo analysis based on the PBPK model was used to estimate the withdrawal period for the optimized regimen. **Results:** The developed PBPK model successfully characterized tilimicosin pharmacokinetics in key porcine tissues, including pulmonary interstitial fluid, liver, kidneys, and muscle. While the model showed slight overestimation of plasma terminal elimination, it demonstrated acceptable predictive performance overall. Based on hollow-fiber infection model studies, AUC/MIC was identified as the optimal PK-PD index. PK-PD targets in pulmonary interstitial fluid and plasma for bacteriostatic, bactericidal, and eradication effects were 12.13, 28.48, 51.08 h and 7.17, 46.54, 78.66 h, respectively. A 40 mg/kg oral dose administered over three days achieved favorable therapeutic outcomes, with Monte Carlo simulations predicting an 8-day withdrawal period for the optimized regimen. **Conclusions:** This study utilized an integrated PBPK/PD modeling approach to establish the PK-PD target parameters of tilimicosin against *P. multocida* in pigs. Based on these targets, an optimized clinical dosing regimen was developed and a corresponding withdrawal period was proposed, thereby providing a scientific basis for enhancing the clinical efficacy of tilimicosin and delaying the development of bacterial resistance.

PS 3657 Knowledge, Attitudes, and Practices of Pre-Service Teachers Toward Food Additives

F. Z. Sheabar^{1,2}, N. Najami², and R. Hasbani². ¹Panaceas, Midlothian, VA; and ²The Academic College for Education-Haifa, Haifa, Israel.

Background and Purpose: Food additives fall into two main groups: those intentionally added to improve the quality, taste, and appearance of food, and those unintentionally introduced during manufacturing, storage, or transport. While food additives provide clear technological and nutritional benefits, they may also cause health risks such as allergies, behavioral changes, and cancer. Previous studies examined knowledge, attitudes, and behaviors toward food additives among various populations, but little is known about pre-service teachers, who play a vital role in shaping public health awareness. This study aimed to assess the levels of knowledge, attitudes, and behaviors toward food additives among 96 pre-service teachers in a teacher-education college. **Methods:** A quantitative study was employed, using a computerized questionnaire developed specifically for the current study. The study tool was adapted from published and validated questionnaires (Osaili et al., 2023; Ingram, 2020; Bellad & Doyizode, 2017; Jagadeesan et al., 2017; Xue et al., 2021; Kna'an et al., 2022; Dongmo et al., 2023; Omatola, 2017; Oyewande et al., 2019). **Results:** Our findings indicate that females showed higher knowledge (M=0.45) and attitudes (M=0.38) than males (M=0.40; M=0.31). Singles demonstrated higher knowledge (M=0.45) but lower behavior (M=3.47) than married participants (M=0.40; M=3.64). Participants aged 36+ exhibited the highest levels (knowledge M=0.55; attitudes M=0.50; behavior M=3.69). Language majors had higher knowledge (M=0.56) and behavior (M=4.11), while science majors showed more positive attitudes (M=0.54). Fourth-year students reported higher scores across all variables. Druze participants presented higher knowledge (M=0.52) and attitudes (M=0.44), while Muslims demonstrated higher behavior (M=3.59). Positive correlations appeared between knowledge and behavior (r=0.170) and between attitudes and behavior (r=0.177). **Conclusions:** These findings highlight the importance of taking educational initiatives to enhance knowledge, attitudes, and informed behavior toward the benefits and potential harmful effects of food additives among future teachers in charge of education our future generations.

PS 3658 Risk Assessment of Mycotoxin Exposure Through Plant-Based Meat Alternatives from Spain and Portugal

P. Llorens¹, C. Juan¹, A. Juan-García¹, M. Leite^{2,3}, C. Moyano-López¹, K. Salinas⁴, J. Blesa¹, A. Pena⁵, and L. Silva⁵. ¹University of Valencia, Burjassot, Spain; ²National Institute for Agricultural and Veterinary Research, Porto, Portugal; ³REQUIMTE/LAQV, Porto, Portugal; ⁴SRIC, Inc., North Syracuse, NY; and ⁵University of Coimbra, Coimbra, Portugal.

Background and Purpose: Plant-based meat alternatives (PBMA) are gaining popularity as sustainable substitutes for conventional meat products. However, their complex composition (based on cereals, protein isolates, legumes, spices) may increase the presence of fungal metabolites such as mycotoxins. This study aimed to perform a risk assessment of dietary exposure to twenty mycotoxins analyzed in PBMA from Spain and Portugal. **Methods:** A total of 100 PBMA samples (burgers, sausages, nuggets, and mince) were analyzed, and mean concentrations were used to estimate the Estimated Daily Intake (EDI) for the adult population. Exposure was calculated using two consumption scenarios: an average consumer (42.8 g/day; 70 kg b.w.) and a high consumer (100 g/day; P95). Risk characterization was performed using EFSA reference values (TDI, MOE, or TTC) depending on the toxicological profile of each mycotoxin. **Results:** Results showed frequent detection

of emerging mycotoxins such as moniliformin (MON), tentoxin (TTX) and enniatin B (ENNB), whereas regulated mycotoxins like DON, HT-2/T-2 and ZEN were not detected. For most compounds, hazard quotients (HQ) and percentages of TTC were below 1, and margins of exposure (MOE) exceeded 10,000, indicating no concern for health. For the average consumer, only aflatoxin B1 (AFB1) and aflatoxin G2 (AFG2) showed a possible risk, while AFB1, AFG2 and ocratoxin A (OTA) showed MOE values approaching the limit of potential concern in the high-intake scenario. **Conclusions:** The estimated exposure to mycotoxins through PBMA does not represent a health risk for Spanish and Portuguese adults under current consumption patterns. Continuous monitoring and extension of data to other European markets are needed. **Acknowledgements:** This work was supported by the Conselleria d'Educació, Universitat I Ocupació from Generalitat Valenciana under Grant CIAICO2022/199; and FCT/MCTES under Grant UIDB/50006/2020 DOI 10.54499/UIDB/50006/2020 through national funds. Llorens, P. would like to acknowledge the pre-PhD scholarship program of the University of Valencia "Atracció de Talent". **References:** EFSA Panel CONTAM. (2011). *EFSA Journal*, 9(12), 2481. PS 3659 ITALIAN POPULATION UPDATED RISK ASSESSMENT FOR ACRYLAMIDE AND MYCOTOXINS FROM MARKETED BISCUITS

A. Navarré^{1,2}, V. Zingales², H. Berrada², Y. Rodríguez-Carrasco², and L. Izzo¹. ¹Department of Pharmacy, University of Naples Federico II, Naples, Italy; and ²Toxicology Laboratory, Faculty of Pharmacy and Food Sciences, University of Valencia, Valencia, Spain. Sponsor: A. Anadon

Background and Purpose: Italy is one of the European countries with the highest per capita consumption of biscuits, and these foods can become contaminated throughout their production stage, either with acrylamide (AA) formed during cooking (classified as 2A by the IARC and with neurotoxic effects) and mycotoxins, fungal secondary metabolites with harmful effects on health. Knowing the occurrence of these contaminants in marketed foods is essential for assessing population exposure, and therefore risk. This study evaluated biscuits marketed in Italy to determine the occurrence of mycotoxins and AA, using data from the INRAN SCAI IV study on Italian food consumption and anthropometry, updating their risk assessment. **Methods:** A total of 34 samples of biscuits marketed in Italy were analyzed by QuEChERS and UHPLC-Q-Orbitrap HRMS to determine their AA and mycotoxin content (trichothecenes, aflatoxins, zearalenone, ochratoxin A, enniatins and beauvericin). Based on median and P₉₅ biscuit consumption and anthropometric data, the estimated daily intake (EDI) was calculated and used to calculate the margins of exposure (MoE) for AA, and the percentage of the tolerable daily intake or threshold of toxicological concern (% of TDI or TTC) for mycotoxins, in order to assess risk. Four exposure scenarios were modeled using the maximum, minimum, median, and average contaminant levels. **Results:** AA was detected in all samples, and mycotoxins co-occurred in 97%. DON appeared in 68% of samples, ZEA in 6%, BEA in 38%, and at least one ENN in all but one sample. AA levels ranged from 1, B, and B1) between consumption.. **Conclusions:** In this study, the naturally occurring AA and mycotoxins contamination was analyzed in 34 samples of biscuits sold in Italy. Although no sample exceeded the maximum or benchmark levels established by European legislation, a significant number of samples showed co-occurrence of several analyzed food contaminants. The risk assessment revealed a potential hazard for cancer-related effects (MoE <10,000) with median consumption and average levels of AA found, especially among children (aged 1 to 17) of both sexes. In addition, a 100% exceedance of TTC for BEA was observed in children of both sexes (1 to 9 years) with the highest recorded consumption. This is the first study, to the authors' knowledge, to evaluate the co-occurrence of AA and mycotoxins in biscuits samples sold in Italy, and to assess the risk using the most recent consumption data of Italian population. The potential genotoxic effects observed highlight the importance of continuous monitoring of contaminants in products marketed. **Acknowledgements:** This research was funded by MICIU/AEI/10.13039/501100011033/FEDER, UE through the project PID2024-1605270B-I00. A. De Carvalho E Silva¹, A. D. Kallian², D. McDonald³, S. He³, G. D. Loizou¹, K. McNally⁴, A. M. C. Iserle⁵, O. J. Osborne⁶, C. Potter⁶, J. K. Colbourne¹, and M. R. Viant¹. ¹Centre for Environmental Research and Justice (CERJ), University of Birmingham, Birmingham, United Kingdom; ²King's College London, London, United Kingdom; ³AIA Insights, Birmingham, United Kingdom; ⁴Predictive Technologies Division, Certara UK Ltd, Sheffield, United Kingdom; ⁵Health & Biomedicine Department, LEITAT, Barcelona, Spain; and ⁶UK Food Standards Agency, London, United Kingdom. Sponsor: A. De Carvalho E Silva, EUROTOX

Background and Purpose: Tropane alkaloids (TAs) are naturally occurring plant toxins that can contaminate food and feed, leading to recent poisoning incidents. The European Food Safety Authority (EFSA) established a group acute reference dose (ARfD) of 0.016 µg/kg body weight for (-)-hyoscyamine and (-)-scopolamine, while the Joint FAO/WHO Expert Committee on Food Additives derived a point of departure (PoD) of 1.54 µg/kg body weight. Reported levels of TAs in food may exceed these reference values. This study aims to generate comparative data for multiple TAs to prioritise the most potent compounds and determine which should be included for future monitoring by the UK Food Standards Agency (FSA). A four-tiered framework was developed to address this need. Here we report results on Tier 1 and early Tier 2. **Methods:** Tier 1 included literature and database searches, *in silico* identification of molecular initiating events (MIEs), and potency prediction through QSAR modeling. Tier 2 focuses on *in vitro* cytotoxicity and mechanistic testing, Tier 3 on multi-omics analysis to establish molecular PoDs, and Tier 4 on quantitative *in vitro-in vivo* extrapolation (QIVIVE) to derive health-based guidance values. For Tier 1, SMILES structures of approximately 30 TAs were analyzed using DrugEngine (AIA Insights) to predict relevant MIEs and affected pathways. MIEs with credibility scores above 0.65 across all compounds were selected for further evaluation. Regression QSAR models were developed to predict potency against the most relevant MIEs using publicly available data and applied to prioritise a subset of TAs to be tested *in vitro* in tier 2. **Results:** Computational analysis identified mAChRs as the key MIEs associated with TA toxicity, consistent with their known antimuscarinic mode of action. A dataset of ~6100 chemicals with published *Ki* values for muscarinic acetylcholine receptors (mAChRs; M1-M5) from BindingDB supported development of regression QSAR models, which were generated and validated following OECD principles and applied to rank-potency across the 30 TAs. Only compounds with predicted $-\log(Ki) \geq 7.0$ for at least one mAChR were acquired to be tested. Ten TAs were prioritized for *in vitro* evaluation in Tier 2: atropine, scopolamine, 2-hydroxymethylatropine, aposcopolamine, noratropine, anisodine, convolvine, phylalbine, O-acetylscopolamine, and norscopolamine. Tier 2 testing commenced in SH-SY5Y neuronal cells, assessing cytotoxicity (AlamarBlue and SYTOX), mitochondrial membrane potential (MMP; Mitotracker), and intracellular calcium dynamics. Cytotoxicity was observed only at higher concentrations for aposcopolamine, convolvine, and O-acetylscopolamine. Significant MMP reductions occurred for most TAs at high concentrations, except scopolamine (no effect) and noratropine, anisodine, convolvine, and phylalbine (weak or non-significant effects). No increases in intracellular calcium flux were observed, aligning with their action as mAChR antagonists. Further tests and integrative analysis across Tier 2 are underway to refine relative potencies and select candidates for Tier 3 evaluation. **Conclusions:** A four-tiered framework has been developed to assess the toxicological potential of TAs. Findings from Tier 1 were consistent with the known antagonism of mAChRs. Further, predictive regression QSAR models were used to select 10 TAs to be acquired and tested *in vitro*. Early Tier 2 work results were reported, although further *in vitro* tests and an integrative analysis of all tier 2 results are still underway. The reported approach integrates computational modeling, initial mechanistic screening, and extrapolation methodologies to contribute to the UK FSA biomonitoring of the tropane alkaloids to protect the health of consumers.

PS 3661 **Apportionment of Food Safety Guidance Values: Practical Applications for Food Ingredient and Contaminant Exposures**

C. Llewellyn¹, and S. Vandyousefi². ¹J.S. Held LLC, Alpharetta, GA; and ²J.S. Held LLC, Reston, VA.

Background and Purpose: The chemical safety of food impacts all consumers, and the application of toxicological concepts to determine safe exposure levels is a fundamental aspect of food chemical safety assessments. Safe exposure values for intentionally or unintentionally present chemical components in food are established with consideration of total dietary intake. A common misunderstanding in food chemical safety is the misapplication of these values to a single food rather than the whole diet. For example, aspartame, a nonnutritive sweetener used in numerous foods, has an FDA-established acceptable daily intake (ADI) of 50 mg/kg body weight/day, intended for cumulative intake from all sources. Lead (Pb), an unwanted contaminant found in many foods, provides another example. The FDA has set an interim reference level (IRL) for dietary exposure to Pb from foods at 2.2 µg/day for children, reflecting total dietary intake. **Methods:** Using the entire IRL for a single product or consumption occurrence is inappropriate; instead, the dietary contribution of the food product to the overall diet, as determined by US National Health and Examination Survey (NHANES) and What We Eat in America (WWEIA) data, guides the portion the ADI for aspartame and IRL for Pb to be used in safety assessments, ingredient use levels, or for setting science-based specifications in food products

or ingredients. **Results:** A case study is presented as an example associated with the misapplication of the ADI for aspartame in food safety assessment and demonstrates the appropriate approach to apportioning the ADI for beverages to determine appropriate use levels for ingredients such as aspartame. A second case study is presented as an example for the occurrence of Pb in a food ingredient intended for use in food for young children and demonstrates the appropriate approach to apportioning the IRL for Pb. **Conclusions:** Case studies for aspartame and Pb illustrate the necessity of apportioning safe exposure values to ensure appropriate safety assessments and specifications for food products and ingredients.

PS 3662 **development of improved tlc and hplc-dad methods for identification and quantification of quillaia extract type 2**

S. Kwon, S. Cho, and K. Lee. Korea University, Seoul, Korea, Republic of.

Background and Purpose: Quillaia Extract Type 2 is a natural food additive mainly used as an emulsifier, obtained by aqueous extraction and further purification steps of the bark of *Quillaia saponaria* MOLINA. However, the analytical methods described in various national food additives standards, including the Korean food additives code, CODEX Alimentarius, and Japan's specifications and standards for food additives, lack sufficient specificity for reliable identification and quantification. Therefore, this study aimed to improve the analytical methods for Quillaia Extract Type 2 by optimizing thin-layer chromatography (TLC) and high-performance liquid chromatography with diode array detection (HPLC-DAD). **Methods:** For the identification test, TLC was applied to separate the characteristic saponins of Quillaia Extract Type 2. Various ratios of chloroform, methanol, water, and acetic acid were tested to determine optimal solvent conditions. For the quantification test, the extract was acid-hydrolyzed and analyzed by HPLC-DAD using quillaic acid as a standard compound. **Results:** The optimal TLC system was established as chloroform:methanol:water:acetic acid (20:7.5:2:1, v/v/v/v), which produced four distinct saponin spots within an *R_f* range of 0.1-0.5. The developed HPLC-DAD conditions provided accurate quantification of quillaic acid derived from the hydrolyzed extract. Method validation was performed to verify the analytical procedures, and the results satisfied the Codex Alimentarius criteria, satisfying the coefficient of determination ($R^2 \geq 0.99$), intra- and inter-day accuracy (recovery; 80-120%), and precision (RSD; $\leq 22\%$). **Conclusions:** The optimized TLC and HPLC-DAD methods improved the identification and quantification of Quillaia Extract Type 2. These methods enhance analytical reliability by improving the resolution of overlapping spots or peaks and can serve as a foundation for revising international food additive standards related to Quillaia Extract Type 2.

PS 3663 **Human Exposure to FD&C Red No. 3: Maximum Dietary Intake Assessment Using Latest NHANES Data and Toxicological Context**

C. Hoedlmoser, K. Ngo, A. Markle, T. Osako, and L. A. Haighton. Intertek, Mississauga, ON, Canada.

Background and Purpose: FD&C Red No. 3 is a synthetic color additive permitted for use in foods in the European Union and Canada. The acceptable daily intake (ADI) is 0.1 mg/kg/day; derived by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) and the European Food Safety Authority (EFSA) from a no-observed-adverse-effect level (NOAEL) of 1 mg/kg/day from a 14-day human study. FD&C Red No. 3 is used to produce a cherry-red color in various foods and beverages. A color additive petition submitted to the U.S. Food and Drug Administration (FDA) in 2022, included data that showed the development of non-malignant thyroid follicular adenomas in male rats fed high doses of FD&C Red No. 3 for 30 months. Although the FDA has long been aware of this finding, since the finding lacks biological relevance to humans, the use of FD&C Red No. 3 as a color additive was approved by the FDA. Despite the FDA reporting that "the available data does not raise safety concerns for humans", the Delaney Clause (FD&C Act; Chapter VII, section 721) prohibits the addition of compounds found to be carcinogenic in humans or animals to foods or pharmaceuticals. There is no acknowledgement in the Delaney clause that some tumor types and mechanisms of carcinogenesis are not relevant to humans, as it was enacted prior to modern understanding of carcinogenesis (*i.e.*, in 1958). Thus, on 15 January 2025, the FDA was bound by the Delaney clause to revoke the authorization of FD&C Red No. 3 as a color additive in foods and pharmaceuticals. Food producers were provided with a deadline of 15 January 2027 to reformulate their products. The objective of this work is to determine the maximum dietary intakes based on the recent U.S. National Center for Health Statistics' National Health and Nutrition Examination Survey (NHANES) data using a conservative approach. **Methods:** Concentration data and types of foods containing FD&C Red No. 3 as a color additive were obtained from the U.S. FDA and other public sources. Concentrations of FD&C Red No. 3 levels range from <1 to 2.4% in various foods. These data were used in conjunction with food consumption data included in the NHANES 2011-2023 to estimate dietary exposures. Intakes for the consumer-only mean and 90th percentile intakes of FD&C Red No. 3 were determined on an absolute (per person) and per kilogram body weight basis for the total population (ages 2 years and older). The mean and 90th percentile intakes were compared to the ADI for FD&C Red No. 3, as determined by JECFA and EFSA (*i.e.*, 0.1 mg/kg/day). **Results:** Total population (ages 2 years and older) mean and 90th percentile intakes of FD&C Red No. 3 were deter-

mined to be 9.0 and 16.6 mg/person/day, respectively (equivalent to 0.2 and 0.3 mg/kg/day, respectively). These intake estimates are 0.2 mg/kg/day higher than the ADI of 0.1 mg/kg/day. Additionally, when compared to the 2016 exposure assessment conducted by the FDA, the mean and 90th percentile intakes were reported as 3.7 and 4.2 mg/person/day (body weight results not reported), respectively, which is notably lower than the current dietary assessment. **Conclusions:** Conservative assumptions were used which may explain the higher intakes: food products were assumed to contain FD&C Red No. 3 at the maximum specified use levels however, the use levels will vary depending on the nature of the food product; food codes that have or likely have FD&C Red No. 3 were selected using the latest NHANES dataset whereas the 2016 FDA publication used an older dataset; and as the NHANES dataset does not indicate if certain food dyes are present in a food code, when selecting food codes for inclusion a conservative approach was taken in which generic or broad food products were all included (unclear if a berry/red flavored product actually contains FD&C Red No. 3 or an alternative red color). The results of the current exposure assessment, which can be considered as worst-case based on the conservative assumptions used, exceeded the ADI by 3-fold but are below the human NOAEL of 1 mg/kg/day. As the current intake estimates were based on many conservative assumptions, it is anticipated that typical intakes would be below the established ADI. Adverse toxicological effects on thyroid hormone levels in humans, which differ from male rats and was observed at 200 mg/kg/day, are not expected to occur at 0.3 mg/kg/day, which is a worst-case estimate.

PS 3664 Development of Supplemental Intake Limits for Nutrients

R. G. Henderson¹, J. Hinerman², A. Franzen³, H. Nguyen⁴, and A. Wong⁴.

¹ToxStrategies LLC, Houston, TX; ²ToxStrategies LLC, Cincinnati, OH; ³ToxStrategies LLC, Monroe, LA; and ⁴Council for Responsible Nutrition, Washington, DC.

Background and Purpose: With increasing use of dietary supplements, including those containing nutrients, it is important to determine levels that may be safely consumed. The Council for Responsible Nutrition (CRN) previously derived upper levels (ULs) for supplemental intake for 28 nutrients. The objectives of the current work were: 1) to update the safety evaluation methodology to provide an enhanced systematic approach to identifying and evaluating available data and 2) to update or derive new ULs in healthy adults for 21 nutrient forms commonly consumed in dietary supplements based on this methodology (calcium, iron, magnesium, potassium, selenium, zinc, vitamin B6, vitamin E, menaquinone-7 (vitamin K2), vitamin A (pre-formed), lutein, zeaxanthin, meso-zeaxanthin, choline, citicoline, folic acid, methylfolate, nicotinic acid, nicotinamide, nicotinamide riboside, and inositol hexanicotinate). **Methods:** The CRN approach based on its principal points of departure for risk analysis was employed, which included a focus on human data from clinical trials (when available); direct evaluation of supplemental intakes (rather than total intakes, when possible); derivation of ULs based on true hazard (vs. nuisance effects); and conservative selection of human NOAEL values that justify selection of an uncertainty factor (UF) of 1.0. For each nutrient, systematic searching and screening of human clinical trials were performed. Data from epidemiological studies were assessed when necessary to evaluate a potential hazard or endpoint of concern. Studies meeting the inclusion criteria were reviewed and data extracted. The critical effect and associated toxicity value (e.g., NOAEL), if available, were identified. The supplemental UL was derived by application of UF(s) to the toxicity value. History of use data were used, if necessary, to identify a highest observed intake (HOI) when adverse effects in humans were not identified. **Results:** A standard operating procedure was developed to ensure systematic and transparent searching and screening of human clinical trials. Upper intake limits for nutrients derived by global regulatory and authoritative bodies were reviewed and summarized within each nutrient update for context. New or revised supplemental ULs/HOIs in adults were derived for all 21 nutrient forms. For example, the UL for vitamin B6 was maintained at 100 mg/day based on human clinical studies in which no adverse effects occurred; excess vitamin B6 (pyridoxine) is associated with adverse neurological effects (e.g., neuropathy) at higher intake levels in human studies. Osmotic diarrhea related to unabsorbed magnesium was identified as the critical endpoint for magnesium. The UL for this nutrient was increased from 400 mg/day to 500 mg/day based on a lack of adverse effects in clinical trials at this dose; however, the magnesium UL does not apply to those with known risk factors related to kidney impairment. HOIs for three xanthophyll carotenoids were also derived based on the lack of any adverse effects across all clinical trials identified: lutein (22 mg/day), zeaxanthin (26 mg/day), and meso-zeaxanthin (17 mg/day). **Conclusions:** This work is part of an overall project to update supplemental ULs for 14 vitamins, 4 minerals, and 10 trace elements previously published by CRN, as well as newly derived supplemental ULs for additional vitamin forms and bioactives. These methods and the resulting ULs/HOIs are valuable tools for manufacturers to guide formulations and can be used internationally by policy makers and authoritative bodies in scientific discussions about setting upper intake levels for nutrients.

PS 3665 Health Promoting Antioxidant activity of Rosemary Extract (*Salvia Rosmarinus*) in Food Preservatives

J. Rubio Villa. JS Held, Redmond, WA.

Background and Purpose: Rosemary (*Rosmarinus officinalis*) extracts are increasingly utilized as natural antioxidants and antimicrobials in food systems, driven by clean-label trends and the need to replace synthetic preservatives. The efficacy of Rosemary extracts depends on factors such as plant maturity, extraction method, concentration of phenolic compounds, and interactions with other components. These extracts have demonstrated potential applications in meat products, oils, dressings, and functional foods, as well as pharmaceutical and plant-based products. While uses of rosemary extracts have been determined to be safe and cost-effective, challenges remain regarding solubility, sensory impact, variability in active constituents, and regulatory compliance. Formulation strategies, including encapsulation and synergistic blending, are often required to optimize performance. This review presents the antioxidant and antimicrobial properties of rosemary extracts, their safety data, and generally recognized as safe (GRAS) regulatory framework governing the use of natural preservatives in foods and highlighting their role as viable ingredient for food preservation. **Methods:** A comprehensive search strategy was implemented by using PubMed. For this review, a series of searches were conducted to thoroughly assess and compare literature, each utilizing the search key term "Rosemary" combined with the search terms "preservative," using the Boolean operator "AND." We also included "Salvia Rosmarinus" AND "Food." These terms were chosen due to the FDA recognizing rosemary as generally safe as a natural preservative in foods. A majority of peer reviewed studies were, published between 2006 and 2025. Exclusion criteria included studies published in languages other than English, and those outside the specified time frame. Of the 30 studies identified, 24 studies met the criteria for inclusion. The focus was the use of Rosemary extracts in food. We acknowledge potential limitations such as selection bias, lack of generalizability in case studies, and lack of full-text manuscripts that could hinder results. However, despite these limitations, this approach ensures a comprehensive review of current literature on Rosemary extracts in food. **Results:** In summary, Rosemary extracts demonstrate notable antioxidant and antimicrobial properties, making it a valuable natural option for food preservation. Regulatory approval in the EU followed comprehensive safety evaluations, confirming that its NOAEL range poses no significant health risks. Research indicates that the majority of Rosemary extracts antioxidant activity is attributed to its carnosic acid (CA) and carnosol (CL) content, which serves as a benchmark for ensuring consistent efficacy and safety in food applications. Furthermore, the antimicrobial effects of Rosemary extracts and Rosemary essential oils enhance preservation by inhibiting bacterial and fungal growth, reinforcing their role as multifunctional preservatives. **Conclusions:** Rosemary extracts offer a promising approach to natural food preservation because of their bioactive compounds that help prevent spoilage and inhibit microbial growth. In addition to their preservative function, research indicates they may support gastrointestinal health. These findings suggest that the gut health benefits of rosemary extract provide an added advantage when using it as a natural preservative in food products.

PS 3666 Antioxidant, anti-obesity, and anti-aging effects of *Melicoccus bijugatus* seed extract in *Caenorhabditis elegans*

B. J. Arroyo-Salgado, L. Tejeda-Benitez, and J. Durango-Villalba. Biomedical, Toxicological and Environmental Research Group BIOTOXAM – SEMILLERO SEMIDET, School of Medicine, Universidad de Cartagena, Cartagena, Colombia.

Background and Purpose: The increasing prevalence of age-associated diseases such as obesity and other chronic disorders linked to oxidative stress poses a major global health concern. Oxidative stress, resulting from an imbalance between the generation of reactive oxygen species (ROS) and the body's antioxidant defenses, plays a central role in cellular damage, accelerates aging, and contributes to the onset of metabolic diseases. Consequently, the identification and development of new therapeutic and preventive agents capable of alleviating oxidative stress, combating obesity, and slowing the aging process have become pressing scientific priorities. These biologically complex substances obtained from plants, fungi, and marine life form a vast reservoir of chemically diverse and bioactive compounds. Because age-related diseases are driven by multiple interconnected biological pathways, natural extracts and their purified constituents offer significant potential for multi-targeted treatments that can simultaneously modulate inflammation, metabolic imbalance, and cellular senescence. Harnessing this immense natural diversity is essential for the discovery of innovative drugs with improved efficacy and potentially fewer adverse effects compared to synthetic alternatives, ultimately advancing both preventive and therapeutic medical approaches. In this study, the aqueous and ethanolic extracts of *Melicoccus bijugatus* seeds were evaluated using *Caenorhabditis elegans* as an *in vivo* biological model. **Methods:** *M. bijugatus* seeds were collected in Bolívar, Colombia (María la Baja), under the relevant environmental permit. Seeds were washed, dehusked, frozen and freeze-dried for 72 h. The pulverized seed material was subjected to ultrasound-assisted maceration using water and chromatographic-grade ethanol as solvents for 24 h. The solvent was removed using a rotary evaporator. Thin-Layer Chromatography was used with specific reagents to detect alkaloids, tannins, flavonoids, triterpenes, saponins, quinones, and cardiotonic glycosides. Gas Chromatography coupled with Mass Spectrometry was used for a detailed chemical profiling. *C. elegans* were maintained on NGM agar plates

with *E. coli* OP50 and synchronized using an alkaline hypochlorite/sodium hydroxide solution to obtain an adult-only population. For lethality assay, L4-stage worms were exposed to 0.1, 1, 10, and 100 ppm of extract for 24 h. Survival was monitored by physical stimulation, comparing results against an ultrafiltered water control. For antioxidant activity assay, worms were pre-treated with the ethanolic extract for 48 h, then exposed to hydrogen peroxide 5 mM. Survival was monitored for 5 h. Lipid accumulation was quantified using Oil Red O (q-ORO) staining. Worms were subjected to three different extract concentrations, involving pre-exposure to the extract, co-exposure with sucrose, or exposure only to the combination, followed by sucrose exposure. Orlistat was used as a positive control. The staining intensity was analyzed via optical microscopy. For lifespan assay, nematodes were treated with the extracts and 5-fluoro-2'-deoxyuridine was added to inhibit reproduction. Worm survival was monitored daily until the death of the last organism, and the data was used to generate a survival curve. **Results:** The extracts showed no basal toxicity, confirming their safety within the experimental system. When exposed to pro-oxidant agents, the ethanolic extract provided significant and dose-dependent protection, with the 10 ppm concentration being the most effective. Furthermore, lipid quantification using q-ORO staining evidenced a reduction in sucrose-induced lipid accumulation, indicating a preliminary anti-obesity effect. Longevity analyses revealed a favorable trend toward increased survival in the treated nematodes, suggesting a potential anti-aging effect. **Conclusions:** Collectively, these results position *M. bicuspidatus* as a promising source of metabolites with antioxidant, anti-obesity, and anti-aging properties, with potential relevance in the prevention of metabolic diseases and the physiological deterioration associated with oxidative stress.

PS 3667 Mutagenic Potential of Higenamine in Cultured V79 Cells

E. M. Veh, E. Fleischmann, P. Wenninger, and L. Lehmann. University of Würzburg, Institute of Pharmacy and Food Chemistry, Chair of Food Chemistry, Würzburg, Germany.

Background and Purpose: Higenamine (HIG), also known as norcoclaurine, is found in widely available sports and weight-loss supplements. However, there is limited information on HIG's safety. Recently, when exposed to mouse and human liver microsomes and recombinant human CYP enzymes, HIG was observed to oxidize into ortho-quinone and quinone methide. These biotransformation products of HIG might cause DNA damage and lead to mutations. Consequently, this study investigated the mutagenic potential of HIG in cultured V79 cells using the hypoxanthine-guanine phosphoribosyltransferase (HPRT) assay (detecting primarily gene mutations) and the micronucleus (MN) assay (detecting chromosome and genome mutations). **Methods:** V79 cells were exposed to HIG for 4 h both in the absence and presence of S9 fraction derived from livers of β -naphthoflavone/phenobarbital-treated male rats (S9). In the HPRT assay, V79 cells were treated with HIG concentrations ranging from 150 to 423 μ M, 1% DMSO, and the positive controls 4-nitroquinoline-N-oxide (NQO, -S9) and benzo[a]pyrene (BaP; +S9). To assess cytotoxicity, the plating efficiency was determined immediately after treatment. In the MN assay, V79 cells were seeded onto slides and exposed to three HIG concentrations (249-423 μ M), solvent (1% DMSO), and positive controls patulin (PAT; -S9) and BaP (+S9) for 4 h, followed by a compound-free post-incubation period of 16 and 24 h. After staining of DNA and immunostaining for centromere-associated proteins (to distinguish MN containing whole chromosomes and chromosome fragments) and α -tubulin (to evaluate midbodies and mitotic spindles), cells were analyzed by fluorescence microscopy for micronuclei formation, mitotic index, spindle structure, cell death, and recent cell divisions. **Results:** As expected, the positive controls significantly induced 6-thioguanine-resistant mutants in the *Hprt* locus, while HIG did not significantly affect mutant frequency either without or with S9, across a concentration range that caused no reduction up to 68% (-S9) and 61% (+S9) reduction in plating efficiency. In the MN assay, treatment with the highest concentration of HIG resulted in a significant decrease in the frequency of recent cell divisions and the mitotic index by up to 93% immediately after exposure. However, cell proliferation resumed during the post-incubation period. As expected, MN containing whole chromosomes as well as chromosome fragments were observed after treatment with PAT, while BaP mainly induced MN containing chromosome fragments. After treatment with HIG (-/+S9) followed by a 16-h HIG-free post-incubation period, a concentration-dependent increase in MN frequencies from 4.6 to 39.8 (without S9) and from 6.1 to 64.3 (with S9) per 1000 cells. The effect's magnitude decreased at 24 h post-incubation but remained significant. **Conclusions:** HIG did not induce gene mutations at the *Hprt* locus but did induce chromosome mutations *in vitro*. Thus, the mutagenic potential of HIG requires further investigation and should be considered in the safety evaluation of dietary supplements containing HIG.

PS 3668 A combined chemoproteomics and 3D molecular modeling approach identifies small GTPases as potential target proteins of the mycotoxin Ochratoxin A

J. Borchers¹, F. Perugini², A. Schlosser³, S. Lamer³, L. Pedroni², L. Dellafora², and A. Mally¹. ¹University of Würzburg, Department of Toxicology, Würzburg, Germany; ²University of Parma, Department of Food and Drug, Parma, Italy; and ³University of Würzburg, Rudolf Virchow Center, Würzburg, Germany.

Background and Purpose: Ochratoxin A (OTA) is an abundant mycotoxin and food contaminant that presents a health concern due to its nephrotoxicity and renal carcinogenicity in rodents. Although recent findings suggest a causal link between mitotic aberrations, genetic instability and replication stress induced by OTA, the molecular initiating event responsible for these effects remains unclear. To fill this knowledge gap critical for OTA risk assessment, we applied a chemoproteomic strategy to identify direct molecular targets of OTA and characterize early key events in the mechanism of OTA carcinogenicity. **Methods:** OTA and OTB were covalently bound to amino-functionalized agarose beads via their carboxyl group to create an affinity matrix. Lysates obtained from HK-2 renal epithelial cells were incubated with OTA- and OTB-functionalized beads to enrich for OTA- and OTB-binding proteins. Captured proteins representing putative OTA/OTB target proteins were subsequently identified by tandem mass spectrometry. Molecular docking and molecular dynamics simulations were performed to study mycotoxin-protein complex stability over time. **Results:** Our chemoproteomics approach identified several members of the small GTPase superfamily as most significantly enriched OTA and OTB interacting proteins, including representatives of all subfamilies such as RhoA, Ran, Rab5, Sar1a and K-Ras. These small GTPases act as central regulators of essential cellular functions, including vesicular transport and budding (Rab and Arf), nuclear import (Ran), cytoskeletal organization (Rho), as well as cell cycle regulation (Ras) and cell division, thus offering plausible links to key events thought to be critical in OTA genotoxicity. Molecular docking and molecular dynamics simulations predicted OTA binding within the conserved GDP/GTP binding sites of small GTPases, with complex stability over toxicodynamically relevant timeframes comparable to complexes with the natural ligands GTP/GDP. **Conclusions:** Taken together, these findings highlight small GTPase as primary molecular targets of OTA and offer new mechanistic hypotheses that link small GTPases to cellular effects observed in response to OTA.

PS 3669 Complex *Alternaria* toxin mixtures: an underestimated risk for consumer safety?

F. Call, F. Crudo, and D. Marko. University of Vienna, Vienna, Austria. Sponsor: W. Bisson

Background and Purpose: Since the discovery of aflatoxins in the 1960s, more than 300 fungal metabolites have been characterized as so-called „mycotoxins“. In 1985, the FAO estimated that about 25% of the global food crop are contaminated with mycotoxins. Since then, global climate change has impacted the occurrence spectrum of respective fungi and, at the same time, improvement in analytics has enabled milestones in sensitivity. Nowadays, estimations speculate up to a contamination rate of 90%, at least in trace amounts. In addition to the few regulated mycotoxins such as aflatoxins or ochratoxin A, now numerous additional secondary metabolites can be detected. For most of these potentially „emerging“ mycotoxins data on occurrence and/or toxicity are not sufficient yet for comprehensive risk assessment. Moreover, recent studies demonstrate that mycotoxins are rarely found as single toxins but often occur in mixtures, thus further challenging risk characterization. A special challenge is represented by *Alternaria* mycotoxins with more than 70 compounds out of different chemical classes reported so far. Only a limited number of secondary metabolites formed by *Alternaria* fungi are commercially available and thereby accessible as reference material and test compounds for hazard characterization. **Methods:** Toxicity-guided fractionation combining the alkaline comet assay in HT29 colon carcinoma cells with LC-MS/MS analysis was used to identify genotoxic impact constituents. Key compounds were identified, isolated as single constituents and individually tested. Subsequently, a respective mixture of characterized single toxins was used to determine whether the genotoxic impact of the naturally occurring mixture can be achieved. Finally, a gastromimetic approach was used to determine the proportion of genotoxic *Alternaria* toxins expected to reach the intestinal tissue for absorption. **Results:** Toxicity-guided fractionation demonstrated that the genotoxic potential of naturally occurring *Alternaria* toxin mixtures is strongly imprinted by the presence and structural composition of perylene quinones formed by the fungus. Altertoxin-II (ATX-II) and stemphytoxin III (STX-II) were identified as potent genotoxic mutagens. Both compounds possess a reactive epoxide moiety and can form DNA adducts. But due to the reactivity of the epoxide moiety, reactions with food matrix might already occur during food processing or digestion. Indeed, the addition of ATX-II to tomato-based matrix showed a substantial loss of free and detectable amount of ATX-II during gastromimetic analysis. In contrast, non-epoxide analogues of the perylene quinone class formed in quite considerable amounts by several *Alternaria* strains, altertoxin-I (ATX-I) and alterperyleneol (ALP) were only marginally affected by digestive processes and are therefore expected to reach the small intestine to be absorbed. Both compound were found to possess moderate genotoxic properties but induce comparably potent immunosuppressive effects. **Conclusions:** *Alternaria alternata* is able to grow on a broad spectrum of substrates and growth conditions. But the resulting toxin pattern strongly depends

on the strains, substrates and environmental factors. Further studies are urgently needed to clarify the occurrence of perylene quinones formed by *Alternaria* species in food and feed.

PS 3670 Early Glycation Products Modulate Glucose Homeostasis and Gut Microbiome and Produce Sex-Specific Behavioral Changes in Murine Models of Type 2 Diabetes and Neurodevelopmental Disorders

F. Eldefrawy, D. Jiang, and T. L. Guo. University of Georgia, Athens, GA.

Background and Purpose: Glycation products form when proteins or fats react with sugars, and they are widespread in modern diets. Advanced glycation end products produced from prolonged or high-temperature cooking have been linked to negative health effects and increased risks of diabetes. The physiological effects of early glycation products (EGPs) generated through controlled reactions, however, remain much less understood. It is hypothesized that EGP consumption can beneficially influence metabolic health, gut microbiota, and behaviors related to brain function. To test this hypothesis, three complementary mouse studies were conducted.

Methods: In the first study, male and female C57BL/6 mice were fed a Western diet and daily given EGPs (600 mg/kg) or non-reacted (NR; glucose and whey protein only) controls by gavage over six months. Body weight, blood glucose, and food intake were recorded weekly, while glucose tolerance (GTT) and insulin tolerance (ITT) tests were performed monthly. The gut microbiome was analyzed using 16S rRNA gene sequencing. The second study employed both Western diet-fed male and female BTBR-mtB6 mice, a model for autism spectrum disorder, dosed daily with EGPs, NR, or water for six months. In addition to the above endpoints, behavioral tests were conducted for grooming and three-chamber sociability. In the third study, male and female C57BL/6 mice were placed on a Western diet and treated with vancomycin (0.5 g/L in drinking water) to deplete gut microbiota, then administered water, NR, or EGPs (600 mg/kg/day) by gavage for six months. In addition to the above endpoints, behavioral tests included the Y-Maze (spatial working memory), Open Field (locomotor and anxiety-like behaviors), Novel Object Recognition (recognition memory), and Tail Suspension (depression-like behavior). **Results:** EGP-treated C57BL/6 mice demonstrated significant improvements in glucose homeostasis compared to controls, evidenced by lowered blood glucose levels, reduced insulin resistance and beneficial shifts in the gut microbial community. Female C57BL/6 mice also showed reductions in body weight. In BTBR-mtB6 mice, EGP supplementation improved social behaviors in both sexes: females showed increased social interactions, while males exhibited higher social behavior index scores than controls. Additionally, males had significantly improved glucose tolerance and insulin sensitivity with EGP treatment. In the antibiotic-treated C57BL/6 mice, EGPs decreased body weight gain and led to substantial improvements in glucose tolerance and insulin sensitivity, especially among females. EGP treatment also enhanced recognition and spatial memory, and decreased anxiety- and depression-like behaviors, with more pronounced behavioral improvements observed in female mice. **Conclusions:** Across the three murine models, EGPs consistently produced sex-specific improvements in glucose metabolism, neurobehavioral outcomes, and gut microbiota profiles. These findings suggest that early glycation products have potential as dietary interventions for the management of metabolic and neurodevelopmental disorders. The beneficial effects observed may be mediated by both gut microbiome-dependent and independent mechanisms. Continued investigation into EGPs as functional dietary components is warranted. This project was supported by NIH R41DK121553 and partly supported by the Interdisciplinary Toxicology Program at UGA and the USDA National Institute of Food and Agriculture [grant no. 2016-67021-24994/project accession no. 1009090].

PS 3671 Distinct production of advanced glycation endproducts by the microbiome of Crohn's disease patients and healthy controls

H. A. van der Hout¹, M. Kolovou¹, C. Driessen², D. M. Jonkers¹, J. Penders², F. van Schooten¹, D. T. Sijm¹, and M. F. Vrolijk¹. ¹Maastricht University, Maastricht, Netherlands; and ²Maastricht University Medical Center+, Maastricht, Netherlands. Sponsor: H. van der Hout, EUROTOX

Background and Purpose: Crohn's disease (CD), a subtype of Inflammatory Bowel Disease (IBD), is a chronic relapsing-remitting inflammatory condition and is associated with an altered intestinal microbiota composition. Diet is known to play a role in the onset and development of CD, e.g. by exposure to inflammatory compounds and/or via the intestinal microbiota. One of the dietary factors of interest are advanced glycation endproducts (AGEs), which form during the non-enzymatic glycation of amino acid residues. AGEs can form during cooking, but can also be formed endogenously and be produced by the microbiome. AGEs, and an increased expression of their receptor RAGE, have been associated with IBD. Which specific AGEs are involved and what the contribution of the intestinal microbiome is, is so far not clear. The current study therefore investigates AGE production by the fecal microbiome of CD patients and healthy controls, to identify specific AGEs associated with CD. **Methods:** Fecal samples (1% w/v in simulated ileal efflux medium, containing casein and cysteine but no carbohydrates) from four CD patients and four healthy controls, matched for age, BMI and smoking status, were incubated at 37°C in a well-con-

trolled anaerobic environment. These samples were incubated with one of four added carbohydrate sources (1% w/v): glucose, fructose, galacto-oligosaccharides (GOS), or fructo-oligosaccharides (FOS). Moreover, a non-carbohydrate medium control was included. Samples were collected before (T0), after 4h (T4) and 24h incubation (T24). These samples were immediately diluted 1:10 in ice-cold PBS, sonicated in an ice-bath for 30min and spun down at 18000g for one hour. Supernatant was collected and used to determine the concentrations of 23 AGEs using UPLC-MS/MS on a C18 column and water as eluent. Incubations with the four carbohydrates were also performed without faeces, to correct for non-microbial AGEs formed in the medium. **Results:** Eight AGEs could be identified in the collected samples. All AGE concentrations (CMC, CML, CEL, CMA, MG-H, pyrraline and furosine) increased over time, ranging between 2- and 4-fold for most, up to a 44-fold increase for CMC. The exception was 2-SC, which showed a 2- to 6-fold increase at T4 and then a decrease to T24, for both CD and controls. Six of the eight individual AGEs (CMC, CML, CEL, CMA, pyrraline and 2-SC) were more abundant in the samples of CD patients as compared to the controls. Only MG-H was higher in control as compared to CD samples, whereas furosine was produced by the microbiome of one control sample only. Although differences in individual AGEs between groups were prominent, they were not statistically significant, possibly due to high intra-group variability. Exceptions were CEL after 24h incubation with glucose (mean difference in CD vs. controls: 103 µg/L, p<0.01) and MG-H after 24h incubation with fructose (mean difference in controls vs CD: 36.6 mg/L, p<0.05). Principal component analysis (PCA) revealed a significant clustering of AGEs based on CD status (p<0.001). PCA on AGE production stratified by carbohydrate source showed the most apparent separation between CD patients and healthy controls after FOS exposure, while AGE production profiles from medium only incubations were most similar between CD patients and controls. **Conclusions:** These results indicate that AGE production by the fecal microbiome is significantly different between CD patients and healthy controls, with pronounced interindividual variability within both groups. Interestingly, a subset of AGEs appeared to be produced at higher rates by CD samples. The effect of these on immunity and intestinal barrier function warrants further study. Future work will involve microbiome sequencing of the incubated fecal samples to provide insight into the bacterial taxa responsible for AGE production. Overall, these results show a distinct subset of AGEs produced by CD patients, indicating functional differences in the microbiome between CD patients and healthy controls.

PS 3672 Species specific responses of human, rat and rabbit hepatocytes to the next-generation refrigerant R-1132(E)

N. Mori¹, H. Sakaue¹, R. Takeda¹, A. Kuno¹, R. Kobayashi¹, Z. Guo², and Y. S. Kida¹. ¹National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; and ²Daikin Industries, Ltd., Osaka, Japan. Sponsor: T. Fukuyama

Background and Purpose: In recent years, climate change associated with global warming has become a major worldwide concern. R-1132(E), trans-1,2-Difluoroethylene, is a promising next-generation refrigerant with an extremely low environmental impact, having a global warming potential (GWP) of <1. For the full-scale practical use of R-1132(E), a safety evaluation is indispensable. Previous animal studies showed the different responses among different species, rat, dog, and rabbit. Mortality was only observed in the rabbit after repeated exposure to R-1132(E). Since the liver is a critical organ for metabolizing chemicals, the hepatocyte responses might be different among different species. In this study, we conducted *in vitro* exposure tests of R-1132(E) gas using primary hepatocytes from three species, human, rat, and rabbit, to infer its effects on the liver, the organ responsible for detoxification. **Methods:** Cryopreserved primary hepatocytes from human, rat, and rabbit were thawed, cultured, and exposed to gas phase R-1132(E). A gas-tight Tedlar bag was used for gas exposure. One side of the bag was cut open, culture plates were placed inside, the opening was sealed with a heat sealer, and the bag was filled with gas at the concentrations of 0, 1k, 10k, 15k ppm for 5 days. Gas exposure began one day after cell seeding; gas and culture medium were replaced daily. The culture medium used had been pre-equilibrated with the gas since the previous day. Cells of 0 and 15k ppm were collected on Day 2 and Day 5 after exposure, and protein and RNA were extracted for proteomic and transcriptomic analyses. On Day 5, cellular viability/metabolic activity was assessed using the WST-8-based Cell Counting Kit-8 (CCK-8). **Results:** Microscopic evaluation of cell morphology showed no differences across gas concentrations in human hepatocytes. In rabbits, the cuboidal morphology characteristic of hepatocytes was preserved in the gas-exposed groups. In rats, gas exposure modestly promoted cell detachment and aggregation. However, the morphology changes in rats were not aligned with the cell viability. No statistically significant differences of cell viability (CCK8-assay) were observed in human or rat cells at all exposure levels during exposure. In contrast, rabbit cells in the non-exposed group (0 ppm) showed lower activity than the exposed groups (1k, 10k, 15k ppm), with significant differences particularly at 1k and 15k ppm on Day 5 after exposure. Proteomic and Transcriptomic analysis showed the different cellular responses after exposure among the three species. Rabbit hepatocytes exhibit the different responses compared to human and rat, especially in metabolism, inflammation and elimination. Proteomic analysis identified more than 7,000 protein groups in each species, providing sufficient depth for statistical analysis. Gene Ontology (GO) and pathway analyses comparing the R-1132(E)-exposed (15k ppm) versus non-exposed (0 ppm) groups revealed activation of immune responses, inflammatory responses, transcription factor-related pathways, autophagy, and cytoskeleton/migration across species. Analyses focusing on liver function-related proteins indicated minimal commonality

among species and pronounced interspecies differences. Notably, rabbits exhibited a marked and distinctive response compared with the other species, with strong upregulation of CYP2C isoforms, especially CYP2C3. Transcriptomic results were broadly consistent with the proteomic findings. **Conclusions:** At all tested exposure concentrations, no substantial toxicity indicative of acute hepatocellular death over a period of several days was observed in any species, suggesting that the acute hepatotoxicity of R-1132(E) is low. The omics analyses indicate a high likelihood of R-1132(E) exposure related effects on hepatocellular metabolic functions, immune responses, and inflammatory pathways in all three species. However, the responses in rabbit were different compared to human and rat. Given the substantial interspecies differences observed, caution is warranted when extrapolating animal data to humans, as variations in drug-metabolizing enzymes may yield different metabolites.

PS 3673 Establishing a quantitative and advanced *in vitro* test system to evaluate chemical-induced liver fibrosis

T. Hagens¹, L. Winkelman¹, L. Bajard², S. Langouët³, E. Blanc⁴, L. Wik⁵, M. Kiamehr⁶, J. Beltman¹, M. Niemeijer¹, and B. v. Water¹. ¹Leiden Academic Centre for Drug Research, Leiden University, Leiden, Netherlands; ²Research Centre for Toxic Compounds in the Environment (RECETOX), Masaryk University, Brno, Czech Republic; ³Institut de Recherche en Santé, Environnement et Travail (IRSET), INSERM Rennes, Rennes cedex, France; ⁴INSERM Paris, Paris, France; ⁵Statens Arbeidsmiljøinstitutt, STAMI, Oslo, Norway; and ⁶Stem Cell Institute Leuven, Department of Development and Regeneration, KU Leuven, Leuven, Belgium.

Background and Purpose: Integrated Approaches to Testing and Assessment (IATAs) are developed to provide safety information about chemicals and eliminate animal testing. Chemical-induced liver fibrosis is characterized by activated hepatic stellate cells that accumulate extracellular matrix proteins which is a key event within the adverse outcome pathway (AOP) for fibrosis. Currently, no IATA is available for liver fibrosis, and therefore, this study aims to systematically develop a quantitative and advanced *in vitro* test system to evaluate chemical-induced liver fibrosis.

Methods: Four monoculture liver test systems (primary human hepatocytes (PHH), immortalized cell lines HepG2 and HepaRG, and human induced pluripotent stem cell (hiPSC)-derived hepatocytes-like cells (HLC)) in 2D and 3D, and two coculture primary cell models in 3D (3D InSight™ Liver Microtissues, InSpherO) have been evaluated on predictivity of acute liver toxicity and fibrosis. All test systems were treated with chemicals known to induce fibrosis: allyl alcohol, thioacetamide, and monocrotaline. After 24h single or repeated exposure across a concentration range, cytotoxicity was determined, and whole transcriptome analysis was performed using TempO-Seq technology. **Results:** The similarity in gene expression of the systems compared to the human liver was established using the liver-specific gene expression panel (LiGEP) algorithm. This showed that primary cell systems were most comparable to the human liver, followed by HepaRG, HLCs, and HepG2, respectively. Moreover, 3D format resulted in higher LiGEP similarity compared to 2D. primary cells showed the highest expression of CYP enzymes, while HepaRG had increased expression of ADH genes. Transcriptomics analysis provided mechanistic insight into the test systems' capability to identify fibrosis development after exposure. Known stressor pathways, such as NRF2 and HSF-1, were activated in PHH and HepG2 upon exposure. Cocultures of primary cells showed additional immune response module activation, serving as the second key event. Under repeated exposure conditions, ECM-related modules were perturbed, showcasing the late key event. **Conclusions:** This shows the importance of the inclusion of non-parenchymal cells for the detection of liver fibrosis-related key events and gene networks. Therefore, our study will further focus on implementing the non-parenchymal cells (e.g., hepatic stellate cells and Kupffer cells) using hiPSC-derived organoids or human-primary-cell-derived spheroids. The development and characterization of advanced liver models, including essential mature cell types, could aid in the recognition of early fibrosis and will therefore drastically improve the prediction of liver toxicity. This work has received funding from Partnership for the Assessment of Risks from Chemicals (PARC) (grant agreement No 101057014).

PS 3674 Co-regulated gene network analysis to uncover mechanisms of liver toxicity liabilities *in vitro*

S. Bahtiri, S. Kunnen, L. Wijaya, T. Hagens, G. Callegaro, M. Niemeijer, and B. van de Water. Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands.

Background and Purpose: Next-generation chemical risk assessments require mechanism-based approaches that integrate human-relevant new approach methodologies (NAMs) in order to protect human health and ensure readiness for future regulatory needs. High-throughput transcriptomics has emerged as an ideal platform to effectively capture early biological responses resulting from chemical exposures in human *in vitro* test systems. However, in-depth understanding on the preservation of adverse responses across different test systems, as well as the interpretation of *in vitro* transcriptomic data remain major hurdles for regulatory implementation. Considering the liver as a predominant target for chemical-induced toxicities, our aim is to improve liver toxicity prediction by employing co-expression network analysis across multiple test systems. These networks facilitate biological inter-

pretation of transcriptomic changes and enable evaluation of response concordance, thereby supporting the definition of applicability domains for each system.

Methods: In order to build co-expression networks, toxicogenomics datasets were generated for differentiated HepG2 cultured in amino acid-rich medium (AAGLY-HepG2), HepaRG, and primary human hepatocytes (PHH). Based on the previously established human hepatocyte TXG-MAPr (Callegaro et al., 2021), the minimum required set of compounds for a preserved gene network was determined and used for the generation of new toxicogenomic datasets. The resulting exposure library consisted of 39 hepatotoxic compounds, 8 reference compounds for specific stress response pathways, and 4 growth factors and 4 cytokines to trigger other endogenous signaling pathways of interest. All compounds were tested at three concentrations, and samples were collected for TempO-Seq at 8 and 24 hours after exposure. Differential gene expression analysis was employed using the DESeq2 package. Based on the differentially expressed genes, Weighted Gene Correlation Network Analysis (WGCNA) was used to construct co-expression networks. On these WGCNA networks, preservation analysis using Z-summary statistics was performed to identify robust modules. Also previously established HepG2, PHH, and human induced pluripotent stem cell-derived hepatocyte-like cells (hiPSC-HLCs) TXG-MAPr tools available from <https://txg-mapr.eu/> were taken along for the cross-test system preservation analysis. **Results:** WGCNA networks from PHH TG-GATes data and newly obtained PHH TempO-Seq data displayed ~75% module preservation. Among these preserved modules were important stress-response related modules enriched for unfolded protein-response and inflammatory pathways. Between normal HepG2 and AAGLY-HepG2, we found that ~80% of modules were preserved. HepaRG showed the highest preservation to 'golden standard' PHH, followed by AAGLY-HepG2, HepG2, and lastly hiPSC-HLC. Among the preserved modules, UPR is generally well captured across the different test systems, as well as heat shock and oxidative stress responses. **Conclusions:** A WGCNA-based data-reduction approach effectively captures the preservation of transcriptomic perturbations induced by chemical exposure across different test systems. This framework enables identification of conserved stress-response signatures and provides an overview of the applicability domains of different liver *in vitro* test systems.

PS 3675 Comparative Analysis of Species-Specific Hepatocyte Function and Drug Effects in Static Monolayers, Spheroids, and a Perfused Microphysiological System

C. K. Negi¹, C. Sakolish¹, P. Hewitt², and I. Rusyn¹. ¹Department of Veterinary Physiology and Pharmacology, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University, College Station, TX; and ²Chemical and Preclinical Safety, Merck KGaA, Frankfurterstrasse 250, 64271, Darmstadt, Germany.

Background and Purpose: Drug-induced liver injury (DILI) remains a major challenge in drug development, highlighting the need for reliable *in vitro* tools to assess hepatotoxicity and improve translation from animal to human studies. Models using hepatocytes from preclinical species are also needed to evaluate species-specific toxicity.

Methods: In this study, we evaluated the basal performance of primary hepatocytes from human, monkey, rat, and dog in several *in vitro* liver platforms, including static monolayers, static microspheroids (Elplasia ULAP), and the microfluidic TissUse HUMIMIC Chip2 microphysiological system (MPS). Cells were maintained for 14 days, and cultures were characterized using functional (albumin, urea) and DILI (AST, LDH) biomarkers. In addition, we tested the effects of several species-specific DILI compounds: chlorpromazine (CPZ; toxic across species), bosentan (BOS; human-specific), and flialuridine (FIAU; human-specific); these were dosed every second day starting on day 6 until the end of the experiment. **Results:** Human hepatocytes in the HUMIMIC Chip2 showed gradually increasing albumin and declining urea over time. These patterns were similar in the static monolayer and spheroid cultures. In hepatocytes from other species, we observed overall declines in these biomarkers. Rat hepatocytes performed comparably across systems, while monkey and dog cells showed slightly higher biomarker levels in the HUMIMIC Chip2. In monolayer hepatocyte cultures, CPZ and BOS induced significant cytotoxicity in human and monkey hepatocytes, as indicated by increased LDH and AST and reduced albumin production. No effects of CPZ or BOS were observed in rat and dog hepatocytes. FIAU treatment resulted in a significant dose-dependent decrease in albumin production in human hepatocytes. In monkey hepatocytes, a significant increase in albumin was observed. Liver injury markers, AST and LDH, were increased in human cells, but in monkey cells, only LDH was increased. No effects were found in either rat or dog hepatocytes on any of the biomarkers. In static microspheroids, CPZ and BOS resulted in dose-dependent decreases in albumin in human and monkey hepatocytes. LDH and AST increases were also observed in human and monkey hepatocytes. Effects on dog and rat hepatocytes were inconsistent. FIAU responses mirrored monolayer results, limited to human and monkey cells. LDH and AST were unchanged, and no effects were observed on rat and dog hepatocytes. In HUMIMIC Chip2 perfused microspheroids, only FIAU was tested due to the limited throughput of this MPS. In human hepatocytes, FIAU reduced albumin and other biomarkers, but variability and low sample size prevented statistical significance. Responses in other species were variable. **Conclusions:** Across platforms, human and monkey hepatocytes demonstrated the highest functional stability and sensitivity to known DILI compounds, while rat and dog hepatocytes showed limited or inconsistent responses. The TissUse HUMIMIC Chip2 supported comparable or slightly improved hepatocyte function relative to static models, though variability and low throughput limited statistical power. FIAU, BOS, and CPZ produced species- and compound-spe-

cific hepatotoxic responses consistent with known *in vivo* outcomes, supporting the translational relevance of these *in vitro* systems. Overall, integrating multi-species hepatocyte models across static and microphysiological platforms provides a promising approach for comparative DILI assessment and preclinical-to-clinical translation.

PS 3676 Preliminary evaluation of donor variability in albumin secretion for fit-for-purpose applications of primary human hepatocytes

M. Nautiyal¹, L. Nguyen¹, K. Grady², and A. Sharma¹. ¹Lonza Durham, Morrisville, NC; and ²Lonza Walkersville Inc., Walkersville, MD. Sponsor: K. Dunnick

Background and Purpose: Primary human hepatocytes (PHHs) are widely used in toxicology, drug discovery, and advanced microphysiological system (MPS) applications. Albumin secretion is a key marker of hepatocyte function; however, donor-to-donor variability may affect experimental outcomes and influence the suitability of PHHs for different applications. This proof-of-concept study provides preliminary data on albumin secretion across PHH donors as a potential fit-for-purpose guide for use in MPS and ADME-TOX applications. **Methods:** Cryopreserved PHHs from multiple donors were thawed and cultured either as 2D monolayers on collagen-coated plates or self-assembled 3D spheroids. Albumin secretion was quantified over time using BioAnalyzer (2D hepatocytes) or ELISA (3D spheroids). Donors were categorized into higher- and lower-secreting groups based on internal reference ranges, and QC metrics (viability, attachment, CYP activity) were compared. Four representative donors (two per group) were further evaluated for acetaminophen (APAP) cytotoxicity in both formats, with ATP-based assays used to generate dose-response curves and EC₅₀ values. **Results:** PHHs maintained stable morphology for up to 5-7 days (2D) and 3 weeks (3D). Albumin secretion levels (N=26 lots) enabled donor stratification into high and low secretors; no consistent correlation was observed with viability or CYP activity. Both groups exhibited time- and concentration-dependent ATP loss upon APAP exposure in 2D and 3D cultures. EC₅₀ values after 72 h repeated exposure were comparable between groups and formats. Importantly, at least one high-secreting donor has been externally validated in an MPS application, further supporting the link between albumin secretion capacity and suitability for long-term advanced models. **Conclusions:** Both high- and low-secreting donors performed reliably in routine cytotoxicity assays. High-secreting donors above a reference cutoff may be preferentially suited for long-term applications such as NAMs, MPS platforms, and chronic ADME-TOX studies, while lower-secreting donors remain fit-for-purpose for short-term testing, acute toxicity screening, mechanistic pathway studies, and exploratory ADME applications.

PS 3677 Targeted Lipidomics as a High-Throughput New Approach Method for Mechanism-Based Assessment of Drug-Induced Liver Injury In Vitro

T. Yen, C. K. Negi, C. Sakolish, and I. Rusyn. Texas A&M University, College Station, TX.

Background and Purpose: Traditional toxicity testing is limited in throughput and mechanistic characterization, underscoring the need for cell-based new approach methodologies. Incorporating mechanistic readouts, such as lipidomics, can enhance the translational relevance of hepatocyte-based assays; however, the addition of this analysis to *in vitro* studies has its limitations. For example, traditional untargeted lipidomic analyses are time-consuming and may also require greater sample volumes. Therefore, this study focused on developing a targeted lipidomics method that can be used to characterize drug-induced liver injury-related lipid responses in small volumes from *in vitro* studies. **Methods:** Lipid species characteristic of normal hepatic function and those associated with adverse drug responses were identified and used to establish the analytical target list. A focused lipid profiling assay targeting 181 lipid species was conducted using LC-triple quadrupole MS in positive electrospray ionization mode with multiple reaction monitoring. Next, primary hepatocytes from human, rat, monkey, and dog were cultured in collagen I-coated 96-well plates and exposed to known human hepatotoxins that act via different mechanisms of action: chlorpromazine (1, 10, and 30 μ M), bosentan (10, 30, 100, and 200 μ M), and flialuridine (1, 10, 30 and 100 μ M). Cells were exposed to test compounds every other day from culture day 4 to day 8. **Results:** We found that test compounds not only resulted in changes in biochemical markers of liver injury (increases in alanine and aspartate aminotransferases and a decrease in albumin production) but also elicited compound- and species-specific lipid perturbations. Chlorpromazine exposure had significant effects on lipid profiles in all species; specifically, increases in diacylglycerols were observed in human, rat, and monkey, but not in dog hepatocytes. Triglyceride levels exhibited species-dependent patterns, increasing in human and monkey hepatocytes, decreasing in dog hepatocytes, and showing chain length-dependent alterations in rat cells. Bosentan exposure induced ceramide accumulation in human hepatocytes, providing insight into a mechanism underlying its human-specific hepatotoxicity. Flialuridine resulted in few effects on lipid profiles, potentially reflecting the low sensitivity of this method for the detection of mitochondrial toxicity. **Conclusions:** The targeted lipidomics platform proposed herein enables high-throughput, mechanism-based characterization of compound-induced lipid responses in cultured hepatocytes. This approach provides a strategy for

mechanistic toxicological evaluation, comparative studies across different species, and demonstrates the potential of lipidomics as a mechanistic complement to traditional *in vitro* hepatotoxicity phenotypes.

PS 3678 Evaluation of Drug-Induced Liver Injury in Microphysiological Human Liver-on-Chip Models

T. Kaden^{1,2}, K. Graf¹, K. Rennert¹, R. Li³, A. Mosig^{2,4}, A. Noerenberg⁵, T. Evenburg⁵, and M. Raasch¹. ¹Dynamic42 GmbH, Jena, Germany; ²Institute of Biochemistry II, Center for Sepsis Control and Care, Jena University Hospital, Jena, Germany; ³Biopredic International, St Gregoire, France; ⁴Cluster of Excellence Balance of the Microverse, Friedrich Schiller University Jena, Jena, Germany; and ⁵Upcyte Technologies GmbH, Hamburg, Germany. Sponsor: C. Roper

Background and Purpose: Drug-induced liver injury (DILI) remains a major challenge in drug development, often resulting in late-stage drug withdrawals, substantial financial losses, and serious risks to patient safety. Conventional preclinical models, such as two-dimensional (2D) cell cultures and animal models, frequently fail to predict human-relevant hepatotoxicity due to their limited cellular complexity, lack of physiological perfusion, species-specific differences, and inability to capture immune-mediated mechanisms. To overcome these limitations, we leveraged three-dimensional (3D) human cell-based microphysiological liver models with varying levels of cellular complexity and compared their performance to that of conventional 2D monocultures and co-cultures. In these models, acetaminophen (APAP), trovafloxacin (TVX), and levofloxacin (LVX) were tested to evaluate their ability to reproduce clinically relevant hepatotoxic responses. **Methods:** Liver models for APAP exposure were assembled using upcyte human hepatocytes and liver sinusoidal endothelial cells (LSECs), forming a co-culture liver-on-chip system. APAP was tested exclusively in this model at clinically relevant concentrations (0-10 mM) for up to 7 days. For TVX and LVX, a more complex, triple-cell model was used, incorporating HepaRG hepatocytes, LSECs, and monocyte-derived macrophages (MDMs) as Kupffer cell surrogates to recreate multicellular liver microenvironments with integrated immune function. These drugs were perfused at clinically relevant concentrations (0-20 μ M) for up to 7 days. Endpoint readouts included immunofluorescence and live-cell imaging to assess morphology and toxicity markers, alongside cell viability comparisons with conventional 2D cultures. Effluents from hepatic and vascular channels were analyzed for lactate dehydrogenase (LDH), alanine aminotransferase (ALT), and cytokine release. Mechanistic analyses examined glutathione depletion and mitochondrial reactive oxygen species (ROS) formation to investigate the underlying mechanisms of DILI. **Results:** APAP induced concentration-dependent hepatocellular and vascular toxicity exhibited by reduced cell viability, elevated LDH release, and disrupted morphology at supraphysiological concentrations. Perfused liver-on-chip models showed enhanced sensitivity compared with 2D mono- or co-cultures. TVX exposure caused pronounced hepatic and vascular tissue damage at clinically relevant concentrations, accompanied by glutathione depletion, mitochondrial ROS formation, and pro-inflammatory cytokine release. Similar to *in vivo*, cytokine secretion was dependent on a multicellular immune response, highlighting the potential of the liver model for detecting idiosyncratic immune-mediated toxicity. Similar to APAP treatment, TVX-induced liver injury was more pronounced in the liver-on-chip compared to 2D cultures. In contrast, LVX exposure caused no toxicity. These results underscore the importance of perfusion, cellular complexity, and immune components in these 3D liver-on-chip models for accurately assessing hepatotoxicity. **Conclusions:** Collectively, we have demonstrated that 3D liver-on-chip models exhibit higher sensitivity than 2D cultures in detecting DILI for the tested drug compounds. Importantly, we were able to reproduce TVX-induced liver injury and elucidate associated toxicity mechanisms, which were not observed in mice studies without inflammatory co-stimulation. These findings underscore the potential of human liver microphysiological models as predictive *in vitro* platforms for evaluating drug-induced liver injury. By addressing the limitations of conventional animal models, this approach may improve the detection of undesirable drug-induced adverse events and reduce unnecessary animal use during preclinical testing.

PS 3679 A Translational 3D Spheroid Assay for Preclinical Assessment of Drug-Induced Liver Injury

J. Jia, Z. Wang, C. Zhang, and M. M. Xu. Pharmaron (Ningbo) Technology Development Co., Ltd., Ningbo City, Zhejiang Province, China. Sponsor: S. Luo

Background and Purpose: Drug-induced liver injury (DILI) remains a major challenge in drug development, often leading to compound attrition, post-market withdrawal, and usage restrictions. While traditional 2D hepatocyte cultures are limited in their physiological relevance and longevity, 3D liver spheroid models provide a more *in vivo*-like microenvironment, enabling sustained hepatocyte function and chronic toxicity assessment. In this study, we established a 3D spheroid model using primary human hepatocytes to better predict human DILI risks. **Methods:** Primary human hepatocytes were cultured in an ultra-low attachment platform to form 3D spheroids. Functional validation included monitoring CYP enzyme activity, albumin and urea secretion, and LDH release over four weeks. Transporter functional investigation was performed using benzbramarone (BSEP inhibitor) and PSC833 (P-gp inhibitor), with substrate accumulation measured via Choly-Lys-Fluorescein and Calcein-AM,

respectively. For hepatotoxicity screening, 110 drugs with known clinical DILI classifications were tested. The margin of safety (MOS) for each drug was calculated based on the ratio of human maximum plasma concentration (C_{max}) to the EC₅₀ derived from viability assays. **Results:** The 3D hepatocyte spheroids maintained functional stability throughout the 4-week culture period, as demonstrated by sustained CYP enzyme activity, stable urea production, consistent albumin secretion, and LDH release. Functional transporter studies showed that benzobromarone (a BSEP inhibitor) significantly increased bile acid accumulation without evidence of mitochondrial toxicity. Similarly, PSC833 (a P-gp inhibitor) enhanced intracellular retention of Calcein-AM, confirming P-gp transporter activity. Multiparameter analysis using mBCL (GSH content), Sytox Green (DNA damage), and Mitotracker Deep Red (mitochondrial mass) revealed compound-specific injury patterns following drug treatment. Using a margin of safety (MOS) cut off of 50 for DILI prediction yielded 85.29% sensitivity for positive compounds and 76.92% specificity for negative compounds. **Conclusions:** The 3D primary human hepatocyte spheroid model demonstrates robust functional maintenance and enables comprehensive assessment of drug-induced liver injury. Through chronic exposure studies, this system successfully identified known hepatotoxic drugs. The implementation of an MOS threshold of 50 provided high predictive accuracy for clinical DILI. These findings establish the 3D spheroid model as a valuable tool for evaluating chronic drug toxicity and improving drug safety assessment.

PS 3680 Untargeted Lipidomics Reveals Mechanistic Signatures of Drug Induced Hepatotoxicity in Rat Hepatocytes

S. Zhang, X. Li, J. Lai, D. Li, C. Han, and M. M. Xu. Pharmaron Beijing Co., Ltd., Beijing, China. Sponsor: S. Luo

Background and Purpose: Drug-Induced Liver Injury (DILI) remains a leading cause of drug withdrawal from the market. A thorough understanding of DILI mechanisms is critical for ensuring the safety of drug candidates. Predicting mechanism-based toxicity can aid in identifying potential adverse effects and optimizing drug design. However, evaluating hepatotoxicity *in vitro* and translating these findings to clinical outcomes remain challenging. Untargeted lipidomics offers a sensitive approach for comprehensively profiling biological changes, particularly when mechanistic knowledge is limited, making it a valuable tool for elucidating the toxic mechanisms of novel drugs. Primary hepatocytes are regarded as the gold standard for *in vitro* drug toxicity assessment, and rodent plated hepatocytes provide a cost-effective model that can be compared with *in vivo* data prior to clinical trials. **Methods:** Mechanism specific lipidomic changes were investigated in rat plated hepatocytes to explore pathways underlying drug induced hepatotoxicity. Primary hepatocytes were treated for 24 hours with twelve toxic and three non toxic reference compounds representing different mechanisms, including oxidative stress, apoptosis, mitochondrial injury, and cholestasis. Untargeted lipidomic profiling of nonpolar metabolites was conducted using high resolution liquid chromatography coupled with mass spectrometry. Processed data were analyzed using Orthogonal Partial Least Squares Discriminant Analysis (OPLS-DA) to identify metabolite patterns associated with specific toxicity mechanisms. Key discriminatory metabolites were further evaluated through statistical testing and machine learning to identify potential biomarkers for predicting mechanism specific hepatotoxicity. **Results:** OPLS-DA revealed clear separation among hepatocyte nonpolar metabolites treated with apoptotic, mitochondria-disrupting, and cholestasis-inducing drugs compared with their respective non-toxic controls. Several metabolites showed significant changes even at low concentrations. Potential biomarkers for predicting drug toxicity were identified using machine learning. **Conclusions:** These findings demonstrate the potential of combining *in vitro* rat hepatocyte models with lipidomic profiling to predict mechanism-specific hepatotoxicity and provide early warnings of toxicity risks during drug development.

PS 3681 Phenotypic Profiling of Drug-Induced Liver Injury Using Cell Painting in 2D and 3D Human Hepatocyte Models

J. Xu, Z. Wu, Y. Wang, and F. He. Pharmaron Beijing Co., Ltd., Beijing, China. Sponsor: S. Luo

Background and Purpose: Drug-induced liver injury (DILI) remains a critical challenge in pharmaceutical development, emphasizing the need for more comprehensive and physiologically relevant evaluation methods. While conventional 2D primary human hepatocyte (PHH) cultures are widely used for high-throughput toxicity screening, they suffer from rapid dedifferentiation and limited physiological relevance. In contrast, 3D PHH spheroid models exhibit a higher degree of physiological relevance to the native liver, maintaining long-term phenotypic stability and enhanced metabolic function. Conventional approaches in both systems often focus on viability endpoints, offering limited insight into cellular morphological perturbations. This study explores how the Cell Painting assay can complement established viability assessments in both 2D and 3D PHH models by capturing rich, high-dimensional morphological information. **Methods:** PHHs were cultured both as conventional 2D monolayers and as self-assembled 3D spheroids. Both models were exposed to a panel of FDA-categorized DILI compounds representing different concern levels, across eight concentrations spanning sub-cytotoxic to cytotoxic ranges. Cytotoxicity was assessed using the CellTiter-Glo (CTG) assay to determine IC₅₀

values. In parallel, the Cell Painting assay was performed using a multiplexed staining panel. High-content images were acquired on an Operetta CLS system, and quantitative morphological features were extracted to construct phenotypic profiles for both culture formats. **Results:** Both the CTG viability assay and the Cell Painting morphological assay revealed clear, concentration-dependent responses in the 2D PHH and 3D spheroid models. In general, the 3D spheroids exhibited different sensitivity profiles to the DILI compounds compared to 2D cultures. Cell Painting successfully captured phenotypic alterations that correlated with viability readouts in both models. Furthermore, it identified distinct, often more complex, morphological changes at sub-cytotoxic concentrations, with the 3D spheroids frequently showing a richer diversity of phenotypic features. Feature-based analysis in both models indicated compound- and concentration-dependent phenotypic patterns, suggesting potential differentiation among compounds with different DILI concern levels and provided complementary insights into hepatocellular responses to toxic exposure. **Conclusions:** The integration of Cell Painting with viability assessment offers a more informative and multi-dimensional framework for evaluating DILI. This combined methodology adds morphological context to conventional viability data, yielding a more comprehensive understanding of compound-induced toxicity in hepatocytes. By comparing 2D and 3D models, this study highlights the value of more physiologically relevant culture systems for capturing complex toxicological responses. It holds promise for improving early safety assessment by revealing subtle phenotypic perturbations that complement standard viability metrics.

PS 3682 Assessment of Primary Human Liver Microtissue Performance Consistency Across Donor Lots and Production Runs

L. Fäs, M. Colombo, D. Busler, A. Borgström, B. G. Filippi, and A. Raghunathan. InSphero AG, Schlieren, Switzerland. Sponsor: W. Tong

Background and Purpose: Hepatotoxicity remains a major cause of drug development failures and post-marketing withdrawals. To enhance the liver safety of drug candidates, researchers are increasingly integrating human-centric *in vitro* test systems into the drug development process. However, the use of the most physiologically relevant models is often constrained by issues of reproducibility, scalability, and high cost. In particular, the reliance on primary cells in these models introduces variability due to donor-to-donor differences. Manufacturing liver models using batches of primary cells pooled from multiple donors can help average out donor-specific differences, thereby reducing variability between primary cell batches. Culturing cells as spherical aggregates is well suited for standardized large-scale production and is particularly relevant for modelling globular organs, or organs composed of contiguous globular subunits, such as the liver. Liver microtissues are spherical aggregates composed of primary hepatocytes and a crude non-parenchymal cell fraction in physiological proportions. They are suitable for uniform, standardized production at scale in 96- or 384-well microplates and can be used both for high-throughput screening in early drug development and for more detailed mechanistic investigations conducted before or during clinical trials. **Methods:** The consistency of liver microtissue performance was assessed by comparing their volume, ATP content, drug metabolism, and inflammatory response across three different 10-donor liver cell lots, each produced in two independent manufacturing runs. The cytotoxic responses to 20 orally administered FDA-approved drugs were also evaluated twice for each cell lot. **Results:** Cytotoxicity dose-response curves for all twenty drugs were consistent across cell lots and production runs, yielding distinct ATP IC₅₀ values for each drug but similar values for the same drug across experiments. Liver microtissue volume, ATP content, and drug metabolism were also consistent across all three cell lots. **Conclusions:** Liver microtissues manufactured from 10-donor cell pools produced consistent results across different cell lots and production runs. Combined with their physiological relevance, miniaturization, and compatibility with scalable production and use, liver microtissues represent a promising analytical platform suited to the rigorous demands of industrial and regulatory applications.

PS 3683 Development of a human-relevant *in vitro* model of early-stage cholangiocarcinogenesis using HepaRG spheroids

N. Takahashi^{1,2}, P. Padiaditakis¹, R. Cortes¹, S. Ferguson¹, and A. Pandiri¹. ¹NIHES, Durham, NC; and ²IET, Ibaraki, Japan.

Background and Purpose: Despite its increasing incidence and poor prognosis, cholangiocarcinoma remains poorly understood. One known risk factor for intrahepatic cholangiocarcinoma (ICC) is chronic liver injury, which is often observed in chemical toxicity studies. Therefore, the development of new approach methodologies (NAMs) with high human relevance is essential for more accurate risk assessment. Recent evidence suggests that ICC may originate not only from cholangiocytes but also from progenitor cells or hepatocytes undergoing aberrant differentiation, a process thought to play a key role in early carcinogenic transformation. HepaRG cells, capable of differentiating into both hepatocytes and cholangiocytes, exhibit enhanced hepatic functionality in 3D spheroid culture compared with conventional 2D culture, making them a promising *in vitro* model for studying early events in human cholangiocarcinogenesis. This study aimed to determine whether aberrant differentiation observed in early rat ICC models could be replicated *in vitro* using primary rat hepatocyte (PRH) spheroids, and whether similar cellular responses could be modeled in

HepaRG spheroids to establish a human-relevant NAMs for cholangiocarcinogens. **Methods:** PRHs were isolated and cultured as spheroids using ultra-low attachment plates, followed by exposure to the cholangiocarcinogen thioacetamide (TAA) at concentrations of 0, 5, and 20 mM for 14 days. HepaRG spheroids were treated similarly. Samples from both models were collected on days 3 and 14, and cellular responses were analyzed by mRNA expression profiling and immunofluorescence staining, focusing on markers related to cell differentiation and proliferation. **Results:** In PRH spheroids, TAA exposure induced severe hepatocellular necrosis and down-regulation of hepatocyte markers, Albumin and Hnf4a. In contrast, cholangiocyte markers, Ck19 and Sox9, which were scarcely expressed in controls, were upregulated following TAA treatment, accompanied by the appearance of Sox9-positive hepatocytes. In HepaRG spheroids, TAA similarly suppressed hepatocyte markers and induced necrosis. Ck19-positive cholangiocytes expanded at the spheroid periphery, and cells co-expressing Sox9 and Hnf4a increased, suggesting a transitional phenotype. Gene expression analysis revealed that in PRH spheroids, differentiation-related genes *Yap1*, *Hes1*, and *Bmp4* were downregulated, while *Tgfb1* was upregulated. In contrast, all four genes were upregulated in HepaRG spheroids. Cell proliferation-related genes *Cyclin D1* and *Myc* were consistently upregulated in both models, while growth factor receptor expression showed model-specific patterns: *ErbB2* increased in PRH spheroids, whereas *Met* and *Egfr* were elevated in HepaRG spheroids. **Conclusions:** TAA exposure triggered hepatocyte-to-cholangiocyte phenotypic conversion in both PRH and HepaRG spheroids, highlighting aberrant differentiation as an early hallmark in cholangiocarcinogenesis. Distinct regulation of differentiation-related genes suggests species- and cell-type-specific mechanisms. The shared upregulation of proliferative markers along with increased growth factor receptor expression indicates common initiating events. These findings support the potential of HepaRG spheroids as a human-relevant NAM platform for predicting early cholangiocarcinogenesis.

PS 3684 Role of Hydrolysis in the Cytotoxicity of 3-(3,5-Dichlorophenyl)-2,4-thiazolidinedione (DCPT) and Its Metabolites in HepG2 Cells

Z. Feng, and P. Harvison. Saint Joseph's University, Philadelphia, PA.

Background and Purpose: Troglitazone (TRO), a thiazolidinedione (TZD) antidiabetic drug, was withdrawn from the market due to severe hepatotoxicity. The TZD ring, a distinctive five-membered heterocycle shared by TRO and related compounds, was subsequently identified as a potential contributing factor to the observed toxicity. To investigate the mechanism behind TZD ring toxicity, we evaluated a structurally analogous compound, 3-(3,5-dichlorophenyl)-2,4-thiazolidinedione (DCPT), using human hepatoma HepG2 cells. In addition, DCPT hydrolysis was analyzed in the presence and absence of HepG2 cells over time using reverse-phase HPLC. **Methods:** The experimental design involved seeding HepG2 cells in 96-well plates, incubating them for 24 hours, and then treating them with DCPT and its potential hydrolysis products, S-(3,5-dichlorophenyl) aminocarbonyl thioglycolic acid (DCTA), 3,5-dichlorophenyl isocyanate (DPI), and mercaptoacetic acid (MAA), at with concentrations ranging from 0 μ M to 200 μ M in complete DMEM/F12 media. Hydroxyacetic acid (HAA), an analogue of MAA, was also evaluated. Cell viability was assessed by the Promega MTS cytotoxicity assay after 1, 4, and 24 hours. For monitoring DCPT hydrolysis, HepG2 cells were seeded in 96-well plates as above for 24 hours, and then treated with DCPT (200 μ M). Parallel DCPT treatment solutions were added to wells containing no cells to evaluate the possibility of spontaneous hydrolysis. Samples from the wells were collected at various time points ranging from 0 to 24 hours, and the presence of DCPT and its hydrolysis products was assessed by HPLC. Results were generated using GraphPad Prism (Version 10.2.3; GraphPad Software Inc. San Diego, CA) and are expressed as means $\pm$ standard deviations ($n=4-5$ for cytotoxicity experiments and $n=4$ hydrolysis experiments). The data were analyzed by a one-way ANOVA followed by a Dunnett's post hoc test and/or Student's t-test. Differences in the means were considered significant when $p < 0.05$. **Results:** MTS assay at 24 hours revealed concentration-dependent toxicity of DCPT (14.33% $\pm$ 2.92% viability at 200 μ M), DCTA (32.73% $\pm$ 17.73% at 200 μ M) and DPI (21.42% $\pm$ 8.85% at 200 μ M), while MAA and HAA exhibited no cytotoxicity. Loss of viability was not as pronounced at earlier time points. DCPT exhibited limited cytotoxicity at 1 hour and became more toxic at 4 hours (83.34% $\pm$ 7.42%). DPI produced severe cytotoxicity at both 1 hour (29.21% $\pm$ 11.06%) and 4 hours (23.37% $\pm$ 3.91%). Co-incubation of DCPT with either MAA or HAA produced similar losses of cell viability to DCPT alone. The HPLC data revealed that DCPT hydrolysis was evident as early as 30 minutes. By 4 hours, the majority of DCPT (83.34% $\pm$ 7.4%) had been hydrolyzed to DCTA. DCTA levels peaked at 2 hours and then slowly decreased over 24 hours. DPI was sporadically detected at 4 hours and became more prominent at 24 hours. Degradation of DCPT to DCTA and DPI did not appear to be different in the presence or absence of cells. **Conclusions:** These results suggest that individual treatment with DCPT, DCTA and DPI resulted in severe cytotoxicity in HepG2 cells at 24 hours. Since DCTA and DPI, two hydrolysis products, are formed rapidly and onset time of cytotoxicity is early, they may contribute to DCPT cytotoxicity in the HepG2 cells. The similar degradation pattern observed in media with and without cells indicate that DCPT hydrolysis proceeds largely spontaneously. Altogether, these findings demonstrate that DCPT toxicity in HepG2 cells may result, at least in part, from its spontaneous degradation to cytotoxic intermediates, providing insight into the role of TZD ring metabolism in hepatocellular injury.

PS 3685 3D Spheroid Formation of Rat and Human Cryopreserved Hepatocytes to Develop Model Systems for Liver Disease and Drug Development

D. T. Parks, B. S. Vasquez, J. J. Odanga, S. M. Anderson, S. C. Presnell, J. Chen, and J. R. Weaver. LifeNet Health, Virginia Beach, VA.

Background and Purpose: 3D liver spheroid models are fast becoming useful models for drug development and testing, due to their extended culture lifespan, metabolic stability, and compatibility with high-throughput assays. The goal of these studies was to assess spheroid formation and functional performance over 21 days in culture of cryopreserved primary hepatocytes from: 1) two strains of rat; 2) non-diseased human liver (Non-Alcoholic Steatohepatitis Activity Score (NAS) ≤ 3 ; and 3) diseased human liver (NAS ≥ 4). **Methods:** Cryopreserved rat hepatocytes (Wistar (RW; $n = 1$ lot, 8 donors) (ThermoFisher) and Sprague Dawley (RSD; $n = 1$ lot, 5 donors) (ThermoFisher)) or Primary Human Hepatocytes (PHHs) ($n \geq 2$ non-diseased donors and $n \geq 2$ diseased donors) were thawed, centrifuged, and counted. Cells were then resuspended in TruVivo® Flex Plating Medium (rat) or Human Hepatocyte Plating Medium (human) and seeded at 3,000 hepatocytes/well in a 96-well Nunclon Sphera™ U-shaped bottom plate. These plates were centrifuged at 100 g and placed in an incubator at 37°C/5% CO₂ for 5 days. Beginning on day 5, half volume media exchanges were performed every other day for the remaining culture period, using TruVivo Flex Culture Medium (rat) or Human Hepatocyte Culture medium (human). Albumin and urea levels were determined by ELISA (Abcam) and colorimetric biochemical assay (Stan Bio), respectively. Human Cytochrome P450 3A4 (CYP3A4) activity was measured using P-450 Glo kit (Promega). CellTiter Glo assay (Promega) was used to measure ATP levels. These assays were performed on days 7, 14, and 21. CDFDA (ThermoFisher) was used to stain bile canaliculi. Nile red staining (Abcam) for lipid was performed according to the manufacturer's instructions. **Results:** Spheroids formed with rat hepatocytes by culture day 7 and were maintained over a 21-day period. Urea levels in RW and RSD ranged from 875 $\pm$ 37.0 and 812 $\pm$ 52.6 μ g/10⁶ cells/day on day 7 to 236 $\pm$ 20.2 and 33.9 $\pm$ 5.84 μ g/10⁶ cells/day on day 21, respectively. ATP was measured in both strains on days 7 (RW: 23 $\pm$ 3.2 $\times 10^6$ RLU/10⁶ cells/mL; RSD: 2.0 $\pm$ 1.1 $\times 10^6$ RLU/10⁶ cells/mL) and 21 (RW: 7.5 $\pm$ 1.8 $\times 10^6$ RLU/10⁶ cells/mL; RSD: 1.8 $\pm$ 0.43 $\times 10^6$ RLU/10⁶ cells/mL). Both non-diseased and diseased PHHs formed spheroids by culture day 7 and had expected morphology for at least 21 days of culture. Albumin synthesis was similar between non-diseased and diseased spheroids on days 7 (76.4 $\pm$ 12.1 and 78.3 $\pm$ 8.00 μ g/10⁶ cells/day) and 21 (50.0 $\pm$ 28.2 and 71.7 $\pm$ 5.03 μ g/10⁶ cells/day). Urea levels for non-diseased and diseased PHHs ranged from 658 $\pm$ 41.1 and 439 $\pm$ 5.02 μ g/10⁶ cells/day on day 7 to 211 $\pm$ 34.4 μ g/10⁶ cells/day and not detected on day 21, respectively. No major differences were seen in CYP3A4 activity between non-diseased (day 7: 5.5 $\pm$ 1.0 nm/10⁶ cells/min; day 21: 27 $\pm$ 3.7 nm/10⁶ cells/min) and diseased spheroids (day 7: 6.8 $\pm$ 0.40 nm/10⁶ cells/min; day 21: 32 $\pm$ 7.5 nm/10⁶ cells/min) over time. ATP levels differed between non-diseased spheroids (day 7: 14 $\pm$ 1.9 $\times 10^6$ RLU/10⁶ cells/mL; day 21: 18 $\pm$ 1.9 $\times 10^6$ RLU/10⁶ cells/mL) compared to diseased spheroids (day 7: 10 $\pm$ 0.88 $\times 10^6$ RLU/10⁶ cells/mL; day 21: 7.6 $\pm$ 0.5 $\times 10^6$ RLU/10⁶ cells/mL). Human bile canaliculi networks formed within both types of human spheroids by day 7 and became more extensive over the culture period. Nile red staining showed steatosis in both normal and diseased donors. **Conclusions:** In conclusion, rat hepatocytes formed spheroids by day 7 and demonstrated functionality via urea production throughout the 21-day culture period. Although differences were seen between strains, additional lots need to be tested. Spheroids were also formed using non-diseased and diseased PHHs by day 7 that maintained albumin and urea function and CYP3A4 activity throughout the 3-week culture period. Although differences in urea and ATP levels were measured, it was unexpected to determine similar albumin levels along with CYP3A4 activity in spheroids derived from diseased versus non-diseased PHHs. In addition, bile canaliculi were detected, and lipids were detected from both non-diseased and diseased spheroids. Overall, these spheroids demonstrate characteristics that can be used to develop a model system for studies of liver disease and toxicity of drugs and chemicals.

PS 3686 Precision-Cut Liver Slices provide a human, immune-competent tissue model for mechanistic assessment of immune-related Drug-Induced Liver Injury

S. Dehmel¹, K. Schmidt¹, F. Dahlmann¹, J. Fiedler¹, C. Hesse¹, H. Aselmann¹, J. Fangmann², S. Escher¹, and K. Sewald¹. ¹Fraunhofer Institute for Toxicology and Experimental Medicine (ITEM), Hanover, Germany; and ²KRH Siloah Hospital, Hepatobiliary Surgery, Hanover, Germany.

Background and Purpose: Immune-related mechanisms in drug induced liver injury (irDILI) are pre-clinically understudied. Sitaxsentan, an endothelin-A and B receptor antagonist (ERA) was withdrawn from the market due to hepatotoxicity. The benefit of anti-inflammatory corticosteroid treatment during sitaxsentan-induced liver injury, particularly in severe cases, suggests immune-mediated mechanisms which are, however, still elusive. Here we aim to unravel early immune reactions to ERA and the well-known DILI APAP using human Precision-Cut Liver Slices (PCLIS) *ex vivo*. **Methods:** Immune competence of human PCLIS was characterized by flow cytometry and cytokine responses to anti-CD3/28, LPS, poly I:C and concavalin A. Sitaxsentan, ambrisentan, and APAP were tested for immune modulation using multiplex cytokine analysis and qPCR of inflammatory markers after 48h cultivation. Cytotoxicity was

assessed by LDH release, KRT18 and CDKN1a expression, while metabolic activity using WST-1 assay and CYP450 function (CYP3A4, CYP2C9) were measured as liver functionality parameters. **Results:** Flow cytometry revealed substantial immune cell presence (20-40%), dominated by T cells (66%, CD8/CD4 ratio 2.5) and 17% NKT cells. Human PCLiS secreted distinct cytokines upon cultivation with immune stimuli, confirming immune reactivity. Sitaxsentan (255 μ M) preferentially induced IL-12p70 (1.4-fold), IL-13 (1.13-fold), and IL-2 (1.07-fold), indicating Kupffer cell activation and potential NKT involvement. Ambrisentan (23.5 μ M) lacked this profile, consistent with its lower clinical toxicity. APAP induced IFN- γ response and at high doses reduced metabolic activity, with decreased *KRT18* and *CDKN1a* gene expression. ERAs enhanced CYP3A4 and CYP2C9 gene expression without cytotoxicity at tested concentrations. **Conclusions:** Our model reflects APAP-induced hepatitis across key events of AOP 362, while sitaxsentan-induced inflammation may involve alternative mechanisms. Early IL-12p70 secretion point to Kupffer cell activation, warranting further studies deciphering immune cell activation of liver tissue-resident cells. PCLiS provide essential mechanistic insights into immune-mediated hepatotoxicity, supporting translational preclinical safety assessment, enhancing human relevance, reducing animal use, and enabling mechanism-based prediction of DILI.

PS 3687 Microphysiological liver-on-chip integrating HepaRG™ cells and liver sinusoidal endothelial cells (LSECs) for drug-induced liver injury assessment

H. Coppens-Exandier¹, A. Giau¹, A. Mesic², L. Blasco³, P. Bachour El Azzi¹, A. Jamin¹, and E. Subileau¹. ¹Biopredic International, Saint-Grégoire, France; ²ENS Paris – Saclay Laboratoire LUMIN (UMR9024), Orsay, France; and ³Institut FEMTO-ST (UMR6174), Besançon, France. Sponsor: M. Pallardy

Background and Purpose: Drug-induced liver injury (DILI) remains a leading cause of drug attrition and withdrawal, highlighting the need for more predictive *in vitro* liver models. Conventional 2D hepatocyte cultures often fail to reproduce the complex microenvironment and intercellular interactions that impact hepatic responses to xenobiotics. In particular, the crosstalk between hepatocytes and liver sinusoidal endothelial cells (LSEC) plays a crucial role in maintaining liver homeostasis, influencing metabolism, transport, and inflammatory responses. To better mimic these physiological features, we developed a microphysiological system (MPS) combining human HepaRG hepatocytes and primary LSEC under dynamic flow conditions. The aim of this study was to assess whether this co-culture model improves the prediction of drug-induced cytotoxicity compared to conventional static monocultures. **Methods:** The MPS chip consists of two channels: one containing HepaRG™ cells and the other containing LSECs, separated by a communicating hydrogel (20 mg/mL alginate solution). Hepatocyte differentiation was evaluated by immunofluorescent labeling of HNF4a and by assessing bile canaliculi formation using the fluorescent probe Fluobite™ 1. Albumin secretion was quantified by ELISA and labeled by immunofluorescence. To assess hepatotoxicity, cells were exposed to 2 mM APAP for 48 or 72 hours to mimic toxic stress conditions. Cellular viability was measured via LDH release, while oxidative stress and mitochondrial integrity were monitored using MitoTracker live staining. Activities of seven major CYP450 enzymes were determined by incubating cells with Xenomix™ CYP substrates and measuring substrate clearance by LC-MS/MS. In addition, CYP3A4 activity was assessed using a live staining approach. **Results:** HNF4a and albumin immunolabeling, together with quantitative measurement of albumin, demonstrated a high level of differentiation and functionality of HepaRG™ cells within the liver-on-chip model. This was further confirmed by the presence of bile canaliculi structures formed by HepaRG™ hepatocytes. Albumin secretion was significantly reduced following APAP exposure compared with control conditions, as shown by both ELISA quantification and immunofluorescence analysis. This decline reflects an impaired hepatic synthetic function, a hallmark of hepatocellular injury. A strong increase in LDH release was observed after 48 hours of exposure to 2 mM APAP, confirming cytotoxicity induced by APAP overload. MitoTracker staining showed a pronounced reduction in mitochondrial signal in treated cells, consistent with elevated oxidative stress and mitochondrial dysfunction, in line with the well-established mechanism of APAP-induced hepatotoxicity. CYP3A4 staining revealed a significant decrease in enzyme expression following APAP treatment, accompanied by increased signal heterogeneity and tissue disorganization. Similarly, enzymatic activity assays indicated a general reduction across multiple CYP450 isoforms in APAP-treated hepatocytes, further supporting the loss of metabolic competence under toxic stress conditions. **Conclusions:** We successfully established a co-culture liver-on-chip model integrating HepaRG™ cells and primary LSECs. The system effectively reproduced key features of APAP-induced liver injury, demonstrating its relevance for hepatotoxicity assessment. Future developments should focus on evaluating additional DILI-associated compounds and incorporating other hepatic cell types, such as Kupffer and stellate cells, to more closely recapitulate the hepatic microenvironment and enhance the physiological relevance of the system.

PS 3688 Systematic characterization of transcriptional reprogramming by non-genotoxic carcinogens after single or repeated exposure of hiPSC-derived hepatocyte-like cells

L. Xu, P. J. Bouwman, and B. van de Water. Leiden Academic Centre for Drug Research, Leiden University, Leiden, Netherlands.

Background and Purpose: Exposure to environmental chemicals is an important risk factor for cancer. The standard 2-year rodent bioassay limits the rapid and cost-effective evaluation of possible carcinogenic risk and may not represent human relevant mechanisms of chemical carcinogenesis. Both genotoxic as well as non-genotoxic carcinogenic can drive tumorigenesis. While genotoxic carcinogens are relatively easy to detect using non-animal approaches, the complexity of mechanisms and repeated dosing that drive non-genotoxic carcinogen (NGTxC) cancer formation creates challenges to predict carcinogenic risk using non-animal approaches. The liver is the most important target of chemical carcinogenesis. High-throughput transcriptomics allows the identification of the mode of action (MoA) of NGTxC for the liver. We utilized human-induced pluripotent stem cell (hiPSC)-based hepatocyte-like cell (HLC) cultures and systematically defined the potential differences in transcriptional reprogramming of HLCs after single 24 hr treatment or 8-day repeated exposure to six different chemicals. **Methods:** Six compounds with different modes of action were selected: cyclosporin A, nitrofurantoin, potassium bromate, ochratoxin A, phorbol 12-myristate 13-acetate (PMA), and etoposide. hiPSC-derived HLCs were treated at different concentrations for either 24 h (single exposure) or every 48 h for eight days (repeated exposure). Cytotoxicity was measured using propidium iodide staining at two time points through live-cell confocal imaging. Concentrations for transcriptomics analysis were based on the highest non-cytotoxic concentrations after 8-day repeated exposure. Samples were collected at 24 h and 8 days, and followed TempO-Seq targeted RNA sequencing. The DESeq2 package was applied for differential gene expression analysis. The data were further analysed using hiPSC-derived HLC TXG-MAPr application tool to identify up- and down-regulated gene modules to get deeper insights into the different responses from the two time points. **Results:** The transcriptomics data showed robust differentiations of hiPSCs into HLCs, maintaining transcriptomic stability over eight days of repeated exposure. Transcriptomic analysis revealed time- and compound-dependent responses: cyclosporin A showed a similar number of differentially expressed genes (DEGs) at both time points; nitrofurantoin, potassium bromate, and ochratoxin A exhibited a significantly increased number of DEGs and stronger concentration responses following repeated exposure, while etoposide and PMA showed decreased DEG numbers. Gene network activity analysis using the HLC TXG-MAPr provided more mechanistic insight into each compound at two time points. The module correlation analysis indicated that compound responses from the same time point overall clustered together. The regulations of gene network modules markedly differed among compounds. E.g., modules associated with endoplasmic reticulum stress were upregulated under cyclosporin A treatment, whereas potassium bromate induced oxidative stress-related modules. Comparing the module patterns of the same compound across two exposure time points, some modules exhibited consistent regulation at both time points, while some modules displayed unique regulatory patterns or even reversed after repeated exposure. The data indicate that the assessment of MoA for NGTxC characterization is highly dependent on the treatment scenario. **Conclusions:** hiPSC-derived HLCs represent a robust human *in vitro* test method to assess NGTxC MoA. 8-day repeated exposure uncovered altered and more pronounced transcriptomic responses with the selected compounds that were not apparent after single exposure. This study highlights that repeated exposure could provide more insightful toxicological profiles of compounds for identifying and characterizing NGTxC.

PS 3689 Trends in Intrinsic Clearance of Drugs in *In Vitro* Liver Test Systems: Insights from a CRO's Microsome and Hepatocyte Data

T. A. Mueller¹, L. J. Haupt², C. E. Noah¹, and B. W. Ogilvie². ¹BioIVT, Hicksville, NY; and ²BioIVT, Kansas City, KS. Sponsor: T. Mueller, International Society for the Study of Xenobiotics

Background and Purpose: Drug developers have long aimed to design molecules with low metabolic turnover. *In vitro* assays, such as metabolic stability studies, are commonly used as an initial approach to assess how rapidly compounds are metabolized and to estimate turnover rates to guide early drug development. We therefore used *in vitro* metabolism study data to examine whether there has been a shift over time toward drug candidates with lower turnover. **Methods:** To evaluate trends in metabolic turnover, we analyzed more than 400 sponsored metabolism studies conducted by XenoTech (now part of BioIVT) between 2000 and 2023, focusing on human liver microsomes and hepatocytes as test systems. Intrinsic clearance (CL_{int}), a key determinant of hepatic metabolism and systemic exposure, was used when reported or calculated from half-life data to normalize results. The drug candidates were then categorized into groups representing high, medium, and low turnover compounds based on the CL_{int} values adjusted to the typical incubation times of the two test systems. **Results:** In microsomal assays, approximately 40-48% of compounds exhibited $CL_{int} > 23 \mu\text{L}/\text{min}/\text{mg}$ protein, while a similar proportion showed low intrinsic clearance of $< 5.78 \mu\text{L}/\text{min}/\text{mg}$ protein. These proportions remained consistent over the time periods analyzed. In contrast, 60-80% of compounds tested in hepatocytes had half-lives exceeding 120 or 240 minutes corresponding to $CL_{int} < 5.78$ and $< 2.89 \mu\text{L}/\text{min}/\text{million cells}$. Notably, there was a slight

increase in the proportion for these low-turnover compounds in the most recent time period (2016-2023) compared to 2008-2015. However, the overall number of studies decreased over these years complicating the interpretation. **Conclusions:** Analysis of *in vitro* test systems revealed no significant trend toward lower turnover in micro-somal assays, while hepatocyte studies suggest a modest increase in low-turnover compounds. Taken together with the overall decrease in study numbers and tested drug candidates, this could also indicate that drug developers are looking for test systems that are better suited to measure low-turnover compounds.

PS 3690 Microphysiological Systems as Predictive Tools for Liver Toxicity and Metabolic Function: A Multi-platform Comparative Study

C. Sakolish¹, P. Hewitt², R. Villenave³, H. Nah⁴, S. Khetani⁴, and I. Rusyn¹. ¹Texas A&M University, College Station, TX; ²Merck KGaA, Darmstadt, Germany; ³Roche Pharma Research and Early Development, Basel, Switzerland; and ⁴University of Illinois, Chicago, IL.

Background and Purpose: To advance the utility of *in vitro* liver models, it is essential to characterize their robustness, reproducibility and comparative performance. This study evaluated the baseline function and drug-induced responses of primary human hepatocytes (PHH; BioIVT) across three *in vitro* liver models of varying complexity: the TissUse Humimic Chip2 microphysiological system (MPS), 24-well micro-patterned co-cultures (MPCCs) of PHH and 3T3-J2 fibroblasts, and 96-well static monolayers of PHH. **Methods:** The Humimic Chip2 MPS employed in-chip formation of PHH microspheroids and was assessed exclusively in BioIVT hepatocyte maintenance medium (HMM). Both the MPCC and 96-well models, which offer higher throughput, were tested under two media conditions, HMM and a co-culture medium (CoCM) optimized to support both hepatocytes and stromal fibroblasts, yielding five total culture conditions for comparison. In all models, PHH were maintained for 10 days prior to drug treatment. Hepatotoxicity was evaluated using Troglitazone (243 µM) and Fialuridine (25.6 µM), administered every second day for two weeks. Functional endpoints (albumin secretion, lactate dehydrogenase (LDH) activity, blood urea nitrogen (BUN) production, and alanine (ALT), aspartate (AST) aminotransferase activity, and CYP3A4 activity) were monitored over time. Drug metabolism function was assessed using Acetaminophen and Warfarin (both at 1 µM), with LC-MS/MS quantification of the kinetics of compound disappearance from the media. **Results:** Baseline function analyses indicated that albumin secretion was highest in the TissUse MPS. LDH activity was strongly influenced by media composition, with higher baseline levels observed in MPCCs cultured in CoCM. Following drug exposure, the 96-well and MPCC models demonstrated comparable toxicity profiles over time, whereas the TissUse system exhibited delayed and muted toxicity responses. In the 96-well and MPCC models, hepatotoxic responses were much more pronounced with HMM as compared to CoCM, suggesting that media formulation significantly impacts *in vitro* toxicity outcomes. In addition, baseline CYP3A4 activity was approximately 3-fold higher in MPCCs vs 96-well monocultures when cells were cultured in HMM, indicating that co-culture with fibroblasts enhances hepatocellular metabolic function. The use of CoCM further increased baseline CYP3A4 activity, producing roughly a 4-fold elevation in both MPCC and 96-well models relative to their counterparts in HMM, underscoring the combined impact of media composition and cellular context on metabolic competency. These findings suggest that while increased model complexity (e.g., Humimic Chip2 MPS) may enhance baseline hepatocyte function, media composition may be a dominant determinant of model performance. In addition, the incorporation of fluid recirculation may attenuate toxic responses. **Conclusions:** Overall, this study underscores the importance of harmonizing culture conditions across platforms, particularly through standardized media formulations, as a critical step toward enabling the comparison of advanced *in vitro* liver models predictively without the confounding effects of non-cellular factors.

PS 3691 Novel Role of Macrophage Migration Inhibitory Factor in Hepatocyte Organellar Stress

D. J. Moinet, A. Zaman, N. Fatima, and K. L. Poulsen. Michigan State University, East Lansing, MI.

Background and Purpose: Alcohol-related Liver Disease (ALD) is a major cause of chronic liver disease and poses a significant socio-economic burden globally. Our lab found that hepatocyte-specific Macrophage Migration Inhibitory Factor (Mif) drives ethanol-induced liver injury in mice. Mif is a pleiotropic cytokine/chemokine that contributes to acute and chronic liver injury. The current study sought to investigate the mechanism by which Mif drives liver injury in response to ethanol feeding and exposure and expand on the current knowledge of the Mif signaling axis in ALD. **Methods:** Livers of hepatocyte-specific Mif knockout mice and Mif replete mice were sequenced and transcriptomes were analyzed by Gene Set Enrichment Analysis. Knockout clones of AML-12 hepatocyte of Mif and homologue d-dopachrome tautomerase (Mif2) were generated to interrogate the mechanisms of Mif-mediated hepatocyte damage. Cells were exposed to ethanol, hydrogen peroxide or ER stress inducing SERCA inhibitor Thapsigargin (TG) for 6, 24 and 48 hours and hepatocellular function and viability were determined. **Results:** Protection from liver injury due to ethanol exposure in hepatocyte Mif deficient mice was observed after 10 days of ethanol feeding. Surprisingly, Mif deficiency was associated with marked improve-

ment in expression of gene sets associated with mitochondrial function, opposed to canonical Mif-driven inflammation. Stable Mif knockout clones had improved mitochondrial function compared to wild type when exposed to ethanol, hydrogen peroxide or TG, as well as decreased mitochondrial DNA damage. A divergent response was noted between Mif and Mif2, wherein the rescue effect of Mif deficiency was not found in Mif2 clones which were more susceptible to mitochondrial dysfunction and cytotoxicity from either stimulus. **Conclusions:** These findings further illustrate a novel protective role of hepatocyte-specific Mif knockout in ALD and a divergent role for Mif2 in similar contexts. Moreover, a distinct mechanistic role might exist for Mif in organellar stress outside of its canonical role of a cytokine/chemokine. Further research will define the specific mechanisms by which Mif leads to organellar damage and the homologue-selective roles Mif or Mif2 might play in cytotoxicity.

PS 3692 Hepatic Stellate Cell Activation Drives Hepatocyte Sensitivity to *in vitro* Drug Toxicity

K. Twaroski, I. Gurevich, K. Willis, R. Fiene, and C. Carlson. FUJIFILM Cellular Dynamics, Inc, Madison, WI. Sponsor: R. Vaidyanathan

Background and Purpose: Hepatic Stellate Cells (HSC) play a critical role in hepatic homeostasis. In healthy liver, hepatic stellate cells exist in a quiescent state, storing Vitamin A and maintaining extracellular matrix. HSC activation occurs in response to liver injury, resulting in matrix deposition and cytokine release. This activation has the potential to sensitize the liver to hepatotoxic drugs such as Trovafloxacin and Chlorpromazine. Human iPSC-derived HSC offer a consistent, renewable source of quiescent HSC to interrogate acute and chronic liver injury. **Methods:** iCell Hepatic Stellate Cells (FUJIFILM CDI) were thawed and maintained as 3D spheroids in ultra-low attachment (ULA) plates to maintain quiescent state. Flow cytometry, RNA expression, and ELISA were used to characterize HSC quiescence and using the markers CD271, LRAT, Type I Collagen, and α-SMA. Vitamin A storage was determined by fluorescent intensity of cell lysates. iCell Hepatic Stellate Cells were cultured with either isogenic iCell Hepatocytes 2.0 or primary human hepatocytes. Co-cultures were assayed for spheroid formation, drug metabolism, hepatocyte maturity, and culture longevity. HSC were also co-cultured with hepatocytes in 3D on PhysioMimix "liver-on-a-chip" platform from CN-bio. **Results:** High expression of CD271 and LRAT combined with low expression of Type I Collagen, α-SMA, GFAP, and Desmin indicated iCell HSC can be maintained in a quiescent state. Upon activation by plating into 2D culture or addition of TGFβ, secretion of Type I Collagen was increased 8-fold by protein ELISA, while Vitamin A storage was significantly decreased. Trovafloxacin and Chlorpromazine treatment of mono-culture HSC led to detectable activation after 2 days at concentrations as low as 100 nM. Primary human hepatocytes cultured with iCell HSC became spheroid competent and maintained ALB secretion for 7 days. iCell Hepatocytes 2.0 cultured with isogenic quiescent HSC became sensitive to *in vitro* treatment Trovafloxacin and Chlorpromazine at 10 µM after 2 days. Improvements in hepatocyte functionality (from both primary and iPSC-derived) were observed with HSC co-culture, but further optimizations are required. **Conclusions:** Identifying and harnessing HSC activation state is a critical missing link in many liver toxicology workflows. The practical application of incorporating hepatic stellate cells can be technically and scientifically challenging, however, understanding HSC/Hepatocyte interactions is critical for these studies. Quiescent iPSC-derived iCell Hepatic Stellate Cells are a critical piece of liver biology providing the alternative to inherently variable primary HSC. Functional *in vitro* liver biology may be possible with complex Organ-on-a-Chip systems, media optimization, and culture conditions.

PS 3693 Development and Characterization of a Patient-Derived Liver Organoid Biobank

R. Bhowmick¹, B. O'Donnell¹, F. Pan¹, M. Rahman¹, S. Wani¹, W. Kools², P. Hewitt³, and V. Chu¹. ¹MilliporeSigma, Temecula, CA; ²MilliporeSigma, Burlington, MA; and ³Merck Healthcare KGaA, Darmstadt, Germany.

Background and Purpose: The liver, as the largest solid internal organ, is responsible for numerous essential functions. In addition, liver diseases account for about 2 million deaths annually worldwide (1). Traditional models for studying liver biology, such as 2D cultured primary cells, 3D spheroids and cell lines, do not accurately represent the *in vivo* metabolic and structural complexities. Additionally, animal models are often ineffective, costly, time-consuming and associated with ethical concerns. Thus, there is a critical need for advanced, tissue-mimicking liver models. Organoids are self-organizing 3D-cultured structures that replicate the structure and functionality of the original tissue (2). Patient-derived organoids (PDOs) closely resemble the source tissue and may mimic individual responses to therapies. In this study, we report the development and characterization of a biobank comprising 11 individual liver PDO lines, reflecting donor variability and enhancing the relevance of these models for toxicology applications. **Methods:** Liver tissue were obtained with donor consent. PDOs were generated by modifying a previously published protocol (3). In brief, samples were minced, digested, filtered, mixed with Matrigel (Corning) and cultured in liver PDO-specific growth media. When appropriate, undifferentiated (immature) PDOs were differentiated (matured) using media tailored for this purpose. **Results:** PDO lines were successfully expanded and cryopreserved. The

immature PDOs could be thawed and further expanded using our standard operating procedures, confirming the robustness of these lines. All PDO lines expressed liver-specific biomarkers, as confirmed by qPCR and confocal microscopy. When matured, these lines showed increased albumin and urea production, as well as inducible cytochrome P450 (CYP) activity, confirming their functional maturity. Levels of these phenotypes were donor dependent, suggesting that the biobank could represent the patient pool. Each PDO line was also established as microbial and viral contamination free and confirmed as unique through short tandem repeat analysis. **Conclusions:** This liver PDO biobank provides a representative snapshot of patient populations and may serve as a valuable tool for pharmaceutical clients. To date, we have successfully established and characterized 11 liver PDO lines, with further characterization ongoing. Our liver PDOs will significantly enhance the understanding of liver biology and disease mechanisms, offering substantial applications in drug testing, including DMPK and ADME/Tox studies. Future efforts will focus on scaling up, developing liver-specific assays, and generating PDOs from patients with specific liver conditions, such as hepatocellular carcinoma, MASLD, and NASH. PS 3694 FUNCTIONALLY RELEVANT hPSC-DERIVED HEPATOCYTES AND LIVER ORGANOIDS FOR HEPATOTOXICITY AND LIVER BIOLOGY MODELING

R. Sharma¹, C. Haston¹, J. Christie¹, A. V. Sampaio¹, E. Nolan¹, A. C. Eaves^{1,2}, S. A. Louis¹, and R. K. Conder¹. ¹STEMCELL Technologies, Vancouver, BC, Canada; and ²Terry Fox Laboratory, BC Cancer, Vancouver, BC, Canada. Sponsor: K. Tse

Background and Purpose: Functionally relevant human hepatocyte models are critical for drug safety and efficacy screening, cell therapy, and disease modeling. However, currently available *in vitro* models, such as primary human hepatocytes and immortalized cell lines, often rapidly de-differentiate or lack metabolic maturity. We developed workflows for the generation and culture of human pluripotent stem cell (hPSC)-derived hepatocytes and liver organoids to address these challenges, as convenient, scalable, and patient-representative alternatives to conventional models that can be banked and used for long-term studies. **Methods:** hPSC-derived hepatocyte-like cells (HLCs) were generated over 21 days using STEMdiff™ Hepatocyte Kit; hPSCs were first patterned to definitive endoderm cells, then differentiated to hepatic progenitors, and finally matured to HLCs. HLCs were also replated in Matrigel® domes to establish passageable liver organoids using STEMdiff™ Hepatic Organoid Growth Medium. These organoids were further matured in 3D culture using STEMdiff™ Hepatic Organoid Differentiation Medium (ODM). Hepatic functions were characterized in HLCs and organoids using an albumin ELISA kit for assessment of albumin secretion and the P450-Glo™ CYP3A4 Assay and Screening System for measurement of baseline and calcitriol or ketoconazole-modulated CYP3A4 activity. HLCs and organoids were also used for proof-of-concept toxicity testing, where dose-response viability data was generated using the CellTiter-Glo® 3D Cell Viability Assay following treatment with known hepatotoxic compounds ketoconazole, rifampicin, and acetaminophen. Organoids were also used for cholestasis modeling via an imaging-based readout, using 5-chloromethylfluorescein diacetate (CMFDA) for assessment of bile transporter functionality in the presence of compounds troglitazone and cyclosporine A, which are known to inhibit bile acid efflux. **Results:** hPSC-derived HLCs expressed hepatic proteins (66 ± 8% ALB+A1AT+; mean ± SD) and exhibited mature functionality, including CYP3A4 enzymatic activity and albumin secretion (n = 2 - 15). Subsequent culture and differentiation as organoids resulted in significant downregulation of fetal hepatocyte gene *AFP* (5.7-fold decrease; p < 0.0001), and increased expression of several mature hepatic genes, including *ALB*, *ASGR1*, *CYP3A4*, *CYP2C9*, *UGT1A1*, and *OTC* (n = 2 - 20). ODM-differentiated cultures also exhibited increased albumin secretion (2.9-fold increase; p = 0.0199) as well as CYP3A4 activity that was modulated using ketoconazole (average 2.0-fold decrease) and calcitriol (average 2.5-fold increase). HLC-derived organoids were sensitive to ketoconazole-, rifampicin-, and acetaminophen-induced hepatotoxicity (average ODM-differentiated organoid IC₅₀ = 58 µM, 527 µM, and 1.8x10⁴ µM, respectively; n = 2), and also exhibited dose-dependent responses to high liver injury-causing compounds, troglitazone and nefazodone. In contrast, organoids exhibited low or no responses to related low/no liver injury-causing compounds pioglitazone and buspirone, respectively. Organoids could also model bile transport and efflux. Fluorescence intensity, corresponding to the product of cytosolic CMFDA cleavage, in cultures treated with 50 µM troglitazone or 12.5 µM cyclosporine A was significantly higher (3.0-fold and 2.7-fold increase respectively; p < 0.0001) than the DMSO vehicle control, while 50 µM pioglitazone-treated cultures exhibited fluorescence intensity comparable to the vehicle control (1.1-fold increase; p = 0.9999) (n = 2). **Conclusions:** hPSC-derived HLCs and hepatic organoids represent a convenient, scalable, and patient-representative model of hepatic function, and could successfully be used in toxicity screening applications to model compound-specific responses. Organoids could be used to distinguish between low and high liver injury-causing compounds as well as between cholestatic and non-cholestatic compounds that modulate bile efflux and transport. These results demonstrate the utility of STEMdiff™ Hepatocyte Kit and STEMdiff™ Hepatic Organoid Media in hPSC-derived liver modeling and drug screening applications.

PS 3695 Chronic Cadmium and Glucose Crosstalk Drives Hepatic Lipid Dysregulation through PPAR Signaling and Membrane Remodeling in Hepatocellular Carcinoma cell lines

R. Kumar, A. Chinala, and R. R. Gullapalli. University of New Mexico, Albuquerque, NM.

Background and Purpose: The incidence of hepatocellular carcinoma (HCC) is increasing in the Western world over the past decades. Within the United States, rise of HCC cases has been mainly observed in the Southwest part of country including State of Texas, New Mexico, and Arizona. In New Mexico elevated numbers of HCC cases are seen among Hispanic and Native American populations of the states. Historically, these populations are prone to key risk factors of HCC such as diabetic and obesity. However, those risk factors alone are not sufficient to explain the rapid increase of HCC incidence observed in the past decades. We hypothesize additional environmental risk factor (i.e. heavy metal exposure) plays a key role in the Southwest United States including New Mexico. Cadmium (Cd) is a major key metal pollutant of global implication. Environmental cadmium (Cd) exposure and metabolic stressors such as hyperglycaemia are emerging as critical co-factors in the pathogenesis of metabolic-associated fatty liver disease (MASLD). However, their combined mechanistic impact on hepatic lipid homeostasis remains poorly understood. **Methods:** In this study, we chronically exposed human hepatocellular carcinoma cell lines (HepG2 and HUH7) to low-dose Cd (1 µM) for 24 weeks under normoglycemic (5.5 mM) or hyperglycemic (15 mM) conditions to mimic physiologically relevant, prolonged environmental and metabolic challenges. **Results:** Chronic Cd exposure alone modestly elevated lipid synthesis markers (ACCT1, FASN) and increased intracellular lipid content, suggesting enhanced *de novo* lipogenesis. Hyperglycaemia further exacerbate this lipogenic response. Interestingly, while Cd exposure alone increased the fatty acid transporter CD36, its expression markedly declined under combined Cd + hyperglycaemic conditions, indicating a possible adaptive downregulation of lipid uptake in response to lipid bilayer remodeling or oxidative stress. The concomitant upregulation of lipogenic enzymes and suppression of CD36 suggest a metabolic reprogramming that favors lipid synthesis over uptake, potentially contributing to intracellular lipid disequilibrium and mitochondrial burden. RNA-seq data analysis revealed transcriptional perturbations in PPAR-mediated dysregulation of lipid transport, and oxidation. Pathway enrichment highlighted alterations in linoleic acid and glycerophospholipid metabolism, aligning with metabolomic analysis from Cd-exposed systems that demonstrate disrupted TAG, DAG, and phosphatidylcholine (PC) profiles which were exacerbate in the hyperglycemic and cadmium exposed cells. Furthermore, we observed several remarkable differential lipidomics metabolites enriched these pathway. **Conclusions:** These results support a “two-hit” paradigm where environmental Cd exposure and metabolic dysregulation combinedly disturb hepatic lipid homeostasis, potentially linking disease to environmentally driven liver carcinogenesis.

PS 3696 The effect of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) on human liver cells-derived spheroids

A. Wojtowicz, K. Orlowska, and T. R. Zacharewski. Michigan State University, East Lansing, MI.

Background and Purpose: Three-dimensional (3D) *in vitro* liver models are essential tools in toxicology, as they support the Replacement, Reduction, and Refinement (3R) principle by reducing animal testing while providing physiologically relevant data. In contrast to traditional two-dimensional culture, 3D liver models, such as spheroids, more accurately replicate the complex structure and function of the liver *in vivo*, maintaining drug metabolism, enzyme activity, and cell-cell interactions over an extended period of time. These models improve the accuracy and relevance of toxicology studies to human risk assessment. This is particularly important, given the well-documented *in vivo* hepatotoxicity of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) in mice, which manifests as hepatic inflammation, steatosis, and fibrosis. This study examined the dose dependent effects of TCDD on human liver-derived spheroid viability, cytotoxicity, and gene expression. **Methods:** Spheroid models included (i) human hepatocytes only, and (ii) quad-cellular spheroids consisting of hepatocytes, liver endothelial cells, stellate cells, and Kupffer cells. Spheroids were treated with DMSO vehicle or TCDD (0.1, 1, 10, and 100 nM) for 24 hours. Effects on cytotoxicity, viability, *CYP1A1* and *CYP1A2* expression, as well as ethoxyresorufin activity were determined. Immunofluorescence staining confirmed the presence of the different cell types within the spheroids. **Results:** TCDD did not affect viability or LDH release in hepatocyte-derived spheroids. Moreover, TCDD dose-dependently induced *CYP1A1* and *CYP1A2* expression and ethoxyresorufin activity, consistent with AhR activation by TCDD. **Conclusions:** Human 3D liver spheroids provide a robust and mechanistically valuable model for elucidating AhR-mediated hepatotoxicity. This approach represents a critical step toward more predictive and human-relevant toxicological testing. Funded by SRP P42ES004911.

PS 3697 Integrated Assessment of Drug-Induced Cholestasis Using Sandwich-Cultured Human Hepatocytes: Combining Kinetic High-Content Imaging, Cytotoxicity Endpoints, and Transporter Inhibition for Early Discovery De-Risking

S. Madden, B. Park, S. Bevan, J. Eakins, and P. Walker. Cyprotex Discovery Ltd, Alderley Park, Cheshire, United Kingdom. Sponsor: C. Strock

Background and Purpose: Drug-induced liver injury (DILI) is a major challenge in drug development, contributing to clinical trial failures and post-marketing withdrawals. The liver's central role in xenobiotic metabolism makes it highly susceptible to adverse drug reactions. DILI can result from mechanisms such as hepatocellular toxicity, mitochondrial dysfunction, oxidative stress, and immune-mediated responses. A complex subtype, cholestatic DILI (cDILI), involves impaired bile flow due to inhibition of hepatic transporters (e.g., BSEP, MRPs, OATPs), leading to toxic intracellular bile acid accumulation. Sandwich-cultured hepatocyte models (SCH-PHH) and vesicular transport assays are established *in vitro* approaches for assessing bile acid transporter inhibition and cholestatic risk. These assays form part of new approach methodologies (NAMs) designed to improve human relevance and reduce reliance on animal testing. To enhance predictive power, NAMs increasingly incorporate advanced tools such as high-content imaging (HCI), which enables multiparametric phenotypic analysis. When combined with cytotoxicity endpoints like ATP depletion, HCI provides a more comprehensive view of hepatotoxic potential, complementing transporter inhibition data. **Methods:** Primary human hepatocytes were seeded in collagen-coated 384-well plates and overlaid with Matrigel to establish SCH-PHH. Cultures matured for four days before exposure to a proficiency set of 59 compounds (cDILI, DILI, and no-DILI) across concentration ranges for 24 h, with or without a bile acid/free fatty acid cocktail. Post-incubation, CMFDA staining enabled kinetic HCI of bile canaliculi morphology and bile acid accumulation. ATP-based viability assays complemented phenotypic data. Transporter inhibition profiles for BSEP, MRP2, MRP3, and MRP4 were generated for all compounds. **Results:** cDILI compounds exhibited strong BSEP inhibition (0.19-1,000 μ M) and variable MRP inhibition (MRP2: 21.9-708 μ M; MRP3: 3.34-2,610 μ M; MRP4: 0.6-226.7 μ M). DILI compounds showed moderate effects (BSEP: 79.8-10,000 μ M; MRP2: >100-399.7 μ M; MRP3: >100-281.3 μ M; MRP4: 1.7-10 μ M), while no-DILI compounds demonstrated minimal inhibition (BSEP $\geq$ 100 μ M; negligible MRP inhibition). Kinetic HCI revealed bile canaliculi disruption and bile acid accumulation in cDILI compounds, correlating with transporter inhibition and cytotoxicity. Integrated phenotypic and mechanistic data improved discrimination of cholestatic risk compared to single-endpoint assays. **Conclusions:** This NAM-based approach combining SCH-PHH, kinetic HCI, cytotoxicity, and transporter profiling enables mechanistic assessment of cholestatic liability. The integrated dataset supports early identification of cDILI risk, enhancing predictive power and reducing reliance on animal testing in drug discovery.

PS 3698 Effects of chronic overnutrition on mitoNEET in mouse livers

J. Shin, Y. Lin, W. Chapman, and J. Kim. Washington University in St. Louis, St. Louis, MO.

Background and Purpose: Mitochondrial dysfunction after prolonged consumption of high fat diets contributes to the onset of nonalcoholic fatty liver disease (NAFLD), the most common liver disorder globally. While lean livers tolerate moderate stressors well, fatty livers do not. How chronic steatosis impacts mitochondria remain elusive. mitoNEET (mNT) is a homo-dimeric mitochondrial outer membrane protein that regulates mitochondrial redox, bioenergetics, autophagy and iron homeostasis. **Methods:** Hepatocytes were isolated from male C57BL/6J mice either on a chow diet (CD) or on a high fat diet (HFD: 60 Kcal % fat, Research Diet # D12492) for 8 weeks. Cells were treated with dithiobis (succinimidyl propionate), a covalent crosslinker, to separate mNT monomers (mNTm) and oligomers (mNTo) from mNT dimers (mNTd). Changes in mNT expression, autophagy, mitochondrial membrane potential ($\Delta\psi$ m) and steatosis were assessed by immunoblot and imaging analysis. Some experiments were conducted in whole mouse livers. Since isolated hepatocytes do not represent cell-to-cell interactions, three-dimensional architecture, and zonal structure in the liver, we also generated precision-cut liver slices (PCLS) from mouse livers using a Krudieck automatic tissue slicer (Alabama R & D, Munford, AL). Thickness of individual PLCL was 200 microns. To investigate roles of $\Delta\psi$ m in steatosis-mediated disassembly of mNTd, hepatocytes from CD mice were incubated with 500 nM of carbonyl cyanide m-chlorophenylhydrazone (CCCP), a mitochondrial uncoupler, for up to 90 min. **Results:** The expression of mNTm and mNTo, nonfunctional forms of mNT, in HFD hepatocytes and livers was significantly greater than that of CD counterparts. Confocal imaging analysis with tetramethylrhodamine methylester demonstrated that $\Delta\psi$ m of HFD hepatocytes was 28.1% of CD hepatocytes. Confocal microscopy of rhodamine-123 confirmed substantial mitochondrial depolarization in PCLS from the HFD group, not from the CD group. Treatment of lean hepatocytes with CCCP progressively depolarized $\Delta\psi$ m and accumulated mNTm followed by mNTo, suggesting the disassembly of mNTd by mitochondrial depolarization. HFD hepatocytes failed to respond to autophagic stimuli such as starvation and rapamycin, which was, however, reversed by genetic deletion of mNT. **Conclusions:** Chronic overnutrition depolarizes mitochondria, leading to the dissociation of mNTd into mNTm and the formation of mNTo. The accumulation of nonfunctional mNT consequently impairs autophagy, thereby sensitizing steatotic livers to moderate stressors.

PS 3699 Multidrug Resistance-Associated Protein 4 (MRP4) Deficiency Disrupts Hepatic Lipid Homeostasis and Exacerbates Metabolic Dysfunction-Associated Steatotic Liver Disease

H. Wu, A. P. Laddha, and J. E. Manautou. University of Connecticut, Storrs, CT.

Background and Purpose: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) is characterized by dysregulated hepatic lipid metabolism, resulting in fat accumulation ($\geq$ 5%) in the liver without significant alcohol consumption. MRP4 (ABCC4) is a sinusoidal efflux transporter that exports a broad range of xenobiotics and endogenous substrates. Recent studies indicate that loss of MRP4 function alters hepatocellular signaling networks that regulate energy balance and lipid handling, contributing to metabolic disturbances, including obesity and diabetes. Consistent with its highly inducible and protective role in the liver, MRP4 expression is markedly elevated in hepatic tissues of obese individuals, implying a compensatory response to metabolic stress. Given these observations, we aimed to define how MRP4 deficiency disrupts hepatic lipid homeostasis using complementary *in vivo* and *in vitro* MASLD models. **Methods:** To assess the systemic impact of MRP4 deficiency, an *in vivo* high-fat, high-sucrose diet (HFHSD) study was performed using wild-type (WT) and *Mrp4*^{-/-} C57BL/6J mice. Animals were maintained on either a standard chow diet or HFHSD for 24 weeks. At study completion, serum ALT and triglycerides were quantified using commercial assay kits to evaluate liver injury and systemic lipid metabolism. Liver tissues were examined histologically to assess steatosis and inflammation. Hepatic expression of genes involved in lipid metabolic pathways was measured by RT-qPCR. To translate the *in vivo* findings into a human-relevant system, an *in vitro* hepatic MASLD model was established using the HC-04 human hepatic cell line. Steatosis was induced with oleic and palmitic acid (OA: PA, 2:1 molar ratio) at concentrations ranging from 100 to 400 μ M. MRP4 activity was pharmacologically inhibited with MK-571 (2.5-20 μ M). Cell viability was determined by MTT assay, and intracellular lipid accumulation was visualized and quantified using Oil Red O staining. **Results:** As previously reported, *Mrp4*^{-/-} mice displayed elevated serum ALT and triglycerides levels following HFHSD feeding compared with WT mice, indicating enhanced liver injury and systemic dysregulation of lipid metabolism. H&E staining showed increased steatosis and inflammation in *Mrp4*^{-/-} livers. RT-qPCR analysis showed altered expression of key lipid-regulatory genes, including *Ppara*, *Fxr*, *Cd36*, *Apob*, *Scd1*, *Cpt1a*, *Dgat2*, and *Glut2* in liver tissue under both chow and HFHSD diet conditions. Guided by these *in vivo* findings, we developed an *in vitro* MASLD model using HC-04 hepatocytes. MK-571 treatment for 24 hours did not cause cytotoxicity. Free fatty acid (FFA) treatment alone (100-400 μ M OA: PA) did not affect cell viability either. Based on these results, MK-571 at 10 μ M, with or without FFAs, was selected for functional studies. After 24 hours, MK-571 alone induced notable lipid droplet accumulation, whereas the MK-571 and FFA combination did not produce a further increment in lipid accumulation. However, extending exposure to 48 hours resulted in greater lipid accumulation by the combined treatment compared to MK-571 alone. These preliminary observations indicate that acute inhibition of MRP4 activity promotes steatosis in human hepatocytes, consistent with phenotypes observed in *Mrp4*^{-/-} mice. **Conclusions:** Together, these *in vivo* and *in vitro* findings demonstrate that loss of MRP4 function disrupts hepatic lipid homeostasis and promotes steatosis. *Mrp4*^{-/-} mice exhibit increased lipid accumulation and altered expression of genes regulating lipid uptake, oxidation, and export, while pharmacological inhibition of MRP4 enhances lipid deposition in human HC-04 hepatocytes. These data support a model in which MRP4 activity is required to maintain metabolic balance through the export of endogenous signaling molecules.

PS 3700 Integration of HLA-Typed PBMC into a Long-term, Functional Hepatocyte Co-culture, HEPATOPAC®, for Detection of Immune-Mediated Drug-Induced Liver Injury

K. E. Cottier¹, J. Gaffney², S. Heyward¹, C. Smith¹, J. Griffith¹, and C. Lewis¹. ¹BioIVT, Baltimore, MD; and ²BioIVT, Medford, MA. Sponsor: K. Cottier, International Society for the Study of Xenobiotics

Background and Purpose: Preclinical prediction of idiosyncratic drug induced liver injury (iDILI) is important in drug development both to safeguard patients from serious adverse outcomes and to reduce late-stage candidate drug failure. Standard preclinical *in vitro* models fail to identify DILI potential for several reasons including lack of relevant immune cell types in the model and/or factors that are specific to particular patient populations. Retrospective studies have identified compound interaction with T-cells in patients with specific human leukocyte antigen (HLA) types as a contributing factor for iDILI in some compounds which showed liver toxicity in the clinic. Based on these observations, we developed a co-culture model which incorporates human PBMC into a long-term micropatterned hepatocyte co-culture model (HEPATOPAC) in order to better model peripheral immune system contribution to DILI development. In these studies, culture conditions were optimized to maintain both hepatocyte and PBMC viability and function for up to 7 days. To investigate the utility of this model for immune DILI studies, HEPATOPAC cultures with and without HLA-typed PBMC were treated with amoxicillin-clavulanate (AC), which is known to cause DILI in patients having specific risk associated HLA-types (DRB1*15:01-DQB1*06:02). The TC50 in cultures with and without PBMC was compared to determine if the presence of PBMC increased toxicity as indicated by a shift of the concentration-response curve. **Methods:** HEPATOPAC plates were manufactured using HLA-typed single donor human hepatocyte lots. After maturation, 75,000 allo-

genic PBMC/well were added. The impact of HLA-mismatch (low resolution allele group match vs. mismatch) was investigated for up to 10-days of co-culture. Urea production was used to assess hepatocyte function, CellTiter-Glo® 2.0 Cell Viability Assay was used to assess general toxicity, and PMA/ionomycin (6.3 ng/mL PMA and 250 ng/mL ionomycin) or CD3/CD28 beads (8 µL/well) induced cytokine production was used to assess PBMC function. For AC toxicity studies, PBMC and hepatocytes having the DRB1*15:01-DQB1*06:02 DILI risk HLA-types were used. Cultures with and without PBMC were treated with AC. The clinical C_{max} for a 875 mg (A)/125 mg(C) dose given every 12 hours (A: 11.6 ± 2.78 mcg/mL and C: 2.2 ± 0.99 mcg/mL): was used to generate a concentration curve using multiples of C_{max} (500x, 250x, 125x, 50x, 10x, 1x, 0.1x and vehicle control). Cultures were treated with AC for 48 hours. Hepatocyte specific toxicity was determined by measuring urea production. For analysis, data was normalized to inter-group vehicle controls. Concentrations were log transformed and a nonlinear fit of the transformed data was performed in GraphPad Prism to determine the TC_{50} . **Results:** PBMC-HEPATOPAC co-cultures that were HLA-matched or mismatched showed no difference in hepatic urea production, ATP content, or cytokine production (IL-2, IL-6, IFN-γ) following stimulation with either PMA/ionomycin or CD3/CD28 dynabeads. Cultures with and without PBMC maintained similar urea production through day 7 of co-culture, however, hepatic function was reduced by day 10. AC-treatment reduced viability of hepatocytes as measured by urea production in a concentration dependent manner. The TC_{50} of AC in cultures without PBMC was 24 mM (A)/ 42.4 mM (C), while the TC_{50} of AC in cultures containing PBMC was significantly lower at 15 mM (A)/26.5 mM (C). **Conclusions:** The long-term micropatterned hepatocyte co-culture, HEPATOPAC, supports co-culture with HLA-typed PBMC while maintaining hepatocyte function and PBMC responsiveness for up to 7 days. Incorporation of PBMC into the model did not alter baseline hepatic function or cytokine production but resulted in a significant leftward shift in the amoxicillin-clavulanate concentration-response curve, consistent with increased susceptibility observed in patients carrying risk-associated HLA alleles. The ability to integrate functional immune cells with metabolically competent hepatocytes enables evaluation of immune contributions to idiosyncratic DILI. This approach expands the utility of HEPATOPAC as a physiologically relevant platform for mechanistic investigation and preclinical detection of immune-mediated hepatotoxicity.

PS 3701 Impairment of Chaperone-mediated autophagy leads to TRIM44-mediated TLR4 deubiquitination and hepatic inflammation

B. Lee¹, J. Hyun¹, Y. Choi², and Y. Choi¹. ¹Seoul National University, Seoul, Korea, Republic of; and ²Daegu Catholic University, Gyeongsan, Korea, Republic of.

Background and Purpose: Tripartite motif-containing protein 44 (TRIM44), a TRIM family member, participates in ubiquitination and protein degradation through E3 ligases. Chaperone-mediated autophagy (CMA) selectively targets cytosolic proteins to lysosomes, and CMA impairment has been associated with metabolic dysfunction-associated steatohepatitis (MASH). TLR4 is a key receptor mediating hepatic inflammation, and its dysregulation contributes to MASH progression. In this study, we investigated the role of CMA in regulating TRIM44 degradation in the liver. **Methods:** Using RNA interference, we silenced LAMP2A and HSPA8 to observe effects on TRIM44 protein levels. We examined TRIM44 accumulation in response to altered LAMP2A expression in LAMP2A knockdown mice and mice fed a CDAHFD. **Results:** Sequence analysis of TRIM44 revealed a KFERQ-like motif. We verified the interaction between TRIM44 and heat shock protein family A (Hsp70) member 8 (HSPA8/HSC70) in HEK293 cells, indicating that CMA contributes to TRIM44 degradation. Mutations within the KFERQ-like motif reduced the binding between TRIM44 and HSPA8, underscoring the motif's importance in CMA recognition. Knockdown of lysosome-associated protein 2A (LAMP2A) or HSPA8 by siRNA increased TRIM44 protein levels. TRIM44 accumulated in lysosomes upon leupeptin treatment. Co-treatment with siLAMP2A altered this accumulation, demonstrating that TRIM44 degradation depends on CMA. Additionally, a cycloheximide chase assay in primary mouse hepatocytes transfected with siLAMP2A showed a reduced rate of TRIM44 degradation in CMA-deficient cells. Ubiquitination assays demonstrated that overexpressing TRIM44 decreased TLR4 ubiquitination, potentially enhancing TLR4 signaling and promoting hepatic inflammation. In a MASH mouse model, reduced LAMP2A expression coincided with TRIM44 accumulation. **Conclusions:** Our results demonstrate that TRIM44 is a substrate of CMA, and further suggest that CMA-regulated TRIM44 may influence hepatic inflammation by deubiquitinating TLR4.

PS 3702 Effect of cytokines on human angiotensinogen acute phase response: an *in vitro* study

A. Khan, Y. Omid, J. Barar, and R. A. Ansari. Nova Southeastern University, Fort Lauderdale, FL.

Background and Purpose: Human angiotensinogen (hAGT) is an acute phase response type II (APR II) protein modulated by interleukin-6 (IL-6) and glucocorticoids. The advent of presence of the response element of nuclear factor-kappa B (NF-κB) in its promoter opens the possibility of modulation by tumor necrosis factor-alpha and interleukin-1beta (IL-1β), which can activate NF-κB. Angiotensinogen is the source of angiotensin II, playing a significant role in blood pressure regulation, and increased AGT levels are found among hypertensives. Besides, AGT participates in the fibrotic

transformation of the liver after hepatotoxicant-mediated liver injury. Levels of circulating cytokines (i.e., IL-1β, IL-6, and IL-8) are increased among chronic alcoholics. **Methods:** The cells were grown in DMEM media supplemented with 10% FBS and antibiotics in a humidified chamber with 5% CO₂. The cells were treated with 10 ng/ml cytokines (IL-1β, IL-6) and/or 50 ng/ml phorbol 12-myristate acetate (TPA) for 24, 48, 72 and 96 hrs. The control samples were not treated with any reagent. The media were collected, while cells were washed with PBS and lysed in PBS containing triton X-100. The cellular levels of protein were determined by dye binding method. The proteins were size separated on denaturing 10-12% acrylamide gel, transferred to PVDF membrane. The levels of AGT in secreted samples and cellular levels were determined using Western blotting technique using mouse monoclonal antibody against human angiotensinogen (sc-374511). **Results:** It was observed that IL-1β, PMA, and IL-6 increased the level of secreted hAGT and cellular levels from both HepG2 and Huh7 cells from 24 -96 hrs. The effects of IL-6 on AGT secretion from both hepatocytes were more sustained compared to IL-1β or PMA. The cellular AGT levels were increased commensurate with their secretion after IL-1β, PMA, or IL-6 treatment. The secreted AGTs were glycosylated, and the non-glycosylated form was not observed with any treatment. **Conclusions:** Based on the sustained effects of IL-6 on AGT secretion from hepatocytes compared to IL-1β or PMA, it is concluded that human AGT remains a type II acute phase response (APR II) protein.

PS 3703 Pioglitazone-Mediated Upregulation of Hepatic Low-Density Lipoprotein Receptor-Related Protein 1 (LRP1): Exploring a Metabolic Link to Alzheimer's Disease

G. Ehlburg¹, J. Garcia¹, and D. Han². ¹University of La Verne, La Verne, CA; and ²Keck Graduate Institute, Claremont, CA.

Background and Purpose: One risk factor for Alzheimer's Disease (AD) is the accumulation of Amyloid-Beta (Aβ) in the brain. Enhancing Aβ clearance is a potential method of reducing the risk of AD. The Peroxisome Proliferator-Activated Receptor Gamma (PPARγ#120516;;) pathway plays a role in lipid metabolism and may increase Aβ clearance by upregulating low-density lipoprotein receptor-related protein 1 (LRP1). LRP1, a member of the low-density lipoprotein receptor (LDLR) family, facilitates Aβ clearance from the brain by ejecting Aβ into the bloodstream to then get degraded by the liver. Pioglitazone, a type-2 diabetes medication, is a PPARγ#120516;; agonist shown to increase LRP1 expression in the hippocampus, suggesting it may be a potential target for reducing Aβ accumulation. **Methods:** A liver model was adapted in this study to observe whether pioglitazone can increase LRP1 expression, which in turn could promote hepatic endocytosis of Aβ and eventual degradation. HepG2 cells were treated with one of two pioglitazone concentration ranges (0µM - 100µM or 0µM - 25µM). After 24 hours of pioglitazone treatment, cell viability was measured using the MTT Cell Viability Assay, and protein expression was measured through Western Blot analysis. **Results:** Compared to the control, LRP1 expression increased at lower concentrations of pioglitazone. Proprotein convertase subtilisin/kexin type 9 (PCSK9) expression also increased, consistent with previous findings. **Conclusions:** These results suggest that pioglitazone can increase hepatic LRP1 expression, which may facilitate Aβ clearance and highlight its potential as a repurposed therapy for AD. These findings also emphasize the metabolic connection between the liver and brain, providing insight into how drugs targeting hepatic pathways may influence neurodegenerative disease progression.

PS 3704 Oleic Acid as a Potential Modulator of LRP1 and BACE-1 in the Treatment of Alzheimer's Disease

E. Fasih¹, and J. Garcia^{1,2}. ¹University of LaVerne, La Verne, CA; and ²Keck Graduate Institute, Claremont, CA.

Background and Purpose: Alzheimer's disease (AD) is a neurodegenerative disease caused by the buildup of amyloid beta (Aβ#120515;;) plaques in the brain. According to the Alzheimer's Association, 7 million people are diagnosed with AD every year. However, no cure has been found and at best, drugs only slow the progression of the disease. The scale of AD diagnosis and lack of treatment makes finding a treatment for AD imperative. Removal of Aβ#120515;; plaques is key to treat AD, so any proteins that can modulate Aβ#120515;; is a potential drug therapeutic target. One such protein is the lipoprotein receptor related protein 1 (LRP1). LRP1 is found in the liver and brain. Liver LRP1 binds to peripheral Aβ#120515;; and the Aβ#120515;; is endocytosed by the liver to be processed (van Uden et al., 1999). Liver LRP1 reduces peripheral Aβ#120515;; that can travel to the brain, which if left unchecked, can initiate pathogenesis of AD in the brain. The relationship between the liver and the brain through the blood brain barrier is key in Alzheimer's disease development, and is commonly known as the liver-brain axis. Another method of AD treatment is to target key proteins involved in Aβ#120515;; formation, such as beta-secretase cleaving enzyme 1 (BACE-1). Aβ#120515;; plaque formation occurs when amyloid precursor protein (APP) is cleaved into Aβ#120515;; by various secretases. The most important secretase in this cleavage process is BACE-1 because BACE-1 catalyzes the rate-limiting step in Aβ#120515;; cleavage (Gorji et al., 2017). This means that once APP is cleaved by BACE-1, the formation of Aβ#120515;; is inevitable. Therefore, treatments that target BACE-1 are imperative because drugs that down-regulate BACE-1 will downregulate APP cleavage into Aβ#120515;; plaques. Many

studies have focused on BACE-1 regulation in the brain, but very few have focused on liver BACE-1 regulation. Minimal research has been conducted on the effects of natural remedies targeting key proteins in the treatment of AD. Oleic acid (OA) is a monounsaturated fatty acid that is known to target BACE-1, while little is known on its effects on LRP1 regulation in the liver. Diabetic models suggest that OA's effects increase insulin sensitivity through LRP1 upregulation (Y. Ding et al., 2016). Taken together, it can be hypothesized that OA may prevent/delay AD development by regulating liver BACE-1 and LRP1. **Methods:** HepG2 liver cells were seeded, grown, and then treated with Oleic Acid suspended in media for 24 and 48 hours. Cells were then used for either MTT Viability Assay or prepped for Western Blot Protein Analysis, Imaging, and Image J software analysis. **Results:** MTT assay showed that the cells did not die from treatment, so Oleic Acid was not toxic towards liver cells. Western Blot analysis of Actin showed equal loading. LRP1 did not show much change, levels stayed relatively constant throughout 24 and 48 hour treatments. PS1 decreased, while PS2 remained consistent. BACE-1 decreased in the 24 hours, as did APP. Both BACE-1 and APP didn't change in the 48 hour treatment. **Conclusions:** OA down-regulated PS1 at higher concentrations, but LRP1 levels slightly decreased. BACE-1 decreased, which means less APP is getting processed, and this was confirmed because APP trends are similar to BACE-1. Overall, OA may have protective effects against AD through the β -secretases but not through LRP1 regulation. Since LRP1 is slightly downregulated, OA may be best used as a preventative measure instead of as a direct treatment to AD. More research is needed, perhaps performing the same experiment on a BBB or mouse model will modulate AD related proteins as expected.

PS 3705 Nitroalkene therapy for allergen-induced hepatic inflammation and dysregulated metabolism

S. A. Heinig, S. Donepudi, D. Volz, and S. L. Gelhaus. University of Pittsburgh, Pittsburgh, PA. Sponsor: S. Gelhaus, Society for Redox Biology and Medicine

Background and Purpose: Environmental allergens including house dust mite (HDM) trigger airway inflammation and downstream extrapulmonary organ and metabolic dysfunction. Allergic asthma is a complex disease characterized by chronic airway inflammation. The noncommunicable disease affects >260 million people worldwide and causes ~250,000 deaths per year. HDM is a primary trigger for the allergic asthma response with sensitization present in 50-85% of patients. Injured bronchial epithelium results in airway cells interacting with immune cells to promote inflammation through Type 2 (T2) mediated airway hyperresponsiveness. In compromised asthmatic airway epithelium, cell-cell contacts are disrupted, leading to increased allergen permeability. HDM contains proteases that trigger the immune response, mediate lung epithelial cell activation, and compromise barrier integrity. Preliminary data from our lab utilizing RNA sequencing and proteomic approaches has also demonstrated that mice with HDM-induced allergic airway disease (AAD) have altered hepatic metabolism compared to their control counterparts regardless of dietary influence. These changes are predominantly related to Phase 1 and 2 metabolic enzyme expression and redox signaling. Observed in epidemiological asthma studies, systemic inflammation is correlated with downstream extrapulmonary organ and metabolic dysfunction consistent with cases of obesity and liver disease. We have observed increased hepatic inflammation (e.g., NF- κ B) and dysregulated hepatic metabolism (e.g., glutathione-related pathways) in our mouse model of HDM-induced AAD. It is unclear whether these changes are a direct effect of HDM on hepatic function or a result of increased pulmonary and systemic inflammation. Nitroalkenes (CP-6 and CP-7) are potential pleiotropic therapies for co-occurring asthma and liver disease. CP-6 has been shown to improve glucose metabolism and lower hepatic triglyceride levels in an obese mouse model for liver disease. Additionally, CP-6 treatment reduced small airway resistance in our obese AAD mouse model. The nitroalkene, CP-7 is a new chemical entity and promising AAD therapeutic. Unpublished data from our lab shows that CP-7 reduced airway inflammation, total cell counts, and protein concentrations in bronchoalveolar lavage fluid from AAD mice. **Methods:** To begin to answer this question, human liver cells, HepG2, were treated with HDM to observe its direct inflammatory effect and optimize parameters for treatments in primary human hepatocytes. HepG2 cells were also treated with either CP-6 or CP-7 in combination with HDM to determine if they abrogate HDM-directed gene expression changes in phase 1 and phase 2 metabolic enzymes, proinflammatory markers, and redox-regulated signaling pathways. **Results:** Hepatic mRNA expression of inflammatory markers (*NFKB1/p105*, *RELA/p65*, *MAPK1*, and *Nrf2*) increased with HDM treatment and are restored by nitroalkenes ($p < 0.05$, $p < 0.0001$, $p < 0.01$, and $p < 0.0001$, respectively). Likewise, with HDM treatment hepatic mRNA expression of glutathione-related pathways and receptors (*GCLM*, *NR1I3/CAR*, and *NR1I2/PXR*) increase and are restored by nitroalkenes (trend, $p < 0.0001$, and $p < 0.0001$, respectively). Ongoing studies investigating how HDM treatment impacts glutathione-related enzymes, including glutathione-S-transferases and peroxidases, are being conducted. **Conclusions:** Preliminary findings thus far support evidence from the AAD model for lung-liver crosstalk through increased liver inflammation and the need for therapeutics that target multiple signaling pathways. Treatment with HDM and nitroalkene therapies will be recapitulated in primary mouse hepatocytes, primary human hepatocytes, and 3D microphysiological systems (MPS) for a holistic assessment of hepatic inflammatory, redox, and metabolism markers. Thus far, measured changes are predominantly related to phase 1 and 2 metabolic enzyme expression and redox signaling. Overall, further characterization of the extrapul-

monary toxicology of the environmental allergen house dust mite is warranted for subsequent exploration into the pathways directly involved in lung-liver crosstalk in the context of allergic asthma.

PS 3706 Scaling Without Compromise: Liver MPS for Lead Optimization Screens to Investigative Toxicology

O. Novac¹, E. Richardson¹, C. Roper², and T. Kostrzewski¹. ¹CN Bio Innovations, Cambridge, United Kingdom; and ²Roper Toxicology Consulting Limited, Edinburgh, United Kingdom.

Background and Purpose: Drug-induced liver injury (DILI) remains the most common cause for acute liver failure in the USA and Europe and is a leading cause of attrition of compounds in drug development. Prediction of clinical safety is still a major hurdle in drug discovery and development, with many late-stage attrition events still occurring due to limited translatability of current *in vitro* or *in vivo* preclinical models. Microphysiological systems (MPS), otherwise known as organ-on-a-chip (OOC), provide a solution to this challenge by enabling the long-term culture and in-depth examination of highly human relevant liver microtissues. However, scaling and throughput of OOC have in the past been perceived as a challenge. Here, we present two solutions based on their different contexts of use. Firstly, a higher throughput approach, the PhysioMimix® Multi-chip Liver-48 plate can be applied within the lead optimization process for screening of compounds, up to 288 samples (or chips) per run. Secondly, due to its enhanced tissue size and sampling volume, the Liver-12 plate can further characterize DILI events at a deeper level and their associated mechanisms of toxicity through a wide range of liver-specific endpoints. **Methods:** Using the PhysioMimix® Core System, primary human hepatocytes and Kupffer cells were cultured in 3D microtissues on engineered scaffolds in either the Liver-48 or Liver-12 plates under perfusion for eight days. The Liver-48 microtissues were subjected to 4-day exposure to two tool compounds recommended by the IQ MPS Consortium for DILI validation (troglitazone and pioglitazone) tested at seven concentrations alongside positive control (chlorpromazine) and vehicle control (0.1% DMSO). Each condition was tested in triplicate. For mechanistic studies, the Liver-12 microtissues were subjected to 10-day exposure to three tool compounds (diclofenac, troglitazone and pioglitazone). An equivalent dose to clinical concentration and 1.5x the Minimal Important Difference (MID) clinical concentration doses were tested alongside vehicle control (0.1% DMSO). Treatments were randomised across the plates and each condition tested in triplicate. **Results:** Liver-48 plate microtissues were able to successfully differentiate the DILI risks of the tool compounds, using liver functionality (albumin, urea, ALT, AST) and viability (ATP) markers. The DILI profile of troglitazone was found to match those predicted by Liver-12 plate microtissues, demonstrating equivalence between the two plate types. The results of pioglitazone testing accurately predicted this compound to be safe. By assessing a range of test compounds recommended by the IQ MPS Consortium for DILI validation, the Liver-12 was able to correctly capture differing mechanisms of toxicity and mirror clinical outcomes. Oxidative stress, mitochondrial dysfunction, steatosis, dysregulation of bile acid synthesis or transport and inflammatory responses were investigated using a wide range of clinically relevant biomarkers. **Conclusions:** OOC/MPS has long been considered a useful tool for better predicting human outcomes, however providing scalable throughput to meet lead optimization requirements and recoverable material at scale to enable biomarker detection sensitivity, plus deep mechanistic insights - has been a challenge. Here we demonstrate that the PhysioMimix Liver MPS can be scaled to enable specific contexts of use. By incorporating human-relevant insights into the earlier lead optimization phase of drug discovery using the Liver-48 plate facilitates the design of more refined pre-clinical studies. Conversely, when the context of use shifts from compounds screening to investigative toxicology, the Liver-12 DILI assay provides the optimal solution. Data-rich analyses from a wide range of clinically relevant biomarkers can be derived to make informed decisions to modify drug design and de-risk clinical progression of drug candidates. Together, this enables more efficient drug development and safer medicines in the future.

PS 3707 Clinically Benchmarked 3D Human Liver Spheroids Advance DILI Prediction and Within-Class Differentiation

M. Mehrabi, R. Dudum, P. Olson, C. Toohey, H. Aidnik, C. Rosette, and K. Murphy. VivoSim Labs, San Diego, CA. Sponsor: C. Tyree

Background and Purpose: Drug-induced liver injury (DILI) remains a leading cause of attrition and market withdrawal. Conventional 2D systems often miss clinically relevant liabilities especially when medicinal chemistry teams need series-level guidance. Traditional animal models may not fully recapitulate human-specific DILI risk, underscoring the need for more predictive, human-relevant platforms. By leveraging multicellular 3D liver spheroids, which enable crosstalk between hepatocytes and non-parenchymal cells, we establish a platform that enhances mechanistic insight and supports series-level differentiation for improved risk assessment and candidate prioritization. **Methods:** A multicellular 3D human liver spheroid platform (NAMkind™ Liver; primary hepatocytes with non-parenchymal support) was run under repeat-dose exposure (7-21 days). Drug toxicity was revealed by reduced hepatocellular function (decline in albumin levels) as well as overt cytotoxicity (LDH

release) and metabolic stress (depletion of ATP levels). We benchmarked against a 50-compound clinical reference set and profiled within-class analogs to emulate SAR decision-making at lead optimization. A proprietary machine-learning calibration integrated multivariate assay features with clinical outcomes to obtain probabilistic risk scores, confidence intervals, and series-level prioritization. **Results:** The platform achieved 91% accuracy for clinical DILI classification. It discriminated analogs within the same chemotype, aligning *in vitro* rank-ordering with known clinical risk and supporting medicinal-chemistry triage. **Conclusions:** This NAMkind™ Liver 3D spheroid assay provides robust, mechanism-aware DILI prediction beyond the limitations of animal models. For small molecules and practical analog rank-ordering to guide SAR. This advances a NAMs-aligned, translational Context-of-Use Case for early candidate selection.

PS 3708 Human Liver Organoid Models: Advancing Drug Toxicity Assessment

B. Torenvliet¹, J. Frias Aldegue¹, J. Wijnaker¹, X. Fan², F. Pourfarzad¹, R. Palstra², R. G. Vries¹, T. Mahmoudi², and S. Boj¹. ¹HUB Organoids B.V., Utrecht, Netherlands; and ²ErasmusMC, Rotterdam, Netherlands. Sponsor: R. Vries, American Association for Cancer Research

Background and Purpose: Current drug toxicity assays predominantly rely on the HepG2 hepatocarcinoma cell line, which lacks key liver-specific metabolic functions, exhibits limited cytochrome P450 enzyme activity, and poorly reflects the physiology of healthy human hepatocytes. To establish a more physiologically relevant *in vitro* system, we developed a novel differentiation medium that enables adult stem cell-derived liver organoids, which primarily consist of cholangiocytes, to mature into hepatocyte-like cells suitable for drug toxicity testing, thereby bridging the gap between tumour cell models and *in vivo* systems. **Methods:** In this study, we sought to identify a differentiation condition that robustly generates human hepatocyte-like organoids. We established liver organoids from five different donors and subsequently differentiated them towards a hepatocyte-like state. The organoid model was characterised before and after differentiation using RNA sequencing, cytochrome P450 activity assays, and immunofluorescence staining. Finally, we benchmarked our differentiated organoid model against HepG2 and primary human hepatocytes, based on their ability to detect Fialuridine toxicity, a compound historically withdrawn from clinical trials due to unpredicted hepatotoxicity. **Results:** We successfully established a reliable and physiologically relevant human hepatocyte organoid model. By applying our novel differentiation medium, the adult-derived organoids matured into hepatocyte-like cells that exhibited characteristic hepatic morphology and demonstrated functional cytochrome enzyme activity. Compared to the commonly used HepG2 cell line, our organoid-derived hepatocytes showed higher metabolic activity and more accurate dose-dependent responses to known hepatotoxic compounds. **Conclusions:** The results indicate that the developed organoid system more closely resembles *in vivo* liver physiology than the transient primary hepatocyte cell model and hepatocarcinoma-derived HepG2 cells. This new hepatocyte-organoid model provides a stable platform for assessing drug toxicity in preclinical drug screening.

PS 3709 Human 3D Liver Spheroids Establish a NAM for ADC DILI Risk Assessment

M. Mehrabi, R. Dudum, P. Olson, C. Toohey, H. Aidnik, C. Rosette, and K. Murphy. VivoSim Labs, San Diego, CA. Sponsor: C. Tyree

Background and Purpose: Antibody-drug conjugates (ADCs) can present hepatic liabilities arising from conjugate design and clinical exposure paradigms. There is a need for human-relevant, throughput-compatible assays to generate early translational signal even when mechanistic uptake or payload analytics are not yet available. Here, we introduce a multicellular 3D human liver spheroid platform that enables functional profiling and comparative ranking of intact ADCs, facilitating early risk assessment and supporting decision-making in ADC development. **Methods:** A multicellular 3D human liver spheroid platform (NAMkind™ Liver; primary hepatocytes with non-parenchymal support) was run under repeat-dose conditions (7-21 days). Intact ADCs were evaluated across clinically relevant exposure ranges using ATP (CellTiter-Glo), LDH, and albumin as a functional triad. **Results:** Intact ADCs produced concentration- and time-dependent changes across ATP/LDH/albumin, enabling initial hepatic risk profiling and comparative ranking of conjugates. Signal patterns differentiated functional impairment versus overt cytotoxicity, providing actionable readouts for program teams while orthogonal mechanistic assays are being planned. **Conclusions:** The NAMkind™ Liver 3D spheroid platform offers a translational, mechanism-aware approach for intact-ADC DILI risk assessment, providing decision-quality functional data ahead of deeper mechanistic deconvolution, supporting NAMs-aligned development.

PS 3710 Development of iPSC-Derived Human Liver Organoids for Preclinical Drug Testing and Toxicology Studies

F. Pan¹, M. Rahman¹, D. Austin¹, S. Krieg², L. M. Pfeifer², P. Hewitt², S. Johnston³, L. Braeuninger-Weimer², W. Kools⁴, and V. Chu¹. ¹MilliporeSigma, Temecula, CA; ²Merck KGaA Darmstadt, Darmstadt, Germany; ³MilliporeSigma, Tempe, AZ; and ⁴MilliporeSigma, Burlington, MA.

Background and Purpose: Over 90% of drug candidates fail during clinical trials, often due to insufficient efficacy and unmanageable toxicity. Drug-induced liver injury (DILI) is frequently missed in preclinical testing due to a lack of robust and predictive liver models. We report the *de novo* development of iPSC-derived human liver organoids as scalable, reliable, and physiologically relevant preclinical toxicology models. **Methods:** Using an efficient and reproducible iPSC-differentiation protocol, we generated long term expandable, cryopreservable bipotential 3dGRO™ Human iPSC-derived Liver Progenitor Organoids, which differentiate into mature liver organoids (MLOs) containing multiple liver cell types. **Results:** The iPSC-derived mature liver organoids display long-term stability, secrete albumin and urea, and express key biomarkers of mature hepatocytes (albumin, CYP3A4, HNF4a, PCK2) and cholangiocytes (Sox17, Sox9, CK7, MRP2). They also exhibit functional Phase I/II liver enzymes (CYP3A4, CYP2C9, CYP1A2, ALT, AST, GST) and active bile salt/drug transporters. Compared to primary hepatocytes, our 3dGRO™ Human iPSC-derived Mature Liver Organoids demonstrate comparable functionality and outperform HepG2 cells and liver spheroids. In DILI assays, MLOs responded to drug treatment with elevated liver enzymes, confirming their potential for toxicology screening. **Conclusions:** These liver organoids represent a powerful tool for high-throughput drug screening, DMPK and toxicological studies, with future applications including disease modeling of hepatocellular carcinoma, MASLD, and NASH.

PS 3711 DEVELOPMENT OF HUMAN IPSC-DERIVED HEPATOCYTES FOR DRUG DISCOVERY, TRANSLATIONAL RESEARCH AND TOXICITY TESTING

G. Mastrogiovanni, S. Ghimire, R. Piscupescu, J. Hundling, N. James, V. Cornelius, S. Milde, A. Knights, V. Yianni, T. Harris-Brown, B. Newman, K. Firth, and W. Bernard. bit.bio, Cambridge, United Kingdom. Sponsor: T. Harris-Brown, Safety Pharmacology Society

Background and Purpose: Hepatocytes are responsible for the primary functions of the liver, including detoxification and xenobiotic metabolism, making them essential for *in vitro* toxicology. Despite their critical role, their use is hampered by significant challenges with traditional models, such as the scarcity and variability of primary human hepatocytes (PHHs), the poor physiological relevance and metabolic function of immortalised cell lines, and the poor scalability and high lot-to-lot variability of conventional human induced pluripotent stem cells (hiPSCs) directed differentiation methods. These limitations hinder the ability to effectively predict drug-induced liver injury (DILI), heavily contributing to the 90% attrition rate of drug candidates in clinical trials and underscoring the need for better liver models. Here, we used opti-ox™, a deterministic cell programming technology, to generate consistent, scalable, hiPSCs-derived hepatocytes, termed ioHepatocytes, and demonstrated their suitability for toxicology, research and disease modelling. **Methods:** ioHepatocytes were generated through forward programming of hiPSCs using proprietary opti-ox™ technology and were characterized by immunofluorescence, transcriptomics, and assays for hepatic function (e.g., albumin secretion) and metabolic competency (CYP450 activity). DILI prediction was validated by assessing viability (CellTiter-Glo) after challenge with known hepatotoxins. **Results:** ioHepatocytes display classic cobblestone morphology with distinctive nuclei and well-defined borders. Cells express key pan-hepatocyte markers including ALB, HNF4A, ASGR1 and SERPINA1, and present a transcriptomic signature similar to PHHs. Additionally, ioHepatocytes derived from hiPSCs with opti-ox™ demonstrate high batch-to-batch consistency. Functionally, ioHepatocytes perform critical hepatocyte functions including albumin secretion, glycogen storage, and accumulation of lipids. Most importantly, ioHepatocytes show expression of genes involved in phase I, II and III of drug metabolism and have functional cytochrome P450 enzymes (CYP3A, CYP2B6 and CYP1A2). When challenged with compounds known to cause toxicity, ioHepatocytes show a clear dose-dependent decrease in cell viability that strongly correlates with the known DILI severity of the compounds. Importantly, the toxic response very closely mimicked that of PHHs, validating the predictive capability of ioHepatocytes. **Conclusions:** ioHepatocytes offer a highly consistent, functional and scalable human hepatocyte model, overcoming the limitations of existing technologies. Their demonstrated ability to respond to toxic insults similarly to PHHs suggests their use as a reliable, predictive tool for improving DILI risk assessment in drug development.

K. Headrick, M. Culbreth, R. Sprando, and K. Eckstrum. US Food and Drug Administration, Laurel, MD.

Background and Purpose: Hepatotoxicity can occur as a consequence of exposure to adulterants in foods and dietary supplements. Traditional animal studies are too inefficient to assess all potential hepatotoxicants in the food supply. Therefore, more cost effective and efficient new approach methods (NAMs) have emerged to address this urgent public health need, and facilitate the replacement, reduction, and refinement of *in vivo* studies. Described, herein, is the development of a three-tiered NAM for the assessment of potential hepatotoxicity, with each tier offering increased toxicological and mechanistic data. To demonstrate the applicability of this tiered approach, a known hepatotoxicant, usnic acid (UA), was evaluated as a performance compound. **Methods:** In the first tier, primary human hepatocytes (PHH) seeded in 96-well plates were exposed to a 10-point concentration range of the potential toxicant for 48 hours. Tier 1 examined markers of both liver function and viability. Concentration-response modeling was then applied to determine an effective concentration (ACC) at which liver function was altered without impacting cell viability. In Tier 2, PHH again were seeded in 96-well plates and exposed to a single effective concentration, as identified in Tier 1, of the potential toxicant for 48 hours. Tier 2 consisted of imaging of pertinent functional biomarkers to gather mechanistic data about the potential hepatotoxicant. Tier 3 incorporated four distinct liver cell types (PHH and non-parenchymal cells (NPCs): liver sinusoidal endothelial cells (LSECs), Kupffer cells, and stellate cells) in a microphysiological system (MPS), a liver-on-a-chip. After initial exposure, effluents were collected every 2-3 days, for 9 days. The same endpoints assessed in Tier 1 and Tier 2 were evaluated in Tier 3, with additional endpoints added for the NPC channel. **Results:** For assay development, UA was applied at a 10-point concentration range from 0-50 μM to demonstrate Tier 1 performance. A decline in hepatocyte function and cytotoxicity was observed after 48 hours of exposure. The least sensitive functional endpoint (urea content) had an ACC at 9.6 μM , while the most sensitive cytotoxicity endpoint (alanine transferase (ALT)) had an ACC at 15.9 μM after 48 hours. Therefore, 10 μM UA was selected for subsequent evaluation in Tiers 2 and 3. In Tier 2, UA exposure disrupted transporter activity (80% decrease) and phospholipid content (20% decrease). Tier 3 similarly showed a significant decrease in hepatocyte function resultant to UA exposure, with the most sensitive functional endpoint (albumin) being reduced by 82% after 9 days of exposure compared to pre-exposure values. Cytotoxicity significantly increased compared to day-matched control after 48hrs with a more pronounced increase after 7 days of exposure. Most notably, ALT levels were 3000% higher than control. Cells collected after 9 days of exposure demonstrated a 40% reduction in glutathione, a 60% reduction in adenosine triphosphate (ATP) content, as well as a significant disruption of mitochondrial membrane potential and transporter activity. An inflammatory cytokine panel also exhibited significant decreases (53-58%). **Conclusions:** Application of this tiered approach demonstrated that a known hepatotoxicant can be appropriately evaluated with enhanced toxicological and mechanistic information gained from each tier. Tier 1 allowed for a rapid evaluation of effects on functional endpoints, with the determination of an effective concentration for assessment in subsequent tiers. Tier 2 expanded the mechanistic information collected in Tier 1, allowing for a more thorough investigation of functional endpoints, albeit with fewer concentrations. Tier 3 furthered the cell types included, as well as relevant physiology, demonstrating greater biological complexity which allows for further enhanced toxicological and mechanistic information. Further investigation into the use of this tiered approach using more complex materials is required, however, this method has potential to more efficiently evaluate foods and dietary supplements for possible hepatotoxicity.

PS 3713 Evaluating the hepatotoxic potential of Green Tea and Kava Root Extract in primary human hepatocytes

K. Headrick, Y. Zhao, E. Sepehr, Y. Liu, and K. Eckstrum. US FDA, Laurel, MD.

Background and Purpose: Evaluation of botanical safety is a rising need due to increased use in dietary supplements and other consumer products. Hepatotoxicity can sometimes occur when consumers are exposed to potentially toxic constituents in botanicals. Traditionally animal studies have been utilized for safety assessment. However, animal studies are often limited by the time and cost necessary to evaluate compounds. New Approach Methods (NAMs) are becoming more widely used to reduce animal testing and can potentially aid in decreasing the time and cost commitment of studies. However, NAM designs also have important considerations such as stability of the treatment compounds and their interaction with experimental components. In this study, our goal was to determine the ability of a higher throughput NAM to identify potential hepatotoxicity of complex materials using two botanical extracts, green tea and kava root, which have been reported to cause hepatotoxicity in humans. **Methods:** To evaluate the hepatotoxicity of green tea extract (GT) (Indena) and kava root extract (Kava) (Mountain Rose Herbs) UHPLC/MS was performed to confirm the concentrations of constituents and the solubility in dimethyl sulfoxide (DMSO). Subsequently, a 10-point concentration-response was created based on the solubility of the extracts in DMSO and the necessity to maintain a minimal level of DMSO (0.25%) in cell culture medium. For GT, concentrations ranged from 1.22-313 $\mu\text{g/mL}$ and for Kava, concentrations ranged from 0.059-15

$\mu\text{g/mL}$. Solubility, stability, and interaction with the cell culture media and plate were evaluated at treatment concentrations, in the absence of cells, to ensure the cells receive the intended concentrations of the extracts. Primary human hepatocytes (PHH) from three separate donors were seeded into 96-well plates and treated with the extracts for 48 hrs, with media exchanged every 24 hrs. A positive performance compound of 20 mM acetaminophen (APAP) was also included on each plate. After 48 hrs, key hepatotoxicity endpoints (i.e., changes in secretions of albumin, urea, lactate dehydrogenase (LDH), alanine transaminase (ALT), adenosine triphosphate (ATP), and glutathione (GSH)) were measured. **Results:** GT showed hepatotoxicity within 48 hrs in this study. ATP and GSH were the most sensitive endpoints with decreased levels starting at 19.5 $\mu\text{g/mL}$; whereas albumin was reduced and ALT was increased starting at 39.1 $\mu\text{g/mL}$. However, the stability of GT in hepatocyte media was low. After 24 hrs in glass vials, recovery of (-)-Epigallocatechin gallate (EGCG), the most abundant constituent in GT, was reduced, albeit variably. Additionally, after incubation in the 96 well plates, without cells, recovery was reduced even further, at least 80% less than expected. Unlike GT, Kava showed minimal hepatotoxicity. There was a slight reduction in albumin starting at 7.5 $\mu\text{g/mL}$ and a very slight increase in ALT at the same concentration. ATP was reduced slightly starting at 0.234 $\mu\text{g/mL}$ and GSH was reduced starting at 1.88 $\mu\text{g/mL}$. Albumin, ATP, and GSH were only reduced about 30% compared to control at the highest concentration. In all experiments APAP strongly affected all endpoints evaluated. Conversely to GT, Kava was stable in hepatocyte media in glass vials. However, similar to GT there was some interaction with the cell culture plate. Three constituents; methysticin, flavokawain A, and flavokawain B, lost 40-90% when incubated without cells within 24 hrs. **Conclusions:** New approach methods can help increase the throughput necessary to evaluate complex materials such as botanical extracts. However, evaluation of the stability and interaction of the compounds of interest in the experimental design should be examined. Here, two opposite situations occurred. GT appeared to affect PHH in a dose dependent manner, however, closer evaluation of the stability of GT in the media and potential interaction with the culture plate questions the accuracy of the GT concentration the cells received. Alternatively, Kava did not appear to have a great effect on PHHs. However, three constituents, including flavokawain B, which is believed to be the hepatotoxic component of kava root, appeared to interact with the culture plate, which may explain the limited toxicity seen in this model.

PS 3714 ML/AI assisted digital measure of pica behavior in emetic-induced rat emesis model

C. Liu¹, B. Lawrence², and Z. Wright³. ¹Pfizer, Groton, CT; ²Pfizer, Cambridge, MA; and ³SwiftScience, Pittsburgh, PA. Sponsor: X. Tang

Background and Purpose: Drug-induced emesis is a major symptom of gastrointestinal toxicity in both humans and laboratory animals. In drug development, preclinical assessment of emesis risk remains challenging due to the lack of suitable animal models and sensitive behavioral or functional biomarkers. While humans, dogs, and several other mammals exhibit emetic reflexes, commonly used toxicological species such as rodents do not. Instead, rodents rely on alternative defense mechanisms, such as pica, to cope with toxicosis. In rats, daily kaolin consumption is typically measured as an indicator of pica behavior. However, environmental stressors can also trigger pica, potentially confounding research outcomes. Although useful, the kaolin pica method faces challenges, including measurement difficulties, individual variability, and limited diagnostic specificity. **Methods:** In this study, we employed computer vision and machine learning (ML)/artificial intelligence (AI) algorithms to analyze continuous video recordings of Wistar Han rats in their home cages, enabling automated identification of pica behavior—specifically, kaolin consumption—over a 24-hour period following administration of copper sulfate, apomorphine, and semaglutide ($n = 6$ per treatment group). Rats were pair-housed, with one animal identified by an ear tag. In each cage, one animal was dosed with the emetic and the other with vehicle. A convolutional neural network model was trained on approximately 500 images and validated using manual annotations of feeding behavior sampled every other minute from the video data. All pica events were verified by human observers. **Results:** Copper sulfate (40 mg/kg, p.o.), apomorphine (10 mg/kg, i.p.), and semaglutide (0.12 mg/kg, s.c.) induced kaolin consumption behavior, particularly during nighttime (combined, $p < .001$ compared with 18 vehicle controls). Pica behavior occurred between 2 to 9 hours post-dosing and lasted from several seconds to approximately one minute per bout, with most animals exhibiting only a single bout. Pica appeared earlier in copper sulfate-treated animals and later in semaglutide-dosed animals. Additional toxicological effects—such as apomorphine-induced stereotypic peripheral cage rotation—and pharmacological responses—such as semaglutide-induced reductions in feeding behavior frequency and duration—were also observed within 24 hours post-dose. The AI-generated results were reasonably accurate and comparable to manually analyzed data, though some false positives indicate the need for further model training. The models achieved F1 scores ranging from 0.27 to 0.55 for feeding and drinking behavior. **Conclusions:** This study demonstrates the utility of ML/AI-assisted digital measurement—or digital biomarkers—for monitoring pica behavior in rat toxicity and pharmacology studies using an emetic-induced emesis model.

R. Saikhov, and K. Favre. MultICASE, Inc., Mayfield Heights, OH.

Background and Purpose: The ICH M7 guideline recommends an initial *in silico* assessment of pharmaceutical impurities using two complementary (Q)SAR methodologies to predict bacterial mutagenicity. It also suggests expert review if warranted (i.e., cases where model predictions are discordant, inconclusive, or outside the applicability domain). This study investigates whether a large language model (LLM) can assist in generating expert-level justifications for mutagenicity predictions based on *in silico* outputs. **Methods:** A dataset of 684 chemicals with known experimental results was analyzed using CASE Ultra statistical and expert rule-based models. Outputs were further analyzed with the Konsolidator tool, which uses structural alerts in the query compound to identify structural analogs and generate a final call: POSITIVE, NEGATIVE, or NO CALL. From this dataset, 75 compounds (25 per category) were randomly selected. Each Konsolidator report was submitted to ChatGPT v4o for interpretation under a standardized prompt, which asked for an executive summary aligning with ICH M7, including a mutagenicity prediction, ICH M7 classification, and supporting rationale. ChatGPT was configured without memory and allowed to browse the web. The same 75 compounds were also independently evaluated by a human expert under conditions of a blind experiment. The results produced by ChatGPT and the human expert were compared with experimental outcomes for each compound to evaluate performance. **Results:** The human expert achieved the highest prediction accuracy for bacterial mutagenicity (80%) and 100% coverage. ChatGPT's performance was notable, with 61% accuracy and 91% coverage. ChatGPT also demonstrated a marked ability to correctly identify negative compounds with a specificity of 79%. In contrast, its ability to correctly identify positive compounds was low (sensitivity of 38%). The LLM's handling of "NO CALL" cases were particularly interesting. It provided a conclusive interpretation in 21 out of 25 cases (84%), with an accuracy rate of 64%. All outputs referenced structural alerts and analogs, but the quality and depth of analysis varied across compounds. A recurring issue involved the ICH M7 classification: ChatGPT misclassified 9 compounds, labeling them as ICH M7 Class 3 while predicting them as negative. Of these, 7 were originally predicted as NO CALL and 2 were POSITIVE; only the POSITIVE mentioned "Class 3." Still, ChatGPT correctly predicted 8 of these 9 outcomes. It also labeled 3 compounds as ICH M7 Class 4, despite not being provided an API or other compounds for comparison. **Conclusions:** This study highlights the strengths and limitations of generative AI in regulatory toxicology, as well as the role of human experts in this field. While the human expert outperformed the LLM in both accuracy and coverage, the LLM's ability to process and summarize complex *in silico* data, particularly in NO CALL cases, was promising. The study was limited to the use of a single LLM, a fixed prompt, and a manual input process, which may not reflect variability or scalability in real-world applications. Future work should explore automated workflows, alternative LLMs, and the interpretation of raw (Q)SAR outputs and outputs from other software. Overall, LLMs may serve as valuable tools for generating structured summaries that assist expert workflows, but they should not yet be used as a standalone tool for interpreting *in silico* results.

D. Geter. Bayer CropScience, Chesterfield, MO.

Background and Purpose: The increasing complexity of regulatory toxicology and the volume of scientific literature present significant challenges for timely and auditable human safety assessments. This work explores the feasibility of an agentic artificial intelligence (AI) framework to simulate a virtual Human Safety (HuSa) team, enabling automated, multi-agent collaboration for pesticide risk assessment and adverse effect screening. **Methods:** A proof-of-concept system was developed in Python using large language models (LLMs) configured as domain-specific agents representing toxicology, dietary, occupational, and director roles. The system orchestrated structured, multi-round 'virtual meetings' where agents analyzed regulatory assessments and peer-reviewed literature. Key design elements included document chunking, numeric and citation enforcement, and iterative decision-making under predefined rules. **Results:** The virtual HuSa team successfully synthesized evidence from regulatory documents and literature, producing auditable outputs with traceable evidence chains. The system demonstrated the ability to classify study relevance, summarize findings, and evaluate potential regulatory implications. A second proof-of-concept extended the approach to adverse effect screening, identifying findings warranting further consideration under regulatory criteria. **Conclusions:** This work illustrates the potential of agentic AI to augment regulatory toxicology workflows by improving efficiency, transparency, and reproducibility. Future development will focus on creating a more user-friendly interface and enhancing model specialization, establishing a strong foundation for integrating AI-driven decision support into human safety risk assessment.

K. Jagiello, A. Sosnowska, M. Stepnik, M. Gromelski, E. Wyrzykowska, K. Falkiewicz, S. Zdybel, and T. Puzyn. QSARLab, Gdansk, Poland.

Background and Purpose: In the European Union, the Safe and Sustainable by Design (SSbD) concept is a cornerstone of the EU Chemicals Strategy for Sustainability, aiming to promote innovation of safer and more sustainable chemicals while ensuring a high level of protection for human health and the environment. Achieving this goal requires systematic access to transparent, reproducible, and mechanistically anchored data. New Approach Methodologies (NAMs) are transforming chemical safety assessment by reducing reliance on animal testing while providing mechanistic insight into toxicity pathways. Despite their scientific maturity, the widespread regulatory uptake of NAMs remains limited due to challenges in accessibility, interoperability, and contextual fit-for-purpose application. The NAMs.Network (<https://nams.network/>) initiative addresses these challenges by creating a digital ecosystem that supports the searching, integration, and application of NAMs within regulatory frameworks. It connects regulatory needs with curated assays, Adverse Outcome Pathways, and computational models, ensuring transparent evidence generation across diverse endpoints. In this study, we present a practical, regulation-oriented workflow that leverages NAMs.Network to identify and apply ready-to-use NAMs for specific regulatory contexts: assessing the safety of flame-retardant (FR) alternatives. Our objective was to conduct a critical review of existing NAMs and to demonstrate how they can support SSbD implementation. **Methods:** A regulation-oriented workflow was developed using the NAMs.Network platform to identify and apply NAMs supporting SSbD assessment of FR alternatives. Regulatory needs were translated into a structured evidence plan and data-gap matrix to pinpoint missing or insufficient information. The NAMs.Network was queried for suitable *in vitro* assays, computational models, and other mechanistically anchored tools addressing these gaps. Collected NAMs were critically evaluated for scientific robustness, mechanistic relevance, validation status, regulatory applicability, data quality and transparency, and availability of SOPs. **Results:** To identify and apply ready-to-use NAMs within the SSbD framework, the first step involved defining the regulatory decision context, specifying the intended uses of FRs, and their exposure scenarios. Based on applicable EU regulations and supporting guidance documents, a requirements map was constructed to outline the relevant endpoints necessary for regulatory compliance. This map served as a structured evidence plan, defining what needs to be demonstrated for different regulatory purposes, including screening or comprehensive hazard assessment. In the second step, the map was translated into a data-gap matrix, which systematically captured available data and pinpointed information gaps across hazard domains. Particular attention was paid to regulatory-driven endpoints with limited existing data, such as neurotoxicity, developmental and reproductive toxicity, and endocrine disruption. Using the NAMs.Network platform, these gaps were queried against a curated inventory of available NAMs. More than 20 candidate methods were identified and subsequently subjected to a critical evaluation according to predefined criteria. Based on this evaluation, methods were categorized as "ready-to-use", indicating direct applicability in a regulatory context, or "conditionally applicable", requiring further data generation, optimization, or validation to reach regulatory readiness. This structured and transparent approach enabled the translation of regulatory needs into actionable safety assessment strategies within the SSbD paradigm. **Conclusions:** The application of the regulation-oriented workflow demonstrated that NAMs.Network can effectively support the systematic identification and integration of ready-to-use NAMs for assessing the safety of alternative FRs. By linking regulatory requirements to mechanistically anchored evidence, the approach enables transparent, reproducible, and efficient safety evaluation.

M. Rao¹, V. Nassiri², P. Bajaj¹, P. Monecke³, and C. Sachs⁴. ¹Sanofi Pharmaceuticals, Cambridge, MA; ²Open Analytics, Antwerpen, Belgium; ³Sanofi Pharmaceuticals, Frankfurt, Germany; and ⁴CS, San Diego, CA.

Background and Purpose: Drug-induced liver injury (DILI) remains a leading cause of drug attrition, highlighting the limitations of traditional preclinical models and static computational tools in predicting human hepatotoxicity. **Methods:** We developed a dose-enabled AI/ML framework that integrates physicochemical descriptors, predicted off-target interactions, and exposure as a continuous variable to generate dynamic, mechanistically interpretable risk profiles. A curated dataset of compounds annotated for most (M-DILI), no (N-DILI), and less (L-DILI) hepatotoxicity was used to train ensemble classifiers. **Results:** Physicochemical features such as aqueous solubility (logS) and fraction of sp³ carbons (Fsp³) differentiated risk classes, consistent with mechanisms of hepatic accumulation and promiscuous binding. Off-target networks enriched for cytochrome P450s, nuclear receptors, and adrenergic proteins further stratified high-risk compounds, while predicted metabolites captured bioactivation liabilities. Incorporating dose enabled simulation of dose:response trajectories, estimation of hepatotoxic thresholds (Probability score EC₅₀), and identification of latent risks. Acetaminophen and fluoxetine transitioned into high-risk categories at low exposures, whereas streptomycin remained below toxic thresholds even at elevated doses. Although trained on binary endpoints (M-DILI vs. N-DILI), the model generalized to L-DILI compounds, yielding a bimodal risk distri-

bution that reflected ordinal toxicity relationships. The ensemble classifier outperformed individual models (AUC = 0.88; balanced accuracy = 0.80), demonstrating that predictive strength emerges from the convergence of chemistry, biology, and dose. **Conclusions:** By embedding exposure into model architecture, this framework reframes predictive toxicology from static classification toward exposure-informed, mechanistically grounded prediction, offering a scalable, non-animal tool aligned with FDA's New Approach Methodologies.

PS 3719 Novel Machine Learning Algorithms Allow Fast and Accurate Automated Counting of Primary Hepatocyte Samples

D. Schieffer¹, D. Ash¹, and K. Cottier². ¹DeNovix Inc, Wilmington, DE; and ²BiolVT, Baltimore, MD. Sponsor: K. Cottier, International Society for the Study of Xenobiotics

Background and Purpose: Primary hepatocytes are a critical cell type in toxicity and drug metabolism workflows. Given the sensitive nature of these experiments, accurate and precise hepatocyte counts are essential for achieving reproducible results for downstream applications. We have developed a machine learning-based model for counting hepatocytes and determining viability on an automated cell counter to 1) help standardize results across laboratories and 2) reduce user to user variability. This study aims to test if an automated machine learning model can provide the same level of counting accuracy for hepatocyte quantification against the established gold standard method of manual hemocytometer counts by trained scientists. Data sets were generated independently by internal DeNovix scientists and collaborating scientists at a leading supplier of commercial hepatocytes (BiolVT). **Methods:** This study evaluated the viability and concentration of cryo-preserved and freshly isolated hepatocyte cells. The cells, sourced from common toxicology species (human, rodent, and canine), were isolated or thawed according to recommended protocols. Subsequently, they were stained with either 0.4% trypan blue or a combination of 12 uM Acridine Orange and 140 uM Propidium Iodide (AO/PI). Cell concentration and viability were then determined using either a hemocytometer manual counting technique using trypan blue and a Neubauer grid by trained technicians on a 4x brightfield microscope or with an automated cell counter with a machine learning based algorithm using AO/PI staining to distinguish between live and dead cells. **Results:** Results of hepatocyte counts and sample viability determinations between the counting methods were compared using the unpaired two tailed Welch's t-test in GraphPad Prism version 10.6.1, for Mac OS GraphPad Software, Boston, Massachusetts USA. Calculated p-values across data sets of all three species showed p-values greater than an alpha value of 0.05. Additionally, these p-values were supported by the calculated 95% confidence intervals for each of the Welch's t tests performed. Overall, the hepatocyte count data collected in this study between the two methods showed no significant statistical differences in the mean values of sample concentration or percent viability. **Conclusions:** Automation provides significant advantages over manual counting in both time and consistency, especially when accounting for multiple technicians and variations in technique and training within or between various labs. The CellDrop's Hepatocytes App also quickly and accurately provides additional information about the sample not captured in manual counting such as the level of debris, free floating nuclei, and the number of non-parenchymal cells vs hepatocytes present.

PS 3720 Beyond spatiotemporal modeling: applications of machine learning for traffic-related airpollution toward non-exhaust emissions

N. Ho¹, S. Dhayade², Y. Zhang³, Y. Zhang², J. Li¹, Y. Li², Y. Shen², Y. Zhu¹, and F. Gao¹. ¹University of California Los Angeles, Los Angeles, CA; ²University of Texas at Arlington, Arlington, TX; and ³Texas A&M University, College Station, TX.

Background and Purpose: Traffic-related air pollution (TRAP), including tailpipe emissions and non-exhaust emissions, is a major health concern in urban areas and is associated with various adverse health outcomes. As tailpipe emissions decrease due to regulatory efforts, non-exhaust emissions have become a more significant source of pollution. Machine learning (ML) has been widely used to better characterize and quantify traffic-related air pollutants, enhancing understanding of their compositions and spatiotemporal distributions related to health implications. In this study, we hence reviewed publications on applying ML for traffic-related air pollution to summarize recent applications of ML in traffic-related air pollution studies with a special focus on non-exhaust emissions and cover wider applications beyond spatiotemporal modeling. **Methods:** Over 50 peer-reviewed papers related to ML and TRAP were collected from Google Scholar and PubMed using key words, including "machine learning", "traffic-related air pollution", "deep learning", and "air pollution". Widely used features/variables that are involved in TRAP modeling were collected and summarized, with special emphasis on traffic-related features. We further summarized major applications of ML in TRAP research, and discussed existing challenges and opportunities. **Results:** We identified four major applications of ML in TRAP research: (1) TRAP spatial modeling, (2) identification of contributing factors to TRAP, (3) characterization of non-exhaust emissions, and (4) source tracking and apportionment. We found that random forest models were predominantly used in TRAP spatial modeling while deep learning models were often used to process image-based air pollution data and/or capture temporal information. ML models

have also been used to identify and classify types of PM components, especially from brake and tire wear, using image and spectrum data from instrumental analysis. The interpretation of ML models can improve our understanding of how traffic related features such as traffic patterns and driving characteristics contribute to TRAP. **Conclusions:** Machine learning has shown great potential in TRAP research, which helps generate high-resolution spatial exposure maps and improve our understanding of TRAP exposures. With the advancement of ML methods and their further integration with environmental health, ML will continue to contribute to better assessing the effects of TRAP exposure on human health. Furthermore, the use of ML models coupled with the diverse traffic-related air pollution measurements will provide essential information for risk assessment and inform public health policies.

PS 3721 Harnessing Artificial Intelligence To Advance Clinical Pharmacology And DMPK In Drug Development

D. Thomas¹, A. Nielsen¹, T. Vargues², O. Barberan², and D. Skopina². ¹Elsevier, Inc., San Diego, CA; and ²Elsevier, Inc., Amsterdam, Netherlands. Sponsor: D. Thomas, International Society for the Study of Xenobiotics

Background and Purpose: Drug development relies heavily on the accurate interpretation of pharmacokinetic, pharmacodynamic, and safety data to guide clinical dose selection and regulatory decision-making. However, these processes are often hindered by the complexity and volume of unstructured information within regulatory submissions, reviews, and product labeling. Extracting relevant data to inform modeling, FIH dose estimation, or risk assessment typically requires extensive manual effort, limiting efficiency and reproducibility. Recent advances in artificial intelligence (AI), particularly natural language processing (NLP) and machine learning, provide new opportunities to systematically identify, extract, and contextualize pharmacological and regulatory data from historical documentation. Integrating these approaches within regulatory intelligence platforms has the potential to streamline analysis, improve data transparency, and support evidence-based decision-making across Clinical Pharmacology and DMPK disciplines. **Methods:** PharmaPendium AI was built upon a structured database of over 5,000 approved drugs encompassing FDA and EMA reviews, labeling, and approval packages. Advanced natural language processing (NLP) and machine learning algorithms were applied to extract, normalize, and classify pharmacokinetic and pharmacodynamic data, dose rationale information, and safety findings from unstructured text. The system was designed to support natural language queries, enabling scientists and regulatory professionals to obtain context-specific information efficiently. Targeted modules were developed to identify transporter- and enzyme-mediated drug-drug interactions (DDIs), evaluate hepatotoxicity risks by mining Risk Evaluation and Mitigation Strategy (REMS) and clinical hold documents, and retrieve precedent-based language and rationales used in regulatory decision-making. **Results:** The platform's capabilities were assessed through a case study involving a novel tyrosine kinase inhibitor targeting colony-stimulating factor 1 receptor (CSF1R), developed to improve upon pexidartinib for treatment of tenosynovial giant cell tumor (TGCT). AI-driven text mining aggregated preclinical selectivity data, pivotal trial outcomes (e.g., ENLIVEN study), and hepatotoxicity observations to inform dose optimization strategies. Analysis of REMS and regulatory correspondence identified mechanistic insights into liver toxicity, supporting refinement of liver monitoring protocols. Extraction of transporter and enzyme data informed DDI risk assessments, while analysis of biomarker-related content supported patient stratification approaches. These outputs provided multidisciplinary teams with data-driven evidence to guide dosing, safety monitoring, and submission preparation. **Conclusions:** Integration of AI-based text mining and data normalization into regulatory intelligence platforms can substantially improve the accessibility and utility of pharmacological and regulatory data. The PharmaPendium AI framework demonstrates how machine learning and NLP can enhance decision-making across Clinical Pharmacology, DMPK, and Regulatory Affairs by reducing manual data retrieval, improving safety signal detection, and supporting evidence-based regulatory interactions. Broader implementation of such tools may contribute to more efficient, transparent, and scientifically grounded drug development processes.

PS 3722 Interpretable Deep Learning Framework for Predicting Protein Corona Adsorption and Abundance on Nanoparticles

K. Li, A. Canchola, K. Chen, A. Borboa-Pimentel, C. Chou, and R. D. Rama. University of California, Riverside, Riverside, CA.

Background and Purpose: Nanoparticles (NPs) hold great promise for diverse biotechnological applications, including molecular sensing and therapeutic delivery. However, their interactions within biological systems remain unpredictable, as spontaneous protein corona (PC) formation alters surface properties and governs biological identity, transport, and cellular uptake. Understanding and predicting PC composition is essential, but it remains challenging due to inconsistent data and complex interactions between NP properties and experimental conditions. This study aims to develop an interpretable machine learning framework to predict protein adsorption and abundance on NPs. By integrating comprehensive physicochemical and experimental descriptors, the framework elucidates key determinants of PC formation and provides a systematic basis for rational nanomedicine design. **Methods:** Data were obtained from a curated PC database (PC-DB) that consists of 817 NP-PC

samples, and 2,497 proteins identified across 4 different species (human, mouse, rat, and bovine), as described in detail in our previous publication. For this analysis, only human-derived proteins were included, and those detected in more than 5% of samples were retained to reduce sparsity. Eleven physicochemical and experimental features were selected as model inputs after cleaning and encoding categorical variables. Two deep neural network (DNN) models were developed: a binary classifier to predict protein adsorption and a regression model to estimate relative abundance. Model training incorporated Synthetic Minority Oversampling Technique (SMOTE) for data balancing, logarithmic transformation and scaling of abundance values, and Bayesian optimization with early stopping to improve robustness. The applicability domain (AD) was defined using the Euclidean distance in the standardized feature space to identify reliable prediction regions and detect out-of-domain samples. Model interpretation was performed using SHapley Additive exPlanations (SHAP) to identify NP and experimental features driving protein adsorption and abundance predictions. **Results:** The adsorption (classification) model achieved a mean accuracy of 0.90 and an AUC of 0.96 on independent test sets, showing strong reliability across diverse NP-PC pairs. The abundance (regression) model reached an average R^2 of 0.52 despite the highly variable and skewed protein distribution, indicating realistic capture of biological trends. AD analysis indicated that most of the test samples fell within the defined domain, and predictions within this region showed markedly higher accuracy and lower error compared to out-of-domain samples. SHAP analysis revealed distinct feature importance patterns between tasks: protein adsorption was primarily driven by nanoparticle physicochemical properties such as core material and surface modification, while protein abundance was more strongly influenced by experimental parameters, especially incubation and centrifugation time. **Conclusions:** This study presents an interpretable deep learning framework for predicting both the presence and abundance of proteins on NP surfaces. By integrating curated experimental data with standardized preprocessing and SHAP-based interpretation, the models captured key physicochemical and procedural factors that determine PC formation. These findings provide a data-driven foundation for understanding nano-bio interactions and offer practical guidance for designing safer and more reproducible, and functionally optimized nanoparticles in biomedical applications.

3723 Uncertainty Quantification in Toxicity Machine Learning Models for Use in MegaTox

J. S. Harris, M. Hamilton, P. A. Vignaux, T. R. Lane, and S. Ekins. Collaborations Pharmaceuticals, inc., Raleigh, NC.

Background and Purpose: Uncertainty quantification is crucially important for predictive machine learning (ML) models, and particularly relevant to toxicity predictions, where prediction confidence can impact life-or-death decisions. Regardless of how a model performs in cross validation or on a test set, it is useful to know the uncertainty associated with a particular prediction. There are two flavors of uncertainty to consider: aleatoric and epistemic. Aleatoric uncertainty is due to noise in the training data (e.g. measurement error). Epistemic uncertainty is due to lack of knowledge (i.e. the sample is out of domain). We now describe a novel approach to quantifying uncertainty in ML models and apply it to a wide array of toxicity endpoints. **Methods:** We have developed a new approach to uncertainty quantification called Domain Classification (DC) modeling. We begin with a dataset with "inactive" and "active" compounds (e.g. IC_{50} or LD_{50} above or below a threshold). We also draw a random sample of molecules from the ChEMBL database. We then train three binary classification models to predict the probability that a given molecule came from one set versus another: ChEMBL vs. inactive, ChEMBL vs. active, and inactive vs. active. Predictions from these models are combined into four probabilities: P(inactive), P(active), P(ambiguous) and P(out-of-domain), where the latter two represent aleatoric and epistemic uncertainty. Since the prevalence of the out-of-domain distribution (random ChEMBL molecules) is unknown, we can define an uncertainty window based on P(out-of-domain), which sets bounds on the probability prediction for any given molecule. **Results:** We demonstrate the efficacy of this approach by building DC models for acetylcholinesterase (AChE) inhibition, for which we have a large and well-understood training set. We show that, for test sets specifically chosen to be distinct from the training set, the true probability of activity (i.e. the fraction of active compounds in the test set) stays within the bounds defined by the DC uncertainty window; moreover, we show that the uncertainty window widens as a function of the average domain coordinate (e.g. Tanimoto distance) of the test set. We also observe a significant improvement in cross validation model performance metrics if we filter out samples where the uncertainty window overlaps with both classes (equivalently, if we only count samples where either P(inactive) or P(active) is greater than 50% regardless of uncertainty probability). For the AChE model, this leads to a balanced accuracy improvement of 5.4% (specificity and recall improvement of 2.2% and 8.7%, respectively) over the full training set, at the cost of discarding about 25% of cross validation predictions due to uncertainty. We then extend the DC modeling approach to a wide range of toxicity models, including over 40 "safety screen" targets, skin irritation and sensitization, eye irritation, acute inhalation, cardiotoxicity (hERG, hypertension, arrhythmia, etc.), DART, carcinogenicity, genotoxicity, endocrine disruption, LD_{50} , DILI, nephrotoxicity, and CYP inhibition. These ML models represent a small selection of those in our MegaTox software, a commercially available web app which predicts properties of molecules using ML models integrated into the software. Having demonstrated our DC method successfully for AChE inhibition, we are now in the process of validating it against this wider array of toxicological

endpoints. **Conclusions:** MegaTox provides a platform to deploy a customized set of models enabling prediction of toxicological properties from molecular structure. Our continual development of additional algorithms and molecular descriptors points to the benefits of an extensible platform for toxicology predictions that is modular and can be rapidly updated as technology advances. We now describe the development of novel uncertainty-aware models for a wide array of toxicity endpoints. We are also applying this uncertainty technique to help guide the generative design process in drug discovery projects, where we are using this approach with drug targets.

3725 A second-generation artificial intelligence-assisted physiologically based pharmacokinetic model to predict nanoparticle tumor delivery in mice

K. Mi^{1,2}, Q. Chen^{1,2}, V. Sundaram³, I. J. Santhosh³, H. Quazi³, C. He¹, N. A. Monteiro-Riviere^{4,5}, J. E. Riviere^{5,6}, S. Arya³, and Z. Lin^{1,2}. ¹College of Public Health and Health Professions, University of Florida, Gainesville, FL; ²Center for Environmental and Human Toxicology, University of Florida, Gainesville, FL; ³The Ben and Maytee Fisch College of Pharmacy, The University of Texas at Tyler, Tyler, TX; ⁴Nanotechnology Innovation Center of Kansas State, Kansas State University, Manhattan, KS; ⁵Center for Chemical Toxicology Research and Pharmacokinetics, North Carolina State University, Raleigh, NC; and ⁶Data Consortium, Kansas State University, Olathe, KS.

Background and Purpose: Nanoparticle (NP)-based drug formulations are characterized by high drug loading, extended circulation time, and targeted delivery, holding great promise for cancer treatment. However, the low delivery efficiency of nanoparticles (NPs) to tumors remains a challenge and hinders clinical translation. This study aimed to develop the second-generation artificial intelligence (AI)-assisted physiologically based pharmacokinetic (PBPK) model for predicting NPs' tumor delivery efficiency (DE) based on NPs' physicochemical properties and experimental strategies. **Methods:** A generic PBPK model was applied to describe NPs' tumor kinetics (N=152), and six different tumor-related PBPK parameters were determined. Local sensitivity analysis was conducted to determine the influence of parameters on PBPK predictions. By combining published (N=378) with current datasets (N=152), a total of 530 datasets were used to construct machine learning (ML) and AI models for predicting the tumor-related parameters. Incorporating the ML model-predicted parameters into the generic PBPK framework, an AI-assisted PBPK model was developed to predict NPs' tumor kinetics. The AI-assisted PBPK model performance was internally evaluated by comparing observed DEs (maximum DEs, DEs across different time points, and DE at 24h) with the model predictions. In-house experimental data of tumor DEs for gold nanoparticles in MCF-7 tumor-bearing mice were generated and used to externally validate AI-assisted PBPK model. **Results:** The generic PBPK model can capture the tumor kinetics for various NPs, which achieved the overall determination coefficient (R^2) of 0.92. Distribution (PT) and permeability (PATC) coefficients at the tumor site were identified as the important parameters in predicting tumor DEs. A total of 30 ML/AI models are developed. The deep neural network (DNN) model was the best-performing model and selected for estimating tumor-related parameters. The AI-assisted PBPK model achieved R^2 of 0.57, 0.42, and 0.57, for maximum DEs, DEs across different time points, and DE at 24h, respectively. For the external validation, most predicted concentrations were within the two-fold error of the observed data, indicating acceptable predictive accuracy. **Conclusions:** This study improved performance in predicting tumor-related parameters and enhanced practical applicability over the first-generation model, which can serve as a screening tool for tumor DE predictions and NP formulation optimizations, informing the clinical translation of NPs.

3726 Prediction of Ocular Toxicity using Machine Learning Models

R. Xu, T. Xu, J. Zhao, M. Xia, A. Simeonov, and R. Huang. NIH, Rockville, MD.

Background and Purpose: The ocular surface is routinely exposed to various chemicals, some of which can lead to negative outcomes ranging from mild irritation to permanent blindness. To reduce the risk of damage from exposure, chemicals (e.g., cyclohexanol, and sodium oxalate) must be tested for ocular toxicity. However, traditional animal-based toxicology testing is expensive, time-consuming, and associated with ethical concerns, prompting researchers to turn to new methods for testing toxicity, such as computational models. Specifically, the goal of the study is to develop machine learning models to predict whether a compound with unknown mechanism of toxicity is toxic to the human eye by applying chemical structure data, bioactivity assay (e.g., assays that screen for small molecule agonists of the hypoxia (HIF-1) signaling or thyrotropin-releasing hormone receptor (TRHR) signaling pathways) data, or a combination of both to the models. **Methods:** In this study, three classification algorithms were used to build the models: random forest, support vector machine (SVM), and XGBoost. Feature selection was applied to some of the models to improve model performance. **Results:** Model performance varied according to the data type applied to the model, the model used, and the train/test split generated. Models only using assay data did not perform as well as models using only structural data or both data types. Interestingly, the latter two model types had comparable performances with the structural data models sometimes outperforming the models using the combined data set. The top-performing model, with an area under the receiver operating characteristic curve (AUC-ROC) value of approximately

0.75, was derived by applying feature selection to the random forest algorithm trained on a combination of structural and assay data. **Conclusions:** This random forest model is a strong candidate for future investigation to improve performance and for large-scale ocular toxicity screening. The optimized model will be applied to virtually screen the Tox21 10K compound library to identify potentially ocular toxic compounds. The predicted toxic compounds will be prioritized for experimental validation.

PS 3727 Integrating Machine Learning Approaches for Neurotoxicity Prediction: Combining Tox21 Assay Datasets and Chemical Structures

Z. Li, T. Xu, L. Zhang, M. Xia, and R. Huang. NCATS, Rockville, MD.

Background and Purpose: Environmental and pharmaceutical chemicals pose significant neurotoxicity risks, potentially causing cognitive, behavioral, and neurological disorders. Traditional *in vivo* testing is costly, time-consuming, and often poorly predictive of human outcomes. To address this, the U.S. Tox21 consortium, a collaborative initiative among several federal agencies, has developed a suite of *in vitro* assays for quantitative high-throughput screening (qHTS) of the Tox21 10K compound library. This study evaluates the predictive performance of Tox21 assay data and chemical structure for neurotoxicity assessment. **Methods:** We constructed predictive models using five machine learning algorithms: Random Forest, Naïve Bayes, eXtreme Gradient Boosting, and Support Vector Machine and Neural Network. Model performance was evaluated using the area under the receiver operating characteristic curve (AUC-ROC). **Results:** These models were then applied to the full Tox21 10K compound library, and the compounds with the highest predicted probability of neurotoxicity were selected for experimental validation. Key contributor to neurotoxicity prediction included the activation of glucocorticoid receptor. In parallel, structural features such as pyridine rings and tertiary amine-aliphatic nitrogen bonds were strongly associated with neurotoxic potential. **Conclusions:** Overall, this study demonstrates the effectiveness of integrating assay data with chemical structure information to enable reliable *in silico* prediction of neurotoxicity, offering a scalable and animal-free approach for chemical safety assessment.

PS 3728 Combined evaluation using three *in vitro* testing methods for skin sensitization of medical device materials

M. Okada, H. Tabata, K. Suzuki, and A. Kaneki. Terumo, Nakaimachi, Japan. Sponsor: M. Okada, Japanese Society of Toxicology

Background and Purpose: The evaluation of skin sensitization hazards is required for all body-contacting medical devices. Currently, the Guinea Pig Maximization Test (GPMT) is widely used for evaluating skin sensitization hazards. From the perspective of animal welfare, the development of alternative methods to replace GPMT is strongly desired. However, there are not internationally standardized alternative methods for the evaluation of medical devices. A unique feature of skin sensitization evaluation for medical devices is the use of organic solvent extracts and extract solutions obtained with polar and non-polar solvents. Furthermore, because skin sensitization is elicited through multiple biological responses *in vivo*, no single alternative method can fully substitute for GPMT. Therefore, it is important to scientifically examine how to combine the results of various alternative methods to accurately predict GPMT results. Unfortunately, there has been little research addressing this issue. In this study, we evaluated organic solvent extracts from medical device materials using three alternative methods listed in the OECD test guidelines—Amino acid Derivative Reactivity Assay (ADRA), Epidermal Sensitization Assay (EpiSensA), and human Cell Line Activation Test (h-CLAT)—and investigated how best to combine these results to predict GPMT outcomes with high accuracy. **Methods:** The nine medical device materials (Rubber A and B, Catheter, Catheter hub, Medical adhesive bandage, Polymer pellet A, B, A+B, and C) were selected as test samples. Each material was extracted with acetone, methanol, or *n*-hexane according to ISO 10993-10, and the extracts were obtained by evaporating the organic solvents. These extracts were re-dissolved in solvents appropriate for each assay and subjected to testing. The GPMT was conducted at an AAALAC-accredited facility, and guinea pig skin reactions were scored according to Japanese guidelines. ADRA was performed according to OECD TG 442C, and the depletion rates of NAC and NAL were measured by HPLC. EpiSensA was conducted following the developer's protocol, using a three-dimensional skin model (LabCyte EPI-MODEL24), and the expression of four genes (*ATF3*, *GCLM*, *DNAJB4*, *IL-8*) was analyzed by Real-time PCR. h-CLAT was performed according to OECD TG 442E, and the expression of CD86 and CD54 in THP-1 cells was measured by flow cytometry. To predict the results of GPMT, two combined approaches were adopted: the "2 out of 3" approach and the Sequential Testing Strategy (STS) approach. The "2 out of 3" approach, based on OECD Test Guideline No. 497, determined the outcome when at least two of the three alternative methods yielded concordant results. The STS approach, based on papers ^{1,2}, determined the outcome based on the results of h-CLAT and ADRA. 1) Y. Nukada *et al.* Data integration of non-animal tests for the development of a test battery to predict the skin sensitizing potential and potency of chemicals. *Toxicol. in Vitro*, 27 (2013), pp. 609-618. 2) O. Takenouchi *et al.* Test battery with the human cell line activation test, direct peptide reactivity assay and DEREK based on a 139 chemical data set for

predicting skin sensitizing potential and potency of chemicals. *J. Appl. Toxicol.*, 35 (2015), pp. 1318-1332. **Results:** In the GPMT, 7 out of 9 materials showed positive, while 2 materials showed negative. The concordance rates between each alternative method and the GPMT were as follows: ADRA showed concordant results for 7 materials, with discrepancies observed for polymer pellet A (GPMT positive) and rubber B (GPMT negative). EpiSensA showed concordance for 8 materials, with a discrepancy for catheter hub (GPMT positive). h-CLAT showed concordance for 7 materials, with discrepancies for catheter and medical adhesive bandage (both GPMT positive). These discrepancies may have been influenced by factors such as the solubility of organic solvent extractables in the test solvents. When combining the results of the alternative methods, the "2 out of 3" approach achieved complete concordance with GPMT for all 9 materials. In contrast, the STS approach showed concordance for 8 materials, with a discrepancy for rubber B. **Conclusions:** The combination of three alternative methods (ADRA, EpiSensA, and h-CLAT) demonstrated the potential to accurately predict GPMT outcomes for medical device materials. In particular, the "2 out of 3" approach may serve as a highly accurate alternative to GPMT.

PS 3729 Development of an Artificial Intelligence tool to support processing data from Extractables & Leachable studies for toxicological risk assessments.

O. Odia, V. F. Thoranath, V. Dowling, J. Noyes, M. Ibres, and G. Frost. Cardinal Health, Dublin, OH.

Background and Purpose: Currently, extractable and leachable testing per ISO 10993-1 and ISO 10993-18 requirements generate reports containing numerous chemicals. In many instances, processing the data involves selection of a replicate that reflects largest amount, grouping similarly structured chemicals to evaluate potential additive effects and lastly, identification of the chemicals for a toxicological evaluation. Depending on the number of chemicals extracted, this refinement process can take a significant amount of time. The reports are accessible PDFs with chemical grouping data in tables, requiring manual extraction and interpretation. This process has the potential to be streamlined by the application of "Artificial Intelligence" (AI) tools. The purpose of the AI tool is to develop a comprehensive solution for extracting, analyzing, and processing data from leachables and extractables studies, especially from scientific PDF reports. **Methods:** The software developed is a proprietary artificial intelligence tool that automates the processing of extractables and leachable data, based on a scientific rationale for grouping similar chemicals in terms of structure or toxicological activity. The artificial intelligence tool uses chemical attributes such as structure and functional groups, mirroring a human expert's decisions for toxicological risk assessments, saving time and improving accuracy and efficiency in the process. It leverages AI, document parsing, and data science tools to automate and streamline the extraction and analysis of chemical data from complex documents. The tool was developed using Google Cloud & ADK including, Google Cloud Build Console and Vertex AI Workbench and Cardinal Health in-house extractable studies data. Over 6,000 chemical constituents spanning 30+ different devices have been used to train and refine the artificial intelligence tool. **Results:** The artificial intelligence tool developed was able to process data from extractable studies. It also generated scientific rationales for grouping certain chemicals together. In order to mitigate the effects of possible artificial intelligence errors, a separate artificial intelligence tool critiqued the grouping from the first data output. **Conclusions:** This artificial intelligence tool provides opportunities for decreasing effort spent on the processing stage of extractables and leachable studies. Continuous effort to refine the tool is ongoing.

PS 3730 Chemical Characterization of Medical Devices: How Creativity and Care Play a Role in Effective Study Design

C. D. Oberle. Eurofins EAG, St. Louis, MO. Sponsor: S. Parker

Background and Purpose: Biocompatibility testing of medical devices per ISO-10993-18 is a resource intensive process. Careful front-end study design leverages efficiencies to reduce timelines and minimize the total number of devices required for testing. Creative strategies for optimizing device extraction, determining appropriate testing conditions, building protectivity into the AET, and planning for foreseeable misuse are crucial for executing the most effective studies. Furthermore, new draft guidance and recent changes to 10993-1 should be addressed during the study design phase to ensure that up-to-date testing requirements are satisfied prior to submission to a regulatory body. A well-designed and well-executed chemical characterization study plan will both facilitate the generation of an accurate TRA and avoid the need for re-testing. Crucially, testing laboratories must follow best practices to save time and cost while ensuring studies are protective of patient safety. **Methods:** In this study we seek to demonstrate how chemical characterization testing can be optimized on a case-by-case basis and how creative study design is essential in creating efficiencies. **Results:** A variety of creative approaches to chemical characterization will be presented as case studies, as well as primers on foreseeable misuse and recent changes to ISO 10993-1 which may affect future biocompatibility study design. **Conclusions:** Testing laboratories must actively partner with manufacturers and toxicologists in the design and execution of chemical

characterization studies to maximize the value of these results to the TRA. Careful and creative study design will help guide the medical device product from the testing phase to regulatory submission as efficiently as possible.

PS 3731 Extractable and Leachable Tin from Medical Devices: Influence of Speciation on Toxicological Limits and Considerations for Chemical Characterization

A. DeGraw, S. Bond, M. Galati, N. Fredrick, and M. Louis. Jordi Labs, Mansfield, MA.

Background and Purpose: Assessment of inorganic elements by inductively coupled plasma mass spectrometry (ICP-MS) is a standard component of the characterization of extractable and leachable (E&L) medical device constituents performed in accordance with ISO 10993-18:2020. However, ICP-MS does not provide speciation of the element detected and chromatographic screening methods for organic compounds included in E&L studies may not detect or identify organometallics. Tin (Sn) is an element included in ICP-MS analyses based on ICH Q3D Guidance for Elemental Impurities for Pharmaceuticals. While the ICH Q3D focuses on the toxicity of inorganic tin, E&L tin from medical devices could be from inorganic or organic compounds, each differing in biological activity and toxicity. In this study, we evaluated potential sources of tin from medical devices and derived tolerable intake levels for commonly used species. To highlight the potential for mischaracterization of toxicological risk when there is inadequate information on device materials of construction and manufacturing, a case study is presented. **Methods:** Potential sources and species of tin as a medical device constituent were examined through a review of commonly reported device materials, additives, and manufacturing processes. Standard analytical techniques for E&L studies were evaluated for their ability to characterize different tin species. Toxicological reference values (NOAELs, LOAELs) were compiled from sources including ATSDR, NTP, OECD, and ECHA dossiers for different tin species including stannous chloride, octyltins, and butyltins. Tolerable intakes (TIs) were derived for tin species when sufficient data was available using the ISO 10993-17:2023 framework, incorporating standard uncertainty and route-to-route extrapolation factors for chronic parenteral exposure. To characterize the toxicological risk associated with different tin species, a simulated-use chemical characterization study where tin was detected by ICP-MS was considered. Materials of construction that may be contributing tin to the chemical release profile, and what species of tin could be a potential E&L constituent were examined. A maximum estimated exposure dose (EED_{max}) for tin was calculated and a comparative analysis of margin of safety (MOS) values was performed by comparing the EED_{max} to the derived TIs for the different tin species. **Results:** Both inorganic and organic tin compounds are potential E&L from medical devices and analytical techniques vary in their sensitivity and specificity. Inorganic tin compounds are of relatively low toxicological concern while organotins exhibit toxicity at much lower exposure levels. Derived TIs spanned four orders of magnitude, ranging from 16 µg Sn/kg/day for inorganic tin to 0.006 µg Sn/kg/day for dibutyltin. For a representative extract containing 11.92 µg Sn/device by ICP-MS analysis, toxicological risk characterization varied from acceptable levels of risk for inorganic tin to potentially unacceptable levels of risk for certain organotins. These findings demonstrate that tin speciation is a critical driver of toxicological risk assessment outcomes. **Conclusions:** Tin speciation substantially influences allowable exposure limits and overall assessment of toxicological risk. Standard ICP-MS analysis does not allow for definitive characterization of tin as an E&L medical device constituent and chromatographic screening methods require additional considerations to detect and identify organotins. Incorporating knowledge of manufacturing processes and material chemistry provides a scientifically defensible basis for characterizing the toxicological risk of exposure to tin as an E&L medical device constituent.

PS 3732 Hazard Evaluation and Structural Analysis of Organophosphorus in Medical Device Extractables and Leachables Datasets

M. T. Matsushita¹, B. A. Cronin², H. J. Gadol², and R. Y. Chang¹. ¹Gradient, Seattle, WA; and ²Gradient, Boston, MA.

Background and Purpose: Medical devices (MDs) are composed of a wide range of materials that have the potential to release chemical constituents, including organophosphorus compounds (OPs), during patient use. OPs are listed as one of the cohort of concern (COC) chemical classes by the International Organization for Standardization/Technical Specification (ISO/TS) 21726 (ISO, 2019). OPs are neurotoxins often used as pesticides and nerve agents with a well-studied mechanism of action involving inhibition of the acetylcholinesterase (AChE) enzyme. In MDs, OP-related compounds are commonly used as plasticizers and have been identified from extraction studies (Builee *et al.*, 2025; Borton and Coleman, 2025). As COCs are expected to be potentially toxic and their risk cannot be assessed using a threshold of toxicological concern (TTC), assessments of OPs identified in MD extractables can involve an additional effort to identify suitable surrogates. The ISO/TS 21726 (ISO, 2019) does not provide details on how to identify OPs that are potentially neurotoxic. A TTC of 0.3 µg/kg-bw/day has been derived for OPs based on 31 OP insecticides (Munro *et al.*, 1999; Kroes *et al.*, 2004), and has been reaffirmed by the European Food Safety Authority (EFSA) using neurotoxicity data of 59 OPs and 14 carbamates (EFSA, 2012). Our aim is to evaluate toxicity and potency of

OP species identified in MDs, and to identify chemical structural features that can help to better identify OPs with neurotoxic concern. **Methods:** To better understand potential hazards associated with OPs identified in MDs, we set out to investigate the following with published MD-constituent lists (Borton and Coleman, 2025; Builee *et al.*, 2025): 1. Identify overlap between OPs reported in MD extractables with OPs used to derive (Munro *et al.*, 1999) and verify (EFSA, 2012) the OP TTC; 2. Identify risk points of departure (PODs) based on available data and compare with the OP TTC; and 3. Identify structural features associated with neurotoxic outcomes. **Results:** Approximately 600 unique chemicals were identified in the published MD-constituent lists. Four OPs were uniquely identified in the MD-constituent list to be in the Munro and/or the EFSA dataset; 2 of 31 OPs from the Munro dataset and 4 of 51 OPs from the EFSA dataset were on the list of MD-constituent OPs. MD-constituent OPs that were in the Munro and/or EFSA dataset were thiophosphate-related compounds. Our preliminary results suggest that all toxicity PODs for MD-constituent OPs are at least three orders of magnitude higher than the approximate 5th percentile no observed adverse effect level (NOAEL) of 0.03 mg /kg-bw/day from which the OP TTC was derived (Munro *et al.*, 1999; Kroes *et al.*, 2004). **Conclusions:** Our preliminary findings show that the OP TTC that was derived based on insecticides (Munro *et al.*, 1999) is sufficiently protective for neurotoxicity; however, these findings suggest that there may be room to further refine the OP TTC with chemicals detected from MDs.

PS 3733 Integrating Total Organic Carbon (TOC) Analysis into Chemical Characterization for Toxicological Risk Assessment: A Case Study Evaluating the Relationship Between TOC and Gravimetric Residues

S. Kearing, C. Meakin, and L. Borton. Gradient Corp, Boston, MA.

Background and Purpose: ISO 10993-17 recommends the use of conservative, quantitative exposure data for the purposes of toxicological risk assessment. ISO 10993-18, Section 6.3 identifies total organic carbon (TOC) analysis and non-volatile residue (NVR) determination (via gravimetric analysis) as acceptable methods for quantifying organic extractables from medical devices. While both techniques are non-specific and primarily used to demonstrate exhaustive extraction, few studies have systematically compared their relative performance or explored their utility in informing exposure assessment in toxicological risk assessments. **Methods:** In this case study, test articles (titanium alloy orthopedic plates and screws) were exhaustively extracted under five conditions. For this orthopedic system, the materials of construction are well characterized. These devices provide a unique opportunity to assess whether TOC-derived total organic carbon values can be used to estimate total extractables and inform toxicological risk assessments by applying TOC results to known manufacturing process chemicals. Three organic solvent extractions (non-polar, mid-polar, and polar solvents) were performed for 72 hours with agitation at 50°C, representing exhaustive extraction conditions for a long-term implant device per ISO 10993-18. Two aqueous extractions were performed to evaluate TOC compatibility: (1) 24 hours with agitation at 50°C and (2) 30 minutes with sonication at room temperature. Gravimetric (NVR) analysis was performed on all extractions, and TOC analysis was performed on all aqueous extracts. A separate spiking study was conducted using compounds of varying volatility and solubility to evaluate the classes of analytes detectable by TOC. **Results:** Across all extractions, the highest total residue by NVR was obtained from the 72-hour aqueous extraction (340 µg). The highest TOC residue was measured in the 30-minute sonicated water extraction (141 µg). At first, this study suggests NVR is the more efficient means of quantifying gross residue. However, TOC measurements only quantify carbon-containing chemicals. When adjusted to account for non-carbon elements based on the device's extractables profile, the estimated total extractables increased to approximately 324 µg, which more closely matches the NVR results. These findings indicate that TOC can serve as a viable alternative to NVR. TOC can quantify the gross residues in aqueous extractions of metallic devices as well as NVR for the purposes of an exposure assessment. When the contact chemicals of a medical device are known, TOC values can serve as the quantitative exposure value for each chemical constituent for the purposes of toxicological risk assessment. The use of TOC as the exposure value for each contact chemical results in a highly conservative exposure estimation. **Conclusions:** In conclusion, TOC analysis can be effectively leveraged as a conservative exposure value for toxicological risk assessment of metallic devices. When adjusted for non-carbon composition, TOC provides a conservative estimate of total extractables and offers an efficient means to evaluate manufacturing residuals in support of biological safety assessments.

PS 3734 Considering Physiological Environment in Study Selection for Toxicological Evaluation of Implantable Devices: Case Study of Polyurethane Foam-Coated Implants

M. A. Arnold¹, B. Head¹, and M. J. Kratochvil². ¹Exponent, Inc., Washington, DC; and ²Exponent, Inc., Bowie, MD.

Background and Purpose: ISO 10993-17:2023 states the point of departure (POD) selected for deriving a constituent-specific tolerable intake (TI) should represent the most clinically relevant study and account for the route, duration, and conditions of exposure. Although not explicitly stated, the physiological environment of the peri-im-

plant space can be an important consideration for the toxicological evaluation of some medical device constituents. For example, regulatory agencies have expressed concern over the potential release of toluene diisocyanate (TDI), and hydrolysis to the rodent carcinogen toluene diamine (TDA), from polyurethane (PU) foam-coated implants. In lifetime cancer bioassays, carcinogenic outcomes have been reported in rodents administered TDI via oral gavage, but not other routes of exposure. Because pH, among other factors, influence PU hydrolysis pathways, selecting a POD for TI derivation from an oral gavage study can misrepresent degradation kinetics and overestimate patient risks to implanted device constituents. The purpose of this study is to demonstrate the importance of considering the physiological environment of the peri-implant space and portal of entry in key studies when evaluating the toxicity of medical device constituents using PU degradation products as an exemplar. **Methods:** Published literature demonstrating PU degradation profiles in similar medical devices, and toxicological profiles were reviewed. *In vitro* degradation data and theoretical estimates of TDA formation were compared to physiological conditions. Carcinogenicity data from lifetime cancer bioassays with rodents exposed to TDI via oral gavage and inhalation were integrated into a risk model considering device aging-related pathways. **Results:** In oral gavage studies, TDI hydrolyzes to TDA as a result of the highly acidic gastric juices, which are not representative of the physiological environment of skeletal tissue or the peri-implant space, which are near-neutral with low water turnover. In the peri-implant space, physiological conditions favor the formation of urea and polyurea adducts rather than hydrolysis to TDA. The physiological environment of the respiratory tract, however, better approximates that of the peri-implant space. In an inhalation lifetime cancer bioassay with rodents, TDI was clearly not carcinogenic, which is consistent with literature indicating low *in vivo* hydrolysis of TDI to TDA. **Conclusions:** POD selection for TI derivation should consider the physiological environment of the implanted device and route of exposure in the key study to ensure toxicity data are clinically relevant. For some medical device constituents, such as PU foam degradation products, failing to consider the physiological environment could result in the overestimation of patient risks related to the intended use of the device.

PS 3736 Evaluation of the carcinogenic potential of nickel-containing implants and associated alloys

M. Kovochich¹, K. E. Heim², A. R. Oller³, S. Buxton², S. L. More⁴, A. M. Schulte⁴, and D. G. Kougiyas¹. ¹K2 Toxicology and Integrated Risk Assessment, LLC, Las Vegas, NV; ²NiPERA, Durham, NC; ³Oller Consulting LLC, Durham, NC; and ⁴MCRA, Washington, DC.

Background and Purpose: Alloys are produced to have unique physicochemical properties, including hardness, toughness, and corrosion resistance, relative to their individual constituents. Nickel (Ni) is a metal used in various medical device alloys to improve corrosion resistance and enhance mechanical properties. The toxicology and carcinogenic potential of metallic nickel and nickel alloys have been reviewed previously; however, an important consideration in this toxicological and carcinogenic assessment is that Ni-containing alloys warrant a separate evaluation compared to the individual metallic ingredients. The purpose of this analysis, therefore, is to evaluate the potential local and systemic carcinogenic response to Ni-containing implants in preclinical studies, including the testing of alloys used for potential human implants. **Methods:** A standardized protocol was employed to systematically retrieve preclinical carcinogenicity data on Ni-containing materials relevant to implant materials, including stainless steel, nickel-titanium (NiTi), and cobalt (Co)-containing alloys. Eligibility criteria included the use of relevant material type, form, and route of exposure for Ni-containing implant materials. Methodology and results from relevant preclinical studies were documented to consider the test article (material type), Ni content, material form/shape, animal model/test species, route of exposure, study duration, local and systemic tumor results, and other considerations for study results, including statistical analysis (or lack thereof) and details of the control group. The assessment also integrated a discussion of relevant clinical data and conclusions from previous regulatory reviews. **Results:** Our systematic evaluation identified eight relevant preclinical studies assessing the carcinogenicity of Ni-containing implants. Four preclinical studies assessed the carcinogenicity of stainless-steel materials, five evaluated Co-containing materials with varying Ni levels, and one provided limited data on nitinol (a NiTi alloy), with some studies addressing more than one material. While two studies demonstrated foreign-body effects that were not specific to Ni, all studies demonstrated no significant increase in local or systemic tumors when compared to controls. Overall, the preclinical data on Ni-containing alloys relevant for medical implants demonstrate a lack of carcinogenic potential. The epidemiological evidence identified by previous regulatory reviews demonstrates no consistent increased overall cancer risk and no consistent indication of site-specific cancers that would be causative of any implant factor related to potential Ni exposure. **Conclusions:** Overall, the preclinical data on Ni-containing alloys relevant for medical implants demonstrate a lack of carcinogenic potential, as no significant increase in local or systemic tumors specific to nickel were observed in various experimental designs. The clinical observations are consistent with preclinical studies, which demonstrate no consistent increased overall cancer risk and no consistent indication of site-specific cancers that would be causative of any implant factor related to potential Ni exposure.

PS 3737 Material Equivalence in Medical Devices: A Risk-Stratified, Weight of Evidence Approach

A. Kozak, and T. Jenkins. Edwards Lifesciences, Irvine, CA. Sponsor: J. Cohen

Background and Purpose: The ability to establish material equivalence is increasingly vital for medical device manufacturers navigating regulatory change management, supply chain disruptions, and product innovation. While ISO 10993 supports material equivalence as a basis for biological evaluation, it does not provide guidance for analytical test selection or acceptance criteria. Such ambiguity triggers inconsistent risk assessment practices, regulatory uncertainty, and inefficient use of resources. We present a risk-based, orthogonal framework leveraging material characterization tests (e.g. FTIR, DSC, TGA, and GPC) with analytical acceptance criteria to define equivalence. Our approach integrates first-principles material science, material-derived sources of biological harm, measurement uncertainty, and statistical equivalence approaches. **Methods:** We conducted a systematic literature review of standards/guidance (ISO 10993; FDA; ASTM; ISO), previous round-robin studies, academic/technical publications, and prior Weight-of-Evidence frameworks (e.g. Street et al 2024). Analytical techniques, from bulk characterization to trace extractables analysis were systematically ranked for suitability in equivalence determination. Risk stratification is enabled by nature/duration of patient contact as well as based on historical evidence ("a priori" knowledge). Materials under investigation are assessed for depth of prior biocompatibility data, clinical history of safe use, and the extent of formulation and process characterization. This informs a risk-based, tiered approach to analytical testing, where materials in low-risk applications with robust prior evidence and well-characterized processes are eligible for streamlined testing and risk-adjusted acceptance criteria. Conversely, novel/implantable materials or those with substantial changes undergo comprehensive orthogonal analysis or additional biological/chemical testing. **Results:** The proposed material equivalence framework is an adaptable decision flowchart for experimental design and analytical test method selection, tailored to the specific material, device, and process context. Acceptance criteria are quantitatively defined for FTIR, DSC, TGA, and GPC, with each metric grounded in measurement uncertainty and statistical rigor. Criteria are mapped from analytical capability to biological relevance: FTIR detects new patient-contacting chemistries; DSC/TGA reflect polymer stability and mobility; GPC reflects oligomer and bulk degradation risk. We define tolerance windows for FTIR oxidation index/correlation factor, DSC glass/melt transitions and oxidation induction times, TGA degradation temperatures and compositional percentages, and GPC molecular weight moments and polydispersity indices. The framework incorporates prior biocompatibility and clinical data to enable risk-based customization of testing depth and acceptance windows. Tests conducted within the framework are additive and complementary; each must independently demonstrate equivalence within predefined limits. Application is demonstrated for common medical polymer families and manufacturing processes, with case studies illustrating both successful and non-equivalent outcomes. **Conclusions:** We present a risk-based material equivalence framework providing a scientifically robust approach for change control, regulatory submissions, and internal decision-making. By enabling practitioners to pre-define and defend analytical test selection and acceptance criteria, the framework enhances consistency, transparency, and regulatory confidence. The adaptable structure supports relevance across diverse materials, manufacturing processes, and device types. Future work will validate the predictive value of the material equivalence framework against biological endpoints and nontargeted chemical characterization. We welcome collaboration from industry and notified body colleagues to support further harmonization, reduce unnecessary testing, and support safe yet efficient innovation in medical devices.

PS 3738 Assessing the application of *In vitro* Irritation in a diverse range of Medical Devices

V. Dowling, B. Patterson, D. Chang, and G. Frost. Cardinal Health, Ohio, OH.

Background and Purpose: Historically, medical devices have been assessed for skin irritation through the current *in vivo* animal rabbit model. The 2021 revision of ISO 10993-23 introduced the *in vitro* protocol for irritation testing of medical devices based on the OECD 439(2013) Reconstructed Human Epidermis (RhE) model. This *in vitro* test has been widely accepted and validated for driving the use of alternative methods to reduce, refine and replace animal testing, in chemical and cosmetic industries. The Reconstructed Human Epidermis (RhE) is currently accepted within the ISO 10993 series as the *in vitro* irritation method for evaluating skin irritation and has been adapted for use in the testing of medical devices. Some of the common challenges faced with the introduction of new approach methodologies (NAMS) can be acceptance in different regulatory landscapes especially where diversity in data from different medical devices is lacking. Cardinal Health's product portfolio contains a wide range of Class I and Class II medical devices such as surgical gloves, wound dressings, enteral feeding devices, urology catheters, among others. These products are comprised of a wide range of raw material constituents making suitable candidates to address the medical devices diversification concerns from regulatory agencies. The purpose of this project is to demonstrate the feasibility of Reconstructed Human Epidermis (RhE) for skin irritation testing across a wide range of products to fulfil requirements of ISO 10993 guidelines for biocompatibility evaluation. **Methods:** Internal Cardinal Health Biocompatibility data was reviewed over the past five years for existing *in vivo* testing data across the overall product port-

folio. Within a subsection of these different product families, around 10-20 devices were selected for *in vitro* evaluation bases on their materials of construction and for which existing *in vivo* animal data is available. These devices were tested in both polar and non-polar solvent using the Reconstructed Human Epidermis (RhE) model as outlined in ISO 10993-23. Data analysis against existing *in vivo* information was also conducted. **Results:** In this work we discuss the outcome of the Reconstructed Human Epidermis (RhE) test on a diverse range (10-20) different products comprising of varying materials and varying categories of patient contact and duration. Favourable correlations were observed between the pre-existing *in vivo* testing and the *in vitro* Reconstructed Human Epidermis test. Post-commercial device changes were also studied to determine the impact of the testing and the suitable integration of the test into the overall biocompatibility risk assessment approach. **Conclusions:** The proposed approach provides a framework to support the acceptance of NAMS by regulatory agencies and notified bodies. This work will show the applicability of the *in vitro* irritation test across a diverse range of medical devices. Furthermore, understanding how material formulations prior to biocompatibility testing will most likely support the 3R concept of Reduce, Remove and Replacement of animal testing in line with other global industries costs and help in the time to market for medical device manufacturers.

PS 3739 Data Deconvolution and High-Resolution Mass Spectrometry in Medical Device Chemical Characterization: Case Studies on TRA Impact

L. Chapman, and C. Chamberlain. EAG Laboratories, St. Louis, MO. Sponsor: S. Parker

Background and Purpose: A chemical characterization study of a medical device per ISO 10993-18 provides invaluable data for the toxicological risk assessment (TRA). It is crucial that high confidence and thorough extractable data be provided by a laboratory to the toxicologist for assessment. Instrumental and interpretative approaches to the extractable data have evolved since the inception of Part 18 and since the 2020 ISO revision. High resolution mass spectrometry with data deconvolution must become a core expectation for chemical characterization of medical devices. **Methods:** Extractable data from chemical characterization studies on diverse medical devices were assessed both with and without high-resolution mass spectrometry and data deconvolution. Comparisons were made, with discussion of the impact to the TRA from instrumental and interpretative approaches. **Results:** Case studies in the application of data deconvolution and high-resolution mass spectrometry for ISO 10993-18 chemical characterization studies will be presented, illustrating the impact to a TRA and ultimately to patient safety. **Conclusions:** Data deconvolution of high-resolution mass spectral data is foundational for modern chemical characterization studies to increase identification confidence and extractable profile coverage, ensuring accuracy in the TRA's assessment of patient safety.

PS 3740 Avoiding False Positives in Medical Device Risk Assessment: Differentiating Real MDI from Analytical Artifact

C. Schultz, C. Shaffer, K. Kalstabakken, P. Steen, A. Marcella, N. Olvera, and J. Warmka. Boston Scientific, St Paul, MN.

Background and Purpose: Polyurethanes, including those used for long-term implantable medical devices, are synthesized by reacting a polyol with an isocyanate such as methylene diphenyl diisocyanate (MDI; CASRN 101-68-8). MDI is of toxicological concern due to its classification as both a skin and respiratory irritant and sensitizer. However, MDI can be artificially generated during extraction studies of polyurethane-containing medical devices. This is due to gas chromatography inlet temperatures reaching temperatures above those where thermoplastic polyurethanes are fully stable. Therefore, it is important to parse detection of MDI as a clinically relevant leachable from an analytical artifact. Standard extractables and leachables screening studies are not sufficient for accurate analysis of MDI from polyurethane-containing medical devices, and herein we propose a simple additional study that can distinguish between extractable MDI requiring toxicological risk assessment and a false positive. In this study, high levels of MDI were initially observed by standard extractables screening methods (specifically, GC-MS) and a targeted derivatization method was implemented to investigate the results. **Methods:** Acetonitrile and hexane device extracts were analyzed for MDI content. An aliquot of each extract was spiked with a solution of a dialkylamine derivatization agent (e.g., dibutylamine) in dichloromethane. The resulting solution was analyzed by LC-MS with a calibration curve generated from MDI standards prepared in the same manner. **Results:** No MDI was observed above the limit of quantitation using the derivatization LC-MS method. This indicates that no free MDI was present in the device extracts and supports the hypothesis that MDI observed by the standard GC-MS screening method are the result of thermal degradation during the analysis. **Conclusions:** This study demonstrates that standard screening of extractables and leachables from polyurethane-containing medical devices by GC-MS may artificially generate MDI, leading to potential false positives in the study report that require toxicological risk assessment. The addition of an LC-MS study with appropriate derivatization provides a simple way to distinguish between real MDI and artificially generated MDI. The addition of this work to

standard extractables and leachables screening studies will help provide a more realistic understanding of clinically-relevant device extractables, and prevent an overly conservative assessment of toxicological risk.

PS 3741 Chemometric Approaches to ISO 10993-18 Workflows - Accelerating Risk-Based Approaches for Rapid Chemical Characterization

M. Rush¹, P. Poudel¹, N. Kothalawala¹, D. Ricker¹, D. Pastarnak¹, and G. Charles². ¹Edwards Lifesciences, Draper, UT; and ²Edwards Lifesciences, Irvine, CA.

Background and Purpose: Chemical characterization studies per ISO 10993-18:2020 are critical for ensuring patient safety by identifying chemical constituents released from medical devices. While applying ISO 10993-18 to the final finished form remains the gold standard, this approach can be overly burdensome when addressing manufacturing changes, sterilization modalities, or alternative suppliers. Some proposals suggest shifting characterization toward bulk property evaluations; however, this overlooks small molecules that are toxicologically relevant, making bulk property analysis an inadequate substitute. A more effective solution is to develop a rapid, risk-based chemical characterization approach that leverages advanced data processing strategies while maintaining ISO 10993-18 principles. In this context, a priori compositional profiling serves as one tool, not a replacement, to accelerate workflows and improve decision-making without compromising patient safety. **Methods:** Utilizing ISO 10993-18 methodologies for volatile, semi-volatile, and non-volatile organic compound analysis, we developed a streamlined data processing workflow focused on small molecules. The approach prioritized extractables and impurities present in the proposed material but absent in the existing material or their estimated concentrations are higher in the proposed material compared to the existing material, enabling rapid identification of toxicologically relevant compounds. We compared outcomes from this workflow against traditional ISO 10993-18 extractables studies, standard information-gathering practices, and bulk property-based evaluations to assess efficiency and scientific robustness. **Results:** Information-gathering alone revealed gaps in detecting relevant differences between materials, and strict reliance on supplier documentation for risk assessment proved insufficient. Equivalence evaluations across polymers, sterilization modalities, and chemical impurities demonstrated that bulk property testing failed to identify changes in small molecules. In contrast, chemometric approaches aligned to ISO 10993-18 workflows successfully detected differences in small molecule extractables and impurities, confirming superior sensitivity, accuracy and specificity for a toxicological risk assessment. **Conclusions:** This work introduces a risk-based chemical characterization strategy that accelerates ISO 10993-18 workflows through advanced data processing while preserving toxicological relevance. By prioritizing small molecule identification and using information gathering as a supporting tool, the approach enables faster, scientifically robust evaluations for equivalency without compromising patient safety.

PS 3742 Survey of Neurotoxicants Released from Medical Devices

M. Khazaei, E. M. Kaye, and J. M. Cohen. Gradient, Boston, MA.

Background and Purpose: Medical devices are made of a diverse range of materials (i.e. plastics, metals, and polymers) which may release various compounds into the patient's body during clinical use that may act as neurotoxicants, adversely affecting the central and peripheral nervous systems and sensory organs. Neurotoxic effects range from reversible symptoms like narcosis, nausea, and dizziness to irreversible outcomes such as neurodegenerative disorders. ISO/FDIS 10993-1:2025 emphasizes medical devices contacting the central or peripheral nervous system or cerebrospinal fluid must undergo neurotoxicity evaluation; including consideration of local (effects near the device) and systemic (neurological effects throughout the body) neurotoxicity. Currently, no comprehensive reference list exists for neurotoxicants associated with medical device extractables. By comparing identified neurotoxicants against robust, published datasets of medical device extractables, we aim to create and classify a consolidated reference list of neurotoxic substances identified from medical device materials. **Methods:** Craenen *et al.* (2025) recently published reference list of industrial chemicals classified as neurotoxic in accordance with classifications listed in Classification, Labelling, and Packaging (CLP) for hazard classification. We screened this reference list of neurotoxic substances against datasets of chemicals established to be released from medical devices recently published by Builee *et al.* (2025), and Borton *et al.* (2025). Next, the identified chemicals were categorized according to Specific Target Organ Toxicity Single Exposure (STOT SE) and STOT Repeated Exposure (STOT RE), as defined in CLP Annex V and the Globally Harmonized System of Classification and Labelling of Chemicals (GHS). GHS category 1 chemicals produce and/or presumed to have significant toxicity in humans based on evidence from studies in experimental animals following a single and/or repeated exposure. Similarly, GHS category 2 chemicals have the potential to produce significant toxicity in humans, solely based on evidence from studies in experimental animals following a single and/or repeated exposure. Finally, GHS category 3 chemicals may produce transient target organ effects only after a single exposure. **Results:** From 113 neurotoxicants identified by Craenen *et al.* (2025), 60 unique chemicals were found in at least one of the two medical device extractables

datasets. A majority of the identified compounds (53 chemicals) were classified as STOT SE3, causing narcotic effects and respiratory tract irritation; and have no fixed pre-defined limits for the exposure guidance values (under GHS). Two compounds, resorcinol and cyfluthrin, were classified as STOT SE1, and are associated with oral (LOAEL $\leq$ 300 mg/kg-bw) or gas inhalation (LOAEC $\leq$ 2,500 ppm per volume (ppmV)/4 hours) exposure ranges in rats. In addition, three neurotoxicants (ethylene oxide, bifenthrin, and indoxacarb) were classified as STOT RE1, indicating LOAELs/LOAECs of $\leq$ 10 mg/kg bw/day for oral exposure and $\leq$ 50 ppmV/6 hours/day for gas inhalation exposure in rats. Two neurotoxicants (cypermethrin and mesotrione) were identified as a STOT RE2 classification, with LOAEL/LOAEC ranges of 10 to $\leq$ 100 mg/kg bw/day for oral exposure and $>$ 50 to $\leq$ 250 ppmV/6 hours/day for gas inhalation exposure in rats. **Conclusions:** Our findings establish a consolidated reference list of neurotoxicants associated with medical device extractables by screening harmonized neurotoxicity classifications against two robust extractables datasets. Among the 60 unique chemicals identified in medical device materials, the majority were classified as STOT SE3, indicating transient neurological effects. A smaller subset exhibited higher toxicity classifications (STOT SE1, STOT RE1, and STOT RE2) following single or repeated exposure. Further delineation of the type and source of these chemicals will be presented in future research. This reference list helps proactive screening of neurotoxic compounds and supporting manufacturers in meeting evolving standards, particularly for devices that contact nervous system tissues or cerebrospinal fluid, as required by ISO FDIS 10993-1:2025.

PS 3743 Comparative Application of ISO 18562-1:2017 and ISO 18562-1:2024 in Toxicological Risk Assessment of VOS Emissions from a Breathing Gas Pathway Device

A. Minich, B. Bowe, H. Reamer, and G. Letellier. Intertek, Boca Raton, FL.

Background and Purpose: Authoritative bodies will soon require premarket submissions for medical devices to follow updated ISO standards. To ensure compliance, toxicological risk assessment approaches for volatile organic substances (VOS) emitted from breathing gas pathway devices must align with ISO 10993-17:2023 and ISO 18562-1:2024. ISO 10993-17:2023 defines principles for deriving tolerable intake (TI) and tolerable exposure (TE) values for chemical constituents of medical devices, while ISO 18562-1:2024 outlines a dedicated framework for evaluating the biocompatibility of breathing gas pathway devices and introduces updated exposure modeling, expanded patient population categories, and improved alignment with ISO 10993-17:2023. This assessment emphasizes ISO 18562-1:2024, comparing its framework directly with ISO 18562-1:2017 to evaluate the impact of the updates on toxicological risk assessment for breathing gas pathway devices. **Methods:** A breathing gas pathway device previously evaluated under ISO 10993-17:2023 and ISO 18562-1:2017 was re-assessed using the ISO 18562-1:2024 framework. A case study on a limited exposure ($\leq$ 24 h) anesthesia workstation, highlighting three representative VOS - naphthalene, diphenyl sulfone, and 2,5-bis(tert-butylperoxy)-2,5-dimethylhexane - was used to show outputs across population groups and assessment approaches. A comparative analysis was then conducted to examine changes in inhalation exposure modeling and TE derivation between the standards. **Results:** Re-evaluation of the device biocompatibility under ISO 18562-1:2024 resulted in altered TE values for select VOS compared to assessment under ISO 18562-1:2017 due to revised breathing parameters and updates to population subgroup definitions, including the addition of new pediatric subgroups. Effects on TE values were process-dependent, and impacts on toxicological risk assessment conclusions were primarily driven by updated default daily breathing volumes. Across the three VOS, representative of differing TE derivation processes, analysis showed that when assessment was based on established limits from authoritative bodies, no notable change in margin-of-safety (MoS) values occurred, whereas when TE values were derived from select toxicological endpoint data or the threshold of toxicological concern (TTC) was applied, MoS values increased in some patient groups but decreased in others. **Conclusions:** Integration of ISO 18562-1:2024 within the ISO 10993-17:2023 framework enhances consistency across toxicological evaluations for breathing gas pathway devices and influences how TEs affect risk assessment outcomes, as demonstrated through a comparative case study of select VOS emitted from an anesthesia workstation. These findings underscore the value of early adoption to strengthen patient protection and support global regulatory readiness through more precise, population-specific risk characterization. Results also suggest that existing assessments may warrant re-evaluation under ISO 18562-1:2024 to best substantiate biocompatibility.

PS 3744 VVOCs in ISO 18562-1:2024: Risk-Based Modelling of Patient Exposure from Breathing Gas Pathway Devices

A. Yip, and J. Hummel. Resmed, Bella Vista, Australia.

Background and Purpose: Breathing gas pathway medical device biocompatibility is covered in the ISO 18562 series of standards, which recently underwent a revision. ISO 18562-1:2017 had VOCs (volatile organic compounds) in scope for airpath assessment, encompassing volatile organic compounds with a boiling point between 50°C to 260°C. ISO 18562-1:2024 redefines VOCs (50-250°C), and adds assessment of VVOCs (very volatile organic compounds) (0-50°C) and SVOCs (semi-volatile

organic compounds) ($>$ 250°C). As regulatory expectations expand to include VVOCs, there is uncertainty regarding whether these highly volatile substances persist long enough to contribute meaningfully to patient exposure. The additional time and significantly increased cost of testing for VVOCs may be disproportionate to the risk posed by VVOCs. Therefore, the likelihood of VVOCs being delivered to medical device patients is explored in this work. Specifically, this study evaluates whether the inclusion of VVOCs in start-of-life testing per ISO 18562-1:2024 is scientifically justified when considering realistic emission and diffusion dynamics. Potential sources of VVOCs are from manufacturing, materials of construction, and ambient contamination. Medical devices are constructed out of materials that are stable over the intended lifetime, and ambient contamination is out of scope of ISO 18562-3:2024. Therefore, the primary potential source of VVOCs are from manufacturing. **Methods:** A model based on molecular weight and vapour pressure was used to calculate the rate of evaporation of various VVOCs from a device, and found emission rates to be on the order of g/m²-s, which implies rapid off-gassing. Given the high vapour pressures and low boiling points, VVOCs are likely to be completely lost from components before they are assembled and packaged. However, for conservatism, the exaggerated case is assumed that all of the VVOCs emitted would be retained in the device until the device is packaged into an LDPE or HDPE (low/high density polyethylene) bag, and thus the entire quantity of VVOCs is present from $t = 0$. The release of VVOCs from inside the bag to the environment was considered as a diffusion problem, with VVOCs inside diffusing through the PE barrier and being released into open air (treated as an infinite clean sink with concentration = 0). The time taken to establish a steady-state flux across the membrane was calculated based on Piringer's correlation for the diffusion coefficient. Under steady-state flux, a model was derived showing exponential decay in the concentration of VVOCs in the bag, assuming an initial concentration of VVOCs present in the bag. **Results:** The findings showed that the total VVOCs concentration, even if attributed to a single VVOC, was either below the tolerable intake and required no further evaluation, or the concentration would decay to tolerable levels before the device reaches the patient. **Conclusions:** The modelling supports that VVOCs do not pose a meaningful patient risk at start-of-life. A weight-of-evidence approach integrating modelling and post-market data indicates that analytical assessment alone is sufficient for most devices under ISO 18562-1:2024.

PS 3745 How the ASTM F2382-24 Update Is Changing PTT Test Evaluation for Medical Devices

M. Cunningham, A. Knutson, and F. K. Hsia. Global Toxicology, Biocompatibility & Chemical Characterization, Preclinical Sciences, Boston Scientific Corporation, Arden Hills, MN.

Background and Purpose: Partial Thromboplastin Time (PTT) test, Platelet Leukocyte Count (P&L), SC5b-9 Complement Activation test, and hemolysis assays are common *in vitro* tests to assess hemocompatibility of medical devices per ISO 10993-4. The PTT test, as described in ASTM F2382, is a well-recognized test method for screening circulating blood-contacting device materials for their ability to induce blood coagulation via the intrinsic coagulation pathway. The ASTM F2382-18 revision in 2024 included assay validity and test evaluation sections to align with the ASTM F2888 standard for assessing thrombogenicity through P&L counts. The test article is considered to pass the PTT test if there is no statistical difference in the average clotting time between the test article and the negative control (untreated plasma) or the negative reference material control (high density polyethylene HDPE), and a legally marketed comparator device (LMCD) is often assessed alongside the test article to support devices that do not meet this pass criteria. While this acceptance criterion remains in the 2024 version, the revised guidelines also introduce an alternative pass criterion when the test article's average clotting time is $>$ 80% relative to the negative control which is also the acceptance criterion for HDPE. This study presents a comprehensive data mining analysis of PTT test results across a wide portfolio of medical devices to assess the impact of the revision on pass/fail rates and whether including an LMCD is still worthwhile. **Methods:** Our analysis encompassed over five hundred PTT test results which were conducted at two test facilities from 2021-2025. The dataset comprised of roughly equal number of studies conducted under either the previous or the current ASTM guidelines. The pass rates for devices evaluated in accordance with either the 2018 or 2024 guidelines were determined. The percentage of tests performed together with an LMCD was also calculated. Results previously assessed under ASTM F2382-18 guidelines were re-evaluated under the 2024 criteria to determine any change in test outcome. A few case studies are included to examine any change in test evaluation outcome per the revised guidelines and demonstrate the continued importance of having an LMCD in data interpretation. **Results:** A total of 265 and 245 PTT studies, conducted under ASTM F2382-18 and -24 respectively, were included in this analysis. About equal number of PTT studies were conducted with test article (TA) only vs. TA and LMCD. Pass rates for tests under the 2018 and 2024 ASTM guidelines were 93% and 97%, respectively, reflecting a 4% increase in passing evaluations potentially due to the change in pass criteria. To evaluate the true impact in pass rate, all 55 Boston Scientific-sponsored studies conducted under the 2018 ASTM guidelines were re-evaluated using the updated guidelines. Under the 2018 guidelines, 82% (45/55) were given a final evaluation of "pass", while 10/55 did not meet the pass criteria. However, when the results of these 10 studies that did not meet the 2018 pass criteria were assessed using the updated 2024 ASTM guidelines, 6/10 met the new alternate pass criteria, resulting in 93% (51/55) passing the assay under the new

guidelines. In the 4 studies that TA did not meet the 2024 criteria, 3 had LMCD data in parallel and 2 had results comparable to an LMCD. **Conclusions:** The alternative pass criterion introduced in ASTM F2382-24 aligns with the Platelet and Leukocyte ASTM F2888 test methods, and our analysis results support that the updated guidelines **may** reduce the need to rely on an LMCD by lowering the threshold for what is considered an acceptable decrease in plasma clotting time for medical devices. Overall, ASTM F2382-24 reflects a more aligned and reasonable approach to screen for material-related thrombogenicity. The observed recent increase in PTT passing rate, along with additional cost and availability consideration, can guide more effective use of running testing alongside an LMCD.

PS 3746 Modernizing Menstrual Care: Key Insights from FDA's Updated Guidance

A. Schulte, E. Sussman, K. Gallagher, C. Soendergaard, B. Woodford, R. Allen, and S. More. MCRA, an IQVIA Business, Washington, DC.

Background and Purpose: The Center for Devices & Radiological Health (CDRH) of the U.S. Food and Drug Administration (FDA) ensures the safety and effectiveness of menstrual products such as tampons, pads, cups, and pregnancy diagnostic devices in the U.S. In October 2025, the FDA released a draft guidance titled, "Menstrual Products - Performance Testing and Labeling Recommendations." This document includes substantial updates to FDA's previous guidance issued over 20 years prior ("Menstrual Tampons and Pads: Information for Premarket Notification Submissions (510(k)s)," July 2005). Thus, it is important to understand the implications that the draft guidance may have for biological safety evaluation and the future development and marketing of these products. The objective of this work is to compare the recommendations for biological safety evaluation between the proposed draft and previous guidance. Two case studies are presented to illustrate the differences between guidances and the potential impact on the biological evaluation methods needed for menstrual products. **Methods:** A review of current international standards and regulatory guidance relevant to menstrual products was conducted to understand the state of the art for biocompatibility evaluation of these devices. The documents reviewed included the International Organization of Standardization (ISO) standards for evaluating the biocompatibility of medical devices (ISO 10993 series), FDA's guidance on ISO 10993-1 (September 2023), FDA's guidance on menstrual tampons and pads (July 2005), and FDA's draft guidance on menstrual products (October 2025). The review compared each document in key aspects of biological safety evaluation, including contact categorization, applicable biological endpoints, and methods for addressing the endpoints, including testing and risk assessment. Case studies were then presented to illustrate the differences between FDA's proposed and previous biological safety expectations for menstrual products. **Results:** The draft guidance clarifies FDA's expectations for safety evaluation and marketing of menstrual products. These details include recommendations for menstrual cups, which were not addressed in the 2005 guidance, clarification of patient contact type/duration for different menstrual products, recommendations for ingredient disclosure, contaminant evaluation and proposed test methods, and clarifications on non-clinical bench testing of tampons. Importantly, recommendations for the biocompatibility evaluation have been expanded. Case 1: A biocompatibility evaluation plan (BEP) for a diagnostic menstrual pad requiring a 510(k) submission that was marketed prior to the 2025 draft guidance was developed. This BEP was based on the 2005 guidance and assigned a different type of patient contact than suggested in the 2025 draft guidance. Consequently, a subset of evaluations was recommended compared to expectations proposed in the 2025 draft guidance. Case 2: A BEP for a reusable menstrual cup was developed based on the state of the art prior to the 2025 draft guidance (i.e., when menstrual cups were not described in FDA's 2005 guidance). The biocompatibility testing and evaluations in this BEP were compared to those proposed in the 2025 draft guidance. Discussion on whether the prescribed testing may address phthalates and PFAS materials that have been identified in reusable menstrual products was also provided. **Conclusions:** The 2025 draft guidance clarifies FDA's current thinking on the safety evaluation and labeling of menstrual products, addressing gaps left by previous guidance documents and international standards. By expanding recommendations for biocompatibility testing, ingredient disclosure, and contaminant evaluation, and expanding the scope of guidance to include other menstrual products, the guidance reflects evolving scientific understanding and public health concerns. These changes may enhance regulatory predictability and support manufacturers in developing safer, more transparent products. However, these changes may also expand the testing burden and may still not fully address all patient health risks. Expert biological safety evaluation remains essential to complement the forthcoming guidance in promoting biological safety for menstrual products.

PS 3747 Comparative Review of Carcinogenicity Testing Guidelines in Context of Medical Device Risk Assessment

M. Khazaei¹, R. Chang², and J. E. Goodman³. ¹Gradient, Charlottesville, VA; ²Gradient, Seattle, WA; and ³Gradient, Boston, MA.

Background and Purpose: ISO 10993-3 recommends carcinogenicity studies aligned with OECD 451 guidelines, and combined chronic toxicity/carcinogenicity studies aligned with OECD 453. However, if there are sufficient toxicity data, ISO 10993-3 recommends a risk assessment using these data rather than conducting additional carcinogenicity tests. It is common to consider studies conducted under different testing guidelines in the same chemical risk assessment; thus, it is important to understand similarities and differences in requirements of other frequently followed testing guidelines, such as US EPA TG 870.4300, US EPA TG 870.4200, GB/T 15670.28-2017, and GB/T 15670.27-2017. We compare study design requirements in the US EPA and Chinese national standard (GB/T) guidelines to OECD requirements to determine whether these studies could be considered in a risk assessment that complies with ISO 10993-3. **Methods:** We reviewed and compared carcinogenicity testing guidelines in OECD 451, US EPA TG 870.4200, and GB/T 15670.27-2017, and did the same for combined chronic toxicity/ carcinogenicity study guidelines in OECD 453, US EPA TG 870.4300, and GB/T 15670.28-2017. We focused on key study parameters, including the preferred animal model, study size, exposure and observation duration, dose selection, and the endpoints evaluated. We also considered rubrics regarding how study results are evaluated and confounding factors are controlled, acceptance criteria for negative findings, requirements for dose-dependent responses, and criteria for early study termination due to elevated mortality. **Results:** In general, testing guidelines by OECD, US EPA, and GB/T are similar with respect to requirements for study size, exposure duration, dose selection, and the handling of test and control animals. A few noteworthy differences include: 1. US EPA requires carcinogenicity testing in at least two rodent species to better identify species-specific responses, while OECD and GB/T recommend only one species. 2. OECD 451 and 453, and US EPA TG 870.4200 and 870.4300 recommend comparing neoplastic findings in the study with historical controls from the same strain of animal kept in the same laboratory facility. 3. Both the US EPA and GB/T require the dose-response relationship to be included when evaluating a toxicity response. OECD only requires a statistical summary of the findings. 4. Both US EPA and GB/T include a maximum percentage mortality: ≤10% loss per group due to autolysis, cannibalism, and management, and ≥50% survival at 15 months for mice and 18 months for rats. This is to avoid the study being confounded by an elevated mortality rate. **Conclusions:** There are a large number of similarities with respect to key study design parameters and how results should be evaluated in the OECD, US EPA, and GB/T guidelines. This indicates that risk assessments based on studies conducted following any of these study guidelines should be similarly robust and acceptable for an OECD carcinogenicity evaluation.

PS 3748 Varied Global Regulatory Requirements in Medical devices for a Material Formulation Change - A Case Study

S. Vijaykumar, Y. Zhou, S. Roller, and E. Patel. Johnson & Johnson MedTech, Cincinnati, OH.

Background and Purpose: ISO-10993-1 standard provides requirements on the biocompatibility evaluation for medical devices when a material formulation change occurs. For such a change, the risk assessment should consider what is known about the proposed constituent, base material constituents and potential chemical interactions amongst them. Since such information is not easily obtained due to its proprietary nature, standard biological endpoint testing provides a path to evaluate the change. This case study describes the biocompatibility evaluation for a formulation change to a resin used on numerous device components. The resin was re-formulated by replacement of organic additives at a maximum of four ten-thousands of a percent of the formulation, all other constituents remaining same. A modification to the compounding of the resin formulation also occurred. This change was across eight different formulations with the same base resin but differing additives. The proposed new materials would be used in externally communicating components in contact with tissue, bone, or dentin for less than 24 hours, "Limited" as defined in ISO 10993-1. While a vast majority of the devices using these resins would be gamma sterilized, some would exclusively use ethylene oxide. **Methods:** Test articles were pellets representative of four test formulations. These formulations were designed with a "Kitchen Sink" approach. Each test formulation was prepared with some of the constituents including base resin, colors, fillers and additives at the worst-case composition. Collectively, the four test formulations represented the worst-case in terms of composition for each of the constituents, in the eight formulations undergoing the change. Biological endpoint testing per ISO-10993-1 for a "Limited" medical device namely, cytotoxicity, acute systemic toxicity, irritation, sensitization and pyrogenicity was performed. Test articles were irradiated with gamma as the worst-case sterilization modality in terms of impact on polymeric materials, in comparison to ethylene oxide. **Results:** The test formulations favorably met the biological endpoint testing for a "Limited" device and the "Kitchen Sink" approach was acceptable to regulatory agencies. However, one notified body conveyed a deficiency, that toxicological equivalence to the current material was not demonstrated, since the chemical interaction of the constituents in the designed test formulations departed from the proposed resin formulations. In the absence of extractables/ leachables data

to show equivalence to current resin, an alternative strategy was adopted for the response. With vendor consent, the chemical composition for each proposed formulation was shared confidentially. Comparison of the constituent composition of the proposed resins with the test formulations illustrated that the latter approximated closely and underlined the new additive as a minor constituent. The test formulations had been designed to include both ends of the composition spectrum for proposed resins. The worst-case amount of a constituent and the best-case, which could be absence of a constituent. Since different resins had varying constituents, this gave assurance that all possible chemical and toxicological interactions of the proposed resins were captured in the test formulations. Favorable USP Physicochemical data, supported there was not a toxicological concern from heavy metals and non-volatile residue. Predicate use of the proposed additive in similar base resin formulations using both sterilization modalities of gamma and ethylene oxide was highlighted. This Weight of Evidence approach was accepted, the new formulation was considered toxicologically equivalent to the current formulation and approval was granted. **Conclusions:** While ISO-10993-1 provides a standardized framework for biological evaluation of medical devices for material related changes, variations in regulatory requirements exist. Partnering with a vendor on "proprietary" material information or via a "Master File" as recommended in Annex B of ISO-10993-1, helps characterize the chemical and toxicological makeup of proposed formulations. As it is not practical to test all formulations, using representatives is acceptable. A judicious design of test formulations assuring all possible chemical and toxicological interactions are addressed, can help obtain universal regulatory approval.

PS 3749 Evaluation of Degradation of Polyurethane Oligomers to MDI or MDA: Cohort of Concern or No Concern?

E. K. Long¹, M. Giffin², S. M. Street¹, K. L. Pacholke¹, and L. M. Harrington¹.

¹Medtronic, Minneapolis, MN; and ²Medtronic, Ogden, UT.

Background and Purpose: Methylenebisphenyl diisocyanate (MDI) is an important component of poly(ether)urethanes (PEU). Exposure to MDI induced lung adenoma in male rats and is presumed to pose a similar risk to humans. MDI hydrolyzes in water to 4,4'-methylene dianiline (MDA), which is associated with liver and thyroid toxicity. As such, MDI is considered a cohort of concern compound per ISO 21726:2019 due to its polycyclic amine structure. Small MDI-containing oligomers, which may be present as byproducts of PEU synthesis, have the potential to leach from a device into the body over time. As patients may be exposed to these oligomers through medical devices, the approach from a toxicological perspective assumes that these oligomers degrade to MDI or MDA and thus must be assessed toxicologically as the more reactive monomers. This results in increased burden for both the chemist and toxicologist to accurately identify and evaluate these species. Therefore, evaluation of degradation of these compounds in a laboratory setting is needed to better understand this degradation potential in a clinical setting to ensure safety assessments adequately evaluate patient risk. **Methods:** To determine whether MDI-containing oligomers can degrade into MDA or MDI, a literature search was performed. A manuscript by Chaffin et al (2014) showed that MDI/MDA monomers were formed from MDI-containing oligomers at 70 °C, but not at 50 °C, which is well above any reasonable exposure temperature during handling, transport, or *in vivo*. However, this study did not address chemical mechanisms of degradation that could lead to generation of MDI or MDA. Therefore, we synthesized model MDI-containing oligomers and extracted PEU 80A to isolate MDI-containing oligomers and subjected these model compounds and extracts to acid, base, UV, and hydrogen peroxide to determine whether these conditions could induce formation of MDI or MDA from MDI-containing oligomers. Samples were analyzed using LC-MS and GC-MS to monitor loss of oligomers and formation of MDI or MDA. **Results:** Treatment with acidified or alkaline methanol (1% HCl or 1% NaOH) did not result in production of MDI or MDA from PEU extracts or MDI-containing oligomers. Furthermore, no significant degradation of MDI-containing oligomers was observed under these conditions. Consistent with these results, exposure of PEU or MDI-containing oligomers to UV or hydrogen peroxide with cobalt chloride did not result in production of MDI or MDA despite significant degradation of MDI-containing oligomers. These results were consistent with previous studies showing that oxidation affects the methylene group of MDI or the polyether chain, rather than the urethane linkage. This information provides better understanding of the requirements needed to degrade these oligomers, ensuring that clinically relevant compounds are toxicologically assessed. **Conclusions:** Toxicological risk assessments are intended to provide a conservative estimate of risk to patient safety. In the case of MDI-containing oligomers, the most conservative approach assumes that MDI or MDA can form and evaluates that potential risk to patients. However, these oligomers are present in a distribution that includes 1-3 MDI subunits and 3-20 polyether subunits. By assuming the reported amounts are the monomers, data processing, quantitation, and risk assessment are complicated due to the need to treat these oligomers as cohort of concern compounds. The results of this study demonstrated that MDI-containing oligomers do not degrade to MDI or MDA under harsh conditions. Combined with previous results showing that neither MDI nor MDA are formed at 50 °C or lower, it is highly unlikely that MDI or MDA would form under physiological conditions. Therefore, the tolerable intake limits for these oligomers may be higher than those of MDI or MDA, allowing them to be removed from the cohort of concern categorization and be screened out using the TSL when applicable.

PS 3750 LS-100 and LS-200: Novel, hemocompatible nanoparticles with unexpected pharmacological properties

N. Akers¹, A. Harmon¹, M. R. Smith¹, C. E. Astete², C. Sabliov², and T. R. Dugas¹.

¹Louisiana State University School of Veterinary Medicine, Baton Rouge, LA; and

²Louisiana State University, Baton Rouge, LA.

Background and Purpose: Peripheral artery disease (PAD) is a vascular disease associated with atherosclerotic and thromboembolic obstruction in the lower limbs. While obstructed arteries can be cleared using angioplasty and stenting, blockages can recur. Two common mechanisms for reocclusion include neointimal hyperplasia (NIH) and thrombogenesis. Novel nanoparticle (pNP) formulations LS-100 and LS-200 are designed to deliver drugs that address these mechanisms. Neither formulation induces significant hemolysis and LS-200 prolongs activated partial thromboplastin time. However, their hemocompatibility is unknown. **Methods:** Canine blood was obtained with an IACUC-approved protocol. Porcine blood was obtained commercially. Activated partial thromboplastin time (aPTT) was measured using freshly collected citrated canine blood from healthy donors. Platelet activation in pNP-exposed canine blood was measured using PDGF-BB and thromboxane B2 ELISA. Hemolysis assays were conducted in both canine and porcine EDTA anticoagulated blood exposed to LS-100 and LS-200. Endothelial viability and function were assessed using ATP and NO assays. A novel physiologic flow study measured thrombus formation on materials of differing thrombogenic potential inserted into loops containing pNP-exposed porcine blood under flow conditions. **Results:** Hemolysis did not exceed 5% in LS-100 exposed blood. Hemolysis remained below 6% in canine blood and below 2% in porcine blood exposed to LS-200. aPTT was unchanged in LS-100 exposed blood but significantly prolonged in LS-200 exposed blood ($p < 0.05$). Platelet activation markers were unchanged with LS-200. The physiologic flow loop study revealed a significant decrease in platelet and leukocyte counts in blood exposed to highly thrombogenic materials ($p < 0.05$), however, exposure to LS-200 demonstrated platelet and leukocyte counts comparable to unexposed blood. Material thrombus coverage and thrombus dry weight was significantly decreased in LS-200 exposed blood containing thrombogenic test material compared to thrombogenic material without LS-200 treatment ($p < 0.05$). ATP production was unaffected below 0.75 mg/mL of LS-200 pNP and below 1.5 mg/mL with LS-100 ($p < 0.05$). NO production did not significantly decrease with either formulation. **Conclusions:** Overall, LS-200 decreased thrombus formation on thrombogenic materials and maintained hemocompatibility. Measurements of immunogenicity, mutagenicity, and other key aspects of biocompatibility are required. Given the bioactivity of LS-200 absent drug cargo, future studies will assess LS-200 as a hydrophilic coating for cardiovascular medical devices. Early LS-100 data suggests inert behavior in the blood compartment, but additional analysis of hemocompatibility including platelet activation and thrombogenicity are required.

PS 3751 PFAS in Chronically Implanted Cardiac Leads

L. M. Harrington¹, M. Giffin², S. M. Street¹, K. L. Pacholke¹, E. K. Long¹, and K. A. Chaffin¹.

¹Medtronic Inc, Fridley, MN; and ²Medtronic Inc, Ogden, UT.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are a large group of environmentally persistent chemicals, some of which are linked to adverse health effects and are now under regulatory scrutiny, especially in medical devices. Medical-grade PFAS materials like PTFE and ETFE are valued for their chemical inertness and have shown consistent safety in biocompatibility studies. Yet, toxicological concerns remain about residual low-molecular-weight PFAS that might be present after manufacturing, particularly regarding potential bioaccumulation in the patient. Proposed EU regulations could either prohibit PFAS in medical devices altogether or impose strict limits, such as capping targeted water-soluble PFAS at 25 ppb and total semi-quantitated water-soluble PFAS at 250 ppb. Traditional chemical characterization methods generally employ instruments with high mass accuracy but lower sensitivity, resulting in quantitation limits around 20 ppb. While this complies with the requirements of ISO 10993-18:2020, water-soluble PFAS compounds have the potential to bioaccumulate. Thus, even at relatively low concentrations, this potential accumulation in the human body over time may suggest that more stringent limits for PFAS in medical devices are necessary. This study used highly sensitive triple quadrupole LC/MS to screen for trace PFAS in new and explanted cardiac leads, to evaluate if PFAS in these devices pose safety risks over their clinical lifetime. **Methods:** New and 20+ year explanted cardiac leads containing PTFE and ETFE were extracted based on ISO 10993-18:2020 methods to evaluate the patient-contacting portions of the devices. Taking into account the surface area and total solvent volume, the Analytical Evaluation Threshold (AET) for the extracted devices was determined to be 11.0 ppb. Triplicate exaggerated extractions of final, finished medical devices were performed with methanol and analyzed for PFAS using sensitive Sciex 7500 LC/MS/MS triple quad, detecting levels as low as 0.00250 ppb. PTFE and ETFE components from additional leads underwent separate extractions, first with methanol and later with dimethylformamide (DMF), to evaluate the maximum potential concentrations of short-chain PFAS in non-patient-contacting components. Untargeted analysis of the extracts was performed first to identify the compounds present in the extracts. Then targeted analysis was performed on all the detected PFAS and semi-quantitated using perfluorobutanesulfonic acid (PFBS) as the surrogate standard. A toxicological risk assessment was conducted to evaluate whether the PFAS detected in PTFE/ETFE containing medical device extracts posed any safety risk to patients. **Results:** Approximately sixteen water-soluble PFAS were identified above

the limit of detection, 0.0025 ppb, in both new and 20+ year explanted cardiac leads. The semi-quantitative results showed an approximate 88% reduction in total PFAS in the explanted leads compared to new leads. This decrease was also observed in methanol extracts of PTFE components, while ETFE components showed increased PFAS levels after long-term implantation. DMF extraction, used to assess worst-case PFAS presence, revealed that most PFAS in PTFE and ETFE were oligomers, and explanted ETFE contained over 600% more PFAS than new ETFE, likely due to increased surface area or exposure of non-intended patient contacting surfaces.

Conclusions: This study provides one of the most sensitive assessments to date of water-soluble PFAS in new and long-term implanted medical devices containing PTFE and ETFE, using advanced LC-MS/MS methods. PFAS levels in new devices were well below proposed regulatory thresholds, and concentrations in explanted leads decreased by an approximate 88% after 20 years; PTFE components showed an approximate 66% reduction, while ETFE components had increased PFAS, likely due to surface changes or contamination. Importantly, nearly all PFAS detected were at trace levels, with only one potentially regulated compound present in explanted leads and no evidence of significant patient exposure. As all PFAS values in the full devices were below the AET, the limited presence of water-soluble PFAS supports the continued safe use of PTFE and ETFE in medical devices and provides important data for regulatory considerations.

PS 3752 Assessing PFAS Biological Risks from Medical Devices Under ISO 10993-1 - Material Properties and Chemical-Specific Effects on Leachability, Systemic Exposure, Bioaccumulation, and Toxicity

R. Sloboda. Toxicological Data Assessment Consulting, LLC, Pepperell, MA.

Background and Purpose: New requirements are being introduced into ISO 10993-1 for assessing biological safety of medical devices with respect to substances having a potential for bioaccumulation. Perfluoroalkyl substances (PFAS) represent a broad family of substances having significant resistance to chemical/biological degradation, and as a result regulatory restrictions have been proposed for phasing out subclasses of PFAS used in various countries. In particular, recent updates to the biocompatibility guideline, ISO 10993-1 require a recategorization of medical devices containing substances that may bioaccumulate, so that devices intended for less than 30 days contact are reassigned into the long-term contact category (≥ 30 days). This default strategy significantly increases testing rigor and necessitates a very low Analytical Evaluation Threshold for extractables testing of medical devices, requiring more stringent limits of quantitation for chemical analysis that could be excessive in many cases, given the clinical relevance of estimated levels of exposure from short term use applications. **Methods:** Notably, per- and polyfluoroalkyl substances (PFAS) are utilized across diverse medical device applications, including polytetrafluoroethylene (PTFE) in vascular grafts (low-exposure, long-term implant), fluorinated ethylene propylene (FEP) for catheter guide wires (surface coating), poly(ethylene-tetrafluoroethylene) (ETFE) for electrical insulators in pacemakers and implantable pulse generators, polyvinylidene fluoride (PVDF) in dialysis membranes (high-surface-area contact), hexafluoropropylene oxide dimer acid (HFPO-DA) as a processing agent to enhance polymerization (rinsed/removed to minimize residuals), and perfluorobutane sulfonate (PFBS) and other short chain perfluorinated compounds in coatings which are designed to reduce friction. **Results:** A toxicological strategy is outlined which emphasizes a consideration of chemical structure, leaching potential, and biological exposure modeling. Examples are provided to contrast the risk profiles of highly stable polymeric PFAS (e.g., PTFE in vascular grafts) which exhibit negligible leaching and clinical patient exposure, with those of highly mobile, short-chain substances (e.g., PFBS as a replacement for longer chain PFOS due to a shorter biological half-life). The primary emphasis is that different PFAS entities possess fundamentally different physico-chemical properties and toxicokinetic profiles. While high-molecular-weight polymers like PTFE have negligible leaching, low-molecular-weight PFAS like PFBS and perfluorooctanoic acid (PFOA) may contribute significantly greater chemical exposure and bioaccumulation. In addition, one must account for the estimated cumulative dose over the device's duration of use (short term versus longer term) to determine toxicological significance. In some cases, specific routes of exposure (e.g., contact with intact skin or low-leaching fluorinated polymers comprising an inhalation pathway device) may yield inherently low exposure profiles, and do not merit recategorization into the long-term contact category (≥ 30 days). **Conclusions:** In conclusion, assessing PFAS biological risk requires a route-specific evaluation of exposure, consideration of material-specific release potential, and chemical-specific toxicological assessment. The toxicological strategy framework should include an assessment of material integrity/inertness and release mechanisms, estimation of clinical exposure and toxicokinetics of systemic absorption, distribution, metabolism, and elimination, and a comparison to tolerable intakes, acknowledging that toxicity and bioaccumulation potential differ across the broad class of PFAS chemicals.

PS 3753 Prevalence and Toxicity Evaluation of the Types of PFAS Found in Medical Device Extractables and Leachables Datasets

B. A. Cronin¹, M. T. Matsushita², M. B. Knapp¹, R. Y. Chang², and J. Zhang¹. ¹Gradient, Boston, MA; and ²Gradient, Seattle, WA.

Background and Purpose: Medical devices (MDs) have the potential to release a wide range of chemical constituents during patient use. Several common components of MDs, such as seals, valves, stoppers, packaging, lubricants, and coatings, are constructed from materials consisting of per- and polyfluoroalkyl substances (PFAS). While PFAS regulations have been increasing rapidly across the world, most do not make the distinction between fluoropolymers and non-fluoropolymers. This distinction is important, as fluoropolymers have very different chemical, physical, and biological properties compared to non-fluoropolymers (Henry *et al.*, 2018). Additionally, regulatory agencies across the world have differing definitions of PFAS, ranging from a few select PFAS (e.g., perfluorooctanoic acid [PFOA]) to the broad European Union (EU) definition of "fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it)" (OECD, 2021). There is a clear need for identification of the types of PFAS that are in MD extractable profiles. To address this need, we leveraged two large datasets of MD extractable profiles and analyzed the types of PFAS from approximately 19,000 chemicals. Our objectives are: 1) to determine the types of PFAS found using different regulatory definitions; and 2) to determine whether the broad types of these PFAS are associated with reproductive/developmental toxicity, genotoxicity, and carcinogenicity. **Methods:** Published lists of MD constituents from hundreds of extractable and leachable studies (Borton and Coleman, 2025; Builee *et al.*, 2025) were compiled and filtered to contain only unique fluorinated compounds. The fluorinated constituents were classified as PFAS using various regulatory definitions, including that of the EU, United States (US) Toxic Substances Control Act (TSCA), and the Canadian Environmental Protection Act (CEPA) list. The PFAS was further categorized as polymers and non-polymers based on categories described in Henry *et al.* (2018). A comparative analysis was conducted on the fluorinated compounds to assess the percentage of concordance between the list of PFAS in MD extractable profiles according to different regulatory definitions. Literature searches were conducted for chemical-specific toxicity data for the PFAS categories via the data aggregator ToxPlanet (*i.e.*, a federated search engine that extracts content from 500+ websites and databases, such as CompTox and the European Chemicals Agency [ECHA] CHEM). **Results:** We found that approximately 2.6% (N = 488) of the 19,075 chemicals extracted from MDs are fluorinated. Of those 2.6% fluorinated chemicals, approximately 48.7% were considered PFAS according to the EU definition, 24.6% were considered PFAS according to the TSCA definition, and only 1.6% were considered PFAS according to the Schedule 1 substances list published by CEPA. Among the three PFAS definitions, 242 (1.3% of the MD constituents) were found to be unique PFAS - 2 were polymers and 240 were non-polymers. Further, 11% of the fluorinated chemicals had chemical-specific toxicological data available according to the CompTox chemicals dashboard, and only 6% had an oral and/or inhalation point of departure (POD). **Conclusions:** Our results suggest that approximately 1.3% of chemicals extracted from MD extractable and leachable profiles are PFAS; therefore, the likelihood of patient exposure to PFAS through medical devices is low. However, extractable and leachable studies are only conducted on patient-contacting components, whereas most PFAS regulations impacting medical devices are determined based on the entire device (*i.e.*, patient- and non-patient-contacting components). PFAS detected in MD extractables are likely to originate from both patient-contacting components and processing aids. Notably, only two PFAS polymers were identified in this dataset. Since fluorinated side chain polymers are known to break down into non-polymer constituents, this finding does not indicate a lack of PFAS polymers in MDs. Further, fluoropolymers, such as polytetrafluoroethylene (PTFE), were not found in this dataset. There is a paucity of data for PFAS in MD extractables; however, available data show that PFAS chemicals have a wide range of toxicity.

PS 3754 A Tiered Safety Strategy for a Novel Personal Care Product Category - Whole Body deodorant: From *in Vitro* Models to Clinical Validation

L. Wong, H. S. Chaudhari, K. Pryce, D. Orak, and D. Gossai. L'Oréal Research & Innovation, Clark, NJ.

Background and Purpose: The personal care landscape has rapidly evolved with the emergence of a distinct product category: deodorant for whole body application including sensitive intimate regions. Unlike conventional underarm deodorants, which are often spray-based for localized use, these novel products are typically lightweight creams designed for extensive application across diverse body areas prone to sweating and odor. Crucially, many of these target sites, particularly the intimate and intertriginous zones, exhibit unique physiological characteristics such as increased skin permeability due to thinner stratum corneum, higher moisture content, and the potential for prolonged occlusion and/or direct contact with mucous membranes. This expanded use, coupled with the formulations enabling widespread application over a significantly larger total body surface area, introduces specific toxicological considerations, including higher potential systemic exposure due to the large surface area and an increased risk of local intolerance on sensitive skin and mucosal sites. Consequently, a dedicated and robust safety assessment strategy is

crucial to ensure consumer safety for this unique product type. **Methods:** A specific safety assessment strategy was developed to evaluate systemic toxicity and local tolerance, tailored specifically for the unique characteristics of this novel product category. To assess systemic toxicity, a conservative whole-body exposure assessment was employed for all ingredients, using the SCCS body lotion quantity to calculate the Margin of Safety (MoS). This approach maximizes theoretical exposure, thus accounting for potential product misuse. For local tolerance, a tiered testing strategy was executed on the formulation. It began with an initial screening that included assessment of the formulation's physicochemical properties (i.e., pH) and a thorough safety review of each ingredient using published literature and historical data. This was followed by New Approach Methodologies (NAM) based-*in vitro* assays to assess skin irritation (Reconstructed Human Epidermis model) and, critically, potential vaginal mucosal irritation using a Reconstructed Human Vaginal Epithelium model. Following the *in vitro* evaluation, consumer tolerance was confirmed clinically via a Human Repeat Insult Patch Test (HRIPT) and an in-use tolerance study conducted under both dermatological and gynecological supervision. **Results:** We have substantiated the safety of a novel deodorant formulation for its intended use on the whole body and external intimate area using this specific safety assessment approach. The conservative whole-body assessment confirmed all raw materials have a sufficient MoS (>100 per the SCCS Notes of Guidance). In the initial local tolerance screening, the formulation's pH was found to be compatible with the physiological environment of its intended application sites, specifically the external intimate area, and the safety review of its ingredients raised no concerns. Subsequently, the formulation was predicted as non-irritating in *in vitro* reconstructed human skin and vaginal epithelium models. Clinically, the product was proven to be non-irritating and non-sensitizing in a HRIPT. An in-use study conducted under dermatological and gynecological supervision confirmed the product demonstrated excellent tolerance, with no adverse reactions observed. **Conclusions:** The safety assessment strategy presented successfully demonstrated that the novel whole-body deodorant is safe and well-tolerated for its intended use. The integration of a conservative, whole-body systemic safety assessment with a tiered, targeted local tolerance evaluation - notably including a reconstructed vaginal epithelium model and clinical oversight by both dermatologist and gynecologist - proved to be a robust and highly relevant approach. This work establishes a benchmark for the safety validation of innovative cosmetic products for sensitive applications, underscoring the power of a modern testing strategy rooted in Next Generation Risk Assessment (NGRA) principles to ensure consumer safety without animal testing.

PS 3755 Untargeted Exposomic Analysis of CBD Oil Tinctures and Personal Care Products

X. Hu, S. Forsido, Y. Liang, J. Weinburg, M. Orr, D. Wang, B. Minasenko, Z. R. Jarrell, and D. P. Jones. Emory University, Atlanta, GA.

Background and Purpose: Public demand for cannabidiol (CBD) products has expanded dramatically in recent years. Following the 2018 Agricultural Improvement Act, which legalized hemp-derived products containing <0.3% THC, CBD oils and personal care products have proliferated across the United States. However, federal regulation is lacking, and state-level oversight remains inconsistent. Given the diverse cultivation and processing methods, CBD products may contain a wide range of environmental contaminants and synthetic chemicals in addition to phytocannabinoids, raising significant public health concerns. This study applied an untargeted exposomic approach using high-resolution mass spectrometry (HRMS) to comprehensively profile environmental contaminants and phytocannabinoids in CBD oil tinctures and CBD-infused personal care products. **Methods:** Samples were analyzed using inductively coupled plasma mass spectrometry (ICP-MS) for metals and metalloids, and both gas and liquid chromatography coupled to HRMS (GC-HRMS and LC-HRMS) for organic contaminants and phytocannabinoids. **Results:** Natural CBD oil tinctures contained a broad spectrum of phytocannabinoids in both acid and neutral forms, including C4- and C5-CBD, CBDA, CBGA, CBNVA, CBTv, CBGM, and sesquicannabigerolic acid, whereas synthetically derived products (e.g., delta-8 formulations) showed narrower profiles. All oil tinctures contained metal contaminants, with 22 distinct essential and non-essential elements detected. Most essential metals were below 10 ppb, with Mn, Zn, and Cu showing the highest levels. Mn concentrations in some samples exceeded both the EPA secondary Maximum Contaminant Level (MCL) and lifetime health advisory level, suggesting potential neurotoxicity risk. Non-essential metals were generally below regulatory limits, except Tl, which exceeded the EPA MCL in one sample. Ba was the most abundant non-essential metal, and naturally derived tinctures showed higher overall concentrations than the synthetic product. The heavy metals, As, Cd, Hg, and Pb, were present in all samples but below enforceable MCLs; however, this remains concerning since there are no safe levels for As and Pb. GC-HRMS identified 17 non-cannabinoid organic compounds, including naturally occurring and synthetic chemicals such as *m*-cresol. LC-HRMS analysis annotated potential contaminants such as butyl paraben, 4-tert-octylphenol, and the pesticide linuron. Ongoing lab analyses are being performed on 50 personal care products that included naturally derived CBD, with the vendor-disclosed CBD content ranging from 25 mg to 1000 mg. **Conclusions:** This multi-platform, exposomics approach provides an unbiased, systems-level framework to address the chemical complexity and diversity of CBD consumer products, which contains hundreds of phytochemicals alongside potential contaminants. Our findings highlight significant variability in metal and organic contaminant profiles,

emphasizing the need for quality control and regulatory oversight, particularly for plant-derived CBD products that remain vulnerable to agricultural and processing-related contamination. This work was supported by ULRI Discoveries in Safety Grants.

PS 3756 Personal care product ingredient safety disparities based on demographic marketing: opportunities for alternatives assessment and consumer education

K. Beins¹, A. Friedman¹, H. Lin², and L. Sweet Duffy¹. ¹Environmental Working Group, Washington, DC; and ²ChemFORWARD, Washington, DC.

Background and Purpose: Studies have demonstrated that PCP use is associated with changes in biomarkers of exposure, as well as with health outcomes like hormone-dependent cancers and uterine fibroids. These effects may be more pronounced for women of color, which has been attributed to the use of certain products like hair straighteners, skin lightening creams, and fragrances. However, differences in product formulations within product categories may also contribute to these disparities. We used the Environmental Working Group (EWG) Skin Deep personal care products database to evaluate differences in PCP formulations based on demographic marketing. **Methods:** Using online discussion forums and in store product scanning, we identified 4,011 products marketed to Black women based on product or brand name, use instructions, and advertising language. We added any product that did not yet have a Skin Deep product hazard score to the Skin Deep database. Skin Deep hazard scores are based on data from authoritative bodies (ex. ECHA, U.S. EPA, OECD), industry reports (ex. CIR, RIFM), and open literature reviews. The data for each ingredient are grouped into 11 endpoint buckets: allergies/immunotoxicity, cellular/biochemical changes, cancer/mutagenicity, ecotoxicity, endocrine disruption potential, irritation, neurotoxicity, occupational hazards, organ system toxicity, persistence/bioaccumulation, and reproductive/developmental toxicity. Each data point within an endpoint bucket is scored from 0 to 100 according to severity and weight of evidence. The highest score from each endpoint is combined and weighted to calculate overall raw ingredient scores, which are combined by endpoint to calculate the raw product score. Raw ingredient and product scores are scaled 1-10 with lower ratings representing lower hazard based on predetermined score cutoffs established by deciles. Products are also tagged by category to allow direct comparison for products in the same category. We evaluated product and ingredient hazard scores to determine whether formulations, not product category alone, may be driving exposure and health disparities. **Results:** When comparing the Skin Deep hazard scores of 4,011 products marketed to Black women to the remaining 113,959 products without demographic marketing, we found that PCPs marketed to Black women had higher Skin Deep hazard scores. Certain color cosmetics and hair treatment/styling products seemed to drive the hazard score disparity. Of the 4,011 products, 71% were hair products and 6% were makeup. While the prevalence of some higher hazard ingredients in products marketed to Black women decreased since our 2016 analysis, we noted the presence of ingredients the market has started shifting away from including classes of preservatives (isothiazolinones, parabens, and FRPs), cyclic siloxanes, talc, and some fragrance ingredients. **Conclusions:** Because alternatives for many of these ingredients are already well-established in the PCP sector, a shift towards lower hazard formulations should be possible for many of these products. However, while small sample sizes for brand names and some product types may limit the generalizability of the results, this secondary analysis suggests that products marketed to Black women may not be reformulated to avoid hazardous ingredients at the same rate as the rest of the market. This potential lag time in reformulation indicates that 1) third party certifications can address exposure disparities by intentionally partnering with brands marketing to Black women and 2) consumer education initiatives like Skin Deep can be leveraged to reduce exposure disparities while the market catches up.

PS 3757 Evaluation of the Safety of Raspberry Ketone and Its Skin Compatibility in Cosmetics through New Approach Methodologies (NAM) and Mode of Action Mechanism Analysis

S. Kim¹, and I. Garcia². ¹Ashland Inc, Lincoln, CA; and ²Ashland Specialties France, Sophia Antipolis, France.

Background and Purpose: In cosmetics, raspberry ketone has been used as skin conditioning or fragrance ingredient. The use of raspberry ketone as a multifunctional antimicrobial ingredient in cosmetics is new. The maximum recommended use concentration of raspberry ketone in cosmetics is 1% wt. In this research, raspberry ketone is evaluated for its safety as a cosmetic ingredient, particularly focusing on its potential to cause chemical leukoderma, a skin depigmentation disorder, by comparing it to rhododendrol, a structurally similar compound known to cause this condition. The in-use safety of raspberry ketone and its skin compatibility have been further supported by utilizing NAM and mechanism of action (MoA) analysis. **Methods:** Certain phenolic compounds are known to cause contact leukoderma. Based on the currently available information, the action mechanism of leukoderma appearance by phenolic compounds in human involves the following sequences: (1) tyrosinase-mediated oxidation of susceptible phenolic compounds into toxic metabolites, leading to protein-SH unfolding and accumulation in the endoplasmic reticulum (ER) and/or activation of the apoptotic pathway that contributes to the

direct and specific melanocyte cytotoxicity, (2) clinical or pathological symptoms of contact dermatitis, and (3) appearance of leukoderma or localized white depigmented skin. **Results:** The experimental results are summarized as following: (1) the gas chromatography analysis showed no detectable level of rhododendrol in raspberry ketone with a detection limit of 50 ppm, (2) the comparative *in vitro* cytotoxicity and melanin quantification assays showed raspberry ketone is less cytotoxic and has relatively low potency to cause chemical leukoderma when compared to other phenolic substances that are safely used in cosmetics and also to rhododendrol, and (3) no symptoms of contact dermatitis, irritation or sensitization, have been observed at 1%, 5%, 10% and 12% raspberry ketone in multiple and repeated-exposure human patch tests (human repeat insult patch tests and 48-hr human patch tests in different geographical regions). **Conclusions:** The above results provide an adequate weight of evidence (WoE) that 1% raspberry ketone in cosmetics is skin compatible and does not represent any leukoderma risk under the current practice of use and foreseeable misuse conditions.

PS 3758 Proteomic analysis of the effects of the novel refrigerant R-1132(E) on rabbit kidney and liver from a 28-day inhalation study

N. Mori¹, S. Hiroaki¹, R. Takeda¹, A. Kuno¹, R. Kobayashi¹, Z. Guo², and Y. S. Kida¹.
¹National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; and ²Daikin Industries, Ltd., Osaka, Japan. Sponsor: T. Fukuyama

Background and Purpose: Climate change driven by global warming continues to draw worldwide concern, prompting the search for refrigerants with minimal climate impact. R-1132(E), trans-1,2-Difluoroethylene, whose global warming potential (GWP) is <1, has emerged as a promising candidate. R-1132(E) belongs to a chemical family, called haloalkenes, which includes R-1234yf (2,3,3,3-Tetrafluoropropene) and HFO-1123 (1,1,2-Trifluoroethene). Previous animal studies on R-1234yf and HFO-1123 showed the species-specific responses in rabbits. R-1132(E) also showed similar responses in rabbit inhalation studies. In this study, we evaluated the effects of R-1132(E) exposure on the liver, a key organ for detoxification, and on the kidney, which mediates excretion, using proteomic profiling. **Methods:** Control (filtered air) and R-1132(E) atmospheres (500, 1000 and 2000 ppm) were administered as a 6-hour/day, whole-body inhalation exposures on a 5-day per week basis for 4 weeks. At the time of the scheduled euthanasia, a sample of kidney and liver tissue was collected from each animal per group and snap frozen in liquid nitrogen. The tissues from control and 2000 ppm group were used in further analysis. The powdered organs were dissolved in SDS solution and homogenized to extract proteins. The extracts were subjected to reduction, alkylation, and trypsin digestion to generate peptide solutions, which were analyzed by nanoLC-MS/MS. Statistical analysis of the proteomic data was performed using the R package DEqMS. **Results:** In the liver, pathway enrichment analysis revealed alterations related to inflammatory responses and transporters. Focusing on liver function-related proteins, various CYP families showed changes, with particularly pronounced upregulation in CYP2C; this is consistent with results from a separate *in vitro* study. In the exposure group, inflammatory markers centered on IL16 and NFκB1 were activated, and increases in IL16 and ICAM1, an adhesion molecule involved in leukocyte recruitment, suggested recruitment of macrophages and T cells due to inflammation. In the kidney, even more pronounced changes were observed. GO enrichment analysis and gene set enrichment analysis (GSEA) detected downregulation of transporter-related terms (e.g., monoatomic ion transmembrane transport, organic anion transport) in the R-1132(E) exposed group. Pathway-level GSEA also indicated upregulation of inflammation-related categories. At the level of individual kidney function-related proteins, the R-1132(E) exposed group showed broad functional decreases encompassing AQP2 (water channel), the CLDN family (tight junctions), the CA family (acid handling), Na⁺, K⁺, and phosphate reabsorption transporters, and Na⁺/K⁺-ATPase. As in the liver, inflammatory markers centered on IL16 and NFκB1 were activated in the R-1132(E) exposed group. **Conclusions:** Proteomic analysis of liver and kidney from R-1132(E) exposed rabbits revealed changes in the hepatic CYP2C family, transporter alterations, and activation of inflammatory markers in the liver. The kidney exhibited even more prominent changes, including widespread decreases in transporter function, suggesting potential disturbances of urinary and serum electrolyte balance. These findings indicate that inhalation of R-1132(E) may particularly impact renal function in rabbits. However, due to interspecies differences, these results cannot be directly extrapolated to humans. Further evaluation using human cells is warranted.

PS 3759 Normal, But Not Normal, Review of Some Vehicle-Related Histopathology Findings in the Concurrent Control Animals in the General Toxicity Studies

F. Zhou¹, X. x. Zhao², T. s. Zhou², L. Jing¹, L. Zhu², M. x. Zhang², A. Leone², and Y. Zhang². ¹WuXi AppTec (Nantong) Co., Ltd, Nantong, China; and ²WuXi AppTec (Suzhou) Co., Ltd, Suzhou, China. Sponsor: F. Zhou, Society of Toxicologic Pathology

Background and Purpose: Concurrent control groups are essential in general toxicity studies, and are typically composed of animals administered with the vehicle. The vehicle is usually the same solvent used to dissolve the test article, such as saline,

the most abundantly used vehicle. However, some solvents, including surfactants or excipients, may be employed to meet the solubility and absorption requirements of pharmaceutical formulations. This report describes toxicity findings from three less common vehicles used in the general toxicity studies, highlighting the need for toxicologic pathologists and toxicologists to understand that the concurrent control group may not always represent a completely normal baseline. **Methods:** Histopathology data for three vehicles, dimethylacetamide (DMAC), caprylocaproyl macrogol-8 glyceride (Labrasol), and β-cyclodextrin, used in the control groups from preclinical general toxicity studies were reviewed at our facility. **Results:** Toxicities of DMAC as a vehicle, were observed in the liver, testes, and eyes of the Sprague-Dawley (SD) rats or Beagle dogs. Histopathological changes included centrilobular mixed cell infiltration and occasional single-cell necrosis of hepatocytes in the liver, seminiferous tubular degeneration and atrophy in the testes, accompanied by reduced sperm and presence of cellular debris in the epididymides and single-cell necrosis of the corneal epithelium with fibroplasia of the corneal stroma in the eyes. Toxicities of Labrasol, as a vehicle, was observed in the lungs of SD rats, including bronchiolo-alveolar mixed cell infiltration and obliterative bronchiolitis with foreign material. Mortality was observed and likely attributed to these lung changes. Lastly, β-cyclodextrin, used in the control group, was often observed to induce hepatocellular necrosis in the liver of ICR mice and tubular vacuolation in the kidneys of SD rats. **Conclusions:** Some vehicles such as DMAC, Labrasol, and β-cyclodextrin could exhibit some toxicities. Study pathologists and toxicologists may need to pay special attention to the histopathological findings in the concurrent control groups when these vehicles are used in the studies and differentiate them from test article-related findings in the testing groups.

PS 3760 Formalin-Fixed, Paraffin-Embedded (FFPE) Tissues for Retrospective Transgenic Mouse (rasH2) Genotyping

J. A. Detert¹, L. Davenport², R. Neupane³, and M. He⁴. ¹Labcorp, Madison, WI; ²Sanofi, Morristown, NJ; ³Avance Biosciences Inc., Houston, TX; and ⁴formerly of Avance Biosciences Inc., Houston, TX.

Background and Purpose: Following the completion of a transgenic (rasH2) mouse (CByB6F1-Tg(HRAS)2Jic (rasH2 tg/wt)) carcinogenicity study, a *post hoc* confirmation of genotype was required. Standard genotyping methods using fresh tail snip or ear punch were not feasible, as necropsy had been completed. Available biological materials for potential genotyping included formalin-fixed tissues, small volumes of plasma, and formalin-fixed paraffin-embedded (FFPE) tissues. **Methods:** DNA was extracted from formalin-fixed (wet) or FFPE tissues using the Mag-Bind® FFPE DNA 96 Kit (Omega Bio-tek, Cat. # M6958). PCR amplification was performed using established primer pairs, and products were analyzed via 1.5% agarose gel electrophoresis to assess genotype based on the size and number of PCR products. **Results:** Study samples from FFPE liver and intestinal tissues (stored up to 232 days prior to paraffin embedding) were successfully analyzed and genotyped. PCR amplification using DNA extracted from formalin-fixed (wet) tissues was unsuccessful, likely a result of insufficient DNA yield from these tissues. As longer exposure to formalin can lead to increased DNA fragmentation reducing the availability of amplifiable DNA, the extended storage time of these tissues in formalin likely contributed to the insufficient yield. PCR amplification of DNA extracted from FFPE liver and intestinal tissues was successful in amplifying the 260 and 130 base pair amplicons that differentiate the transgenic and wild-type genotypes. The larger amplicon (498 base pair) did not amplify possibly due to DNA degradation from formalin exposure. **Conclusions:** The DNA extraction method developed for paraffin embedded tissues was successful regardless of formalin fixation time. All tested samples were successfully genotyped as wild-type or heterozygous rasH2 using FFPE liver and intestinal tissues.

PS 3761 Refining Acute Oral and Inhalation Toxicity Testing: Current Practices and Opportunities

M. A. Blee, and F. Sewell. National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs), London, United Kingdom.

Background and Purpose: Acute toxicity studies are conducted in animals for classification and labelling purposes, and human health risk assessment and management of chemicals and agrochemicals. Currently there are three Organisation for Economic Co-operation and Development (OECD) test guidelines each for acute oral (TGs 420, 423 and 425) and acute inhalation (TGs 403, 433 and 436) toxicity studies. TGs 423, 425, 403 and 436 use lethality as an endpoint, while TG 420 and TG 433 require fewer animals and replace death with a more refined endpoint based on 'evident toxicity', defined as clear signs that exposure to a higher dose would result in severe toxicity or death. However, it is unclear how widely these refined methods are being used, and the subjective nature of 'evident toxicity' may be preventing wider use. Previously, the UK National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and the European Partnership for Alternative Approaches to Animal Testing (EPAA) collaborated to provide recommendations on the recognition of 'evident toxicity', with the aim of making the endpoint more objective and transferable between laboratories. Guidance for the use of evident toxicity is included in TG 433 (adopted in 2017) for inhalation studies, but it is not included in the corresponding test guideline for acute oral studies (TG 420, adopted in 2001). This poster

investigates the current use of these refined methods and opportunities to promote their use in preference to the methods requiring lethality. In addition, the impact of deleting TG 403, LC50) is discussed, considering that the corresponding oral test (TG 401, LD50) was deleted in 2002. **Methods:** In 2025 the NC3Rs convened experts from industry, CROs, and consultancies across multiple regions (UK, USA, EU, India) to assess guideline use and barriers to refinement. **Results:** Responses indicated that the TGs with death as an endpoint are still widely used and the preference of guideline used is regional. The use of the guidelines were as follows, for acute oral studies TG 420 (14%), TG 423 (57%) and TG 425 (29%) and for acute inhalation studies TG 403 (33%), TG 433 (20%) and TG 436 (47%). Concerns over using 'evident toxicity' as an endpoint, particularly for inhalation (75% had concerns), included global acceptance of these guidelines, not achieving classification cut-offs and considered to use more animals and be more expensive than other guidelines when adapted as limit tests. Cost associated with the unfamiliarity of using 'evident toxicity' was also cited. There were also perceived geographical preferences of regulatory bodies. Concerns (47%) on the implications of deleting TG 403 (LC50), included a perception that some regulatory agencies require a point estimate of LC50, the potential to misclassify chemicals using 'evident toxicity' and the requirement of some regulators for risk assessment (TG 403 only) in addition to Global Harmonised System (GHS) for classification and labelling. The TG 403 also can be used for Concentration x Time studies (CxT) for some gases, vapours and aerosols. TG 403 has also been adapted to use as a limit test, potentially reducing number of animals used and cost. **Conclusions:** The goal is to encourage the use of the more refined methods and to move away from studies using death as an endpoint. Based on the responses from this expert group, less than 20% are currently using these refined tests, so next steps include: 1. convening a larger group of experts and regulators to discuss perceived differences and to confirm that TG 420 and 433 are accepted globally. 2. Provide additional guidance on the use of 'evident toxicity' as an endpoint to increase familiarity and confidence that chemicals will not be misclassified, including the addition of this guidance in the oral guideline (TG 420). 3. Confirm that range estimates of LD50/LC50 can be used to calculate exposure levels and risk assessments instead of point estimates. 4. Investigate if the TGs using 'evident toxicity' can be flexible and adapted, for example used as limit tests or as studies covering shorter durations.

PS 3762 Forensic Sampling and Risk Assessment of Downwind Chlorine Plumes on Paper Products Following a 2024 Chemical Storage Fire

K. McCauley, K. Kissell, and D. Paustenbach. TRC Strategic Health Sciences, Jackson, WY.

Background and Purpose: In 2024, a large chemical fire occurred at a chemical storage facility in Georgia, releasing a visible plume of chlorine-containing decomposition byproducts. As many as 17,000 people were evacuated and 90,000 were advised to shelter in place due to the plume. A paper products manufacturing company located several miles downwind raised concerns regarding potential contamination of their products from the chemical-containing smoke. This concern involved the potential deposition of combustion byproducts onto paper products and that chlorinated chemicals may be adsorbed by various paper products. A team conducted rapid sampling and forensic analysis across the facility and product lines. **Methods:** Surface wipe samples were collected following ASTM D6661-17 and water samples (from the retention ponds at the impacted campus) were collected to assess the presence of polycyclic aromatic hydrocarbons (PAHs) and dioxins, which are combustion byproducts of concern in most fires. X-ray fluorescence (XRF) measurements were taken to assess the presence of elemental chlorine in paper products, where elevated levels may indicate adsorption of chlorine-containing chemicals into paper products. Odor sampling was conducted using samples of paper products exposed during the plume to assess for the presence of any unusual odors, which would qualitatively indicate that they may have been contaminated during the fire and would be unfit for their intended use. Samples were collected from the facility exposed to the plume from the fire and from a control facility that handled the same paper products nearly 100 miles away. In total, over 650 samples and measurements were collected across two facilities. **Results:** One or more of five PAHs (phenanthrene, pyrene, indeno(1,2,3-cd)pyrene, benzo(ghi)perylene, and anthracene) were detected in 52 of the 253 wipe samples analyzed at both the control and exposed facilities. Phenanthrene, the most frequently detected PAH, was reported in 51 of these 52 surface wipe sample detections, with more positive detections identified at the control facility than the exposed facility. Phenanthrene concentrations, when detected, ranged from the detection limit (0.0005 micrograms per cubic centimeter [$\mu\text{g}/\text{cm}^3$]) to 0.0014 $\mu\text{g}/\text{cm}^2$. The detected phenanthrene concentrations were within an order of magnitude of the concentrations of the other four PAHs (pyrene, indeno(1,2,3-cd)pyrene, benzo(ghi)perylene, and anthracene). All four PAHs were detected in samples only once in 253 wipe samples (approximately 1% of samples). Benzo(ghi)perylene, anthracene, and indeno(1,2,3-cd)pyrene were detected at the exposed facility, while pyrene was detected at the control facility. An analysis was conducted for 17 dioxin congeners, including 2,3,7,8 -TCDD. Ten surface wipe samples were collected from various paper products and were reported to have no detectable concentrations of dioxins. Water samples were collected from the retention ponds at the impacted facility and analyzed for the presence of chlorine and PAHs. Twenty of the 27 samples tested positive for chloride, while 10 tested positive for PAHs. The data provided by the XRF analyzer indicated that elemental chlorine was present in all of the paper products at both the exposed and control facilities. Concentrations ranged

from 154 to 11,296 parts per million (ppm) on paper products. It was determined that during the paper-making process, municipal drinking water containing residual chlorine is utilized to mix fiber and additives to manufacture paper. Some of the additives are comprised of various chlorine-containing chemicals, which are added for biocidal and disinfectant purposes. Therefore, the presence of elemental chlorine in the intermediate and finished products was expected and cannot be attributed to chlorine residue from the fire. Odor sampling was conducted using young female scientists (who are known to be the most sensitive to odors) and no unusual odors were detected in the treated or control paper products. **Conclusions:** Data indicate the downwind facility's products were not measurably affected by the fire. PAHs were infrequent and low, and no dioxins were detected. Paper products exposed to the plume did not differ from those at the control site. This outcome aligns with the expectation that only very large, ground-level fires typically generate measurable off-site deposition above background levels.

PS 3763 Rapid Assessment of Skin Integrity Using 1-Hour Tritiated Water (%Absorption) in Regulatory OECD TG 428 Dermal Absorption Studies

R. Nagane¹, K. R. Desai¹, J. R. Ranade¹, V. P. Thakor¹, I. M. Barad¹, A. D. Deshpande¹, C. S. Roper², and M. V. Patel¹. ¹Jai Research Foundation, Vapi, Gujarat, India; and ²Roper Toxicology Consulting Limited, Edinburgh, United Kingdom.

Background and Purpose: The skin integrity assay used in regulatory dermal absorption tests is designed to identify damaged and intact skin. Reliable measurement of skin integrity is a critical step for safety screening of topical and transdermal compounds. The conventional integrity assessment, involving a 2-6 hour absorption phase followed by a 5-minute scintillation counting step, is time-consuming, limits laboratory throughput, and may result in reducing the skin barrier function before test preparation application. Although shorter absorption metrics offer a potential to accelerate testing, their predictive accuracy, classification fidelity, and agreement with standard permeability endpoints must be rigorously validated before implementation. The primary objective of this study was to develop and validate a statistical model capable of predicting the 1-minute permeability coefficient (kp_1 ; cm/h) from early tritiated water (T_2O) absorption data obtained at 1 hour ($\%M_1H_1$) and 2 hours ($\%M_2H_2$) post dose. A secondary objective was to determine whether the 1-minute scintillation count time (kp_1) could reliably substitute for the conventional 5-minute measurement (kp_5), thereby reducing skin integrity duration by 50% without compromising accuracy or data integrity. **Methods:** Historical data collected from GLP studies conducted using a total of 2054 skin samples from the human abdominal or breast were selected. The permeability coefficient (kp) of T_2O was performed in accordance with OECD TG 428 recommendations. T_2O was applied onto the skin, and receptor fluid samples were collected at 1 and 2 hours post dose to yield % absorption values. The kps were calculated from both 1-minute (kp_1) and 5-minute (kp_5) scintillation counts. Robust MM-estimator regression modelled kp_1 as a function of $\%M_1H_1$ (Model A1) and $\%M_2H_2$ (Model A2), and regression inversion identified the % absorption thresholds corresponding to the cutoff kp of 4.5×10^{-3} cm/h (Meidan and Roper 2008). Discrimination was evaluated by ROC analysis. Classification metrics quantified sensitivity, specificity, predictive values, accuracy, F_1 -score, Matthew's correlation coefficient, and Youden's index. Finally, the agreement between kp_1 and kp_5 was examined by Bland-Altman analysis, paired t-test, Two One-Sided Tests for equivalence (TOST), and effect-size estimation. **Results:** The 1-hour absorption model (Model A1) explained 87% of the variability in kp_1 ($R^2 = 0.8705$), whereas the 2-hour absorption model explained variance of 97% of the variability in kp_1 with a strong linear relationship ($p < 0.001$). Inverting the regression equations of both models defined % absorption thresholds of 1.289% for 1-hour and 3.192% for up to 2-hours corresponding to the kp of 4.5×10^{-3} cm/h. Using these threshold values, ROC analysis showed excellent discrimination ($\text{AUC}_h = 0.9735$; $\text{AUC}_h = 0.9953$) with the 1-hour surrogate achieving 96.6% overall accuracy (sensitivity 70.5%, specificity 98.7%), while the 2-hour surrogate reached 98.3% accuracy (sensitivity 87.2%, specificity 99.3%). Agreement between 1-minute (kp_1) and 5-minute (kp_5) scintillation counts was confirmed. Bland-Altman analysis indicated negligible bias (mean difference = -1.29×10^{-5} cm/h), and equivalence testing (TOST) supported interchangeability within $\pm 5\%$ of the mean kp of 0.002838. Effect size was minimal (Hedges' $g = -0.113$), confirming that kp_1 and kp_5 are statistically equivalent, indicating a negligible difference in kp estimation. **Conclusions:** The 1-hour % absorption measurement combined with a 1-minute scintillation count provides a rapid reliable and accurate alternative for evaluating the skin integrity using a T_2O barrier integrity test. The resulting kp_1 values showed statistical equivalence to 5-minute conventional scintillation counts, demonstrating high accuracy, discrimination, and calibration. These findings support the implementation of short absorption time metrics as a validated approach for skin integrity assessments in regulatory dermal absorption studies.

K. G. Norman¹, A. Kowcz¹, L. E. Kaufman², C. D. Ruiz³, and J. F. Nash⁴. ¹Personal Care Products Council, Washington, DC; ²Scriptura Scientific LLC, Wooster, OH; ³dsm-firmenich, Princeton, NJ; and ⁴Procter & Gamble, Mason, OH.

Background and Purpose: Ultraviolet (UV) filters, which are active ingredients in the United States, are essential in sunscreen formulations, providing critical protection against acute and chronic skin damage from UV exposure. However, increasing scrutiny over their human and environmental safety has prompted requests for additional data. The U.S. Food and Drug Administration (FDA), have requested data from traditional toxicological animal studies to address safety concerns. Although rodent studies for endpoints like carcinogenicity have historically been employed to evaluate risk, these models often lack human relevance and are being reconsidered globally in favor of more targeted mechanistic, non-animal approaches. A comprehensive review of existing toxicity data for the six most commonly used UV filters, avobenzone, ensulizole, homosalate, octinoxate, octisalate, and octocrylene, was conducted and then a human risk assessment to evaluate their safety as currently used in sunscreen formulations was performed. **Methods:** Data were compiled from available *in silico*, *in vitro*, and *in vivo* studies, identified in the literature from regulatory and peer-reviewed sources, including dossiers submitted to the European Chemicals Agency (ECHA). Each UV filter was then assessed for pharmacokinetics, acute and repeat-dose toxicity, genotoxicity and photogenotoxicity, developmental and reproductive toxicity (DART), immunotoxicity, neurotoxicity, endocrine activity, and local effects such as skin irritation, sensitization, and photocarcinogenicity. The data were used in margin of safety (MoS) calculations, using conservatively estimated systemic doses, with MoS values >100 generally interpreted to be acceptable and protective for non-genotoxic and non-carcinogenic effects. Additionally, an approach evaluating carcinogenic modes of action (MOA) combined with systemic exposure data to supplement the existing safety assessments was performed to evaluate the carcinogenic potential of the UV filters. **Results:** The six evaluated UV filters have no structural alerts for DNA reactivity and are non-genotoxic in standard *in vitro/in vivo* studies. For each UV filter, the MoS were >100 when assessing the maximum allowed concentration of each UV filter and realistic human exposures, calculated for both daily (facial) and recreational (whole body) use. MOA analyses revealed no biologically plausible carcinogenic pathways, and systemic exposure levels in humans were consistently below thresholds associated with biological activity. **Conclusions:** This approach aligns with evolving international regulatory paradigms, which advocate for the replacement of long-term rodent studies with more human-relevant, mechanistic approaches. Despite some limitations in historical data, the overall evidence supports the continued safe use of these UV filters in sunscreen products. These findings reinforce the importance of modern, science-based risk assessment strategies in ensuring consumer safety while reducing reliance on animal testing.

PS 3765 Mercury disposition in Wistar rats after thimerosal exposure

M. Galicioli¹, L. Joshee², A. M. Kiefer², C. S. Seney², D. Grizzle², C. S. Oliveira¹, and C. C. Bridges². ¹Instituto de Pesquisa Pelé Pequeno Príncipe, Curitiba, Brazil; and ²Mercer University, Macon, GA.

Background and Purpose: Thimerosal is a mercury-based preservative used in vaccines, cosmetics, and pharmaceuticals. It's known that the conversion of thimerosal to ethylmercury and thiosalicylate occurs rapidly. However, its disposition in the human body is not well understood. Thus, the aim of this study was to evaluate mercury accumulation in the organs of Wistar rats after the injection of thimerosal at different concentrations and to document possible histopathological damage in these tissues. **Methods:** Thirteen female Wistar rats were injected via the femoral vein with saline, 0.5, 1.25, 6.175, or 12.35 $\mu\text{mole} \cdot \text{mg}^{-1} \cdot \text{kg}^{-1}$ thimerosal. All rats were anesthetized with an intraperitoneal injection of 30 $\text{mg} \cdot \text{kg}^{-1}$ ketamine and 70 $\text{mg} \cdot \text{kg}^{-1}$ xylazine before the injection. Twenty-four hours after the injection, animals were euthanized, and blood, liver, kidneys, spleen, and brain were collected. Samples were lyophilized and the amount of Hg in each was determined using a direct mercury analyzer (DMA-80). Renal and hepatic tissue from each rat was fixed, processed, sectioned, and stained for histopathological analysis. **Results:** The results showed that Hg accumulated in organs after exposure to each concentration of thimerosal. The greatest accumulation was observed when rats were injected with 12.35 $\mu\text{mole} \cdot \text{mg}^{-1} \cdot \text{kg}^{-1}$ of thimerosal. Among the organs tested, the kidneys had the greatest accumulation of Hg after exposure to every dose of thimerosal. The histopathology analyses shown hemorrhages, protein inclusions and cytoplasmic degeneration in the renal cortex and outer stripe of the outer medulla in the animals treated with 6.175 or 12.35 $\mu\text{mole} \cdot \text{mg}^{-1} \cdot \text{kg}^{-1}$ thimerosal. **Conclusions:** Our findings demonstrate that this preservative induces dose-dependent mercury accumulation across multiple organs, with high doses causing acute renal injury. This highlights the importance of dose as a critical factor in the toxicokinetic and toxicodynamic properties of thimerosal.

PS 3766 A novel air sampler using a wet inertial impactor to collect welding fume particles in liquid media for analytical and toxicological studies

S. Han, C. Lee, and J. Park. Purdue University, West Lafayette, IN.

Background and Purpose: In the United States, over 771,000 welders are employed and are routinely exposed to welding fumes. The particles in welding fumes range from 50 nm to 20 μm and a significant portion of particles are small enough to reach the alveolar regions, where they interact with epithelial cells and macrophages, inducing local oxidative stress and inflammation. The particles consist primarily of iron but also contain hazardous metals (e.g., manganese, chromium, etc.), which can generate reactive oxygen species (ROS) and cause cellular damage. Soluble metals may also translocate into systemic circulation, potentially contributing to cardiovascular and neurological toxicity. Epidemiological and toxicological studies link welding fume exposure to impaired lung function, chronic bronchitis, cardiovascular disease, neurotoxicity, and increased lung cancer risk. Current *in vitro* and *in vivo* toxicological studies typically collect welding fume particles on filters and subsequently extract them into suspension for exposing them to cells or animal models. However, this process is time-consuming, may result in sample loss, and often alters the particle properties. To address limitations, we developed a novel air sampler to collect welding fume particles directly into liquid media. This method preserves the particle composition and reactivity and enables more accurate analytical and toxicological assessments. We tested the developed sampler under laboratory conditions. **Methods:** The developed sampler utilized a wet inertial impactor that consisted of a nebulizer positioned upstream of the impactor nozzle to spray the deionized water (ASTM Type I). Particles collected on the impaction plate were immediately washed by a jet stream containing deionized water droplets and the resulting suspension flowed down to the collection tube (50 mL). The sampler had a cutoff diameter of 120 nm at a flow rate of 8 L/min and collected total suspended particles (TSP) larger than 120 nm. To test the sampler, welding fumes were generated using a custom-built welding station. Specifically, flux-cored arc welding was used. A 225-L exposure chamber was connected to the station. The developed air sampler was placed in the exposure chamber. Simultaneously, an open-face cassette equipped with a 37-mm polyvinyl chloride filter was positioned alongside the sampler to collect TSP at a flow rate of 1 L/min. Welding fumes were generated at three different concentrations (low, middle, and high) by adjusting welding intervals. Real-time fume concentrations were monitored using an optical particle sizer (OPS). After sampling for 20 min, metal content in both the suspension from the developed sampler and the filters was analyzed using field-portable X-ray fluorescence (FP-XRF). Linear regression analysis was used to evaluate the association between two sampling methods. **Results:** The average total mass concentrations measured using OPS were approximately 0.9, 1.5, and 2.8 $\text{mg} \cdot \text{m}^{-3}$ under low, middle, and high generation conditions, respectively. Most particles were smaller than 10 μm and the overall size distribution remained similar across all concentration levels, with a mode diameter smaller than 1 μm . FP-XRF analysis confirmed that Fe was the major metal component in the welding fumes. The Fe mass collected using the developed sampler was 0.14 mg, 0.51 mg, and 2.06 mg for the low, middle, and high concentration conditions, respectively, while the Fe mass collected on the filters was 0.21 mg, 0.50 mg, and 1.62 mg. Linear regression analysis from the two methods showed a strong linear relationship ($R^2 = 0.9$, p -value < 0.05), demonstrating that the sampler provided comparable fume collection performance to the conventional filter method. **Conclusions:** The developed sampler demonstrated collection performance comparable to the conventional filter method and showed good recovery results for the collected sample. By allowing direct collection into liquid media, this novel method can reduce sample process time and steps, minimize potential sample loss, and better preserve the particle characteristics for the toxicological assays. Since the collected samples are already in liquid form, subsequent analyses, including metal quantification, can also be simplified. Overall, the developed method provides a more convenient and versatile platform for analytical and toxicological studies in both laboratory and field settings.

PS 3767 Parental dietary exposure to an arsenic-contaminated natural diet induces neurobehavioural impairments in Zebrafish (*Danio rerio*) offspring

S. K. Putnala, F. da Silva, O. Luo, M. Rachamalla, M. Hecker, and S. Niyogi. University of Saskatchewan, Saskatoon, SK, Canada.

Background and Purpose: Arsenic is a non-essential, highly toxic element and one of the most widespread environmental contaminants, entering aquatic ecosystems through both natural sources and human activities. Owing to its persistence, bioaccumulative potential, and ability to disrupt multiple physiological systems, arsenic has been designated a global priority pollutant. Chronic arsenic exposure is associated with severe health effects in mammals and aquatic organisms; however, current knowledge about arsenic toxicity is largely limited to its direct exposure effects, whereas much less is understood about the multigenerational consequences of parental exposure, particularly under environmentally realistic conditions during early developmental stages when arsenic is maternally transferred from adults to their offspring. Therefore, the main objective of this study was to investigate the neurobehavioural toxicity in larval offspring resulting from parental exposure to an arsenic-contaminated natural diet in zebrafish (*Danio rerio*). **Methods:** Adult zebrafish (F_0) were fed with oligochaete worms (*Lumbriculus variegatus*) with arsenic body burdens

of 0.25 (control), 34.69 (low), and 77.79 (high) $\mu\text{g/g}$ dry weight, respectively, for 60 days. Fish were then bred to generate F_1 embryos, which were reared in clean water and diet until 30 days post fertilization (dpf). In F_1 larvae, oxidative stress and apoptosis were evaluated at 5-dpf by fluorescence imaging, and immunostaining was performed at 24-hpf and 5-dpf to assess neurogenesis and neural signalling pathways. Behavioral assessments included photomotor response (5-dpf), thigmotaxis (15-dpf), social preference (21-dpf), and novel object recognition (30-dpf). Whole-transcriptome analysis in 5-dpf larvae was performed to identify molecular pathways associated with neurobehavioral alterations. **Results:** Parental dietary arsenic exposure resulted in a dose-dependent increase in reactive oxygen species and apoptosis in offspring. Neurodevelopmental impairments were also evident in arsenic lineages, including reduced hypothalamic neurogenesis and impaired development of dopaminergic and motor neurons. Larvae exhibited behavioral abnormalities such as reduced locomotor activity, heightened anxiety, and cognitive impairments. Transcriptomic analysis revealed significant dysregulation in pathways related to early neurodevelopment and synaptic functions. **Conclusions:** This study demonstrates, for the first time, that parental dietary exposure to environmentally relevant concentrations of arsenic via naturally contaminated oligochaete worms induces multigenerational neurodevelopmental and neurobehavioral impairments in F_1 larval Zebrafish mediated primarily by oxidative stress and disruptions in neurogenesis and neuro signaling pathways. These results emphasize the need for monitoring arsenic levels in benthic invertebrates and considering dietary exposure pathways, in addition to waterborne contamination, when assessing ecological risk and establishing regulatory guidelines for arsenic in aquatic environments.

PS 3768 Low Dose Heavy Metal Exposure Reprograms Central Metabolism in Human Fetal Lung Fibroblasts

J. Korn¹, D. Wang², and X. Hu². ¹Emory University, Atlanta, GA; and ²Emory University Rollins School of Public Health, Atlanta, GA.

Background and Purpose: Fetal lung development is a critical process that establishes proper lung functioning in adulthood. Mesenchymal cells such as fibroblast provide essential structural and signaling support during this process. Environmental contamination by heavy metals, including cadmium (Cd) and arsenic (As), represents a significant risk factor that can disrupt metabolic networks essential for lung morphogenesis and may increase susceptibility to respiratory disease later in life. Previous research in lung epithelial cells showed that Cd and As inhibit *de novo* pyrimidine biosynthesis from glutamine, resulting in airway morphogenesis. However, whether this effect is cell type-specific remains unclear. Here, we aim to examine how Cd and As alter fibroblast-specific metabolic activity and identify molecular targets potentially vulnerable to heavy metal toxicity during development. **Methods:** We employed stable isotope metabolomics to determine the impact of Cd and As on metabolite levels and metabolic flux. Human fetal lung fibroblasts (HFL1) were pretreated with 0.1 μM Cd and As (as $\text{CdCl}_2 + \text{NaAsO}_2$) for 24 hours before adding the tracer. [¹⁵N,¹³C₃] Glutamine (2 mM) was added to cell culture media and cells were harvested for metabolomics at four time points (30 minutes, 60 minutes, 120 minutes, and overnight). Metabolites were extracted using ice-cold acetonitrile and water (2:1 v/v) and analyzed via dual liquid chromatography (C18 and HILIC) coupled with Orbitrap ID-X Tribrid mass spectrometry. Processed data were analyzed for metabolic flux and pathway enrichment using *Rodin*, a computational package for analyzing metabolomics data. **Results:** Low dose Cd+As exposure induced extensive remodeling of fibroblast metabolism. Twenty-six metabolic pathways were significantly altered relative to control ($P < 0.05$). Purine metabolism, including inosine and guanosine, and their nucleotide counterparts showed remarkable perturbation, along with several amino acid metabolic pathways, such as methionine and cysteine metabolism and glycine, serine, alanine, and threonine metabolism. Flux analysis revealed that multiple steps of the tricarboxylic acid cycle (TCA) were affected. We found increased synthesis of citrate and fumarate and decreased synthesis of succinate. Enhanced aspartate synthesis, likely via transamination, was also observed. **Conclusions:** Our study shows that low dose Cd+As exposure reprograms central carbon metabolism in fetal lung fibroblasts, revealing cell type-specific metabolic vulnerabilities to heavy metal toxicity during lung development.

PS 3769 Exposure to Hexavalent Chromium in Drinking Water Induces Sex-Dependent Essential Metal Dyshomeostasis in the Liver, Blood, and Brain of Guinea Pigs After 90 Days

M. E. Delnicki¹, S. T. Vielee², G. C. Griffin¹, I. Meaza³, O. Ogunsunsi³, F. Gueye³, A. Brownell³, N. Butzke-Souza³, J. Easley³, H. Lu³, S. S. Diven³, J. C. Kouokam³, J. P. Wise Jr.⁴, J. P. Wise Sr.³, and J. L. Wise¹. ¹Wise Laboratory of Liver and Environmental Health, Department of Pharmacology and Toxicology, University of Louisville, Louisville, KY; ²Marine Biological Research Program, Mote Marine Laboratories and Aquarium, Sarasota, FL; ³Wise Laboratory of Environmental and Genetic Toxicology, Department of Pharmacology and Toxicology, University of Louisville, Louisville, KY; and ⁴NeuroWise Laboratory, Department of Pharmacology and Experimental Therapeutics, University of Toledo, Toledo, OH.

Background and Purpose: Hexavalent chromium [Cr(VI)] is a toxicant that enters the environment due to natural and man-made processes. Drinking water is at an elevated risk of Cr(VI) contamination due to industrial run-off settling in downstream drinking water basins. The liver is the main target organ of oral Cr(VI) exposure through contaminated drinking water, which has been found to induce hepatic inflammation and increase the incidence of liver disease and primary liver cancers in exposed individuals. Recent studies have also identified the liver as a major organ involved in the clearance of plasma amyloid beta (A β) from circulation, posing significant ramifications for the brain. Hepatic inflammation greatly reduces the ability of the liver to clear A β from circulation, allowing it to re-enter the brain and form A β plaques involved in the pathogenesis of Alzheimer's disease. Therefore, it is crucial to understand the role Cr(VI) plays in disrupting crosstalk along the liver-brain axis. One way to investigate crosstalk between these organs is to quantify essential metal levels, as essential metal dyshomeostasis has recently been identified as a potential biomarker for both liver disease and Alzheimer's disease. **Methods:** 10.5- to 11.5-month-old Hartley guinea pigs were separated into sex-matched control and Cr(VI)-exposed groups. Control animals received tap water, and exposed animals received 5 mg Cr(VI)/L in tap water. Sodium chromate was chosen as the representative Cr(VI) compound due to its high solubility in water. Water volume was measured twice daily to monitor water and Cr(VI) consumption, and body mass was recorded weekly. Chromium (Cr) and essential metal levels in the liver, brain, and blood were quantified using inductively coupled plasma mass spectrometry. Brains were micro-dissected to quantify metal levels in different brain regions, with special interest in the hippocampus and entorhinal cortex due to their implications in Alzheimer's disease. Normality of data was determined using a Shapiro-Wilk test. Normally distributed data was assessed using a two-tailed Student's t-test with Welch's correction, and non-normally distributed data was assessed using the Mann-Whitney U test. Significance was reported for p-values < 0.1 . **Results:** After 90 days, significant Cr accumulation was noted in the liver, blood, and hippocampus of exposed guinea pigs, with a notable sex-difference seen in the liver and blood. Considerable essential metal dyshomeostasis was observed in the liver and blood of exposed guinea pigs, with exposed females displaying significantly altered essential metal distribution compared to exposed males and controls. Minimal essential metal dyshomeostasis was seen in the whole brain, hippocampus, and entorhinal cortex. However, significantly decreased zinc levels were noted in the liver and whole brain of exposed female guinea pigs. This is particularly notable given that zinc is a co-factor of superoxide dismutase and glutathione peroxidase which are enzymes responsible for combating the oxidative stress induced by the intracellular reduction of Cr(VI). **Conclusions:** Exposed female guinea pigs appear to be more sensitive to oral Cr(VI) exposure than males, marking a notable sex difference. This was most apparent when assessing Cr accumulation and essential metal distribution in the liver and blood of exposed animals. Future studies will consider how pro-inflammatory cytokine production is impacted by oral Cr(VI) exposure, and how this drives disease severity and progression in the liver and brain. This work was supported in part by the Jewish Heritage Fund for Excellence Faculty Recruitment Grant Program (JLW), NIEHS R35ES032876 (JPWSr) and NIEHS T32ES011564 (JPWSr, MD, GG, SV, OO).

PS 3770 Validation of XRF Bone Lead Measurement in Black Vultures and Developing Next-Generation Portable XRF Instrumentation

T. Grier¹, A. Specht¹, B. Faber¹, S. Silva Costa¹, T. Katzner², S. Proctor³, and D. Goodman⁴. ¹Purdue University, West Lafayette, IN; ²U.S. Geological Survey, Forest and Rangeland Ecosystem Science Center, Boise, ID; ³USARIEM, Natick, MA; and ⁴H3D, Ann Arbor, MI.

Background and Purpose: Chronic lead exposure poses ongoing toxicological risks to wildlife and humans. Bone integrates over 90% of total body lead and serves as a robust biomarker of cumulative exposure, but traditional measurements require destructive digestion and ICP-MS analysis. X-ray fluorescence (XRF) offers a non-destructive alternative, yet its performance for wildlife bone lead assessment and its ability to capture both cortical and trabecular bone markers require further evaluation. This work aimed to (1) validate portable and benchtop XRF systems for measuring bone lead in black vultures (*Coragyps atratus*), and (2) develop a next-generation Cd-109-based K-shell XRF (KXRF) system to advance cumulative exposure assessment. **Methods:** Femora and tarsometatarsi from 19 black vultures were analyzed using portable XRF (pXRF), benchtop XRF, and ICP-MS. *In vivo* and *ex vivo* measurements were compared across instruments, and intraclass correlation coefficients (ICC) were calculated to assess agreement. Soft tissue was also analyzed to evalu-

ate its contribution to *in vivo* signals. Separately, a compact KXRF system pairing a Cd-109 source with a cryogen-free CdZnTe detector was tested with bone phantoms and human cadaver tibias to characterize detection limits and linearity. **Results:** Benchtop XRF showed excellent agreement with ICP-MS ($R^2 = 0.92-0.95$; $ICC \geq 0.959$) and a detection limit of 0.6 ppm. Portable XRF exhibited moderate correlation ($R^2 = 0.62-0.67$) and systematic underestimation but maintained strong agreement between *in vivo* and *ex vivo* measurements ($R^2 = 0.85$). Soft tissue contained ~0.75 ppm lead, below the pXRF detection limit, indicating that *in vivo* signals primarily reflect bone lead. The Cd-109 KXRF system demonstrated linear response up to 100 ppm ($R^2 = 0.987$) and achieved detection limits of 2-3 ppm under optimized conditions. **Conclusions:** These complementary efforts validate XRF as a non-destructive method for assessing bone lead in wildlife and demonstrate the potential of next-generation Cd-109 KXRF instrumentation to measure both cortical and trabecular bone biomarkers. Together, they advance tools for cumulative lead exposure assessment in ecological and public health contexts.

PS 3771 Development and Validation of an HPLC Assay to Measure Anti-Oxidant GSH and Lipid Peroxidation Metabolite MDA to Understand Oxidative Stresses in a Hepatocellular Model

A. R. Chinala, R. Kumar, and R. Gullapalli. University of New Mexico, Albuquerque, NM.

Background and Purpose: Cadmium (Cd) is a highly toxic environmental and industrial pollutant associated with metabolic syndrome (MetS), obesity, type II diabetes, and metabolic dysfunction associated fatty liver disease (MAFLD). Chronic liver disease rates are the highest in the nation in New Mexico, mainly in Hispanic and Native American communities (36.4/100,000 in 2022). Cd exposure drives cellular oxidative stress via mitochondrial dysfunction to generate reactive oxygen species (ROS). Glutathione (GSH) is the key cellular antioxidant that neutralizes damaging free radicals (ROS) and maintains homeostatic balance and cellular health. Tissues contain 1-10 mM GSH in the reduced form. Reduced GSH levels are a biomarker of oxidative stress, indicating poor cellular health. Lipid peroxidation (LPO) is a cell-damaging process triggered by ROS reacting with polyunsaturated fatty acid residues of phospholipids in cells. Malondialdehyde (MDA) is a highly reactive and toxic byproduct of LPO. Thus, accurate quantification of cellular GSH and MDA levels is helpful to evaluate oxidative stress in cells. In the current study, we established and validated methods to quantitatively measure GSH and MDA using high-performance liquid chromatography (HPLC). **Methods:** Measuring GSH levels in biological samples is difficult due to the rapid autooxidation of GSH, leading to an underestimation of GSH levels. The sulfhydryl groups on the cysteine residues of GSH can be blocked by a thiol alkylating agent such as N-ethylmaleimide (NEM), preventing artificial oxidation. The resulting GS-NEM conjugate is detectable by high-pressure liquid chromatography (HPLC) with a diode array detector (DAD). Measuring MDA levels in biological samples requires a derivatization step, for which 2-thiobarbituric acid (TBA) is commonly used. The resulting MDA-TBA₂ conjugate can be measured fluorometrically by HPLC with fluorescence detection (FLD) or with a DAD. The HPLC method is rapid and reliable. **Results:** We established a linear range of detection from 25 μ M to 1 mM for GSH-NEM. The established MDA-TBA₂ linear range was from 55 to 273 nM. We measured the GSH and MDA levels in two epithelial liver cancer cell lines, HepG2 and HUH7, cultured under normoglycemic (5.5mM) and hyperglycemic (15 mM) conditions representing non-diabetic and diabetic states. MDA levels were increasing through Cd exposure and hyperglycemia across both cell lines. GSH levels were increasing under the Cd exposure conditions in both hyperglycemia and normoglycemia conditions, indicating a compensatory mechanism used by the cells to protect themselves against oxidative stress. **Conclusions:** Our HPLC GSH and MDA quantification assays are a valuable tool to understand the impact of chronic, low-dose exposures of Cd (CLEC) on cellular oxidative stress of hepatocellular cells. Our assays are valuable adjuncts to understanding the long-term impacts of heavy metal exposures on hepatic function.

PS 3772 Evaluating the Fibrogenic Effects of Tungsten Particulate Exposure in 3T3 and HFL1 Fibroblasts.

J. A. Tjung, C. M. McVeigh, J. L. Moreno, S. C. Helewicz, and A. M. Bolt. University of New Mexico, College of Pharmacy, Albuquerque, NM.

Background and Purpose: Tungsten (W) is a heavy metal increasingly recognized as an emerging environmental toxicant. Inhalation of W particulates is a key route of human exposure, especially in occupational settings where air concentrations in hard metal manufacturing factories have been reported as high as 6 mg/m³. Inhalation exposure to particulates has been associated with an increased risk of pulmonary and cardiovascular diseases. However, the systemic implications of W-induced lung injury remain unexplored. Recent epidemiological studies have identified a correlation between W exposure and elevated risk of cardiovascular diseases and stroke, but the mechanistic pathways linking pulmonary exposure to cardiac dysfunction have yet to be elucidated. Prior work from our lab has demonstrated that acute inhalation of W particulates induces IL-1 β driven pulmonary inflammation and early signs of cardiac injury, with repeated exposures leading to increased cardiac expression of pro-inflammatory and pro-fibrotic markers. These findings suggest that W exposure

could be contributing to cardiovascular disease through IL-1 β -mediated inflammation and cardiac remodeling pathways. **Methods:** This study explores how W particulate exposure affects the secretion of pro-inflammatory and pro-fibrotic mediators in THP-1 human immune cells, and how these signals affect fibroblast activation and gene expression *in vitro*. Two complementary THP-1 macrophage models were used to characterize W-induced secretion profiles. THP-1 cells were first differentiated with M0 macrophages with 5 μ L of 10 μ M PMA, then exposed for 48h under four conditions: Control, W, LPS, and LPS+W (W concentration - 200ng/mL). In a parallel experiment, THP-1 cells were polarized to an M1 state with LPS and subsequently exposed to W particulates to examine W's effect in a primed inflammatory context. Fibroblast responses were examined in 3T3-L1 mouse fibroblasts and HFL1 (human lung fibroblasts) cell lines to capture tissue-specific effects of W-induced inflammation. The 3T3-L1 and HFL1 fibroblasts were treated for 72 hours with supernatant collected from THP-1 cells exposed to 200 ng/mL W particulates. RNA was isolated, and gene expression was analyzed using qPCR to assess pro-inflammatory (TNF- α , IL-1 β , IL-6) and pro-fibrotic (TGF- β 2, α -SMA, Col1a1, Col3a1, MMP-2, & MMP-9) gene markers. **Results:** Preliminary results indicate that exposure to supernatant from W-exposed THP-1 cells increased gene expression of MMP-9 and TGF- β 2 in 3T3-L1 fibroblasts. Co-treatment with LPS (LPS+W) did not further enhance this response. W exposure did not lead to expression of inflammatory makers TNF- α , IL-1 β in the fibroblasts. Cytokine and remodeling mediators will also be quantified in THP-1 supernatant by ELISA to define condition-specific secretion patterns driving fibrotic changes. These results will guide downstream fibroblast exposures and support optimization of indirect vs direct particulate exposure systems. **Conclusions:** These data will provide insight into how W-mediated pulmonary inflammation could contribute to the development of cardiac fibrosis and define gene expression patterns in fibroblasts that could serve as indicators of early fibrotic remodeling following exposure. Funding R21OH012552

PS 3773 Disruption of Early Human Red Blood Cell Development by Arsenite and Its Primary Metabolite Monomethylarsonous Acid

A. S. Armijo¹, L. K. Heine¹, G. A. Picha¹, M. A. Esquibel², K. N. Gonzalez¹, B. B. Maes², A. M. Bolt¹, K. Liu³, and S. Medina¹. ¹Department of Pharmaceutical Sciences, The University of New Mexico College of Pharmacy, Albuquerque, NM; ²University of New Mexico Health Sciences Center, Albuquerque, NM; and ³Stony Brook University, Department of Pathology, Stony Brook, NY.

Background and Purpose: Chronic exposure to heavy metals is linked to adverse health outcomes, such as anemia. Arsenite (the trivalent inorganic form of arsenic, AsIII), specifically, causes hematotoxicity in both *in vivo* and *in vitro* models. However, little is known about the relative hematotoxicity of the AsIII methylated metabolites. Preliminary *in vitro* studies indicate that the major trivalent AsIII metabolite, monomethylarsonous acid (MMAIII), is more toxic than its parent inorganic arsenical. Therefore, this study investigated the differential hematotoxicity of AsIII and MMAIII in primary human bone marrow CD34+ hematopoietic progenitor cells (HPCs) from male and female donors with varied backgrounds. **Methods:** To evaluate effects on growth and differentiation mediated by AsIII and MMAIII, CD34+ cells obtained commercially from STEMCELL Technologies were cultured in two parallel systems. The first system utilized HemaTox Erythroid™ medium which is selective for erythroid development, and the second system comprised of H4330 MethoCult™ medium which supports both erythroid and myeloid progenitors. HPCs cultured in both conditions were exposed to low concentrations of AsIII or MMAIII. **Results:** At 3- and 7-day timepoints, viability and growth of early RBCs was assessed using acridine orange/propidium iodide staining. Erythroid differentiation at these same timepoints was assessed using flow cytometry by comparing CD71+ and CD235a+ marker expression. AsIII and MMAIII reduced the growth and differentiation of early human RBCs in a dose-dependent manner at the 7-day timepoint. Flow cytometry revealed impaired erythroid differentiation following MMAIII treatment, with early RBCs failing to mature into CD235a+ cells. Impacts on hematopoietic differentiation were further evaluated via colony formation in H4330 MethoCult™ medium after 14 days. Colony-forming assays demonstrated significant reductions in erythroid colony forming units (BFU-E and CFU-E) following exposure AsIII and MMAIII in a dose-dependent manner. **Conclusions:** In summary, these findings indicated that early stages of human RBC development are highly susceptible to hematotoxicity from AsIII and MMAIII, with MMAIII eliciting greater toxicity than its parent arsenical. Future work aims to understand how arsenic biotransformation plays a role in impaired erythropoiesis.

PS 3774 The RAD50 Zinc Hook Motif as a Vulnerable Target in Heavy Metal-Induced Genotoxicity

A. Arroyo, A. N. Nail, M. Banerjee, and J. States. University of Louisville, Louisville, KY.

Background and Purpose: DNA double-strand breaks (DSBs) are linked to development of breast, ovarian, prostate and other cancers. The MRN complex is one of the first responders to DNA double-strand breaks (DSBs), while its disruption impairs DSB repair. The MRN complex consists of the proteins MRE11, RAD50 and NBN. To form functional MRN complex, two RAD50 molecules must bind one zinc (Zn) ion via their

respective Zn hooks forming a tetrahedral Zn-S complex (CXXC-CXXC). This Zn binding allows RAD50 to bind damaged DNA and enables DNA repair. Ataxia telangiectasia mutated (ATM) is activated by MRN complex. Cadmium (Cd), a non-mutagenic metal, causes suppression of ATM activation in breast epithelial cells. Exposure to another Zn displacing metal, inorganic trivalent arsenic (iAs), also causes suppression of ATM activation in skin keratinocytes. Here, we evaluate whether iAs and Cd directly bind to the RAD50 Zn hook motif and displace Zn, providing a mechanism for the observed inhibition of ATM activation caused by each metal. **Hypothesis:** iAs and Cd will bind to the RAD50 Zn hook motif and displace Zn. **Methods:** Synthetic P. furiosus RAD50 Zn hook peptide and UV-Vis spectrophotometry was used to characterize metal-peptide interactions. The peptide (1 Eq, 100 μ M) was incubated with increasing concentrations of Zn (0 - 5 Eq; 0 - 500 μ M), Cd (0 - 5 Eq; 0 - 500 μ M), or iAs (0 - 10 Eq; 0 - 1000 μ M) for 30 min at room temperature followed by monitoring absorbance change to assess binding of Zn (220 nm), Cd (240 nm) and iAs (270 nm). For Zn displacement, the peptide (1 Eq, 100 μ M) was incubated with Zn (1 Eq, 100 μ M) for 30 min followed by incubation with increasing Cd/iAs concentrations (0 - 10 Eq; 0 - 1000 μ M) for another 30 min, followed by assessing absorbance changes. Binding/displacement constants were calculated by curve fitting (Michaelis-Menten/allosteric sigmoidal) as appropriate. **Results:** Allosteric sigmoidal model provided the best fit for all metal binding kinetics. Cd (K_{half} = 0.21 Eq) and Zn (K_{half} = 0.20 Eq) had similar binding affinity for the RAD50 Zn hook motif, ~10-fold higher than that of iAs (K_{half} = 2.16 Eq). Cd displaced Zn from the RAD50 Zn hook motif (Dissociation K_{half} = 0.33 Eq, 33 μ M). **Conclusions:** Metal binding to the RAD50 Zn hook motif likely promotes carcinogenesis by inhibition of DSB repair pathways that normally prevent genomic instability. The marked difference in binding affinity of Cd and iAs for the RAD50 Zn hook suggests that Cd and iAs may differentially compromise cellular DNA-repair capacity. **Grant support:** American Cancer Society PF-23-1153675-01-DMC and NIH-NIEHS grants R01ES027778, P30ES030283, and 1K99ES036286.

PS 3775 Arsenic disrupts autophagosome-lysosome fusion in a zinc dependent manner

M. Banerjee, R. V. Goff, S. Elmoustapha, and S. D. Thomas. University of Louisville, Louisville, KY.

Background and Purpose: Chronic environmental arsenic exposure causes skin and lung cancers, but the molecular mechanisms are poorly understood. We identified that chronic trivalent inorganic arsenite (iAs) exposure at population relevant 100 nM concentration activates autophagy while suppressing downstream protein degradation. We do not understand how environmental iAs exposure uncouples autophagy activation from autophagic protein degradation. Zinc (Zn) regulates the critical autophagosome-lysosome fusion (ALF) step of autophagy that connects autophagy initiation and protein degradation. iAs disrupts zinc dependent processes. **Hypothesis:** We hypothesized that iAs suppresses autophagy by compromising ALF in a zinc dependent manner. **Methods:** We exposed three human skin (HEKn, Ker-CT and HaCaT) and lung (HSAEpC, HBEC3-KT and BEAS-2B) cell lines to iAs (0/100 nM; up to 48 h) with or without Zn or manganese supplementation (0/1 μ M; up to 48 h). HaCaT and BEAS-2B cell lines were exposed chronically to iAs (0/100 nM; 8 weeks) with concomitant Zn supplementation (0/1 μ M). We quantified ER stress (XBP1 splicing) employing Reverse Transcriptase-Polymerase Chain Reaction), autophagy initiation using immunoblots and completion of autophagy using immunoblots and immunofluorescence. ALF was measured employing the GFP-LC3-RFP-LC3 Δ G fluorescent autophagic flux in a 96-well plate format. Data was analyzed using unpaired, two-tailed t-test with Welch correction or two-Way ANOVA with Tukey's post-hoc test as appropriate, $p < 0.05$ was considered significant for all tests. **Results:** Environmental iAs exposure specifically targeted the ALF step of autophagy to suppress autophagic protein degradation across multiple skin and lung cell line models. iAs suppressed ALF in a Zn dependent and possibly zinc specific manner. Physiological Zn supplementation (1 μ M) prevented and rescued against iAs-induced suppression of ALF and autophagic protein degradation in the short and long-term. **Conclusions:** Our work provides a framework to understand the precise molecular mechanisms by which chronic environmental iAs exposure disrupts global protein degradation, inducing proteotoxicity contributing to multi-organ carcinogenesis. **Funding:** This research was supported in part by grants T35ES014559 and P30ES030283 from the National Institute of Environmental Health Sciences and by a grant DBG-23-1143457-01-CDP from the American Cancer Society

PS 3776 Associations Between Environmental and Biological Metal Concentrations and Self-Reported General Physical and Mental Health Status

E. Sededji¹, S. Liu¹, T. Evans², S. Steiner³, and E. M. Wells¹. ¹Purdue University, West Lafayette, IN; ²Blackford County Concerned Citizens, Hartford City, IN; and ³Purdue University Fort Wayne, Fort Wayne, IN.

Background and Purpose: Rural populations in the United States face disproportionate environmental health risks due to proximity to industrial sources, limited infrastructure, and reduced access to healthcare. Our prior analyses in Hartford City, Indiana, identified elevated soil and indoor-dust lead (Pb) and copper (Cu) concentrations near a local metal-recycling facility, with levels significantly decreasing by

distance based on regression and GIS analyses, indicating localized contamination sources. The purpose of this analysis is to examine whether metal exposures measured in environmental and biological media are associated with self-reported physical and mental health among adult residents of this rural community. **Methods:** A community-engaged, cross-sectional study enrolled 80 adults. Soil, indoor dust, and toenail samples were analyzed for metals using X-ray fluorescence and spot urine samples were analyzed for metals by inductively coupled plasma mass spectrometry. Additional data were collected via an online survey. Health outcomes were self-reported physical and mental health in the past 30 days (poor vs good). Multivariable logistic-regression models compared tertiles of metal concentrations with health outcomes, adjusting for age, education, BMI, and urine creatinine. **Results:** Mean age was 59.4 years (standard deviation: 14.2); 65% were female. Poor physical health was significantly associated with higher soil arsenic (tertile 3 vs. 1 adjusted odds ratio (aOR): 6.9; 95% confidence interval (CI): 1.35, 35.4), copper (tertile 3 vs. 1 aOR: 7.3; 95% CI: 1.35, 35.4), and iron (tertile 3 vs. 1 aOR: 12.3; 95% CI: 2.29, 65.8). The association of poor mental health with soil iron (tertile 3 vs. 1) was also statistically significant (aOR: 22.6; 95% CI: 1.07, 4.77). Other comparisons were not statistically significant. **Conclusions:** Findings suggest that localized soil metal contamination may be associated with poorer self-reported physical and mental health among residents living near the metal-recycling facility despite limited evidence suggesting that residents living near the facility demonstrate a culture of denial and are more reluctant to participate in the study than residents living further away. However, these results should be interpreted cautiously given the small sample size. Nevertheless, this community-engaged study offers valuable insight into an under-studied rural population. Larger, longitudinal investigations integrating objective exposure metrics and biomarker validation are warranted to clarify causal relationships and inform equitable, community-driven environmental health interventions.

PS 3777 Investigation of dynamic changes in pain sensitivity induced by methylmercury in mice

R. Yamagata, M. Fujishima, Y. Shoji, N. Yamashita, and G. Hwang. Tohoku Medical and Pharmaceutical University, Sendai, Japan.

Background and Purpose: Methylmercury is a neurotoxic substance that is ubiquitous in the environment and causes severe neurological disorders in many mammals, including humans. Previous studies on methylmercury toxicity mostly reported the decline of sensory functions (mainly motor functions, vision, hearing, and somatosensory systems) and revealed responding pathological disorders in peripheral nerves, dorsal root ganglia, and the cerebral cortex. In recent years, pain disorders caused by methylmercury exposure have been suggested to encompass a diverse spectrum, including not only decreases in pain sensitivity (hypoalgesia) but also neuropathic pain symptoms such as hyperalgesia and allodynia. Thus, although methylmercury exposure can reportedly cause hyperalgesia and hypoalgesia, no study has examined the relationship between these pain disorders and methylmercury toxicity under the same conditions. In addition, no animal model reproduces the biphasic changes of hyperalgesia and hypoalgesia under the same exposure conditions. Therefore, in this study, we created a long-term exposure model in mice and examined dynamic changes in pain sensitivity over time under the same exposure conditions. **Methods:** C57BL/6 male mice exposed to methylmercury chloride (final concentration 30 ppm) in drinking water *ad libitum* were temporally evaluated for changes in pain sensitivity using the von Frey test and Hargreaves test. Furthermore, to clarify the neuronal basis of these dynamic changes, we performed morphological and functional analyses using neuronal activity and number of spinal dorsal horn neurons as indicators. **Results:** The results show that hyperalgesia was induced from 3 to 7 weeks after methylmercury exposure, followed by hypoalgesia from 13 to 15 weeks after exposure. Furthermore, immunohistochemical staining of neuronal activity in spinal cord dorsal horn neurons reveals a dramatic increase in c-Fos-positive neurons (activated neurons) after 4 weeks of methylmercury exposure and a decrease in the number of activated neurons after 14 weeks of exposure. In addition, the amount of mercury accumulated in the spinal cord dorsal horn increased depending on the duration of exposure. These results suggest that gradual dysfunction of spinal dorsal horn neurons, dependent on the amount of methylmercury accumulated, is involved in the observed biphasic change in pain sensitivity. **Conclusions:** This study is the first to examine dynamic changes in pain sensitivity due to methylmercury exposure in a mouse model and provides important information for investigating the molecular mechanisms involved in methylmercury-induced sensory impairment.

PS 3778 Does Hexavalent Chromium Exposure Impact The Gut Microbiome of Guinea Pigs?

J. T. Wise¹, E. Özcan², M. E. Delnicki³, S. S. Diven³, J. Easley³, J. C. Kouokam³, J. P. Wise, Jr.⁴, S. T. Vielee³, I. Meaza³, H. Lu³, A. Brownell³, S. Gueye³, G. C. Griffin³, N. Butzke-Souza³, J. P. Wise, Sr.³, and J. L. Wise³. ¹University of Hawai'i, Honolulu, HI; ²Louisiana State University Agricultural Center, Baton Rouge, LA; ³University of Louisville, Louisville, KY; and ⁴University of Toledo, Toledo, OH.

Background and Purpose: Hexavalent chromium [Cr(VI)] is a known environmental contaminant with widespread exposure through inhalation of polluted air and ingestion of contaminated drinking water. Cr(VI) was recently identified as the number one

chemical hazard in U.S. public drinking water in 2024. The current maximum contaminant levels (MCLs) for total Cr [Cr(VI) and Cr(III)] in drinking water from the World Health Organization (0.05 mg/L) and the U.S. Environmental Protection Agency (0.1 mg/L) were set based on contact dermatitis, and thus these MCLs warrant more investigation. Further, the highest level of Cr in U.S. drinking water was reported at 5.4 mg/L in 2014. Cr(III) is considered non-toxic, while Cr(VI) is toxic. While Cr(VI) exposure in drinking water has been investigated as a potential factor for tumor incidence in the gastrointestinal (GI) tract of rodents, the impacts on the gut microbiome are understudied and unknown. This is a critical knowledge gap, given that GI-related pathologies in humans have increased. **Methods:** Female and male 10.5-11.5 month-old Hartley guinea pigs were exposed to sodium chromate [0 or 5 mg/L Cr(VI)] in drinking water for 90 days. Following completion of the study, the cecal contents were collected, and the microbiome DNA was extracted and sequenced using primers for the V4-V5 region of the 16S rRNA by the Hubbard Center for Genome Studies at the University of New Hampshire. Raw sequences were then analyzed using Quantitative Insights into Microbial Ecology (QIIME2) and assigned to taxonomic classification based on the SILVA138 database. **Results:** There were no statistical differences between in alpha- and beta- diversity between the control and the Cr(VI) exposure (5 mg/L). *Caproiciproducens*, *Eubacterium ventriosum*, *Lachnospiraceae* (NK4A136), NK4A214 group, and *Parabacteroides*, all rare taxa, were significantly decreased ($p < 0.05$) in the Cr(VI) group. Conversely, another rare taxon, *Eubacterium runiantium*, was significantly increased ($p < 0.05$) in the Cr(VI) group. No observable differences were seen between biological sexes. **Conclusions:** While Cr(VI) in drinking water for 90 days did not alter the overall alpha- and beta-diversity in the cecum of guinea pigs, it did significantly alter reduce key rare taxa. These observed taxa that were decreased are associated with different GI tract disorders, including irritable bowel syndrome (IBS). These data are the first to suggest a link between Cr(VI) drinking water exposure and negative gut microbiota changes and indicate that Cr(VI) exposure in drinking water may pose a threat as a precursor or initial "hit" to IBS or other gut-related disorders. Future work is aimed at chronic exposures of Cr(VI) in drinking water and investigations into other microbiota regions in guinea pigs. This work was supported by NIEHS grant R35ES032876 (JPWSr).

PS 3779 As3MT Activity Alters MASLD Phenotypes Following Arsenic Exposure in Mice

M. Zablah^{1,2}, N. Subramanian^{1,2}, C. Guilbert², and K. K. Mann^{1,2,2}. ¹McGill University, Montréal, QC, Canada; and ²Lady Davis Institute, Montréal, QC, Canada.

Background and Purpose: Chronic exposure to inorganic arsenic (iAs) is associated with several metabolic diseases in humans, including atherosclerosis, diabetes mellitus, and metabolic dysfunction-associated steatotic liver disease (MASLD). In the liver, mouse studies have shown that iAs exposure can induce phenotypes consistent with MASLD, such as steatosis, inflammation, and fibrosis. The enzyme arsenic-3-methyltransferase (As3MT) plays a central role in iAs metabolism, yet its contribution to hepatotoxic outcomes upon arsenic exposure remains unclear. While methylation facilitates arsenic clearance, it can also generate reactive intermediates that may exacerbate liver injury. Understanding how differences in As3MT activity influence arsenic-induced hepatotoxicity is key to clarifying disease mechanisms and identifying at-risk polymorphisms. We hypothesize that reduced As3MT activity increases susceptibility to arsenic-induced hepatotoxicity, thus exacerbating MASLD phenotypes. **Methods:** To address this, C57BL/6 mice with varying capacities for arsenic methylation were used: wild-type (WT) mice, which metabolize iAs efficiently; As3MT knockout (KO) mice, which lack methylation capacity; and humanized As3MT (huAs3MT) mice, which exhibit an intermediate rate of metabolism. Male and female mice (6-8 weeks old) were exposed ad libitum to 200 ppb iAs in drinking water for 5 weeks. Following exposure, liver and serum samples were collected for histological and biochemical analyses. Steatosis was assessed using oil red O staining of frozen liver sections to quantify lipid accumulation. Immune cell infiltration was evaluated via immunostaining for CD45 (total leukocytes) and CD68 (macrophages). Collagen deposition, indicative of fibrosis, was visualized using picrosirius red staining. **Results:** Initial analyses revealed that a 5-week exposure to 200 ppb iAs resulted in approximately a 5x increase in lipid accumulation in WT mice. Female WT mice exhibited nearly 10x higher staining intensity compared to males for both control and arsenic exposed conditions. No corresponding changes were observed in CD45 or CD68 immunostaining or in collagen deposition, suggesting an absence of overt inflammation or fibrosis at this exposure duration. The same outcomes are being assessed in KO and huAs3MT mice to determine how differences in arsenic methylation capacity influence these hepatic endpoints. Initial observations suggest a change in CD45 and CD68 immunostaining in the livers KO mice. **Conclusions:** These initial observations suggest that As3MT activity contributes to the development of MASLD phenotypes following inorganic arsenic exposure, with evidence of sex-dependent variation among WT mice. Ongoing work is examining how arsenic metabolism affects liver vasculature and immune organization, including potential changes in endothelial cell fenestration and the spatial distribution of immune cells in these different mouse models. Together, these efforts will help clarify how As3MT activity modulates the balance between arsenic detoxification and hepatotoxicity.

PS 3780 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD)-Elicited Disruption of Trace Metal Homeostasis in Wild-Type and Hepatocyte-Specific Aryl Hydrocarbon Receptor (AHR) Null Mice

Z. Smith, K. Orlowska, K. MacRenaris, and T. Zacharewski. Michigan State University, East Lansing, MI.

Background and Purpose: Trace metals are vital for enzymatic function in processes such as electron transfer, DNA replication, and antioxidant defense. Constant aryl hydrocarbon receptor (AHR) activation by persistent organic pollutants, such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), results in hepatic transcriptome dysregulation. Changes in transporter and metalloprotein expression lead to trace metal imbalance and oxidative stress, potentially exacerbating liver damage. We aim to determine the effect of TCDD-induced AHR activation on trace metals in hepatocytes and the resulting systemic alterations in trace metal homeostasis in wild-type and hepatocyte-specific AHR null mice. **Methods:** This was accomplished by intraperitoneal injection of corn oil vehicle or 75 mg/kg tamoxifen to conditionally knock out AHR in hepatocytes of male *Ahr^{d1v375A}* Alb-CreERT2 mice prior to oral gavage with sesame oil vehicle or 3, 10, or 30 µg/kg TCDD every four days for 28 days. Inductively coupled plasma mass spectrometry (ICP-MS) and hepatic RNA-Seq data were integrated to identify changes in trace metal levels in liver extracts and serum, and correlated with the differential expression of trace metal transporters and chaperones in the liver. **Results:** Out of 15 metals analyzed in the liver, 8 changed in wildtype (WT) and 9 changed in hepatocyte-specific AHR knockout (hep-AHR-KO) animals. In serum, 2 of the 15 changed in WT and hep-AHR-KO samples. Specifically, TCDD decreased hepatic copper levels while simultaneously increasing serum copper levels from hep-AHR-KO mice. The changes correlated with less repression in the copper exporter *Atp7b* in the hep-AHR-KO liver samples compared to WT. Hepatic zinc levels were decreased by TCDD in both WT and hep-AHR-KO samples, however AHR ablation in hepatocytes attenuated the change when compared to WT. There was no correlation with genes associated with zinc homeostasis. **Conclusions:** Hepatocyte-specific AHR ablation altered the expression of metal homeostasis genes, which affected hepatic and serum trace metal levels. These results suggest AHR activation by TCDD disrupts hepatic trace metal homeostasis which may subsequently impact the cellular redox balance, metalloenzymes, and metal-dependent forms of regulated cell death.

PS 3781 THE IMPACT OF APOLIPOPROTEIN E IN THE TOXICITY OF HEAVY METAL MIXTURES

A. M. Gane¹, A. Blendea¹, A. Bita¹, R. Mitru², S. A. Buteica¹, M. Aschner³, and A. O. Docea¹. ¹University of Medicine and Pharmacy of Craiova, Craiova, Romania; ²Clinical County Emergency Hospital, Craiova, Romania; and ³Albert Einstein College of Medicine, Croaiva, NY.

Background and Purpose: The apolipoprotein E (APOE) gene polymorphism has been linked to various human diseases, including Alzheimer's disease (AD), obesity and diabetes, as well as coronary and peripheral vascular diseases. Research has shown that the presence of the APOE polymorphism in isolation is insufficient for triggering pathological decline. However, the presence of other risk factors, such as metal ions, is necessary to interact with apolipoprotein E and elevate the probability of developing these diseases. This systematic review aimed to elucidate this hypothesis. **Methods:** We conducted a systematic review of international databases such as PubMed and Web of Science to examine the impact of heavy metals and their mixtures on apolipoprotein E (ApoE) isoforms, to establish the vulnerability of ApoE carriers and to identify the mechanisms underlying ApoE-mediated neurotoxicity in the presence of heavy metals. We searched the literature using the keywords 'apolipoprotein E', 'ApoE', 'heavy metals', 'lead', 'mercury', 'cadmium', 'arsenic', 'chromium', 'manganese', 'neurodevelopmental toxicity', 'cognitive decline', 'neurological decline', 'memory loss' and 'IQ scores'. **Results:** The identified epidemiological studies revealed a link between exposure to low-to-moderate levels of lead, mercury and cadmium, both individually and in combination, during pregnancy and breastfeeding, and reduced cognitive and fine motor scores, as well as decreased IQ scores. The effects were more pronounced in ApoE4 carriers. The identified studies on humanized ApoE3-KI and ApoE4-KI mice and rats showed an additive toxic effect between cadmium, lead, manganese, and mercury, in conjunction with the APOE4 gene, leading to memory and locomotor impairment, as well as cognitive impairment. **Conclusions:** As daily exposure to metals in real life rarely involves just one element, it is necessary to clarify the possible antagonistic or synergistic effects of heavy metal mixtures in the presence of apolipoprotein E. The results of this study inform on the development of personalized prevention and treatment strategies for neurodevelopmental and neurodegenerative disorders in humans and future research strategies.

C. M. Lucey¹, K. DeSantis², V. Caruana³, N. Subramaniam³, A. Zengin³, N. Gagnon³, N. Kukolj¹, A. Kupsco¹, K. K. Mann³, and B. Pearson². ¹Columbia University, New York, NY; ²Oregon State University, Corvallis, OR; and ³McGill University, Montreal, QC, Canada.

Background and Purpose: Arsenic (As) and uranium (U) are toxic metal(loid)s and co-occurring drinking water contaminants in rural communities in North America. Although chronic exposure to low concentrations of As and U is common, most *in vivo* toxicological studies of As and U rely on acute exposure to large concentrations of these elements. Therefore, there is a need to assess the health risk of As and U exposure in human-relevant exposure conditions. In our previous work, life-long exposures to low (100–200 µg/L) concentrations of As and U in drinking water were not sufficient to worsen atherosclerosis or related cardiometabolic phenotypes. However, it is possible that either 1) there were cardiometabolic effects at these concentrations, but that such effects were only at the molecular, subclinical level, or 2) that low concentration As and U exposure did not affect cardiometabolic health, but disturbed a different disease pathway we did not directly measure. Therefore, we conducted a multi-omic analysis of liver tissue to broadly assess subclinical hepatic responses to As and U in a hypothesis generating manner. **Methods:** Livers were collected from atherogenic (apoE^{-/-}) mice exposed to 112 µg/L As, 200 µg/L natural U, both, or neither (control) from conception until collection at 14 weeks of age. We extracted mRNA and DNA for bulk transcriptomic and DNA methylation analysis with total RNA-seq and methyl-seq, respectively. The metabolome and lipidome were quantified with combined trapped ion mobility spectrometry and time of flight mass spectrometry after dual-phase extraction of the aqueous and organic fractions of homogenized tissue. Each -ome was first analyzed individually by identifying significantly differentially expressed genes, differentially methylated regions, and differentially abundant metabolites and lipids in exposed groups relative to control. Since all four analyses were performed on adjacent tissue from the same mouse, we additionally conducted an integrated multi-omic analysis with DIABLO to identify molecular pathways across all -omes that differed between exposure groups. **Results:** The molecular effects of As, U, or combined As and U exposure in liver tissue were mild across all -omic layers. Exposure groups largely failed to separate in multi-omic analyses, suggesting that molecular signatures were similar regardless of As or U exposure. In single-ome analyses, gene set enrichment analysis of differentially expressed genes suggested that exposure to U upregulated oxidative stress and amino acid metabolism pathways, while As exposure down regulated fatty acid metabolism. Pathway analysis of the metabolomics data with Mummichog demonstrated significant up regulation of folate synthesis in As-exposed mice and upregulation of galactose and glycerolipid metabolism in U-exposed and combined As/U exposed mice, respectively. **Conclusions:** Overall, 112 µg/L As, 200 µg/L U, or both 112 µg/L As and 200 µg/L U only mildly affected the molecular profile of liver tissue from exposed mice. Of the four -omes we assessed, the metabolome was the most sensitive to As/U exposure. Thus, it is possible that human-relevant doses of As and U disturb hepatic metabolism, but not sufficiently to induce overt metabolic disease.

PS 3783 Bayesian Network with Bootstrapping Analysis of the Effect of Exposure to Welding Fume Metal Mixtures on Cognitive Abilities, Motor Functions and Mood Symptoms

J. Kuhn¹, R. Harold², C. G. Lee², J. H. Park², D. Foti², and U. Dydak². ¹Purdue University Northwest, Hammond, IN; and ²Purdue University, West Lafayette, IN.

Background and Purpose: Mild steel welding generates fumes which are comprised mainly of iron, manganese, copper, zinc and aluminum metals. Previous studies have shown decreased Cognitive and Motor functions, and increased Mood symptoms (CMM variables) of welders associated with occupational exposure to individual metals, in particular manganese, from welding fumes. Only a little work has been done on the association between CMM variables and metal mixtures. The aim of this study is to expand on studies investigating the exposure to individual metals, to identify how particular CMM variables are associated with the cumulative lifetime exposure of welders to metal mixtures at different welder exposure bi-stratifications. **Methods:** A cohort of 47 full-time career welders and a non-exposed, matched control group of 42 shift workers were recruited from a local truck trailer manufacturer. Nineteen CMM variables are studied: a battery of neuropsychological tests was administered to the welders to assess performance on 10 cognitive domains and 5 motor domains, and four classes of mood symptoms were assessed using the Brief Symptom Inventory mood survey. The five lifetime welding fume metals breathed in by a welder are approximated using a cumulative exposure model developed by Ward et al (2018), making use of personal air samples from each welder as well as their work history to estimate a lifetime cumulative exposure index (CEI), given in units of mg/m³ x yrs. Various learned Bayesian Network analyses of the effect of different welding fume metal mixtures and welder exposure bi-stratifications on cognitive abilities, motor functions and mood symptoms are conducted. The bi-stratifications procedure involved multiple percentile dichotomizations of the data to allow testing multiple welder exposure levels. The bi-stratifications procedure involved multiple percentile dichotomizations of the data to allow testing multiple welder exposure levels. Bootstrapping the Bayesian Network allows bias corrected and accelerated tests of significance of whether there is a significant association between CMM vari-

ables and metal mixtures at different welder exposure bi-stratifications. **Results:** For verbal fluency, processing speed, implicit learning and fine motor dexterity nondominant hand CMM variables, welders perform worst when exposed to either Mn or Zn and sometimes Al at most welder exposure bi-stratifications. The data gives no clear consensus as to which individual metal exposure(s) most negatively affects welders' cognitive flexibility. Verbal fluency is most negatively affected by exposure to the MnZn mixture pair at all welder exposure bi-stratifications. Cognitive flexibility is most negatively affected by any pair of metal exposures which includes Al, such as FeAl, CuAl, ZnAl or MnAl. Although no clear consensus, many metal exposure pairs including Mn negatively influence processing speed. Although no clear consensus, many metal exposure pairs including Mn or Zn negatively influence implicit learning. Motor dexterity (nondominant) is most negatively affected by any pair of metal exposures which includes Mn, such as MnZn, MnCu, and MnFe. Controlling for exposure level, welders' performance was worse (significantly or not) when exposed to mixtures with 3 or more metals than with 2 or fewer number of metals for most CMM variables. Furthermore, controlling for metal mixture, welders perform worse (significantly or not) when subjected to higher 35% or 30% welder exposure bi-stratifications for some CMM variables. **Conclusions:** This study shows how particular CMM variables (cognitive, motor and mood test scores) are associated with the cumulative lifetime exposure of welders to metal mixtures at different welder exposure bi-stratifications. Significant negative associations between exposures to welding fume metal mixtures, particularly those related to manganese and welder's processing speed, implicit learning and fine motor dexterity have been revealed at different welder exposure bi-stratifications. Welders were found to perform significantly worse on CMM tests for increasing numbers of metals in metal mixtures and when subjected to high metal exposures.

PS 3784 Cadmium toxicity by the disruption of glucose transportation system in human proximal tubular cells

J. Lee, M. Tokumoto, and M. Satoh. Aichi Gakuin University, Nagoya, Japan.

Background and Purpose: Cadmium (Cd) is an environmental contaminant that causes renal toxicity. However, the transcriptional pathways underlying proximal tubular injury remain incompletely defined. In this study, we focused on the transcription factor myocyte enhancer factor 2A (MEF2A), the activity of which is among those reduced by Cd treatment in human proximal tubular (HK-2) cells. Moreover, we investigated whether Cd disrupts the MEF2A-GLUT4 axis and cellular energy production. **Methods:** HK-2 cells were exposed to Cd and assessed for MEF2A transcriptional activity, MEF2A nuclear protein levels, GLUT4 (SLC2A4) expression, intracellular glucose and ATP level, and cytotoxicity. Knockdown of target genes was conducted by the siRNA transfection against MEF2A and SLC2A4. Renal SLC2A4 mRNA was quantified in mice chronically exposed to Cd (6 or 12 months). **Results:** Cd markedly inhibited the activity of transcription factor MEF2A in HK-2 human proximal tubule cells, which generated significant cytotoxicity in the cells. One of the glucose transporters, GLUT4, was downregulated not only by Cd treatment but also by MEF2A knockdown. Knockdown of SLC2A4, encoding GLUT4, eliminated both cell viability and Cd toxicity. Cd treatment or SLC2A4 deficiency reduced the cellular concentration of glucose. ATP levels were significantly reduced not only in the cells treated with Cd for 6 h but also in the SLC2A4-knockdown cells. The levels of SLC2A4 mRNA in the kidney of mice exposed to Cd for 6 or 12 months were significantly lower than those in the control group. **Conclusions:** Cd exerts cytotoxicity in proximal tubular cells by disrupting MEF2A activity and downregulating GLUT4, leading to impaired glucose availability and ATP depletion. These findings identify the glucose transporter pathway as a key determinant of Cd renal toxicity and provide a mechanistic link between transcriptional dysregulation and energy failure in the proximal tubule.

PS 3785 Spatial characterization of immune cell infiltration in the aortic sinus plaque using a multiplex PhenoCycler assay following arsenic-induced atherosclerosis in mice.

C. Guilbert¹, B. Giles², A. Zengin¹, M. J. Abraham¹, C. Goncalves¹, N. Gagnon¹, S. V. Del Rincon¹, and K. K. Mann². ¹Lady Davis Institute for Medical Research, Montreal, QC, Canada; and ²McGill University, Department of Pharmacology and Therapeutics, Montreal, QC, Canada.

Background and Purpose: Arsenic is known to exacerbate atherosclerosis, characterized by the development of plaques in large arteries. As plaques progress, they narrow vessels and become unstable resulting in heart attack or stroke. Atherosclerotic plaques contain a variety of cells, including vascular smooth muscle cells, endothelial cells, and numerous immune cells like macrophages, T cells, B cells, mast cells, and dendritic cells. Arsenic also promotes hypertrophy and fibrosis in cardiac tissue linked to dysregulated immune signaling pathways that cause damage to the heart. Our latest single cell multiome studies of CD45⁺, plaque-resident immune cells suggested that arsenic changes macrophage communication between cell types within the plaque. However, these studies did not provide spatial context or take into consideration other cell types. Multiplex imaging techniques, such as PhenoCycler, are powerful tools for spatially characterizing cell-cell interactions. Here, we created an 18 marker PhenoCycler panel to visualize the various

cells in murine atherosclerotic plaques and surrounding cardiac tissue following exposure to arsenic +/- high fat diet. We hypothesize that the change in the diet and/or the arsenic exposure will trigger an immune cell infiltration into the atherosclerosis plaque and modify communication between cells. **Methods:** Male and female ApoE^{-/-} mice were exposed to either tap water (Ctl) or 200 ppb arsenic (As) in drinking water for 13 weeks while being fed a low-metal purified diet (PD) or a high fat diet (HFD). Formalin-fixed paraffin-embedded (FFPE) sections of heart aortic sinus with atherosclerotic plaque were assembled in a tissue microarray (TMA) and stained using the PhenoCycler technology from Akoya. The staining panel consisted of 18 markers: a cardiac cell marker (Myh6), a hematopoietic cell marker (CD45), myeloid cell markers (CD11b, F4/80, CD206, and CD86), cell adhesion markers/ligands (ITGB1, CD44, ITGA5, and Spp1), a T-cell marker (CD3e), a smooth muscle cell marker (aSMA), endothelial cell markers (CD31 and CD146) and a segmentation marker (Actin). Myh6 was exceptionally detected using Streptavidin-biotin. The fluorescent nuclear dyes 4',6'-diamidino-2-phenylindole (DAPI) and DRAQ5 were included to aid nuclear segmentation. Data were analyzed using QuPath and CytoMAP. **Results:** We successfully created an analysis pipeline for characterizing atherosclerotic plaque and surrounding heart area optimized for our specific context. We observe an increase in the abundance of immune cells in the plaque and the surrounding heart tissue dependent on the treatment used (low purified vs high fat diet, with and without arsenic). Using this spatial profiling, we see a change in the cell-cell interaction between Monocytes/Macrophages and CD206⁺ Macrophages in female compared to male mice. Also, the presence of the Monocytes/Macrophages correlate with T cells and neutrophils. Next, we can compare the correlations between a cell phenotype (e.g. macrophage) and the expression of a marker (e.g. SPP1, CD44). With this, we address one of the findings from our previous multiome studies regarding the prediction that arsenic would change the preferred binding partner of SPP1 from CD44 to integrin receptors (ITGA5, ITGB1). **Conclusions:** We have successfully developed a PhenoCycler panel to spatially visualize and provide insights on cell locations, cell-cell interactions and cell heterogeneity in the arsenic-induced atherosclerotic plaque and surrounding heart tissue in our ApoE^{-/-} mice. This method could help determine what drives plaque instability and progression or what makes "vulnerable" plaques more prone to rupture and deserves to be further explored using our full dataset.

PS 3786 Toxic effects of the environmental low-dose cadmium and obesogenic microbiome metabolite delta-valerobetaine on muscle health

Y. Go, K. Kim, H. Lee, G. Lim, Z. R. Jarrell, C. Lee, H. J. Choo, and D. P. Jones. Emory University, Atlanta, GA.

Background and Purpose: Sarcopenia, the age-related loss of muscle mass and function, drives frailty, morbidity, and loss of independence, yet its environmental determinants remain poorly defined. We recently found that the intestinal microbiome produces a metabolite, delta-valerobetaine (VB), that causes obesity in young mice and is associated with aging and lower lean mass in humans. Cadmium (Cd), a heavy metal with a 10-to-30-year biological half-life, accumulates with age through intake from food, water, air pollution, and tobacco smoke. The objective of this study is to examine the effects of low-dose Cd and VB, alone and combined, on muscle health in aged mice. **Methods:** Twenty-month-old male C57BL/6J mice received standard mouse food (LabDiet 5053) *ad libitum* and drinking water containing CdCl₂ (3.3 mg/L), VB (1.62 mM), Cd+VB, or vehicle control (Cont) *ad libitum* for 12 weeks (n=10 per group). Protocols were approved by the Emory IACUC. Body weight and water intake were recorded weekly. After exposure, skeletal muscle Cd and VB levels were quantified by inductively coupled plasma-mass spectrometry and high-resolution metabolomics, respectively. Muscle damage and function were assessed by serum creatine kinase, gastrocnemius muscle histopathology by H&E with central nucleated fiber quantification, macrophage immunostaining, and beam traversal testing. **Results:** Muscle Cd and VB concentrations increased in their respective exposure groups versus Cont. Cd levels were higher with combined exposure than Cd alone (Cd+VB: 3.0 ± 0.4 ng/mg vs Cd: 2.3 ± 0.3 ng/mg; P< 0.05), indicating that VB potentiates Cd accumulation in aged muscle. Cd+VB elevated serum creatine kinase compared with Cont (270 vs 75 U/L; P<0.01) and prolonged beam traversal time (12 s vs 8 s; P< 0.05). Gastrocnemius muscle histology showed more central nucleated fibers with Cd+VB than Cont (20% vs 10%; P< 0.05), and macrophage infiltration increased >2-fold (P< 0.01). **Conclusions:** Chronic low-dose Cd and VB delivered in drinking water accumulate in aged skeletal muscle, with VB enhancing Cd burden and increasing toxicity. Combined exposure is associated with muscle damage, inflammation, and impaired physical performance, supporting environmental Cd and microbiome-derived VB as modifiable contributors to muscle aging and degeneration. In principle, methods to decrease Cd and/or VB could have a considerable population impact by protecting against sarcopenia and frailty in aging populations.

PS 3787 A Survey of DNA Damage and Metal Exposure in American Alligators (*Alligator mississippiensis*) in Florida

H. Lu^{1,2}, I. Meaza^{1,2}, R. M. Wise¹, J. T. Wise^{1,3}, S. S. Diven^{1,2}, T. J. Croom-Pérez¹, J. H. Toyoda¹, and J. P. Wise, Sr^{1,2}. ¹Wise Laboratory of Environmental and Genetic Toxicology, University of Louisville, Louisville, KY; ²Department of Pharmacology and Toxicology, University of Louisville, Louisville, KY; and ³Wise Laboratory of Nutritional Toxicology and Metabolism, Department of Human Nutrition, Food and Animal Sciences, College of Tropical Agriculture and Human Resilience, University of Hawai'i, Honolulu, HI.

Background and Purpose: One Environmental Health is a research strategy that studies toxicants while integrating human, wildlife, and ecosystem health to establish a more comprehensive understanding of health. We used this approach to study American alligators (*Alligator mississippiensis*), which are apex sentinel organisms and are regularly exposed to environmental toxicants. Because of their long lifespan, use of both terrestrial and aquatic habitats, broad diet, and ability to bioaccumulate metals, alligators serve as effective indicators of heavy metal pollution, which poses risks to both aquatic ecosystems and human health. Metals are widespread environmental pollutants that pose serious ecological risks, and surface water contamination remains a major concern in Florida. In particular, beryllium, chromium, nickel, arsenic, and cadmium are of critical concern because they are classified as known human carcinogens by the International Agency for Research on Cancer. Chronic exposure of alligators to these pollutants can induce DNA damage, potentially compromising their genetic and epigenetic integrity and, in turn, impairing reproductive success and population viability. In this study, we applied the One Environmental Health perspective to examine DNA damage and blood metal levels in alligators from three locations in Florida. **Methods:** We sampled alligators at three sites in Florida: Merritt Island National Wildlife Refuge (Merritt Island), Lake Apopka, and Lake Woodruff. After hand-capturing alligators, blood samples were collected from the occipital sinus and then put on ice. After sample collection, each alligator was examined for any external injuries or behavioral abnormalities (e.g., lethargy) while recording head length, snout-vent length, total length, sex, and age. Lymphocytes were isolated, and the alkaline comet assay was used for measuring DNA damage. Metal analysis was performed using inductively coupled plasma mass spectrometry (ICP-MS). Statistics were performed using GraphPad Prism 9.4.0. Data were expressed as the mean ± SEM. Statistical differences were assessed using a two-tailed Student's unpaired t-test or unpaired t-test with Welch's correction for normal distribution, Mann-Whitney test for non-normal distribution. When comparing two variables, a two-way ANOVA was used for sex and age. **Results:** We found alligators in Merritt Island National Wildlife Refuge had significantly higher DNA damage levels compared to those in Lake Apopka and Lake Woodruff. This trend was consistent across both sexes, with no observed sex differences. Similarly, DNA damage levels were significantly higher in both adult and juvenile alligators from Merritt Island compared to the other locations. Notably, juvenile alligators exhibited higher DNA damage than adults, with animals from Merritt Island, exhibiting particularly elevated levels. Except for cadmium, no significant differences were observed in the blood concentrations of chromium, arsenic, and nickel among alligators from these three locations. Both male and female alligators from Merritt Island had lower cadmium levels than those from the other two lakes, while female alligators from Lake Apopka exhibited higher nickel concentrations. Juvenile alligators showed higher blood levels of chromium and cadmium, whereas adults had higher nickel concentrations. **Conclusions:** Our findings highlight location- and age-dependent differences in DNA damage among alligator populations, with Merritt Island emerging as a hotspot of genotoxic stress. Metal levels alone did not fully explain this pattern, elevated DNA damage (especially in juveniles) signals potential environmental health risks that merit closer scrutiny through expanded contaminant profiling and mechanistic studies. This work was supported by the National Institute of Environmental Health Sciences [R35ES032876 and R01ES016893 to JPW; and T32ES011564 to JHT, RMW, and JPW].

PS 3788 Cell death mechanism of novel iron-containing terpyridine metal complexes for breast cancer cells

C. Hu¹, A. Abreu², A. Kanina², G. Zhang², and S. Cheng². ¹Jericho High School, Jericho, NY; and ²John Jay College of Criminal Justice, New York, NY.

Background and Purpose: Metal complexes have long been utilized as anticancer agents, such as cisplatin which is a platinum-based drug well-known and widely used for treating various solid tumors. A major challenge in anticancer drug development is achieving high selectivity to maximize cancer cell death while minimizing toxicity to normal cells. Terpyridine (tpy) metal complexes have been extensively investigated for decades due to their broad applications in functional materials, supramolecular chemistry, catalysis, and biomedical research, including anticancer, antibacterial, and antifungal studies. Previous work from Cheng's laboratory demonstrated that iron-based tpy complexes exhibit selective cytotoxicity toward either MCF-7 breast cancer cells or MDA-MB-468 triple-negative breast cancer cells. The present study further investigates the detailed cell death signaling mechanisms of the Fe-tpy (Fe9) complex. **Methods:** Protein level changes in MCF-7 and MDA-MB-468 cells treated with Fe9 for 72 hours at its IC50 concentration were assessed using the Full Moon Biosystems Explorer Antibody Array, which contains 656 highly specific and well-characterized antibodies targeting multiple signaling pathways. Fold changes obtained from the array were analyzed using QIAGEN Ingenuity Pathway Analysis

(IPA). Western blotting was performed to validate the expression of apoptosis-related proteins, including Bad, Bax, Bak, p53, Bcl-2, and Bcl-XL. **Results:** The array data showed that treatment of MCF-7 with Fe9 increased the expression of Bax and Bad (fold changes: +1.079 to +1.979), while decreasing Bak, Bcl-2, Bcl-XL, and p53 (fold changes: -1.002 to -1.195). In MDA-MB-468, Fe9 increased Bax and Bak (fold changes: +1.026 to +1.179) but decreased Bad, Bcl-2, Bcl-XL, and p53 (fold changes: -1.001 to -1.270). Western blot analysis validated the IPA results, showing that Fe9 reduced Bcl-2 expression by 44% in MCF-7 and 31% in MDA-MB-468, and decreased Bak and Bad in MCF-7 by 39% and 43%, respectively. However, other validated proteins did not consistently reflect the IPA findings. **Conclusions:** In conclusion, treatment with Fe9 modulates key apoptotic regulators in both MCF-7 and MDA-MB-468 breast cancer cells, suggesting its potential to promote cell death via the intrinsic mitochondrial pathway. The observed downregulation of Bcl-2 in both cell lines, along with decreases in Bak and Bad in MCF-7 cells, supports a pro-apoptotic effect, although discrepancies between array and protein data indicate possible post-translational regulation or pathway-specific modulation. Given the concurrent reduction of p53 expression, these findings suggest that Fe9 may induce apoptosis through a p53-independent mechanism. Future studies should further investigate the mechanisms underlying Fe9-induced cell death, including the potential involvement of oxidative stress and ferroptosis by assessing markers such as GPX4, as well as exploring time- and dose-dependent effects to better understand its therapeutic potential in different breast cancer subtypes.

PS 3789 Spatial transcriptomic profiling of glial and neuronal cells during mouse brain aging

U. Halder¹, H. Hamida¹, E. Saha², P. Nagarkatti¹, and M. Nagarkatti¹. ¹University of South Carolina School of Medicine, Columbia, SC; and ²University of South Carolina Arnold School of Public Health, Columbia, SC.

Background and Purpose: Age is a critical variable that influences both baseline brain function and susceptibility to toxic exposures. Also, aging induces widespread molecular and cellular alterations in the brain, leading to functional decline and increased susceptibility to neurodegenerative disorders. **Methods:** To elucidate the spatial and cell-type-specific transcriptional changes underlying brain aging, we performed spatial transcriptomic profiling of midbrain regions from one-month-old and one-year-old mice. Spatial transcriptomics is a technique that measures gene expression within an intact tissue to demonstrate where different cells and their transcriptional activities are located. Using a high-resolution spatial transcriptomics platform with a neuroinflammation-focused gene panel, we mapped gene expression changes across neuronal and non-neuronal cell populations. **Results:** We observed a reduction in glutamatergic excitatory neurons in the thalamus and cerebral cortex of aged brain, suggesting disrupted thalamocortical communication. Overexpression of inhibitory interneurons in the caudate putamen, coupled with decreased parvalbumin-expressing interneurons in the hypothalamus, indicated a shift toward excessive inhibition and potential autonomic dysfunction. An increased abundance of reactive microglia, immune-interacting epithelial cells, and vascular-associated astrocytes across aged brain regions as compared to young reflected an active neuro-immune crosstalk. In the corpus callosum and caudate putamen, a significant reduction in oligodendrocyte precursor cells, a sign of aging, was accompanied by an increase in myelinating oligodendrocytes, an indication of ongoing pathological condition. Collectively, our analyses reveal distinct transcriptional reprogramming in astrocytes, microglia, oligodendrocytes, and endothelial cells, marked by upregulation of inflammatory and stress-response pathways and downregulation of synaptic and metabolic genes in neurons in aged brain as compared to young. **Conclusions:** Together, these findings suggest that aging recapitulates features of chronic neuroinflammation, characterized by imbalanced excitatory-inhibitory signaling in cortical and thalamic regions and region-specific reactive gliosis in the corpus callosum and caudate putamen.

PS 3790 Astrocytic STING signaling mediates wildfire smoke-induced neurotoxicity in primary murine cells

A. Bibb, A. Schuller, E. Smith, O. Yanouri, M. Hager, L. Montrose, and R. Tjalkens. Colorado State University, Fort Collins, CO.

Background and Purpose: Global increases in wildfire events necessitate assessment of extrapulmonary health effects associated with smoke exposure. Mounting literature highlights the potential of this toxicant to induce neurologic consequences, occurring through unknown mechanisms. Chronic wildfire smoke exposure has been shown significant to disrupt parenchymal gene expression similarly to signatures of neurodegeneration. There is further a growing body of work demonstrating glial activation precedes overt loss of neurons in toxicant-based models of these disorders. The cGAS-STING signaling pathway, which coordinates interferon responses to cytosolic nucleic acids, has recently been implicated in the pathogenesis of age-related degeneration, despite little focus on astrocytes. Together, these data motivated our present assessment of STING-dependent activation in astrocyte-enriched primary mixed glial cells as a mechanistic contributor to smoke-induced neurotoxicity. **Methods:** Simulated wildfire smoke was generated using a laboratory furnace to combust Douglas fir needles at a smoldering temperature. Particulate matter was

collected on filters and extracted via methanol solvent exchange. To ensure the relevance of our smoke extract in a neurotoxic context, we applied two biophysical techniques to characterize particle size, transmission electron microscopy (TEM) and dynamic light scattering (DLS). Wildtype (WT) astrocyte-enriched mixed glial cultures were established from murine neonates and subsequently dosed with smoke extract at half-log concentrations spanning 1-1000 ng/mL. These cells were assessed for cytotoxicity using a permeability-based cell viability assay. To further probe the effect of sub-lethal smoke exposure on astrocytic STING activation, we applied high content immunofluorescence microscopy and deep learning-based image analysis. Additionally, we performed RNAseq on smoke-exposed cells compared to vehicle controls to establish patterns of transcriptomic disruption induced by this toxicant. We next employed a mouse strain with genetic STING ablation (STINGgt) to assess the extent of STING involvement in response to smoke. We compared cytokine and chemokine secretion patterns in WT and STINGgt culture supernatant via the Luminex multiplex immunoassay platform. Lastly, to assess the relevance of astrocytic reactivity to neurodegeneration, we exposed primary cortical and hippocampal neurons to glial conditioned media (GCM) from smoke-treated WT and STINGgt glial cultures. **Results:** TEM analysis resulted in an ultrafine particle size of 60.89 nm ($\pm$ 21.02) and fine particle size of 541.4 nm ($\pm$ 280.4) which was corroborated by DLS with ~90% of the sample particle size at 81.70 nm ($\pm$ 13.02) and ~10% of the particle size at 466.8 nm ($\pm$ 123.1), well within the accepted range of particles capable of direct, olfactory transport to the central nervous system. We next established the LD50 [smoke] in glia to be 747.5 ng/mL at 12 hours of exposure, preceding the doubling time of these cells. We further applied sub-lethal smoke to characterize astrocytic STING activation, reporting significant increase in the number of astrocytic perinuclear pSTING+ foci and nuclear pIRF3+ area via trained machine learning network analysis. Transcriptomic analysis revealed changes in gene expression (603 DEGs, 670 ⁻ DEGs) that mapped to pathways of immune cell recruitment and communication as well as central protein-protein interaction hubs of Tnf and Il1b. We then examined toxicologic endpoints in STINGgt cultures, and report an inability to calculate the LD50 [smoke] for the same dose range due to a strong protective effect of genetic STING ablation. Further, we observed significantly less nuclear pIRF3 signal and TNF- α , IL-6, IFN- γ , and CxCl1 release in the GCM of STINGgt cells. Lastly, WT smoke GCM induced substantially greater neurotoxicity (~50%) when compared to vehicle GCM or STINGgt smoke GCM (~25%) treatments. **Conclusions:** These data suggest that WFS exposure elicits acute glial cytotoxicity and glial-induced neurotoxicity which appear to be mediated through STING signal transduction. This work motivates subsequent assessment of the role that wildfire smoke exposure plays in STING-induced glial reactivity and neuroimmune crosstalk *in vivo* to further parse out relevance of these phenomena to the phenotypes of neurodegeneration.

PS 3791 Protective Effects of the Rho-Kinase Inhibitor Fasudil Against Wildfire Smoke-Induced Neuroinflammation at the BBB

B. Baird¹, M. MazlumiBakhshayesh¹, J. R. Carter¹, J. L. Moreno¹, A. Schuller², A. Briggs², M. Hager², M. Olewine³, E. Barr¹, J. G. Begay¹, S. Noor¹, and M. J. Campen¹. ¹University of New Mexico, Albuquerque, NM; ²Colorado State University, Fort Collins, CO; and ³University of California Los Angeles, Los Angeles, CA.

Background and Purpose: Wildfires across the United States have steadily increased over the past 40 years. Smoke from wildfires can cause cardiovascular and respiratory diseases, with new studies highlighting potential neurological outcomes¹. The purpose of the following studies are to delineate the dynamics of peripheral immune populations in response to woodsmoke, the mechanism of infiltration into the brain, and the treatment options available. This study is the first to deliver a comprehensive timeline of neuroinflammation following wildfire smoke inhalation, collecting tissue from animals 1, 14, and 28 days after exposure. Air pollution has previously shown to impact the blood-brain barrier which serves an essential role in mitigating neuroinflammation. Therefore, we introduced the Rho-kinase inhibitor fasudil to strengthen this barrier and demonstrate an endothelial-dependent mechanism of peripheral immune infiltration. **Methods:** Fasudil was administered via osmotic mini pumps which provide a consistent dose over 21 days. Mice are exposed to either filtered air or a woodsmoke exposure (0.5mg/m³ every other day for 14 days, 4hr/day). Timeline studies will follow these mice over the course of exposure, and extend past 1, 14, and 28 days after exposure. Left hemispheres will be collected for high dimensional flow cytometry analysis using the Aurora Cytex. Markers for peripheral immune infiltration included T cells (CD3, CD4, CD8), adhesion molecules (VCAM, ICAM) resident immune cells (CD11b, TMEM119, ACSA-2) and other inflammation-dependent markers. **Results:** Results demonstrate the presence of CD4 T cells in response to woodsmoke inhalation and the decrease of this population over time. VCAM and ICAM expression also showed similar trends, peaking 1 day after our 14 day exposure paradigm. Treatment with fasudil demonstrates the depletion of VCAM expression which indicates the endothelial-dependent nature of woodsmoke-induced neuroinflammation. Results were conferred with immunofluorescent imaging of the hippocampus with analysis of astrocytes, microglia, and presence of albumin. Albumin levels were elevated with woodsmoke exposure, indicating a leaky blood-brain barrier. Activated astrocytes, quantified via GFAP, and microglia, quantified via Iba-1, were also elevated after exposures. Fasudil lowered levels of albumin in the brain as well as levels of activated astrocytes and microglia. **Conclusions:** Overall, we demonstrate the ability of woodsmoke to cause indirect neuroinflammation through the recruitment of peripheral immune populations. We also observed a

blood-brain barrier dependent mechanism of neuroinflammation through albumin leakage and glial activation. Further research detailing the mitigation of toxicity could lead to public health-based recommendations following air pollution events.

PS 3792 Wildfire Smoke-Induced Neurotoxicity and the Role of Ovarian Hormone Signaling

K. E. Zychowski, S. Yazzie, E. Lim, M. Oh, T. Vue, E. Prossnitz, S. Leng, and J. Gillette. University of New Mexico, Albuquerque, NM.

Background and Purpose: Wood smoke (WS) from wildfires is a growing public health concern due to the increase in extreme weather events and drier climates. Neurological sequelae following wood smoke (WS) exposure an expanding area of study. Wood smoke from wildfires is known to contribute to a range of adverse health outcomes, and growing evidence points to significant neurological and neuroinflammatory effects. Current research has begun to explore how WS impacts the aging brain, yet an important gap remains: little is known about how endocrinological phenotypes that commonly co-occur with aging may influence toxicological susceptibility. **Methods:** In these studies, we exposed mice (n=10/ group) to an acute WS protocol (~0.5mg/m³), compared to filtered air (FA, controls). We compared: 1) male and female mice 2) Sham and OVX mice and 3) mice subjected to accelerated ovarian failure using the 4-vinylcyclohexene diepoxide (VCD) mouse model and 4) WT and GPER^{-/-} mice. **Results:** Emerging data from our lab has determined that wood smoke exposure statistically significantly increases pro-inflammatory cytokines in the brain such as IL-6, CXCL-1 and TGF- β (p<0.05), in male mice, but not ovary-intact females following acute WS exposure, based on a 2x2 factorial ANOVA. On the other hand, ovariectomized females ((OVX), ovarian hormone deplete mice) demonstrated a statistically significant (p<0.05) increase in CCL-2 and CXCL-1 in the brain, compared to Sham females. In a mouse model of accelerated ovarian failure, we found significant (p<0.05) single-cell transcriptomic alterations in astrocytes, oligodendrocytes, cholinergic and glutamatergic neurons following acute WS exposure. Preliminary data from our laboratory suggests that ovarian hormones, estradiol and progesterone, and g-coupled protein estrogen receptor (GPER) may mediate neurovascular sequelae, based on laser speckle imaging following acute WS exposure. **Conclusions:** The sum of these data suggested a robust mechanistic role of ovarian hormones, that naturally decline with age in females, via GPER on neuroinflammatory and neurovascular responses following acute WS exposures.

PS 3793 Disrupted GABAergic Signaling and Microglial Activation Underlie Behavioral Disinhibition in a Preclinical Model of Gulf War Illness

A. Trivedi, S. Roy, M. More, S. Sarkar, R. Kumar, and S. Chatterjee. University of California, Irvine, Irvine, CA.

Background and Purpose: Gulf War Illness (GWI) is a chronic multisymptomatic disorder affecting veterans of the 1991 Gulf War, characterized by neuroinflammation, cognitive impairment, and altered affective and social behaviors. Exposure to the acetylcholinesterase inhibitor, pyridostigmine bromide (PB) and the insecticide permethrin (PER) has been implicated as a key environmental trigger underlying long-term central nervous system alterations. Prior studies, including work from our laboratory, have reported a loss of blood-brain barrier (BBB) integrity in preclinical models of GWI, facilitating the entry of danger-associated molecular patterns (DAMPs) such as high-mobility group box 1 (HMGB1) into the brain and initiating a neuroinflammatory cascade. However, the contribution of peripheral immune cells, particularly infiltrating T lymphocytes in driving microglial activation and subsequent neuronal dysfunction remains poorly understood. Further, the impact of these exposures on social behavior and mechanisms for inhibitory control also remains poorly defined. To address these gaps, the present study investigates how combined PB and PER exposure influences T cell-microglia interactions, inhibitory control, and social behavior in a preclinical mouse model of GWI. **Methods:** Adult C57BL/6J mice were administered PB (2 mg/kg body weight) and PER (200 mg/kg body weight) orally, every other day for a month along with restraint stress for 10 minutes, while control mice received vehicle (0.6% DMSO in PBS). Mice were then maintained Post 7 months of exposure, behavioral assays were performed including the Elevated Plus Maze (EPM) to assess anxiety/disinhibition, the Rotarod test for motor coordination, and the Three-Chamber Social Interaction test to evaluate sociability and social novelty preference. The animals were euthanized and blood, vital organs such as small intestine, liver, kidneys and brain. Molecular techniques such as western blotting, immunohistochemistry, immunofluorescence and ELISA were accessed to evaluate markers associated with GABAergic synaptic (GAD65/67) and microglial activation markers (IBA1, CD68). **Results:** Behavioral assessments revealed significant alterations in anxiety-related and social behaviors in GWI chemical exposed mice compared to controls. In the Elevated Plus Maze (EPM), GWI-exposed mice spent a greater proportion of time in the open arms, indicative of behavioral disinhibition. This behavioral pattern suggests a role of possible impaired inhibitory control and increased risk-taking or hyperactivity behavior in GWI mice rather than true anxiolytic effects. In the Rotarod test, GWI-exposed mice demonstrated a prolonged latency to fall relative to control animals. While this might indicate improved motor coordination, in the context of their disinhibited phenotype, the increased latency likely reflects altered motor responsiveness. In the three-chamber test, exposed mice showed differential social

preference, spending comparable time in social and non-social chambers, indicative of altered sociability than controls. Preliminary molecular analyses revealed altered expression of GABA-synthesizing enzymes GAD65 and GAD67, indicating compromised inhibitory neurotransmission. This was accompanied by increased microglial activation, as evidenced by elevated IBA1 and CD68 immunoreactivity within the prefrontal cortex and hippocampus regions critical for behavioral regulation and social processing. Collectively, these findings suggest that chronic PB and PER exposure induces persistent neuroinflammation and alteration of GABAergic inhibitory tone, contributing to the observed behavioral disinhibition and social deficits in GWI mice. **Conclusions:** Combined PB and PER exposure induces persistent behavioral disinhibition and social deficits in mice, accompanied by altered GABAergic signaling and microglial activation in brain regions regulating social behavior. These findings support the hypothesis that neuroinflammation-driven loss of inhibitory tone contributes to social and cognitive dysfunction in GWI, providing mechanistic insight into the underlying long-term neurological sequelae of Gulf War toxicant exposure.

PS 3794 Sex-independent dopaminergic and region-specific amino acid neurotransmitter dysregulation across brain regions in two Gulf War Illness mouse models

T. P. Kalinowski¹, B. T. Hudson¹, J. M. Carpenter¹, F. Tejadon-Rojas¹, J. J. Wagner¹, D. A. Harn¹, T. Norberg², and N. M. Filipov¹. ¹University of Georgia, Athens, GA; and ²Uppsala University, Uppsala, Sweden.

Background and Purpose: During the 1990-1991 Persian Gulf War, soldiers were exposed to toxicants such as: pyridostigmine bromide (PB), permethrin (PM), N,N-Diethyl-meta-toluidine (DEET), and sarin. After, 25-30% of the 700,000 soldiers, of which 49,000 were women, developed Gulf War Illness (GWI), a chronic, multi-symptom illness, with many exhibiting memory, mood, and cognitive deficits potentially linked to neurochemical dysregulation. GWI exposure exhibits dopaminergic and serotonergic dysregulation in the ventral hippocampus (VHIP), striatum (STR) and prefrontal cortex (PFC). However, these findings remain limited, primarily acute, with sex differences in cognitive and mood deficits being unexplored at a neurochemical level. To address this and account for female veterans, sex-specific neurotransmitter changes were investigated using high-performance liquid chromatography with electrochemical detection (HPLC-ECD) and western blot of limbic and striatal regions in two preclinical GWI models. **Methods:** Eight-week-old male and female C57BL/6J mice were exposed to Gulf War chemicals; The first model (PB/PM) exposed mice to 0.7mg/kg PB and 200mg/kg PM or vehicle DMSO, via daily intraperitoneal (IP) injections for 10 days. The second model (PB/DEET/CORT/DFP) mice were exposed to daily subcutaneous injections of 2 and 30 mg/kg of PB and DEET respectively, or vehicle saline for 14 days. On days 8-14, mice were also administered corticosterone (CORT) via drinking water (200 mg/L in 1.5% EtOH/H₂O) *ad libitum*; control mice were given 1.5% EtOH vehicle water during this period. On day 15 mice underwent a single IP injection of 3.75 mg/kg of the sarin surrogate: diisopropyl fluorophosphate (DFP) or vehicle saline. After 9 months post-exposure, mice were euthanized, and brains were collected and analyzed for neurochemical changes in five regions: the PFC, STR, dorsal hippocampus (DHIP), VHIP, and lateral septum (LS). Tissue samples were analyzed using HPLC-ECD to quantify monoamine and amino acid neurotransmitter analytes: 3-methoxytyramine (3-MT), 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), dopamine (DA), serotonin (5-HT), 5-hydroxyindoleacetic acid (5-HIAA), norepinephrine (NE), glutamine (GLN), L-glutamate (GLU), and gamma-aminobutyric acid (GABA). Neurotransmitter homeostatic and synaptic function-related proteins were analyzed via western blot probing for tyrosine hydroxylase, dopamine transporter, synaptophysin, vesicular monoamine transporter 2 and PSD-95 in the PFC, STR, and VHIP normalized to β -actin. **Results:** Global effects, model-specific, and sex-specific neurochemical effects of GWI were observed. Modulation of DA and/or its metabolites was evident in both sexes and models in all regions of interest, excluding the DHIP. Hippocampal GABA was decreased in males, while PFC 5-HT increased independent of GWI model. Male PB/PM-specific inhibitory/excitatory (I/E) neurotransmitter perturbations were observed, specifically, decreased GABA in the STR and increased GLU in the PFC. PB/PM also decreased 5-HT and/or its metabolite was prevalent in DHIP, VHIP, and STR. PB/DEET/CORT/DFP GLN in limbic structures was significantly reduced independent of sex. PB/DEET/CORT/DFP-specific DHIP DA dysregulation was sexually dimorphic increasing and decreasing in females and males, respectively. **Conclusions:** Overall, GWI-induced neurochemical dysregulation was more prevalent in male mice. Brain neurotransmitter and protein concentrations 9 months following PB/PM exposure reflect a neuroenvironment consistent with tonic shifts in activity in the PFC, STR and VHIP, while PB/DEET/CORT/DFP induced dopaminergic depletion in the STR and PFC. Male hippocampal GABA depletion impacts I/E balance and may drive memory and mood perturbations observed in preclinical models. The combination of region-specific neurotransmitter and protein dysregulation mirrors symptoms of memory recall deficits, depression, anxiety, and post-exertional malaise still reported by veterans with GWI. This underscores heterogeneity in symptom severity following the Gulf War with respect to soldiers' sex and severity of toxicant exposure; both must be considered in the development of efficacious therapeutics.

M. A. García-Marés¹, S. E. Preston¹, H. M. McMurrin¹, L. E. Dean², H. J. Lehmler², and J. A. Doorn¹. ¹University of Iowa College of Pharmacy, Iowa City, IA; and ²University of Iowa College of Public Health, Iowa City, IA.

Background and Purpose: Polychlorinated biphenyls (PCBs) are persistent environmental toxicants linked to developmental neurotoxicity. Inhalation exposure to lower-chlorinated congeners, such as PCB52, is increasingly recognized as a current route of human exposure. Critical gaps remain regarding how PCB52 perturbs glial bioenergetics and redox signaling. This study investigates whether PCB52 and its hydroxylated (4-OH-PCB52) and sulfated (4-OH-PCB52-S) metabolites induce mitochondria-centered toxicity in astrocytes and microglia, and whether astrocyte differentiation enhances susceptibility. **Methods:** C6 astrogloma cells were differentiated with dibutyl- α -cAMP/theophylline. Differentiation was validated by increased GFAP immunofluorescence. Viability (MTT, CellTiter-Blue) was measured in glucose and, to force oxidative phosphorylation (OXPHOS), galactose media to derive IC50 values. BV-2 microglia were assayed in parallel. Cellular ATP was quantified under glucose vs galactose conditions. Oxidative/nitrosative stress was imaged in differentiated C6 and primary rat astrocytes by CellROX (general ROS), MitoSOX (mitochondrial superoxide), and DAF-FM (NO/RNS; DEA-NONate positive control). BV-2 TNF- α output was benchmarked to LPS/IFN- γ . **Results:** Differentiation increased astrocyte susceptibility, with a potency order of 4-OH-PCB52 > 4-OH-PCB52-S > PCB52. In C6 cells, IC50 values (μ M) shifted from 11.7 to 12.1 (PCB52), 3.1 to 2.1 (4-OH-PCB52), and 8.9 to 4.7 (4-OH-PCB52-S) in undifferentiated vs differentiated cells, indicating a differentiation-linked vulnerability most pronounced for the hydroxylated metabolite. Mitochondrial dependence was evident in the glucose-to-galactose (Glc->Gal) paradigm and mirrored by ATP. For differentiated C6 in galactose, IC50 shifted to 10.1 μ M (PCB52), 0.9 μ M (4-OH-PCB52), and 2.1 μ M (4-OH-PCB52-S). Correspondingly, cellular ATP declined sharply in galactose, with a collapse near ~2 μ M 4-OH-PCB52 in both differentiated C6 and BV-2 cells, aligning temporally with loss of viability and pointing to OXPHOS liability rather than nonspecific cytotoxicity. BV-2 microglia followed the same potency order as differentiated C6 cells but were modestly more tolerant (IC50, μ M: PCB52 10.3, 4-OH-PCB52 3.0, 4-OH-PCB52-S 8.7). Despite the viability drop with 4-OH-PCB52, TNF- α release remained low relative to LPS/IFN- γ , suggesting that early mitochondrial stress is not tightly coupled to acute pro-inflammatory responses. Imaging corroborated a mitochondria-centric mechanism. In differentiated C6, CellROX revealed widespread ROS with PCB52 and 4-OH-PCB52-S, while MitoSOX showed the strongest mitochondrial superoxide signal with 4-OH-PCB52 and moderate increases with PCB52 and its sulfate metabolite; menadione and antimycin behaved as expected positive controls. Primary rat astrocytes recapitulated these patterns, showing ROS/mito-ROS elevations with 4-OH-PCB52 (~4.7 μ M) and 4-OH-PCB52-S (~7 μ M). DAF-FM at 2 h detected punctate-to-perinuclear NO/RNS under 4-OH-PCB52 at IC50 and sub-IC50, exceeding vehicle and temporally coinciding with the early ATP drop; DEA-NONate produced the anticipated diffuse positive signal. **Conclusions:** Human-relevant PCB52 metabolites function as glial-directed mitochondrial stressors, with a clear astrocyte bias. 4-OH-PCB52 is the more toxic metabolite of PCB52, producing OXPHOS-dependent ATP loss, mitochondrial superoxide, and elevations in NO/RNS. BV-2 microglia are affected at slightly higher IC50 and exhibit limited immediate TNF- α production. Ongoing work will quantify electron-transport-chain liabilities in Glc->Gal conditions and implement HPLC-ECD dopamine uptake/turnover to functionally connect glial bioenergetic failure to neuron-relevant outcomes. This mitochondria-first framework underscores differentiated astrocytes plus Glc->Gal and DAF-FM/MitoSOX imaging as sensitive detectors of PCB52-metabolite toxicity.

PS 3796 Effect of silver nanoparticle related cytokine storm on neurons in insulin resistance state

A. Engin¹, F. Lebre², E. Alfaro-Moreno², O. Alp³, E. Engin⁴, and A. Engin⁵. ¹Gazi University, Faculty of Pharmacy, Department of Toxicology, Ankara, Turkey; ²International Iberian Nanotechnology Laboratory, Nanosafety Group, Braga, Portugal; ³Gazi University, Faculty of Pharmacy, Department of Analytical Chemistry, Ankara, Turkey; ⁴Dokuz Eylul University, Faculty of Medicine, Department of Microbiology, Izmir, Turkey; and ⁵Gazi University, Faculty of Medicine, Department of General Surgery, Ankara, Turkey.

Background and Purpose: A link has been established between Alzheimer's disease (AD) and type 2 diabetes, and these patients are at a higher risk of developing AD. The prevalence of insulin resistance and type 2 diabetes is increasing at alarming rates worldwide. However, it was exhibited that silver nanoparticles (AgNPs) attenuate diabetic complications and insulin resistance in experimental diabetes. The clinical association between type 2 diabetes and AD leads to the hypothesis that periphery-derived pro-inflammatory molecules could influence pathogenesis in the central nervous system (CNS). Resident macrophages undergo a phenotypic shift to the classically activated proinflammatory type (M1) in high glucose and insulin containing medium of uncontrolled type 2 diabetes. Cytokines at high levels in AD-induced microvessels are not found in non-AD cerebral microcirculation and this was thought to contribute to the pathogenesis of neuronal injury and death in AD. AgNPs are known to penetrate to the brain and cause neuronal death. AgNP cytotoxicity is mainly dependent on the release of Ag⁺ ions. However, it is unknown

whether peripheral macrophages contribute to the detoxification of AgNP in the luminal compartment of the blood-brain barrier (BBB) and reduce the neuronal damage in the brain. The aim of this study was to explore the AgNP related alterations in the cytokine release and respective neuronal damage in insulin resistance state. **Methods:** Triple co-culture BBB model was established by seeding U937 macrophages and HBEC-5i endothelial cells into the luminal compartment and SH-SY5Y cells into the abluminal compartment. The cell culture model was treated with 250 mg/dL high glucose, 40 uU/mL insulin and 100 ng/mL AgNP either alone or in combination for 48 h. Thirty-three cytokines were measured by using multiplex assay in the supernatants, after a 48-h incubation period in a triple coculture. The cytokine levels obtained in medium containing with or without high glucose, insulin and AgNP were compared. The effects of AgNP exposure on cell viability and oxidative stress in coculture and single cell culture of SH-SY5Y neurons were compared with cytokine levels in insulin resistance state. **Results:** With the addition of AgNP to the medium, 12 cytokines were reduced in the luminal compartment, while the IL1Ra/IL1 β ratio decreased by 8%. In the abluminal compartment, MIP1 β , IL18, IP10, MCP1, IL15, IL1 β , and GM-CSF remained elevated, while the other five cytokines decreased. A 21% decrease was observed in the IL1Ra/IL1 β ratio. **Conclusions:** U937 cells, which represent the peripheral macrophages, weakened AgNP related neurotoxicity by coating the surface of nanoparticles with silver sulfide by probably increasing the cystathionine- γ -lyase (CSE)-mediated H₂S. Thus, all cytokine levels decreased in luminal compartment subsequent to AgNP exposure. All cytokines transported through the BBB, which was disrupted due to hyperglycemia, and reduced the inflammation index (IL1Ra/IL1 β) in the abluminal compartment by 21%. Coincidentally, oxidative stress decreased by 75%, while neuronal survival increased 3.7-fold. (This study was partially supported by TUBITAK, projects 214S112 and 112S437)

PS 3797 Acute neurotoxic effects of plastic antioxidant degradation products in rat cortical neurons

H. Kang^{1,2}, and R. H. Westerink². ¹LyondellBasell, Rotterdam, Netherlands; and ²Division of Toxicology, Faculty of Veterinary Medicine, Institute for Risk Assessment Sciences (IRAS), Utrecht University, Utrecht, Netherlands.

Background and Purpose: Owing to their affordability and versatility, plastics have become integral to modern life. Plastics are extensively used in modern day products such as electronics and clothes. To enhance the durability and longevity of plastics additives are added, including antioxidants. Without additives, plastics would degrade more rapidly under prolonged exposure to stress factors, such as heat, UV-light, and mechanical wear. Antioxidants in plastics prevent oxidation by sacrificing themselves to neutralize free radicals, resulting in the formation of Antioxidant By-Products (ABPs). Given the widespread applications of plastics, humans are exposed to plastic degradation products including ABPs. There is currently a data gap in understanding the potential health impacts, especially neurotoxic effects of ABPs. Hence, the aim of this study was to investigate the acute neurotoxic effects of ABPs on rat cortical neurons. **Methods:** Effects on cell viability experiments were determined using an Alamar blue assay following exposure of rat cortical cells for 21 days, 48 hrs and 30 minutes to ABP 1-10 at concentrations of 0.01, 0.1, 1, 10 and 100 μ M. Additional experiments were performed using 48-well microelectrode array (MEA) plates to record changes in spontaneous neuronal activity evoked by acute exposure to ABPs. Cells were seeded at a density of 1×10^5 cells/well. Baseline neuronal activity was recorded on day 11 for 30 minutes using the Maestro Pro™ system. Following baseline recording, cells were exposed to ABPs at concentrations between 0.01 - 100 μ M, with an additional 30 minute recording. Data acquisition was controlled by Axion's Integrated Studio (AxIS version 2.6). Raw data was pre-processed to generate spike files. Spike detection was performed with AxIS's spike detector, and the results were further analyzed using the Neural Metrics Tool (v3.1.7, Axion BioSystems) and custom Excel macros. To investigate a potential mechanism of action, acetylcholinesterase (AChE) enzyme was measured. The enzyme solution was combined in a 48-well plate with or without exposure to ABP and incubated for 30 minutes, followed by addition of DTNB solution. Next, 6 mM acetylthiocholine was added to each well, and absorbance was measured at 436 nm for 10 minutes. ABPs 1, 2, 3, 4, 6, 7, 9, and 10 were purchased commercially, while ABPs 5 and 8 were synthesized and provided by LyondellBasell, as they are not commercially available. **Results:** ABPs 1, 2, 3, 5, 7, 8, 9, and 10 did not induce cytotoxic effects after 21 days of exposure, although significant reductions in cell viability were observed at 100 μ M for ABPs 4 and 6. Following a shorter 48-hour exposure, no cytotoxic effects were noted for ABP 6, while ABP 4 exhibited a significant decrease in cell viability at 100 μ M. Finally, no cytotoxic effects were observed for ABP 4 at any tested concentration after a 30-minute exposure. With respect to changes in neuronal activity, a significant reduction in the numbers of recorded spikes was observed at 100 μ M for ABP 1, 2, 3, 8 and 9. For ABP 4, a reduction in the number of spikes was observed at both 10 and 100 μ M, which was associated with a reduced number of bursts and network bursts. In contrast, ABP 5 and 7 increased the number of spikes at 10 and 100 μ M, while ABP 6 and 10 did not appear to affect neuronal activity. The changes in the number of spikes were often associated with comparable changes in the number of bursts and network bursts. AChE experiments showed an inhibition of AChE only by ABP5 (IC₅₀: 59 μ M), while the remaining ABPs did not affect AChE activity. **Conclusions:** Acute exposure to ABPs at concentrations between 10 and 100 μ M resulted in either reduced (ABPs 1, 2, 3, 4, 8, and 9) or increased (ABPs 5 and 7) spontaneous neuronal activity. The numbers of spikes, bursts, and network bursts were the most significantly affected parameters. ABP 5 was the only compound that inhibited acetylcho-

linesterase (AChE) activity. These novel neurotoxicological findings suggest that exposure to ABPs at high concentrations may adversely affect neuronal function and potentially pose a risk to human brain health.

PS 3798 A Human iPSC-Based Platform for Functional Toxicity Screening of CNS-Targeted RNA Therapeutics

K. Pitsa, J. Koepke, B. Samson-Couterie, S. Schwengberg, T. Smith, and S. Jain. Ncardia, Leiden, Netherlands.

Background and Purpose: Human induced pluripotent stem cell (iPSC)-derived neural co-cultures represent an advanced *in vitro* model that recapitulates key structural and functional features of the human central nervous system (CNS). Such models enable the study of neuron-glia interactions and provide a more physiologically relevant context compared to traditional cell lines or animal-derived systems. Given the growing therapeutic interest in antisense oligonucleotides (ASOs) and the ongoing concerns regarding their potential CNS toxicity, iPSC-derived neural co-cultures offer a valuable platform to evaluate ASO safety, elucidate mechanisms of neurotoxicity, and support the development of safer oligonucleotide-based therapeutics. **Methods:** Building on evidence that ASO-induced neurotoxicity correlates with suppressed calcium transient activity and altered electrophysiology *in vivo*, we sought to develop complementary *in vitro* functional assays to better characterize ASO effects on neuronal activity. To this end, we established high-throughput calcium imaging and multi-electrode array (MEA) platforms containing human iPSC-derived neurons and astrocytes. The calcium imaging assay enables quantitative evaluation of spontaneous calcium transients, providing insights into network excitability and functional integrity, while the MEA assay allows for real-time monitoring of electrical activity across neuronal networks. Together, these physiologically relevant and scalable systems facilitate comprehensive assessment of ASO-induced functional perturbations and support early identification of potential neurotoxic liabilities. **Results:** Under vehicle conditions, key metrics—peak rate (0.15-0.25 Hz), amplitude ($\Delta F/F \sim 1.5\%$), and oscillation score (80-100%)—demonstrated <15% inter-well coefficient of variation, supporting assay reproducibility. Screening of 70 preclinical candidates, we classified ASOs into three categories: (1) highly toxic ASOs causing >60% suppression of calcium oscillation scores with no recovery—correlating with seizures and convulsions *in vivo*; (2) ASOs with partial recovery (20-30%) over 15 minutes—associated with milder behavioural phenotypes; and (3) non-toxic ASOs maintaining normal calcium activity even at 100 μM . Across candidates, *in vitro* calcium scores demonstrated ~80% correlation with rodent CNS toxicity. Furthermore, multi-electrode array (MEA) recordings were employed to quantify ASO-mediated alterations in neuronal network functionality by assessing spike amplitude, network burst frequency, and network burst interval. In alignment with calcium imaging results, a subset of ASOs elicited a pronounced decrease in spike amplitude concomitant with an increase in burst frequency, indicative of enhanced neuronal firing and network hyperexcitability. Conversely, other ASOs induced a pronounced “toxic” electrophysiological signature, characterized by substantial attenuation of spike amplitude and a >50% reduction in network burst frequency, consistent with disrupted synaptic integration and impaired action potential propagation within the neuronal network. Additionally, we used the platform to guide sequence modifications that reduced toxicity. One optimized ASO showed an improved calcium oscillation score of approximately 40% without loss of efficacy, confirming its utility for early-stage screening and structure-activity relationship optimization. **Conclusions:** This iPSC-based platform enables scalable, human-relevant, functional screening of ASO neurotoxicity, supporting the development of safer CNS-targeted RNA therapeutics.

PS 3799 Cyclopiazonic acid downregulates oxidative stress-related genes in SH-SY5Y human neuroblastoma cells

C. Martínez-Alonso, M. Ruiz, and Y. Rodríguez Carrasco. Faculty of Pharmacy. University of Valencia, Burjassot-Valencia, Spain. Sponsor: A. Anadón

Background and Purpose: Cyclopiazonic acid (CPA), a neurotoxin produced by fungi from the *Penicillium* and *Aspergillus* genera, triggers oxidative stress and neuronal injury, processes closely associated with the development of neurodegenerative diseases. This study investigates the oxidative stress induced by CPA in SH-SY5Y human neuroblastoma cells, focusing on the transcriptional regulation of key antioxidant and redox-related genes. **Methods:** SH-SY5Y cells were exposed to increasing concentrations of CPA (400, 500 and 600 nM) for 24 h. Total RNA was extracted using the RNeasy Prep™ RNA Cell Miniprep System, quantified with a Nanodrop2000 spectrophotometer and reverse-transcribed into cDNA using the TaqMan™ MicroRNA Reverse Transcription Kit. Quantitative real-time PCR (qPCR) was performed with SYBR Green detection in a StepOne Plus Real-Time PCR System to analyze the expression of *nrf2*, *nos2*, *ho1*, *cat*, *keap1*, *nqo1*, *gpx1* and *gsr*. Primer specificity and efficiency were confirmed by melting curve and standard curve analyses. **Results:** CPA treatment resulted in a concentration-dependent downregulation of oxidative stress-related genes. At 600 nM CPA, *nos2*, *nqo1*, *ho1*, *gsr* and *nrf2* mRNA levels decreased by 93%, 83%, 79%, 78% and 68%. *Gpx1* and *cat* showed consistent repression across all concentrations. *Keap1* expression remained unchanged at 400 nM but decreased by 45% and 66% at 500 nM and 600 nM, respectively. **Conclusions:** In conclusion, CPA markedly suppresses the expression of genes involved in the

antioxidant defense system of SH-SY5Y cells, disrupting redox homeostasis and promoting oxidative imbalance. These findings suggest that CPA-induced disruption of redox homeostasis could contribute to neuronal vulnerability observed in neurodegenerative disorders. **Acknowledgments:** This research was funded by MICIU/AEI /10.13039/501100011033/ FEDER, UE through the project PID2024-1605270B-I00. C. Martínez Alonso thanks the F.P.U. Grant (FPU21/04950) provided by the Ministry of Education. **Keywords:** cyclopiazonic acid, oxidative stress, SH-SY5Y cells, qPCR.

PS 3800 Evaluation of pesticide- and mycotoxin-induced cytotoxicity in differentiated SH-SY5Y spheroids using a reproducible 3D microchip model

F. Franco-Campos, M. Taroncher, Y. Rodríguez-Carrasco, and M. Ruiz. Faculty of Pharmacy. University of Valencia, Burjassot-Valencia, Spain. Sponsor: A. Anadón

Background and Purpose: Three-dimensional (3D) cell cultures have advanced considerably in recent years, offering greater physiological relevance to *in vivo* systems than traditional two-dimensional (2D) models. These spheroidal cultures improve extracellular matrix organization, nutrient and oxygen gradients, and inter-cellular communication, providing more accurate tools for toxicological assessment. Current efforts focus on enhancing their sensitivity and reproducibility to better mimic *in vivo* conditions. The SH-SY5Y neuroblastoma cell line remains a key model in neurotoxicology due to its ability to differentiate into cholinergic or dopaminergic phenotypes, enabling the evaluation of neuronal damage induced by environmental contaminants such as pesticides and mycotoxins found in food matrices. **Methods:** Based on our previously established model of differentiated SH-SY5Y spheroids, we will generate 3D neuronal spheroids using Honeycomb Cell Spheroid Chips (394 microwells per chip) to ensure high reproducibility. After 22 days of differentiation under previously optimized conditions, spheroids will be exposed to the pesticides Amitraz and Chlorpyrifos, and the T2 mycotoxin. Oxidative damage will be assessed by measuring intracellular and mitochondrial reactive oxygen species (ROS) with CellROX™ and MitoSOX™, together with mitochondrial membrane potential ($\Delta\psi\text{m}$) evaluation using Rhodamine-123. Additionally, apoptosis and necrosis will be quantified by flow cytometry, and changes in neuronal enzymes such as acetylcholine transferase (ChAT) will be analyzed to identify potential alterations in neuronal functionality. **Results:** The generated cholinergic SH-SY5Y spheroids showed high reproducibility and stability, maintaining a uniform morphology and consistent size distribution with a sphericity index (SI) above 0.9 across replicates. Preliminary viability assays revealed reproducible dose-response curves, with IC_{50} values within the range previously reported for other human cell lines in 3D models, confirming the reliability of the established system. When evaluated individually, each contaminant induced a dose-dependent increase in reactive oxygen species (ROS). Similarly, late apoptosis rates increased in a dose-dependent manner after 24h after exposure. Furthermore, changes in the expression of acetylcholine transferase, key enzyme essential for acetylcholine synthesis and marker of the cholinergic neuronal phenotype demonstrated possible alterations in neuronal integrity function. **Conclusions:** Differentiated 3D SH-SY5Y models more accurately mimic *in vivo* neuronal organization and function, establishing a sensitive and reproducible system for evaluating the cytotoxic potential of foodborne contaminants. The implementation of these microchip-based spheroidal cultures enhances model scalability and reproducibility, strengthening their applicability as advanced tools for regulatory and mechanistic toxicology. **Acknowledgments:** This research was funded by MICIU/AEI /10.13039/501100011033 / FEDER, UE through the project PID2024-1605270B-I00. F. Franco-Campos thanks to the scholarship “Santiago Grisolia (CIGRIS/2021/073)”.

PS 3801 Deoxynivalenol induces apoptosis through mitochondrial dysfunction in a 3D model of SH-SY5Y neural spheroids

M. Sánchez, J. Tolosa, and M. Ruiz. Faculty of Pharmacy. University of Valencia, Burjassot-Valencia, Spain. Sponsor: A. Anadón

Background and Purpose: Deoxynivalenol (DON) is a type B trichothecene produced by *Fusarium* species, commonly found in cereals and derived products. It is one of the most prevalent mycotoxins worldwide, and exposure to it can cause damage to multiple organs, including the gastrointestinal tract, liver, kidneys, brain, and immune system. Most studies on DON toxicity have been conducted using two-dimensional (2D) cell cultures, which do not adequately reproduce the cellular microenvironment. For this reason, three-dimensional (3D) models have emerged, as they better reflect cellular architecture and cell-cell interactions, making them more suitable for studying the cytotoxicity of mycotoxins. This study aimed to evaluate the effects of DON on mitochondrial function, reactive oxygen species (ROS) generation, and apoptosis activation in SH-SY5Y spheroids. **Methods:** SH-SY5Y spheroids were exposed to different concentrations of DON (2-16 μM) for 24 hours. Apoptosis and necrosis were assessed by flow cytometry using Annexin V-FITC/PI staining. The expression of apoptosis-related proteins (BAX, Bcl2 and caspase-3) was analyzed by Western blot, using β -actin as a loading control. The mitochondrial membrane potential ($\Delta\psi\text{m}$) was determined by rhodamine 123 (Rh123) fluorescence, and ROS generation was measured by flow cytometry using the CellROX reagent. **Results:** Flow cytometry analysis showed a significant increase in early apoptosis at 16 μM DON. Western blot results revealed an overexpression of the pro-apoptotic protein BAX, along with the

appearance of cleaved active fragments of caspase-3, confirming the activation of apoptotic pathways. Moreover, a loss of $\Delta\Psi_m$ was observed between 2 and 16 μ M. Finally, no increase in ROS was observed at any of the DON concentrations evaluated. **Conclusions:** It has been demonstrated that ROS do not contribute to the mitochondrial dysfunction produced by DON in SH-SY5Y spheroids. However, a direct effect on the mitochondrial membrane was observed, resulting in a loss of $\Delta\Psi_m$ and, consequently, the activation of apoptotic pathways. These findings highlight the relevance of 3D spheroid models as physiologically representative systems for studying mycotoxin toxicity. **Acknowledgments:** This research was funded by MICIU/AEI/10.13039/501100011033/FEDER, UE through the project PID2024-160527OB-I00. Martina Sánchez acknowledges the Generalitat Valenciana for the Santiago Grisolia Fellowship (CIGRIS/2023/071). **Keywords:** apoptosis, mitochondrial dysfunction, 3D neural spheroids, neurotoxicity

PS 3802 Effects of brevetoxin exposure on zebrafish novel object recognition capabilities

M. Hammontree, H. Paz, A. Stafford, and W. Hayes. Florida College, Temple Terrace, FL.

Background and Purpose: Brevetoxins are known to cause harmful effects on vertebrates, including humans. These effects manifest themselves most commonly as upper respiratory symptoms such as nasal congestion, throat irritation, cough, and eye irritation. However, brevetoxin's neurological and cognitive effects on humans have not been studied extensively. A standard measurement of a vertebrate's cognitive activity is the novel object recognition test (NORT). Zebrafish (*Danio rerio*) exhibit anxiolytic behavior when presented with a novel object, indicating the recognition of something new and potentially threatening in its environment. Reduction of this behavior when exposed to brevetoxin indicates alterations to fish cognitive functions, which could have further implications for humans living in areas such as the Gulf Coast of Florida, which experience large brevetoxin releasing algal blooms. **Methods:** A novel object recognition test (NORT) was used to explore the effects that brevetoxin (PbTx-2) may have on cognitive ability since these tests serve as a proxy for measuring memory capabilities. We exposed male and female adult zebrafish (Female-15, Male-16) to 10, 12.5 and 15 nM PbTx-2 solutions and then allowed them to explore a testing tank with a familiar and novel objects on opposite sides of the tank. Results were recorded using EthovisionXT animal tracking and recording software. Mean time within a zone of proximity to each object, and latency to approach each object was recorded, and t-tests compared fish object preference before and after exposure to brevetoxin. Data on animal velocity, acceleration, and total distance moved were also collected. **Results:** There were trends in time around novel objects compared to familiar objects and the latency in which the fish approached the objects, but there were no statistical differences between control and intoxicated groups. Brevetoxin-exposed fish spend more time in proximity to both novel and familiar objects than nonexposed control fish. The data also revealed tangential trends of PbTx-2 on fish locomotion in that the intoxicated fish showed increased swimming velocity and total distance moved yet decreased acceleration compared to control fish. **Conclusions:** Overall, while none of the differences were statistically significant, trends indicate that brevetoxin exposure made the fish less anxious about the objects as they spent more time near novel and familiar objects after exposure to the toxin. We did let the fish wait 5 minutes between trials in a holding tank and previous literature suggests that is the limit of their object discrimination memory. New trials with a shorter inter-trial wait time will be performed in the future.

PS 3803 Zebrafish behavioral profiling as a tool for neuroactivity and neurotoxicity prediction

P. C. Santos¹, E. Bianchi¹, C. Koenig¹, A. Toltin¹, and M. McCarroll². ¹Corteva Agriscience, Indianapolis, IN; and ²University of California San Francisco, San Francisco, CA.

Background and Purpose: The successful assessment of an agrichemical requires extensive toxicological testing in mammals, including evaluation of neurotoxicity, which often occurs late in the product development pipeline and consists of higher tiered animal studies. Concern related to safety and late-stage project failure remains a challenge for discovery programs, hence it is pertinent to implement high-throughput predictive models for neurotoxicity. Additionally, discovery programs support the application of the 3Rs (Replacement, Reduction, and Refinement), by exploring *in vitro* new approach methodologies (NAMs) for predictive testing. Zebrafish assays leverage a complete physiological system and enable medium to high-throughput screening to investigate neuroactivity of compounds. To profile behavioral phenotypes of 7 days post fertilization (dpf) larvae, a unique battery of stimuli has been designed that exposes the animals to light or vibrational stimuli at various intervals on a custom-engineered system. This method has proven effective in identifying new small molecules in pharmaceutical classes such as antipsychotics, sedatives, and anesthetics. In prior collaboration, we demonstrated that the technique of behavioral profiling is sensitive to modes of actions of agrichemicals. Here we evaluate transferability of a multi-stimulus zebrafish behavioral assay to a commercial system and determine whether 5 dpf reproduces 7 dpf neuroactive phenotypes. **Methods:** To replicate the method of the custom engineered system (Sauron), a similar

sequence of light flashes, strobes, solenoid taps, and vibrations were programmed on a commercially available zebrafish behavioral system (Multi-camera array microscope (MCAM)). To assess initial transferability across systems and larval ages, 7 dpf and 5 dpf larvae were tested on the MCAM and Sauron to compare baseline response across systems. To test the ability of the MCAM system to respond appropriately to neuroactive compounds, 5 dpf zebrafish were exposed to six compounds known from previous experimental data on the custom engineered method to induce strong behavioral phenotypes. These included Optovin (TRPA1 ion channel modulator), Etomidate (GABA_AR agonist), Bromocriptine (dopamine receptor agonist), Lidocaine (voltage-gated sodium channel blocker), Pentylenetetrazol (PTZ) (GABA_AR antagonist), and Haloperidol (dopamine and 5-HT receptor antagonist). Larvae were allowed to acclimate with chemical on board for one hour and were then exposed to the series of stimuli while being recorded. Motion index was calculated from the recorded video, and behavioral traces were compared to vehicle control. **Results:** Behavioral traces of 7 dpf larvae were similar across MCAM and Sauron systems; however, due to technical limitations, behavioral phenotypes are not directly comparable across systems. Traces between developmental timepoints (5 dpf vs. 7 dpf) appeared similar within and across systems. Variability between individual runs was much higher in 5 dpf than 7 dpf larvae when assessed via DTW distance matrix analysis. The neuroactive compounds produced the expected behavioral phenotypes and were distinguishable from vehicle. For example, zebrafish exposed to PTZ exhibited increased behavior (approximately +2 SD in comparison to vehicle) specifically in the violet light stimuli portion of the battery, consistent with the phenotype as observed in the custom engineered system. Optovin exposure produced the expected enhanced acoustic startle response. Etomidate exposure produced the expected behavioral response of sedation with enhanced response to solenoid stimuli. **Conclusions:** In conclusion, we have demonstrated the ability to capture strong and expected neuroactive behavioral phenotypes using a method developed for 5 dpf zebrafish on a commercially available system. Further testing is needed to investigate the potential use and appropriate scope of this system for neurotoxicity prediction. Overall, developing this method in a way that is accessible to other laboratories as a NAM may increase in the acceptance of and interest in zebrafish behavioral phenotyping as a tool for neuroactivity and potentially neurotoxicity screening.

PS 3804 Stimulatory Effects of Alcohol in As3MT Knockout Mice

M. Hernández, G. A. Picha, N. D. Morford-Oberst, A. M. Barkley-Levenson, and S. Medina. University of New Mexico, Albuquerque, NM.

Background and Purpose: Few preclinical studies have examined the relationship between arsenic (As) and alcohol, despite evidence of interaction between the two. Recent work shows that alcohol exposure increases the absorption and excretion of As, highlighting the need to investigate their combined effects. The *As3mt* gene encodes the arsenic (+3 oxidation state) methyltransferase (As3MT) enzyme, which catalyzes the metabolism of inorganic As. Human genome-wide association studies have implicated As3MT in anxiety phenotypes and identified an interaction between alcohol consumption and pulse pressure. **Methods:** Based on this evidence, we hypothesized that loss of As3MT would alter anxiety-like behavior and the locomotor response to ethanol (EtOH). As3MT knockout (KO) mice (males and females, $n = 6$ per sex) were compared with wild-type (WT) C57BL/6J controls ($n = 5$ per sex). On days 1 and 2, mice received habituation sessions with saline injections (10 mL/kg, i.p.) followed by testing in an open field for 30 minutes. On days 3 and 10, they received 1 or 2 g/kg EtOH (20% v/v, i.p.), and locomotor activity was recorded for 30 minutes, with analyses focused on total and early (0-10 minutes) activity. **Results:** Significant sex differences emerged on days 1 and 3 ($p < .05$), while a main effect of genetic model (i.e., WT vs As3MT KO) was observed on day 3 ($p < .05$) for total activity. When assessing percent change in early activity on EtOH treatment days, there was a significant main effect of genetic model at each EtOH dose ($p < .05$), with KO mice displayed a greater change in activity at both doses ($p < .05$) compared to WT mice. Moreover, KO mice spend significantly less time in the center of the open field on days 1, 2, and 10 compared to WT mice ($p < .05$), indicating greater anxiety-like behavior. **Conclusions:** These findings suggest that As3MT may contribute to EtOH- and anxiety-related behavioral phenotypes. Ongoing studies will examine and assess how As3MT modulates alcohol responses in both arsenic-naïve and arsenic-exposed mice.

PS 3805 Cytochrome C Oxidase activity across the brain following acute hydrogen sulfide toxicity in mice

D. Kim, A. Miller, and W. K. Rumbelha. University of California Davis, Davis, CA.

Background and Purpose: Hydrogen sulfide (H₂S) is a highly toxic gas that targets tissues with high oxygen demand, such as the brain and heart. Acute H₂S toxicity is widely attributed to its inhibition of cytochrome c oxidase (Complex IV; COX), an essential component of the mitochondrial electron transport chain (ETC) responsible for producing more than 98% of cellular ATP. In the brain, COX activity is not uniformly distributed, and the extent of COX inhibition across brain regions following acute H₂S poisoning is poorly characterized. In our laboratory, we have observed that the neurotoxic effects of acute H₂S exposure—including neurotransmitter alterations and neuropathology—are also region-specific. Given the central role of COX in H₂S-induced neurotoxicity, we designed a pilot study to test the hypothesis that

acute H₂S exposure does not uniformly inhibit COX activity across the brain. This knowledge will be useful developing brain COX activity as a biomarker of H₂S poisoning. **Methods:** All animal studies were approved by the Institutional Animal Care and Use Committee (IACUC). Male C57BL/6J mice (6-7 weeks old) were purchased from Jackson Laboratories (Sacramento, CA, USA). Three experimental approaches were used. In the first approach, mice were randomly assigned to two groups: a room-air control group and an H₂S-exposed group. Control mice were exposed to room air for 50 minutes in a whole-body exposure chamber. H₂S-exposed mice were exposed to 1000 ppm H₂S for 50 minutes, and cohorts of surviving mice ($n = 4/\text{time point/group}$) were euthanized at 5 minutes, 2 hours, 24 hours, or 72 hours post-exposure. Brains were micro dissected, and different regions were analyzed for COX activity. In the second approach, cohorts of twenty 6-7-week-old male C57BL/6J mice were divided into four groups. Control mice ($n = 5$) were exposed to room air for 60 minutes. H₂S-exposed mice were exposed to 1000 ppm H₂S for 15 minutes ($n = 4$), 30 minutes ($n = 4$), or 60 minutes ($n = 4$). Upon euthanasia, brains were rapidly removed and micro dissected for COX activity measurements. In the third approach, mice were exposed daily to either room air or H₂S (1000 ppm for 40 mins on day 0, and for 15 mins once daily) for up to 6 days, and cohorts were euthanized on days 1, 3, and 7. Brains were removed, micro dissected on ice, and stored at -80°C until analysis. COX activity was measured using a commercial Complex IV Rodent Enzyme Microplate Assay Kit (Abcam, Waltham, MA, USA) following the manufacturer's guidelines. Normality was assessed using the Shapiro-Wilk test. COX activity was analyzed using one-way ANOVA with Dunnett's post hoc multiple-comparison test. Statistical analyses were performed in RStudio (Version 2025.05.0+496). A $p\text{-value} \leq 0.05$ was considered statistically significant. **Results:** Across all experimental approaches, acute H₂S exposure did not uniformly inhibit COX activity across the mouse brain. The cortex was the most sensitive region, followed by the olfactory bulb and brainstem. Following a single acute 60-minute exposure to 1000 ppm H₂S, COX activity in the cortex was reduced to 8% of control levels, compared to 30% in the olfactory bulb, 62% in the brainstem, and 66% in the cerebellum. **Conclusions:** There is limited information mapping COX activity across brain regions following acute H₂S poisoning. Our preliminary data suggest that acute H₂S exposure does not uniformly inhibit COX activity across brain nuclei and regions. Additional studies are needed to correlate regional COX activity with neuropathology and neurochemical changes to clarify the role of this enzyme as a biomarker of H₂S-induced neurotoxicity.

PS 3806 Correlation of Brain MRI Alterations with Histopathologic Changes in a Cynomolgus Monkey with Cytokine Release Syndrome

A. Goto¹, A. Sumiyoshi², Y. Nogami¹, Y. Nagayama¹, E. Ota¹, and S. Asakura¹. ¹Eisai Co., Ltd., Ibaraki, Japan; and ²National Institutes for Quantum Science and Technology, Chiba, Japan. Sponsor: A. Goto, Japanese Society of Toxicology

Background and Purpose: Cytokine release syndrome (CRS) is a systemic inflammatory condition caused by a various factors, including infection and drug administration and can sometimes cause CNS symptoms in severe cases. However, there was few information about animal model with severe lethal symptoms induced by chemotherapy. We experienced CRS with CNS symptoms in a cynomolgus monkey treated with paclitaxel. To investigate CRS-related changes and their distribution in a whole brain, we conducted an *ex vivo* MRI with three-dimensional volume reconstruction evaluation, and histopathologic examination of the brain to compared the respective results and evaluate their correlations. **Methods:** A 3-years-old male monkey once treated with paclitaxel at 6 mg/kg showed symptom suggesting infusion reactions from end of dosing with prolonged CNS clinical sign and was sacrificed moribund on the day after administration. Serum samples were collected sequentially from 5 min to 24 hr after dosing and was submitted to blood cytokine level measurement (Milliplex MAP kit NHP Cytokine Magnetic Bead Panel). After necropsy, the brain was fixed with 10% neutral buffered formalin and *ex vivo* MRI was performed on the fixed brain. A Bruker 7 Tesla MRI system (Biospec 70/40) was used, with an 86 mm inner diameter birdcage coil (T12053V3) for transmission and reception. Microscopic examination by Hematoxylin-Eosin (HE) staining, Immunohistochemistry (IHC) staining for fibrinogen was performed on the brain following *ex vivo* MRI. **Results:** In the cytokine measurement, serum IL-10, IL-6, and MCP-1 increased, while IL-8 decreased from 30 min up to 24 hours after dosing, compared to levels in background control pool. In the *ex vivo* MRI, the T2-weighted images revealed hypointense signals around the vasculature in the brainstem region. In the histopathology, there was localized dilatation of arteries and veins in the brainstem region where hypointense signals in MRI, suggesting abnormalities in the circulation. There was focal and very slight neuronal necrosis in the superficial layers of the cerebral cortex adjacent to the cerebral sulci. In the pia mater, reactive infiltration of inflammatory cells was also observed. In the anti-fibrinogen IHC staining, there were perivascular fibrinogen-positive areas with indistinct boundaries around blood vessels in the medulla oblongata. Although no clear changes were seen in these regions in HE stained sections and MRI images, the IHC findings suggested brain edema due to leakage of plasma components out of the vasculature. **Conclusions:** In the monkey presenting CRS with CNS symptoms, MRI using T2-weighted sequences revealed vascular lesions in the midbrain. Histopathologic examination with HE staining showed localized dilatation of arteries and veins in the brainstem region where MRI abnormalities had been detected. In addition to the areas with MRI abnormality, focal and very slight neuronal necrosis, mild inflammatory cell infiltration, and perivascular fibrinogen-positive areas were also observed. In conclusion, combination of MRI and histopathologic examination

could detect highly localized vasculature changes. It was considered that the brain edema caused by CRS contributed to CNS symptoms in this animal, suggested by MRI abnormalities, neuronal necrosis and fibrinogen-positive perivascular area.

PS 3807 Development of Novel Aminopyridines for Safe and Effective Treatment of Peripheral Neurological Disorders

S. Ahmad, W. McClintic, A. Bollapragada, B. Gregg, A. B. Stone, S. W. O'Brien, A. R. Jacobson, and P. M. McNutt. Wake Forest Institute for Regenerative Medicine, Winston Salem, NC.

Background and Purpose: Aminopyridine-based voltage-gated potassium channel (VGKC) blockers, such as 3,4-diaminopyridine (3,4-DAP) and 4-aminopyridine, enhance neurotransmitter release by prolonging presynaptic action potentials. The FDA-approved compound 3,4-DAP provides symptomatic benefit in disorders characterized by impaired presynaptic release, including Lambert-Eaton myasthenic syndrome, myasthenia gravis, and congenital myasthenic syndromes. We have demonstrated that 3,4-DAP acts as a fast-acting reversal agent for botulinum neurotoxin (BoNT)-induced paralysis, a condition marked by reduced acetylcholine (ACh) release due to SNARE protein cleavage. However, widespread clinical use of 3,4-DAP is limited by its narrow therapeutic index, driven by dose-limiting Central nervous system (CNS) toxicity, and by five-fold interindividual variability in plasma exposure caused by N-acetyltransferase 2 (NAT2) polymorphisms. To overcome these limitations, we developed a new class of aminopyridine analogs designed to retain VGKC-blocking activity while reducing CNS penetration and eliminating NAT2-mediated metabolism. **Methods:** Using a structure-based pharmacophore model incorporating a protonatable ring nitrogen and a hydrogen bond donor at the 4-position, we synthesized analogs with targeted substitutions to optimize activity, permeability, and metabolic stability. Lead compounds were screened in a BoNT/A mouse model using unrestrained whole-body plethysmography; several candidates restored respiratory function to normal physiological levels at well-tolerated doses. Pharmacokinetic studies assessed NAT2-mediated acetylation of lead analogs using human liver S9 fractions (*in vitro*) and mouse plasma and urine (*in vivo*) following single-dose infusion. Acetylated metabolites were quantified using highly sensitive LC-MS analysis. *Ex vivo* nerve-muscle preparations and ion channel recordings confirmed potent VGKC inhibition associated with motor neuron repolarization and presynaptic ACh release. **Results:** Lead aminopyridine analogs demonstrated robust efficacy in reversing BoNT/A-induced respiratory impairment in mice, restoring normal function at safe doses. Pharmacokinetic analysis revealed resistance to NAT2-mediated acetylation both *in vitro* (human liver S9 fractions) and *in vivo* (mouse plasma and urine). Electrophysiological studies confirmed strong VGKC blockade and enhanced presynaptic neurotransmitter release. **Conclusions:** Our findings support the advancement of NAT2-resistant aminopyridine analogs as fast-acting therapeutics for BoNT intoxication and other peripheral neuromuscular disorders. This work validates an aminopyridine drug discovery platform with potential applications in additional indications, including pain, muscular dystrophy, and seizure disorders.

PS 3808 A Comprehensive In Vitro Six-Cell Human NVU Model for Coupled Evaluation of BBB Function, Immune Response, CNS exposure, and Neurotoxicity

Z. Xu¹, G. Coomes¹, J. P. Sluka², and G. Knipp¹. ¹Purdue University, West Lafayette, IN; and ²Indiana University, Bloomington, IN.

Background and Purpose: Neurotoxicants and CNS-active therapeutics encounter the highly restrictive blood-brain barrier (BBB), yet most *in vitro* models lack sufficient cellular complexity to predict human-relevant permeability, immune activation, and neurotoxicity. To address this, we developed a physiologically aligned, six-cell human neurovascular unit (NVU) model in a two-compartment format that reconstructs the spatial organization of the BBB and brain parenchyma. On the apical (blood-facing) membrane, human astrocytes, pericytes, and HBEC-5i endothelial cells are cultured in direct contact to establish a restrictive BBB layer, where co-seeding microglia are integrated with astrocytes to impart immune responsiveness at the barrier interface. The basal (brain-facing) compartment contains human neurons, oligodendrocytes, and microglia to recapitulate parenchymal structure and enable measurement of downstream neurotoxic effects. **Methods:** Human primary astrocytes, pericytes, and HBEC-5i endothelial cells were sequentially seeded onto poly-L-lysine-coated 0.4 μm Transwell® inserts to generate a direct-contact BBB layer. HMC3 microglia were co-seeded with astrocytes to establish immune surveillance at the barrier interface. The basal chamber was populated with SH-SY5Y or primary human neurons, MO3.13 oligodendrocytes, and HMC3 microglia to form a parenchymal compartment. Barrier integrity was quantified using Transendothelial Electrical Resistance (TEER) and apical-to-basal apparent permeability (Papp) of lucifer yellow and 4 kDa FITC-dextran. Structural and functional BBB phenotype was evaluated by immunocytochemistry for tight-junction and adhesion proteins (ZO-1, claudin-5, occludin, PECAM-1), cytoskeletal organization (F-actin), and efflux transporters (MRP2, P-gp). Neuroinflammatory activation was assessed using changes in Papp and microglial markers CD68 and IBA-1. Downstream neurotoxicity was evaluated using the neuronal injury marker Tau and neuronal integrity marker MAP2. **Results:** The direct

contact triculture model (endothelial cells, astrocytes, pericytes) established a functional baseline barrier. Addition of neurons generated a four-cell NVU and significantly increased structural BBB markers, including ZO-1, claudin-5, occludin, PECAM-1, F-actin, and efflux transporters (P-gp, MRP). Neuronal integration also improved barrier function, reducing FITC-dextran Papp from 5.83×10^{-6} to 5.34×10^{-6} cm/s. The NVU retained physiological immune sensitivity, with LPS (5 µg/mL) increasing Papp to 10.4×10^{-6} cm/s. Incorporation of microglia produced spatially dependent modulation of barrier integrity. Apical microglia markedly tightened the barrier (Papp $2.06\text{--}2.23 \times 10^{-6}$ cm/s), whereas basal-only microglia induced only modest changes, demonstrating that microglial position—not cell density—is the primary determinant of BBB regulation. Dual apical-plus-basal microglia further enhanced immune responsiveness and strengthened neuron-microglia signaling. An apical astrocyte to microglia ratio of 1:5 achieved both robust immune activation and physiologically relevant neuronal outcomes, including changes in Tau and MAP2 expression and associated alterations in axonal morphology. Completion of the six-cell NVU with oligodendrocytes stabilized neuronal networks and produced the most restrictive barrier observed lucifer yellow permeation rates (Papp 0.6×10^{-6} cm/s) almost 10 times lower compared with the triculture BBB model alone. NVU disruption was induced using potassium cyanide to assess neurotoxicity using the six-cell model. The incorporation of microglia and oligodendrocytes enhanced the barrier tightness and increased the stability of neuronal networks during metabolic stress. This increased resistance supports the use of the six-cell NVU model as a physiologically relevant system for neurotoxicity assessment. **Conclusions:** This optimized six-cell NVU model establishes a structurally and functionally complete human-relevant BBB system capable of capturing permeability, neurotoxicity, inflammation, and neuronal structural alterations within a single platform. Its improved barrier tightness, immune competence, and neuronal readouts position it as a powerful tool for mechanistic toxicology, neuroinflammation studies, and CNS drug screening.

PS 3809 Scalable and well-defined human CNS co-culture platforms suitable for modelling excitatory-inhibitory neuron imbalances in drug discovery and safety studies

T. Harris-Brown¹, T. Oosterveen¹, M. Rios de Anda¹, T. Tatar Ozkan¹, S. Hussain¹, A. Veteleanu¹, S. Milde¹, M. Iovino², D. Magnani², R. Northeast¹, I. Ferreira¹, A. Turner¹, and W. Bernard¹. ¹bit.bio, Cambridge, United Kingdom; and ²Charles River Laboratories, Chesterford, United Kingdom. Sponsor: T. Harris-Brown, Safety Pharmacology Society

Background and Purpose: Cortical neuronal circuits are composed of two principal neuronal classes: glutamatergic excitatory neurons and GABAergic inhibitory neurons (IN). The inputs of IN provide cortical networks with the ability to balance spontaneous and evoked excitatory activities, preventing runaway excitation. Aberrant IN function and resultant excitatory-inhibitory (E/I) imbalances are implicated in various neurological disorders including autism, epilepsy, and schizophrenia. Furthermore, these imbalances can arise from astrocytic dysfunction, given their vital role in the turnover of glutamate released into the synaptic cleft. There is a demonstrable need for scalable methodologies to generate human *in vitro* models that reliably recapitulate E/I imbalances for high-content drug screening and toxicology assays. **Methods:** Leveraging our deterministic cell programming technology, opti-ox™ (optimised inducible overexpression), we have successfully generated the core cell types essential for establishing a platform to investigate E/I neuron imbalances: GABAergic neurons (ioGABAergic Neurons), glutamatergic neurons (ioGlutamatergic Neurons), and astrocytes (ioAstrocytes), derived from human induced pluripotent stem cells (iPSCs). **Results:** Comprehensive molecular characterisation via immunocytochemistry, RT-qPCR, and single-cell RNA-sequencing demonstrates that cultures consist of over 95% pure GABAergic neurons, which express the canonical markers GAD1, GAD2, VGAT, DLX1, and DLX2, and exhibit GABA positivity. Notably, somatostatin (SST) was the sole GABAergic subtype-specific marker detected, further accentuating the purity of the ioGABAergic Neurons. Moreover, three independently manufactured lots of ioGABAergic Neurons exhibited highly equivalent transcriptomic profiles, confirming the consistency and scalability inherent to the opti-ox technology. Functional validation through Microelectrode Array (MEA) assays demonstrated that ioGABAergic Neurons inhibit the excitatory activity of ioGlutamatergic Neurons in a ratio-dependent manner, and that the E/I balance can be further modulated by pharmacological agents targeting GABAergic signalling. In addition, we have developed protocols to culture ioGlutamatergic Neurons with glial cells, specifically oligodendrocyte-like cells (ioOLCs), microglia (ioMicroglia) and astrocytes (ioAstrocytes). These models afford valuable opportunities for investigating the mechanisms underlying immune activation and demyelination, thereby facilitating drug discovery in these therapeutic areas. Furthermore they are critical for drug safety studies as they enable the construction of more complex multi-cell models capable of recapitulating key cellular interactions in the human brain. **Conclusions:** The opti-ox driven co-culture platforms offer a means to model intricate CNS interactions accurately *in vitro*, thereby advancing our understanding of the principles underpinning E/I imbalances and directly supporting human-relevant neurotoxicity assays and drug discovery for debilitating neurological disorders.

PS 3810 Phenotypic Screening Platforms for Neurotoxicity and Neurorepair in CNS Drug Safety Assessment

J. Esselink, G. Mahe, M. Hembury, D. K. Ketskemeti, M. Pliegocaballero, M. B. Torroba, J. van Offenbeek, K. Lo, C. Loomans, M. Musters, M. Bsibsi, L. Ritsma, L. Buti, A. van Marle, S. de Munnik, M. Vlaming, and P. I. Racz. Charles River Laboratories, Leiden, Netherlands.

Background and Purpose: The high attrition rate in CNS drug development underscores the need for predictive, mechanistically relevant *in vitro* models that support both efficacy and safety profiling. We developed complementary phenotypic screening platforms using human iPSC-derived neurons to evaluate neurotoxicity and regenerative potential under disease-relevant conditions, aiming for alignment with recommendation frameworks like OECD for *in vitro* neurotoxicity testing. **Methods:** In one approach, we adapted the Cell Painting assay to profile morphological changes in ioGlutamatergic neurons either carrying pathogenic mutations or being exposed to neurodegenerative disease relevant triggers like βAmyloid. To complement neurotoxicity profiling, we developed neurite outgrowth and axonal regeneration assays using iPSC-derived dopaminergic and motor neurons (including neurodegenerative disease-relevant mutants). **Results:** Cell Painting assays have been widely adopted for morphological profiling to uncover mechanisms of action, disease phenotypes, and toxicity prediction. A modified staining protocol incorporating β-III tubulin enhanced visualization of neuronal architecture. Principal Component Analysis revealed distinct phenotypic separation between mutant and wild-type neurons, with dose-dependent shifts upon β-amyloid oligomer exposure. These shifts correlated with increased neurofilament light chain (NfL) release—a translational biomarker of neurodegeneration—highlighting the assay's sensitivity to neurotoxic insults. OECD guidelines alignment in this case is particularly related to neurite morphology and network integrity. Neurodegeneration was induced via chemically defined triggers, with high-content imaging and viability measurements as key readouts. Regeneration was assessed using axotomy in microfluidic devices, enabling real-time tracking of axonal repair. These assays align with the neurite outgrowth and network formation endpoints in the OECD DNT *in vitro* battery and offer additional insight into functional recovery, complementing current regulatory tools. **Conclusions:** Together, these platforms provide scalable, multiparametric tools to assess compound-induced neurotoxicity and neurorepair potential. Their alignment with OECD test guidelines and guidance documents supports integration of neurotoxicity risk evaluation in early-phase drug development.

PS 3811 Assessing the neurotoxic and cardiotoxic potential of botanical extracts using microelectrode array (MEA) recordings

R. G. van Kleef¹, P. J. Wopken¹, J. Krzykwa², C. A. Mitchell², and R. H. Westerink¹. ¹Utrecht University, Utrecht, Netherlands; and ²Health and Environmental Sciences Institute, Washington, DC.

Background and Purpose: The global use of botanical extracts in medicinal, cosmetic, and dietary products is steadily increasing. However, these complex mixtures vary in composition due to differences in plant growth conditions, extraction methods, and processing, which can affect their biological activity and safety. Despite their natural origin, botanical extracts have been linked to adverse effects, including neurotoxicity and cardiotoxicity. Assessing the safety of these products is challenging because of their chemical diversity and multiple modes of action. Conventional animal-based toxicological testing is often unsuitable, as it is costly, time-consuming, and ethically debated. Consequently, there is growing interest in applying new approach methodologies (NAMs) to evaluate the toxicity of botanical mixtures. The present study aimed to evaluate the suitability of microelectrode array (MEA) recordings to assess the neurotoxic and cardiotoxic potential of 16 botanical extracts by deriving dose-response profiles and activity patterns in neuronal networks and human induced pluripotent stem cell-derived cardiomyocytes. **Methods:** For neuronal activity measurements, primary cultures of rat cortical neurons were grown on 48-well MEA plates. For assessing cardiac activity, human iPSC-derived cardiomyocytes were grown on 96-well MEA plates. Cells were cultured in 5% CO₂/95% air atmosphere at 37°C until use after 10–15 days in culture. MEA recordings were used to determine changes in spontaneous neuronal network activity and spontaneous cardiomyocyte beating, respectively, following acute (30 min) exposure to 16 botanical extracts. All botanical samples were tested at a dose of 50 µg/mL down to the no-observed effect level (NOEL). The botanical extracts were provided by the Botanical Safety Consortium (<https://botanicalsafetyconsortium.org/>; Mitchell et al., 2022). Details on the sourcing, chemical analysis, and botanical details can be found at NIEHS's CEBS website (<https://cebs-ext.niehs.nih.gov/cebs/paper/15717>). Botanicals were selected based on existing literature with respect to toxicity or safety, from human, animal, or mechanistic studies (Kanungo et al., 2024). **Results:** Our results demonstrate that exposure to extracts from ashwagandha, comfrey, and Asian ginseng had limited effects on neuronal network activity, whereas aristolochia, ephedra, green tea, milk thistle, trypterygium and usnea resulted in a dose-dependent, mild inhibition of neuronal activity, albeit with distinct neuronal activity phenotypes. Extracts of kava, kratom, and yohimbe potentially inhibited neuronal activity, with cessation of activity at 50 µg/mL. Despite differences in the maximum degree of inhibition, all these inhibitory extracts show NOELs of 1–5 µg/mL. Exposure to aconite, blue cohosh, goldenseal and oleander results in specific activity phenotypes characterized by hyperexcitation and/or intensification of (network) burst activity, with extracts from aconite, gold-

enseal and oleander being most potent with NOELs of 0.25 - 0.5 µg/mL. Our result from MEA recordings using human iPSC-derived cardiomyocytes show that extracts from ashwagandha, blue cohosh, comfrey and Asian ginseng have limited cardiotoxic potential, whereas aristolochia, green tea, milk thistle, and usnea have only a mild cardiotoxic potential. Extracts of aconite, ephedra, goldenseal, kava, kratom, oleander, tripterygium and yohimbe result in profound cardiotoxicity, evidenced by distinct effects on beat rate, spike amplitude and field potential duration, with extracts from goldenseal and oleander being most potent with a NOEL of 0.05 µg/mL. **Conclusions:** Diverse botanical extracts have a clear neuro- and cardioactive potential. The distinct activity phenotypes suggest that the botanical extracts have diverse modes of action, which are partly shared by the nervous system and the heart. Despite challenges related to *in vitro-in vivo* extrapolation, our combined data highlight the applicability of MEA recordings of neuronal and cardiac activity for hazard identification and potency ranking of botanicals.

PS 3812 Comparative Biodistribution of an Antisense Oligonucleotide following Intrathecal Administration via Three Injection Techniques in Rats

C. Voyer¹, S. Cinquino¹, and T. Fang². ¹Charles River Laboratories, Senneville, QC, Canada; and ²Trace Neuroscience, South San Francisco, CA. Sponsor: M. Vezina

Background and Purpose: Effective delivery of antisense oligonucleotides (ASOs) into the central nervous system (CNS) is essential for evaluating therapeutic potential in preclinical studies. Intrathecal delivery in animal models is the preferred route of administration due to its translational relevance for human route of administration for CNS-targeted oligonucleotide therapies. However, intrathecal delivery presents technical and anatomical challenges that can influence drug delivery efficiency, consistency, and biodistribution, particularly into the brain. **Methods:** Our laboratory has developed and refined procedures to allow for reliable intrathecal administration in rats. To compare delivery approaches, 14-week old Sprague Dawley rats received a single dose of ASO via one of three methods: (1) percutaneous direct injection, (2) direct injection via surgical approach, and (3) administration through an implanted catheter. Animals were monitored for 3 weeks post-dose, after which they were euthanized. Clinical signs, body weight, and clinical pathology parameters were evaluated. **Results:** CNS tissues, including brain and spinal cord regions, were collected and analyzed for ASO concentration using a hybridization electrochemiluminescence bioanalytical method. Robust ASO exposure was observed in both spinal cord and brain tissues. As expected, all three methods yielded high concentrations in the spinal due to proximity to the injection site. However, differences in distribution efficiency along the neuroaxis into the brain were observed. ASO concentrations in the brain - the primary target tissue - ranged between 0.47 to 7.58 ng/mg across the 3 methods. Notably, direct puncture methods resulted in higher brain concentrations compared to the catheter-based approach. Mean ASO concentrations in the caudal cortex were 4.91, 7.58, and 3.72 ng/mg for direct percutaneous puncture, direct puncture via surgery, and the catheter method, respectively. In the middle cortex, concentrations were 3.24, 4.21, and 2.12 ng/mg, and in the cerebellum, 4.97, 5.78, and 3.91 ng/mg respectively. Distribution consistency across animals was assessed using the coefficient of variation (CV). In the spinal cord (cervical, thoracic, and lumbar levels), the CV varied between 0.19 and 0.48 for the direct puncture methods (percutaneous and surgical approaches) while it was 0.41 to 0.75 for the catheter-based method. In the brain (caudal cortex, middle cortex, and cerebellum), the CV varied between 0.29 and 0.38 for the direct puncture methods compared to 0.59 to 0.61 for the catheter-based method. These findings suggest that both surgical and percutaneous intrathecal injection methods provide more reliable and uniform ASO distribution across CNS tissues compared to the catheter-based approach. Direct injection methods offered improved consistency and distribution into the brain. Additionally, transient clinical signs and body weight changes were observed in catheter implanted animals, likely related to the procedure itself. Clinical pathology changes indicative of inflammation were noted in groups receiving surgical and catheter-based dosing. Histopathological changes such as vacuolation and nerve fiber degeneration - consistent with class effects of intrathecally administered oligonucleotides (Berman Booty et al., 2023; Frazier, 2015) - were more prominent in catheter-implanted animals. **Conclusions:** These results are valuable for optimizing delivery strategies in nonclinical CNS-targeted oligonucleotide therapeutic development.

PS 3813 Antioxidant Effects of Partridgeberry Leaf Extract against Perfluorooctanesulfonic Acid (PFOS) and Methylmercury in *Caenorhabditis elegans*.

O. M. Marsanskis. University of Maine, Orono, ME. Sponsor: J. Newell-Caito

Background and Purpose: Perfluorooctanesulfonic acid (PFOS) and methylmercury (MeHg) are environmental contaminants that co-occur in aquatic ecosystems. These compounds bioaccumulate as they move up trophic levels, posing significant risks to human and environmental health. PFOS is a synthetically fluorinated compound that was initially incorporated into products for its ability to resist both oil and water. Although it has been phased out of production due to adverse health effects, it persists in the environment, deemed a "forever chemical." Methylmercury

is a neurotoxic heavy metal that is produced when inorganic mercury enters aquatic environments and undergoes microbial methylation. It then dissolves in water and becomes concentrated in marine organisms. Despite their distinct chemical properties, both PFOS and MeHg exert their toxic effects in part by inducing oxidative stress. Oxidative stress arises from an imbalance between the production of reactive oxygen species (ROS) and the availability of antioxidants. Accumulation of oxidative stress has been implicated with the development of age-related neurodegenerative diseases. This project will explore the protective effects of naturally occurring antioxidants in partridgeberry (*Mitchella repens*) leaf extracts (PBE) against the combination of PFOS and MeHg toxicity in the nematode worm, *Caenorhabditis elegans*. Partridgeberry is a plant that is native to eastern North America and has an extensive history within the medicinal practices of Indigenous tribes. Historical records indicate Indigenous Americans treated pain associated with childbirth and rheumatism with tea created from their leaves. Our hypothesis is that if *C. elegans* are pre-treated with partridgeberry leaf extract before PFOS and methylmercury exposure, then there will be increased survival, increased mitochondrial function, and decreased oxidative stress. **Methods:** This hypothesis will be tested with dose-response survival curves, lifespan assays, quantification of total ROS and glutathione (markers of oxidative stress), and quantification of ATP (marker of mitochondrial function). Prior dose-response curves and oxidative stress experiments have determined that the 5% dose of PBE (LD20 value) has the most antioxidant benefit in *C. elegans*. Therefore, all experiments will be conducted on *C. elegans* in the following treatments with and without 5% PBE pretreatment: WT worms (control), MeHg (LD20 value), PFOS (LD20 value) and PFOS + MeHg (both LD20 values). WT worms will be synchronized before treatment to ensure that all worms are in the L1 life stage. Then, they will be pre-treated with 5% PBE for 30 minutes before treatment of either MeHg, PFOS, or the combination for 30 minutes. **Results:** Previous research in the Newell lab has determined PBE to have a significant polyphenolic content of 1432 ± 280 mg GAE/g. Additionally, PBE pretreatment followed by treatment of the known oxidant manganese chloride resulted in a two-fold decrease in the total ROS, increased glutathione levels, increased ATP production, and a 30% increase in lifespan. Through dose-response survival curves, we have confirmed an LD20 value of 1 µM for methylmercury and are in the process of confirming an LD20 value of 100 µM for PFOS. Our expected results are that PBE pretreatment followed by PFOS and/or methylmercury exposure will decrease total ROS, increase glutathione levels, increase ATP production, and increase *C. elegans* lifespan. **Conclusions:** This is the first study to assess PBE as an antioxidant in PFOS and MeHg-treated worms. The findings of this study could provide insight into how dietary factors could mitigate the toxic effects of PFOS and MeHg, with potential implications for guiding future public health recommendations.

PS 3814 Curating Developmental Neurotoxicity in the Toxicity Reference Database (ToxRefDB)

M. Feshuk¹, S. Watford², K. Paul Friedman¹, and K. Carstens¹. ¹US EPA/OCSPP, Research Triangle Park, NC; and ²former US EPA/ORD, Research Triangle Park, NC.

Background and Purpose: The US Environmental Protection Agency (EPA) has regulatory authority to evaluate pesticides and industrial chemical substances in the United States, as statutorily required by the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and Toxic Substances Control Act (TSCA), respectively. Animal studies are often conducted as part of the chemical evaluation to assess potential hazard and for certain uses. To facilitate the reuse of data from legacy animal studies, the US EPA's Toxicity Reference Database (ToxRefDB) is a publicly available, structured data resource for *in vivo* toxicity information with over 6000 guideline or guideline-like human-relevant studies for over 1000 chemicals. ToxRefDB is largely comprised of curated animal study data from repeat dose studies conducted according to OECD and EPA Health Effects Series 870 guidelines, and many coming from reviews of pesticide registrant-submitted toxicity studies known as data evaluation records (DERs) from the U.S. EPA's Office of Pesticide Programs (OPP). Ongoing curation efforts since 2009 have expanded ToxRefDB to incorporate toxicity studies from additional sources, making ToxRefDB a premier resource for qualitative and quantitative animal toxicity information. Given ToxRefDB-applicable studies follow guideline specifications, any deviations from the guideline are noted, allowing missing (i.e., not tested) endpoints or negative (i.e., tested with no effect observed) effects to be inferred. A developmental neurotoxicity (DNT) study is a specialized toxicity study to screen for adverse effects of pre- and postnatal exposure on the development and function of the nervous system, focusing on the characterization of offspring survival, motor activity, auditory startle response, learning, memory, and brain pathology. The relative diversity of DNT study design variants presents a challenge in creating an adequate format to capture study data as well as apply a standardized vocabulary representing the unique outcomes contained across studies. Given the significant value in developing an aggregated resource of DNT studies that have been conducted, this work presents efforts to extract and collate DNT guideline and other DNT-relevant *in vivo* studies in the structured ToxRefDB format. **Methods:** An important component of ToxRefDB is its controlled vocabulary for studies and effects observed for enhanced data quality. Most terminology was standardized to better reflect the terminology used in the guidelines and study reporting. DNT studies are complex with the guideline requirement for observational and functional assessments collected at specified time points. Given the variations in assessment times and flexibility in tests that are permissible for consideration under the guideline, observations under the ToxRefDB controlled vocabulary often include required time periods associated with the neurological endpoint category.

With the controlled effect vocabulary established and appropriate studies identified, the ToxRefDB document extraction process utilized an application-based modular workflow for curating the heterogeneous and complex *in vivo* study designs. A multi-layer review process was implemented to ensure data integrity and minimize data entry error. **Results:** A major update in ToxRefDB v3.0 was to expand the controlled vocabulary and create a new guideline profile to curate DNT guideline-adherent and "non-guideline" DNT-relevant studies. ToxRefDB v3.0 (August 2025) includes 141 DNT and DNT-relevant studies on 96 chemicals. 9,640 total effects were extracted across 1,680 dose treatment groups. Types of curated effects are differentiated as treatment-related, statistically significantly different from the control group, or critical, deemed adverse by study reviewer. Within the subset of DNT and DNT-relevant studies, 3,194 treatment-related and 390 critical neurological effects were extracted. **Conclusions:** Capturing DNT study data in a relational database enables a systemic and interoperable review of chemical exposures at neurological endpoints. This data extraction effort produced an important resource to benchmark the performance of new approach methods, such as the DNT *in vitro* battery, to support predictive toxicology applications and reduce animal testing. *This abstract does not necessarily reflect U.S. EPA policy.*

PS 3815 High-Throughput Cytokine Detection Platform for Evaluation of Chemical Induced Microglial Activation

S. Yang¹, K. Carstens², I. Ipaye¹, X. Chen¹, H. Hogberg³, N. Kleinstreuer³, T. Knudsen⁴, and M. Xia¹. ¹NIH/NCATS, Rockville, MD; ²EPA, Research Triangle Park, NC; ³NIH/NIEHS, Research Triangle Park, NC; and ⁴Indiana University, Bloomington, IN.

Background and Purpose: Environmental chemical exposure is implicated in neurodegenerative disorders, primarily through neuroinflammation. This study aimed to identify and validate suitable *in vitro* microglial models for assessing cytokine responses to potential neurotoxins, with a specific focus on human induced pluripotent stem cell-derived microglia (hiMG). **Methods:** We evaluated the cytokine secretion profiles of four microglial cell types (hiMG, HMC3, IM-HM, and BV2) upon lipopolysaccharide (LPS) stimulation using cytokine arrays. Subsequently, we developed a homogeneous time-resolved fluorescence (HTRF) assay platform in a 1536-well plate format for high-throughput screening using hiMG cells. We then assessed the response activity of hiMG to various stimuli, including interferon gamma, catecholamine compounds, and nine environmental chemicals with documented cytokine-inducing potential. **Results:** Our findings showed that hiMG cells exhibited cytokine response patterns that most closely resembled *in vivo* conditions, displaying significant increases in interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF-α) levels upon LPS stimulation, with TNF-α being uniquely expressed in hiMG. The HTRF assay demonstrated robust performance, with a 3.71-fold and 2.62-fold increase in the assay window for IL-6 and TNF-α secretion, respectively, after LPS treatment, yielding EC50 values of approximately 50 ng/mL and 90 ng/mL. All nine tested environmental chemicals stimulated IL-6 and TNF-α production, with three compounds (e.g., picoxystrobin) significantly stimulating both cytokines. **Conclusions:** This study successfully established a reliable high-throughput platform utilizing hiMG cells for detecting the inflammatory effects of environmental toxicants. This platform provides valuable insights into their neuroinflammatory potential and potential implications for neurodegenerative disorders.

PS 3816 Reducing animal use in rat fertility studies through use of historical control data and statistical methods

N. R. Catlin, D. Li, T. Tran, C. M. Stethem, S. N. Campion, and C. J. Bowman. Pfizer Inc, Groton, CT.

Background and Purpose: This study evaluates the potential of replacing/reducing conventional control animals in rat fertility studies and improving statistical analysis by leveraging historical control data (HCD). **Methods:** This analysis was conducted using data sourced from a single test facility using consistent animal attributes and study procedures and consisted of 13 datasets from 12 rat fertility studies conducted between 2018 and 2023. For ICH guideline required fertility endpoints, we have evaluated full and hybrid Virtual Control Group (VCG) and Bayesian statistical approaches in comparison with standard statistics used for concurrent control groups (CCG). **Results:** Findings from this pilot study demonstrate that the sensitivity and specificity of most fertility endpoints were generally similar between CCG and full or hybrid VCGs. Bayesian analyses leveraging all available HCD offered similar or superior sensitivity and specificity to CCGs and VCGs (full or hybrid) for all fertility endpoints, with some exceptions. Retrospective implementation of these approaches on previously conducted fertility studies illustrated similar statistical performance across all approaches in addition to the benefit of reduced animal use. **Conclusions:** Overall, this effort illustrates the first steps to improve sensitivity and reduce animal use with VCG (full or hybrid) or Bayesian approaches for required fertility endpoints in the rat.

PS 3817 Ovarian Toxicity of Benzyl Paraben and Butyl Paraben

C. Potts, A. Chowdury, R. Reynolds, V. Malt, S. Martinez, H. Alahmadi, and G. Warner. New Jersey Institute of Technology, Newark, NJ.

Background and Purpose: Benzyl paraben (BzP) and butyl paraben (BuP) are chemicals that are used as preservatives and antimicrobial agents in cosmetics, pharmaceuticals, and foods. BzP and BuP have been detected in urine, placental tissue, and ovarian follicular fluid and are understudied with regards to their endocrine activity, raising concerns on their impact to the reproductive system. In this research we tested the hypothesis that BzP and BuP are toxic to the ovary and behave similarly to other structurally similar endocrine disrupting chemicals, such as phthalates and terephthalates, by altering hormone levels and impacting cell growth and gene expression. To investigate these concerns, we studied the impact of exposure to BzP and BuP on the mouse ovary with a particular interest in the development of follicles, the structures that contain developing oocytes and steroidogenesis, the process of steroid hormone synthesis in the ovary. **Methods:** We performed 96 hr *in vitro* studies in which follicles were dissected from ovaries of adult female CD-1 mice and cultured with vehicle control (DMSO) or 0.1-100 µg/mL of BzP or BuP. Follicle growth was measured every twenty-four hours. At the end of the culture period, media were collected to analyze steroid hormone concentrations and follicles were collected to analyze gene expression. We used enzyme linked immunosorbent assays (ELISA) to measure the hormones estradiol, testosterone, progesterone, and pregnenolone. We also used quantitative polymerase chain reaction (qPCR) to assess gene expression related to steroidogenesis, cell cycle, and apoptosis. **Results:** We found that 100 µg/mL BzP and BuP were highly cytotoxic to follicles. BzP at 1 µg/mL significantly increased levels of estradiol and BzP at 10 µg/mL also significantly increased levels of testosterone. BuP did not significantly alter hormone levels at or below 10 µg/mL. Fabbp4 and Cdkn1a were significantly upregulated from 10 and 1 µg/mL BzP, respectively. **Conclusions:** Our results suggest that BzP and BuP are cytotoxic to the ovary and disrupt hormone levels and signaling at doses below cytotoxicity, suggesting potential endocrine disruption. Further study should be done on the toxicity of these chemicals to ensure they are safe and sustainable for use.

PS 3818 The Effects of Short-term Exposure to Di-(2-ethylhexyl) phthalate (DEHP) and Diisononyl phthalate (DiNP) on Markers of Female Reproductive Aging

R. E. Santacruz-Márquez, V. A. Salgado, M. J. Laws, and J. A. Flaws. University of Illinois Urbana Champaign, Urbana, IL.

Background and Purpose: Phthalates such as di-(2-ethylhexyl) phthalate (DEHP) and diisononyl phthalate (DiNP) are used as plasticizers in polyvinyl chloride plastics, flooring, food packaging, personal care products, and medical tubing. Phthalates are endocrine disruptors, which affect many hormonal functions. Humans are continuously exposed to phthalates via oral, dermal, and inhalation routes. Research suggests that environmental factors such as exposure to endocrine disruptors might accelerate the onset of female reproductive aging. Ovarian aging is characterized by oxidative stress, fibrosis, inflammation, inflammasome activation, and disrupted expression of telomere associated genes (TAGs). We previously found that long-term exposure to phthalates affects markers of reproductive aging. However, little was known about the long-term consequences of phthalate short-term exposure on markers of ovarian reproductive aging. Thus, the goal of this work was to test the hypothesis that short-term phthalate exposure has long-term effects on markers of ovarian aging. **Methods:** Young adult CD-1 female mice were orally dosed with vehicle, DEHP (20 µg/kg, 200 µg/kg, 20 mg/kg or 200 mg/kg), or DiNP (20 µg/kg, 100 µg/kg, 20 mg/kg, and 200 mg/kg) daily for 10 days. Mice were euthanized at 15 months post exposure and ovaries were collected for the assessment of markers of ovarian aging. **Results:** Exposure to DEHP at different concentrations (20 µg/kg, 20 mg/kg, and 200 mg/kg) altered the levels of 17 inflammation markers compared to control, with ICAM-1, IGFBP-6, and LDL affected at all DEHP concentrations. Additionally, DEHP exposure increased the expression levels of *Il-13*, but did not affect the expression of antioxidant enzymes or TAGs compared to control. Exposure to DiNP at different concentrations (20 µg/kg, 20 mg/kg, and 200 mg/kg) altered the levels of 16 inflammation associated molecules compared to control, with fetuin and LDL R affected at all tested DiNP concentrations. DiNP also increased the expression of *Il-13* and decreased the levels of the inflammasome associated molecule *Nlrp3* compared to control. Furthermore, DiNP exposure at the lowest concentration decreased the expression of the TAG *Terc*, whereas DiNP exposure at higher concentrations increased *Terc* expression levels compared to control. DiNP exposure did not affect the expression of antioxidant enzymes compared to control. **Conclusions:** In conclusion, short-term exposure to DEHP and DiNP have long-term effects on markers of ovarian aging. Specifically, DEHP and DiNP mainly target inflammation pathways and TAGs in the mouse ovary. R01 ES028661, R01 ES034112, T35 OD011145.

T. Cavalleri Sousa¹, K. Delalibera Hinokuma¹, V. de Oliveira Pinaffi¹, P. H. Peres Junior¹, M. I. Galiciani Pedro Fernandes¹, A. J. Molero Flores¹, A. C. de Souza Castilho¹, W. R. Scarano², J. A. Flaws³, and L. de Oliveira Mendes¹. ¹University of Western São Paulo, Presidente Prudente, SP, Brazil; ²Institute of Biosciences - São Paulo State University, Botucatu, SP, Brazil; and ³University of Illinois Urbana-Champaign, Urbana, IL.

Background and Purpose: Endocrine disrupting chemicals (EDCs) are compounds that interfere with hormone biosynthesis and may contribute to the development of chronic diseases such as cancer. The prostate, being a hormone-dependent organ, is particularly sensitive to the action of EDCs both during development and in maintaining homeostasis in adulthood. However, most studies evaluate the effects of EDCs in isolation, distancing themselves from actual patterns of human environmental exposure. Given this, this study characterized molecular changes in cell survival and death pathways and possible changes in collagen synthesis in the prostatic microenvironment of rats exposed, from intrauterine life to adulthood, to an environmentally relevant mixture of EDCs. **Methods:** Pregnant Sprague-Dawley rats were randomly divided into two experimental groups: Ctrl (vehicle: corn oil, by gavage) and EDC Mix (32.11 mg/kg/day of a mixture of 12 compounds — phthalates, pesticides, UV filters, bisphenol A, and butylparaben—diluted in corn oil, 2 mL/kg). The treatment was administered from gestational day 7 (GD7) to postnatal day 21 (PND21). After weaning (PND22), male offspring of the F1 generation continued to be exposed to the mixture until PND220, when they were euthanized (CEUA 8556/8559). The ventral prostate of the animals was collected, weighed, and stored at -80°C. Total RNA was extracted with TRIzol®, treated with DNase I, and reverse-transcribed into cDNA. The expression of the genes caspase 3 (*Casp3*), caspase 9 (*Casp9*), Bcl-2-associated X (*Bax*), B-cell leukemia/lymphoma 2 protein (*Bcl-2*), AKT Serine/Threonine Kinase 1 (*Akt*), phosphoinositide 3-kinase (*Pi3k*), mechanistic target of rapamycin (*Mtor*), collagen type I (*Col1a1*) and collagen type III (*Col3a1*), metalloproteinase 2 (*Mmp2*), metalloproteinase 9 (*Mmp9*), and metalloproteinase inhibitors 1 (*Timp1*) and 2 (*Timp2*) were quantified by RT-qPCR (endogenous reference gene: *Rpl30*) and analyzed by the comparative Delta Ct method. The data obtained were analyzed by parametric (Student's t-test) and nonparametric (Mann-Whitney, for *Pi3k*) statistical tests. **Results:** No statistically significant differences were observed in the expression of genes related to cell proliferation and apoptosis between the Ctrl and EDC Mix groups. Regarding collagen synthesis and deposition, no statistically significant differences were found between the control and EDC Mix groups, both in gene expression and MMP enzymatic activity. **Conclusions:** The findings suggest that prolonged exposure to the mixture of EDCs may not induce detectable changes in these molecular markers under the proposed conditions and analysis windows. The absence of effect may be related to post-transcriptional regulation, individual variability, adaptive response, and the temporality of gene expression. In addition, previous studies by the same research group identified a reduction in the proportion and total content of collagen fibers in the prostatic stroma under the same experimental model, as well as the presence of invasive adenocarcinoma, suggesting that other molecular mechanisms, such as epigenetic ones, may be involved in stromal remodeling and cell death and survival pathways not evidenced by the analyses performed in this study (Funding: FAPESP 2024/00912-4; 2018/24044-0).

PS 3820 **Phthalate Replacements Show Similar Effects as Phthalates on Gene Expression and Hormone Production in Mouse Ovarian Follicles**

R. Reynolds, C. Potts, W. Bari, and G. Warner. New Jersey Institute of Technology, Newark, NJ.

Background and Purpose: Phthalates are ortho-substituted phthalic acid esters that are used as plasticizers to make polyvinyl chloride plastics more flexible. Two of the most common phthalates are di(2-ethylhexyl) phthalate (DEHP) and benzyl-butyl phthalate (BzBP). After entering the body, DEHP and BzBP are broken down into monoester metabolites, mono(2-ethylhexyl) phthalate (MEHP) and monobenzyl phthalate (MBzP), respectively. Previous studies indicate that phthalate monoesters are endocrine disrupting chemicals, interfering with hormone production and signaling, which has spurred the use of structural isomers as replacements. However, there is a lack of research on if terephthalate alternatives show similar toxicity as the phthalates they replace. The purpose of this research is to compare the toxicity of phthalate monoesters to their para-substituted isomers to identify how ring substitution affects the toxicity of these chemicals. **Methods:** Ovarian follicles were collected from adult female CD-1 mice. The follicles were cultured for 96 hours in vehicle control or 100 µg/mL of MEHP, mono(2-ethylhexyl) terephthalate (MEHTP), MBzP, or monobenzyl terephthalate (MBZTP). After the culture period, the follicles were collected for analysis of gene expression related to hormone production, apoptosis, and cell growth and proliferation using quantitative polymerase chain reaction (qPCR). Genes were chosen because they were impacted by phthalate exposure in previous studies. Culture media were collected for measuring hormone levels of progesterone, estradiol, testosterone, and androstenedione using enzyme linked immunosorbent assays (ELISAs). **Results:** MEHP significantly impacted 16 of the

21 genes studied and MBZP affected 10 of the genes. In general, similar effects were seen between phthalate and terephthalate treatments, with some exceptions. In steroidogenesis genes, both MEHP and MEHTP downregulated Hsd17b1, along with MBZTP. MBzP and MBZTP also both upregulated gene expression for Star. In peroxisome proliferator-activated receptor (PPAR) controlled genes, MEHP and MEHTP both upregulated expression of Plin1. Additionally, both MBzP and MBZTP upregulated Fabp4. Terephthalates also showed unique toxicity for some genes. MEHTP was the only treatment to significantly upregulate gene expression of the PPAR gene Angptl4 and cell cycle genes Cdkn2b and Ki67. Similar effects were also observed for hormone levels. Both MEHP and MEHTP treatments decreased estradiol levels, and all treatment groups were found to significantly increase progesterone levels. **Conclusions:** Our findings suggest that though ring substitution may change the magnitude of phthalate effects, terephthalates show similar impacts on gene expression and hormone production. This is important because terephthalates are proposed as safer alternatives to phthalates in consumer products. Similar effects as phthalates means that terephthalates may also lead to endocrine disruption and health concerns, specifically for female reproductive health.

PS 3821 **Evaluation of Data Inclusion of Dams with No Viable Fetuses in Maternal Data Analysis in Rat Embryo-Fetal Development Studies**

C. Zhou, D. Harischandra, and P. B. Bushdid. Labcorp, Greenfield, IN.

Background and Purpose: Dams with no viable fetuses (NVF, dams with all implantation resorptions or dead fetuses at necropsy) in rat embryo-fetal development (EFD) studies are not uncommon and the causes can be test article-related or incidental occurrences. Data interpretation of the EFD studies are commonly performed in two ways: excluding or including the NVF dams for maternal data analysis (e.g., body weight, food consumption). The debate of whether to include NVF dams in maternal data analysis has been focusing on the biological differences between dams with NVF and viable fetuses, however, comparison of data analysis results conducted by using study data with or without NVF dams has not been performed. **Methods:** This is a retrospective analysis of Rat EFD studies conducted at the Labcorp Greenfield location between 2018 to 2025. Rat EFD studies with NVF dams were selected to compare the data analysis results and the overall conclusion made with or without NVF individuals. Studies selected included NVF dams noted as incidental occurrences (e.g., in control, in treated, or in both control and treated groups), as well as treatment-related NVF dams. Maternal data were statistically analyzed using analysis of variance (ANOVA) with and without NVF dams for each study and results were compared. **Results:** Including or excluding NVF dams in maternal data analysis reached the same overall study conclusion on treatment-related effects. However, for studies with treatment-related NVF dams findings, including NVF dams in the maternal data analysis showed more impacted maternal data points (e.g., treatment-related reduced weight and/or food consumption) than excluding them. **Conclusions:** Because including NVF dams in the maternal data analysis provides the same conclusion as analysis conducted without NVF dams, but with more robust detection of treatment-related effects, including the NVF dams in the maternal data analysis for the EFD studies may enhance detection of treatment-related effects and is therefore suggested as a consideration.

PS 3822 **Investigating the Direct Effects of Phthalates on the Vaginal Microenvironment**

A. C. Elkins¹, P. C. Powell¹, H. C. Zierden², and K. D. Rock¹. ¹Clemson University, Clemson, SC; and ²University of Maryland, College Park, MD.

Background and Purpose: The vaginal microenvironment is a critical component of female reproductive health, composed of epithelial, immune, and microbial elements that together maintain mucosal integrity, pH balance, and defense against infection. Under healthy conditions, *Lactobacillus*-dominated communities promote an acidic pH and mucosal homeostasis. In contrast, vaginal dysbiosis, defined by loss of *Lactobacillus* dominance and overgrowth of facultative anaerobes such as *Gardnerella vaginalis*, is associated with elevated risk of bacterial vaginosis (BV), sexually transmitted infections, preterm birth, and infertility. Recent epidemiologic evidence links exposure to endocrine-disrupting chemicals (EDCs), including phthalates found in feminine hygiene products, with higher incidence of BV and vaginal inflammation. Yet, the molecular mechanisms connecting phthalate exposure to epithelial dysfunction and microbial imbalance remain poorly understood. We hypothesize that phthalates disrupt the vaginal microenvironment through two mechanisms: (1) by activating inflammatory and stress-response pathways in vaginal epithelial cells, leading to weakened barrier integrity and altered cytokine signaling, and (2) by directly influencing the growth, metabolism, and acid-producing capacity of commensal and pathogenic bacteria. Together, these changes are predicted to shift the vaginal ecosystem toward a proinflammatory, less acidic, and dysbiotic state that may increase susceptibility to infection and reproductive complications. **Methods:** Human vaginal (VK2/E6E7) epithelial cell lines were cultured per ATCC guidelines and exposed to diethylhexyl (DEHP), dibutyl (DBP), diethyl (DEP), dimethyl (DMP), and diisobutyl (DiBP) phthalates, alone or as a mixture, at 0.001-1.0 µg/mL for 24 hours. Gene expression of proinflammatory and barrier-associated targets (IL-6, TNF-α, TGF-β1, occludin, and claudins 1-4) was assessed by quantitative RT-PCR,

and viability was confirmed via CCK-8 assay. Complementary bacterial assays were conducted with *Lactobacillus crispatus* (beneficial) and *Gardnerella vaginalis* (pathogenic), exposed to equivalent phthalate concentrations reflective of levels measured in feminine hygiene products. Bacterial growth and metabolic activity were quantified spectrophotometrically and through pH changes indicative of lactic acid production. **Results:** Phthalate exposure did not significantly alter epithelial viability but induced marked, cell-type-specific transcriptional responses. Vaginal epithelial cells (VK2) displayed significant upregulation of IL-6 and TNF- α , coupled with suppression of TGF- β 1 and tight junction transcripts (occludin, claudin-1), suggesting barrier weakening and proinflammatory activation. Cervical cell lines showed a blunted inflammatory profile, highlighting tissue-specific vulnerability. In bacterial assays, *L. crispatus* growth was significantly reduced following DEHP and DBP exposure, while *G. vaginalis* exhibited increased metabolic activity and pH elevation under the same conditions. These findings indicate that phthalates can directly impair beneficial bacteria while favoring opportunistic species, providing a plausible link between chemical exposure and dysbiotic microbial shifts. Together, epithelial and microbial results reveal convergent effects of phthalates on inflammation, barrier dysfunction, and microbial balance, three hallmarks of vaginal dysbiosis. Ongoing studies include quantifying cytokine protein expression, validating TEER and immunohistochemistry data (claudins, occludin), and testing mixed phthalate exposures for additive effects. **Conclusions:** These findings demonstrate that environmentally relevant phthalate exposures disrupt both epithelial and microbial components of the vaginal microenvironment. Direct exposure upregulates inflammatory mediators, reduces structural barrier gene expression, and selectively alters bacterial growth dynamics, collectively supporting a model where EDCs promote dysbiosis and impair reproductive mucosal health. This work establishes an *in vitro* framework for understanding the mechanisms linking phthalate exposure to vaginal inflammation and microbial imbalance, with implications for reducing EDC exposures in women's health products and mitigating reproductive health disparities.

PS 3823 Polycyclic Aromatic Hydrocarbons Disrupt Placental Gene Regulation in a Sex-Dependent Manner

K. Lingappan¹, A. Cantu¹, M. Hu², B. Moorthy², and M. Suter². ¹Children's Hospital of Philadelphia, Philadelphia, PA; and ²Baylor College of Medicine, Houston, TX.

Background and Purpose: Our laboratory investigates mechanisms behind the increased risk of preterm birth (PTB) with environmental exposures. In this study, we utilized transcriptomics to determine how exposure to polycyclic aromatic hydrocarbons (PAHs) alters gene expression in primary cultured trophoblasts (ie placental cells) and what pathways are disrupted that may contribute to an increased risk of PTB. **Methods:** Primary trophoblasts were isolated and cultured from Cesarean delivered placentae within one hour of delivery (N=7, 4 female and 3 male). Cells were cultured for 48 hours after which cells were either treated with DMSO as a control, or 10uM of Benzo(a)pyrene for 24 hours. RNA was isolated and bulk RNA-seq was performed. Samples were pre-processed using the nf-core/magseq (v3.18.0) pipeline. Reads were aligned to the human reference genome (GRCh38, Ensembl release 111) using STAR. Differential expression analysis employed DESeq2 (v1.46.0) with apeglm log fold change shrinkage. Genes were considered differentially expressed at Benjamini-Hochberg adjusted p-value < 0.05 and |log2FC| > 0.6. Gene set enrichment analysis was performed using clusterProfiler (v4.14.4), MSigDB (v7.5.1) and ReactomePA (v1.50.0) against Gene Ontology Biological Processes, KEGG, Reactome, MSigDB Hallmark, and Disease Ontology databases. Statistical significance for pathway enrichment was determined using q-value < 0.05. All analyses were performed in R (v4.4.2) within Bioconductor (v3.20) docker container. **Results:** Significant sex-specific differences were observed in the transcriptomic response to PAHs in cultured primary human cytotrophoblasts. The female placental cytotrophoblasts exhibited a more robust transcriptomic response, characterized by a greater number of differentially regulated genes, with minimal overlap with the male cells. With BaP treatment, trophoblasts from female placentae had 205 unique genes that were differentially expressed that were not altered in trophoblasts from male placentae, compared with only 8 genes altered in the trophoblasts from male placentae. Biological pathways related to xenobiotic metabolism and detoxification were positively enriched, while pro-inflammatory pathways were negatively enriched in the female cytotrophoblasts. We also observed higher expression of the aryl hydrocarbon receptor (AHR) in female cytotrophoblasts compared with male (2.8-fold, p=0.047), suggesting a sex-specific regulatory role of this pathway. **Conclusions:** These findings highlight sex-specific mechanisms in placental responses to environmental toxicants and their potential contribution to disparities in PTB risk.

PS 3824 The Current Situation in Development and Reproductive Toxicity Evaluation of Pharmaceuticals using Non-Human Primates in Japan

Y. Hoshino, A. Takasu, G. Higashiyama, and F. Mikashima. Pharmaceuticals and Medical Devices Agency, Chiyoda-ku, Tokyo, Japan. Sponsor: Y. Hoshino, Japanese Society of Toxicology

Background and Purpose: In recent years, increasing number of biopharmaceuticals have been developed. On the aspect of the binding affinity to target molecules, non-human primates (NHPs) are often used as relevant species for non-clinical safety evaluation. On the other hand, due to the ethical concern about animal testing, the use of NHP is being reconsidered. **Methods:** In this study, we investigated non-clinical studies using NHPs for development and reproductive toxicity (DART) evaluation of 72 products newly applied for marketing approval in Japan from 2014 to 2024. We mainly examined fertility assessment, study design of ePPND/EFD studies, relationships between the ePPND/EFD study results and mode-of-action (MoA). **Results:** Most of the products using NHPs for DART assessment were therapeutics antibodies. The endpoints for fertility evaluation were usually histopathological examination of the reproductive organs. While in some products, detailed assessment such as the measurement of hormones was conducted. As for ePPND/EFD studies, MoA-related endpoints were often confirmed and most of the findings observed in those studies were related to MoA or its secondary effects. **Conclusions:** The DART evaluation using NHPs are usually limited to the products with high species specificity and those products are rare to induce off-target toxicity. Therefore, the Weight of Evidence approach such as MoA based risk assessment for DART should be considered before animal testing in the balance of the existing data adequacy.

PS 3825 From Development to Ovarian Failure How the Tobacco Smoke Chemical Benzo[a]pyrene Disrupts Egg Quality in Mice

K. N. Leon Parada, N. Vaddella, and U. Luderer. University of California, Irvine, Irvine, CA.

Background and Purpose: Benzo[a]pyrene (BaP) is a reproductive hazard released as a by-product from the incomplete combustion of organic materials such as cigarettes, fossil fuels, wood, or grilled foods. BaP is highly detrimental to ovarian development. The ovarian reserve, or the finite pool of oocytes within the ovary, is established from primordial germ cells (PGCs) during development. Published work from the Luderer laboratory demonstrated prenatal exposure to BaP significantly reduced the number of germ cells, leading to premature ovarian failure, increased oxidative stress in surviving eggs, and reduced fertility in adulthood. The expression of meiosis-related genes in fetal PGCs, including *Tex12*, *Sycp1*, *Sycp2*, *Syce1*, *Stag3*, and *Dmc1* which transcribe proteins needed for the synaptonemal complex and DNA repair pathways that drive homologous chromosome crossing over, was also decreased. The meiotic spindle consists of microtubules that attach to chromosome kinetochores to ensure that each egg receives half of the chromosome set in which euploidy is reestablished upon fertilization. The meiotic window plays a pivotal role in preserving egg quality and genetic integrity. We hypothesized prenatal exposure to BaP would significantly reduce the quantity and quality of surviving oocytes by disrupting egg chromosome alignment, spindle quality, and ploidy. **Methods:** To test this hypothesis, we exposed pregnant F0 dams to 0, 0.033, or 2 mg/kg/day of BaP from 6.5-15.5 dpc which targets the mitotic proliferation window of F1 PGCs and the initiation of meiosis in oocytes. The 10-days of the 0.033 mg/kg/day BaP dose is equivalent to one-third of the cumulative mutagenic PAH dose to a highly, non-occupationally exposed woman throughout pregnancy after allometric species conversion. The 2 mg/kg/day dose is at the low end of doses of BaP used in published toxicological studies. The F1 generation were aged to post-natal day (PND) 35-45 when they were primed with 5IU of pregnant mare serum gonadotropin (PMSG) and superovulation was induced with 5IU of human chorionic gonadotropin hormone (hCG). Eggs were assessed for the following characteristics: a small perivitelline space (PVS), spherical shape, and the presence of a polar body. Eggs missing one or more of these characteristics were labeled as abnormal. Eggs were fixed and stained with antibodies against CREST, alpha-tubulin, and DAPI which labeled kinetochores, spindles, and chromosome structures within. Z-stack images of eggs were obtained, and spindle length, metaphase plate length, spindle volume, chromosome alignment, and ploidy were assessed using IMARIS software. **Results:** Corroborating previous results, the number of eggs collected from BaP-exposed mice did not differ from control (GEE, p>0.05). The prevalence of abnormal eggs (Kruskal Wallis, p=0.007), spindle length (GEE, p=0.005), and spindle volume (GEE, p=0.002) were significantly increased in BaP-exposed mice compared to control mice. Compared to control mice, percent aneuploidy was significantly higher in mice exposed to 0.033 mg/kg/day BaP (Kruskal Wallis, p=0.034). Chromosome alignment and metaphase plate width was not altered by BaP exposure (GEE, p>0.05). **Conclusions:** Prenatal BaP exposure compromised egg quality by increasing abnormal egg and spindle characteristics that are implicated in reduced developmental competence. This exposure also undermines the genetic integrity of eggs at a human relevant dose, which raises an important question of BaP effects on women's long-term reproductive, maternal, and prenatal health.

PS 3826 Chronic exposure to selenium through natural diets causes endocrine disruption and reproductive toxicity in zebrafish (*Danio rerio*): a trophic transfer study

M. Uddin¹, J. Ritu¹, S. Niyogi^{1,2}, and D. P. Chivers¹. ¹University of Saskatchewan, Saskatoon, SK, Canada; and ²Toxicology Centre, University of Saskatchewan, Saskatoon, SK, Canada. Sponsor: S. Niyogi, Society of Environmental Toxicology and Chemistry

Background and Purpose: Aquatic ecosystems face increasing threats from contaminants linked to human activities, particularly the release of selenium from mining processes. While selenium is vital for essential physiological functions, its excessive accumulation poses significant toxicity risks. Although much is known about the developmental and neurotoxic implications of selenium in fish, its effects as an endocrine disruptor during realistic dietary exposure remain inadequately explored. **Methods:** In this pivotal study, we exposed the benthic oligochaete *Lumbriculus variegatus* to selenium, as selenomethionine at concentrations of 0, 50, and 200 µg/L over 14 days. The resulting tissue burdens were 0.65, 17, and 43 µg/g dry weight, respectively. Following this exposure, the worms were fed to adult zebrafish for 60 days, allowing us to assess a range of critical reproductive and endocrine parameters. **Results:** Our findings revealed no significant differences in body length or weight among the groups. However, marked increases in Gonadosomatic index were observed in female zebrafish exposed to Se, while Hepatosomatic index was elevated in both sexes at the highest exposure level. Notably, reproductive performance suffered, as indicated by decreased fecundity, smaller egg diameters, and diminished sperm motility and velocity. At the molecular level, dietary selenium disruption affected the hypothalamic pituitary gonad axis. Females exhibited a down-regulation of *gnrh*, *fshb*, *fshr*, *cyp19b*, *vtg*, and *era*, whereas males displayed mixed responses, including upregulation of *vtgr*, *cyp11a*, and *3βhsd*. Circulating estradiol (E2) levels decreased in females and the highest Se-treated males. Additionally, while 11KT levels remained stable in females, a decline was noted in males at the 17 µg/g Se-exposed group. Notably, vitellogenin (Vtg) levels decreased in females but increased in males. Histopathological assessments uncovered significant ovarian adhesion and oocyte degeneration in females, along with degeneration of Sertoli and Leydig cells in males. **Conclusions:** These results underscore that chronic dietary exposure to environmentally relevant selenium levels disrupts endocrine regulation, impairs gonadal development, and severely limits reproductive success in zebrafish. This research highlights the urgent need to address the ecological risks posed by selenium contamination in aquatic ecosystems.

PS 3827 Parental and Postnatal NDMA Exposure Alters Reproductive and Toxicological Profiles in F1 Rats

A. Arena, J. Stein, L. Nagaoka, R. Castro, G. Rosalem, J. Aquino, J. Tavares, O. Vitale, G. Marraschi, S. Santos, L. Magalhães, B. Manoel, and B. Jorge. Unesp, Botucatu, Brazil. Sponsor: W. Scarano

Background and Purpose: Environmental and lifestyle habits are among the factors that contribute significantly to infertility worldwide. The Developmental Origins of Health and Disease (DOHaD) and Paternal Origins of Health and Disease (POHaD) hypotheses explore how parental health influences offspring development. Nitrosodimethylamine (NDMA) is a harmful environmental contaminant found in water, food and some drugs, with mutagenic, genotoxic and carcinogenic effects, promoting the formation of reactive oxygen species. Data on reproductive and developmental studies is limited, especially at low doses. The aim of this study was to assess the effects of parental (Maternal-M, Paternal-P, and MP-) and postnatal NDMA exposure on toxicological and reproductive outcomes in male and female F1 rats. **Methods:** The animals were exposed to control (distilled water, 1mL/kg/day) or to 7.2 ng/kg/day of NDMA. The F0 were divided into 4 groups: C- (control males X control females); M- (NDMA females X control males); P- (control females X NDMA males); and MP- (NDMA females X NDMA males), exposed from postnatal day (PND) 60 until mating, with continued exposure in females during gestation and lactation. Offspring were exposed from PND 22 until the end of sexual maturation, with 1 pup/sex/litter exposed to the vehicle (groups -) and the other to NDMA (groups +). The F1 offspring were evaluated for reproductive and toxicological parameters in adult life. **Results:** In male offspring sexual behavior, a reduction in the first mount and first intromission latency in the C+ and M+ groups was observed. No significant alterations were found in organ weight, hematological parameters, fertility test, sperm morphology/motility and Leydig cell count. In biochemistry analysis, elevated serum creatinine (P-), elevated urea (P-, C+, M+, P+ and MP+) and reduced total proteins (MP- and M+ groups) were found. In the staging of seminiferous tubules, there was a decrease in the percentage of stages I-VI (MP-, C+ and MP+) and an increase in stages VII-VIII (C+). Glutathione (GSH) and superoxide dismutase (SOD) were reduced in the testis (MP+), while the Malondialdehyde (MDA) showed high levels (MP-). In female offspring, no alterations were found in estrous cycle, sexual behavior, organ weight, hematological parameters or follicle count. However, there was a decrease of alkaline phosphatase (P- and P+) and an increase in gamma glutamyl transferase (M+). Furthermore, in the fertility test, females in the MP- group had a reduction of uterus + fetuses weight, number of implantations and live fetuses. SOD was reduced in the M-, P-, MP-, C+ and M+ groups, while catalase (CAT) and GSH were reduced in the P+ group. **Conclusions:** Low-dose NDMA exposure caused biochemical and oxidative stress alterations in offspring, with mild reproductive

effects, particularly after combined parental exposure. These results support the DOHaD/POHaD concepts and highlight the sensitivity of the reproductive system to even low environmental NDMA levels.

PS 3828 Comparative Toxicogenomics Database Analysis: Relevant Environmental Toxicant Mixtures and Preeclampsia

B. Pace, J. Meeker, and S. Harris. University of Michigan, Ann Arbor, MI.

Background and Purpose: Puerto Rico, a region characterized by a high concentration of Superfund sites and subsequent environmental chemical exposures, also exhibits a high rate of preeclampsia. Given the limited available information on how environmental toxicant mixtures impact preeclampsia, we sought to leverage publicly accessible data to analyze genes, molecular mechanisms and biological events linking relevant environmental toxicant mixtures with preeclampsia. **Methods:** Using the Comparative Toxicogenomics Database (CTD), a database of curated chemical-gene, chemical-phenotype, and chemical-disease associations, we prioritized a set of 70 chemicals found in maternal blood/urine samples as well 40 additional parent chemicals within the pregnant women enrolled in PROTECT (Puerto Rico Test site for Contamination Threats) study. We used CTD's statistical tools to test the curated chemical-disease associations and identified 8 chemicals, including heavy metals, phthalates and perfluoroalkyl substances with a direct marker or mechanistic relationship with preeclampsia. Through a comprehensive approach involving curated chemical-gene interaction analysis and CTD's set analyzer, we examined correlations of the 8 identified chemicals and their interactions with genes. Subsequently, we conducted pathway enrichment analysis on the resulting 29,009 chemical-gene interactions. **Results:** Among the statistically enriched pathways (p-value <0.01) for imputed genes, 16 pathways overlapped with the enriched pathways associated with the disease outcome of preeclampsia, including pathways such as: cytokine signaling in the immune system, extracellular matrix organization and biological oxidations. We utilized the integration of five types of curated interactions within the CTD to establish Chemical-Gene-Phenotype-Disease (CGPD)-tetramers (a 4-unit block of information connecting chemical-gene interactions with phenotypes and diseases). This strategy generated 843 CGPD-tetramers involving the 8 environmental toxicants associated with preeclampsia. The identification of 213 phenotypes and 21 genes shared within these CGPD-tetramers suggests crucial mechanistic roles for cellular proliferation, glucose homeostasis and inflammatory response. **Conclusions:** Our analysis demonstrates biological plausibility for environmentally relevant mixtures of toxicants to dysregulate key biological pathways, potentially contributing to preeclampsia/hypertensive disorders during pregnancy. These findings provide a rationale for future experiments in animal tissue or cell models testing diverse mixtures of toxicants.

PS 3829 Effect of *in Utero* Exposure to the Cannabis Compounds Tetrahydrocannabinol (THC) and Cannabidiol (CBD) on the Developing Fetal Gonads

F. A. Luna, H. Avalos, J. Lim, and U. Luderer. University of California, Irvine, Irvine, CA.

Background and Purpose: There is a growing rise in the use of cannabis and cannabis related products after its legalization in many states. As a result, cannabis use is widely accepted, but studies of its effects on *in utero* development are limited. Studies have shown that in adult male rats, cannabis sativa exposure decreased sperm counts, and in female mice low dose tetrahydrocannabinol (THC) exposure during adolescence decreased ovarian follicle reserve. Much of the focus has been around adolescent to adult exposure, but there is also a growing rise in the percentages of expectant mothers who using cannabis or cannabis related products during pregnancy. However, the impacts of exposure to cannabis during pregnancy on the developing fetal gonads is poorly understood. **Methods:** Pregnant female C57BL/6J mice were exposed by intraperitoneal injection to THC (5mg/kg), CBD (20mg/kg) or a vehicle dose (5% Tween 80 and 95% saline) from E6.5 to E16.5. Mice were sacrificed 24 hours after last injection. Fetal testes and ovaries (E17.5) were harvested, immediately fixed in 4% PFA for 3 hours and embedded in OCT. Embedded fetal gonads were cryosectioned at 7 micron thickness, and immunofluorescence was performed labeling germ cells using GCNA antibody and the cannabinoid receptor 1 (CB1R) using a CB1R antibody. **Results:** Sex dependent differences were found with fetal ovaries expressing no CB1R at E17.5, while fetal testes did express CB1R, confined only at the germ cells. For the testes, the percentage of germ cells positive for CB1R normalized to germ cell-specific marker (TRA-98) positive cells revealed no difference in the average percentage between treatment groups. **Conclusions:** Preliminary results reveal that there is a sex dependent difference of CB1R expression between male and female fetuses at E17.5. CB1R expression in the testes was confined to only the germ cells, emphasizing the role CB1R plays in testicular development at E17.5. Ongoing studies will look further into the expression of CB2R, germ cell apoptosis, and critical enzymes of the endocannabinoid system. These results will provide better information about fetal gonadal development and whether cannabis exposure *in utero* may affect the fetus' fertility in adulthood.

C. J. Hu¹, M. Garcia¹, A. Nihart¹, L. Yin², H. Collins³, J. Thompson³, G. Smith⁴, E. Clarke⁵, M. Campen¹, and X. J. Yu¹. ¹University of New Mexico, Albuquerque, NM; ²ReproTox Biotech, Albuquerque, NM; ³Fertility Center of New Mexico, Albuquerque, NM; ⁴University of Michigan Medical School, Ann Arbor, MI; and ⁵CABQ Animal Welfare Department, Albuquerque, NM.

Background and Purpose: Microplastics (MPs) and nanoplastics (MNPs) have become pervasive contaminants in the environment, detected in air, water, and soil worldwide. Emerging studies reveal that plastic particles can infiltrate multiple human organs, suggesting possible systemic health risks. However, evidence linking environmental microplastic exposure to reproductive outcomes remains limited. This study aimed to evaluate (1) the presence and composition of MPs in canine testes and human semen, (2) their potential associations with sperm quality parameters, and (3) the translational implications of environmental microplastic accumulation for male reproductive health. **Methods:** Freshly excised testes and epididymides were collected from 37 adult dogs (1-9 years old) undergoing routine neutering procedures at local veterinary clinics. Microplastic particulates were visualized using micro-Raman spectroscopy and quantified using pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS) for 12 common plastic polymers, including polyethylene (PE), polypropylene (PP), polystyrene (PS), polymethyl methacrylate (PMMA), polyvinyl chloride (PVC), polyurethane (PU), polyethylene terephthalate (PET), nylon 6 (N6), and nylon 66 (N66). Testes were stratified into high- and low-MP burden groups, and sperm parameters—concentration, motility, viability, and morphology—were analyzed using computer-assisted sperm analysis (CASA). Lipid peroxidation was assessed by quantifying malondialdehyde (MDA) adducts in epididymal sperm. Parallel analyses were performed on semen samples collected from 16 men (aged 28-52 years) attending a fertility clinic. Samples were assessed for semen quality following WHO 6th Edition guidelines. Py-GC/MS quantified MNP polymers in whole semen and in fractionated samples (seminal plasma vs. sperm cell fraction). **Results:** In canine testes, Raman spectroscopy confirmed plastic particles (5-20 µm) identified as PS, PET, PFA, and LDPE. Total polymer concentrations ranged from 2.37 to 485.7 µg/g tissue, with PE, PVC, N66, SBR, and PMMA being predominant. Testes with higher MP loads (mean = 99.7 ± 14.2 µg/g) exhibited significantly elevated lipid peroxidation in sperm (MDA = 0.344 ± 0.04 µM/mg protein vs. 0.255 ± 0.04 µM/mg protein, $p < 0.05$) and altered motility kinetics, while sperm count and morphology remained unchanged. Elevated cadmium and cobalt levels were also associated with high-MP tissues, suggesting co-contamination effects. In human semen, MNPs were detected in all 16 samples, ranging from 10.79 to 334.30 µg/ml (mean = 116.69 ± 94.78 µg/ml). PE and PU were the most frequent polymers. Approximately 70% of MPs were located in the seminal plasma fraction, while sperm cell fractions contained minimal detectable levels. Although no statistically significant correlation was observed between total MNP concentration and standard semen indices, eight samples displayed at least one subnormal WHO parameter, indicating a potential subclinical impact. **Conclusions:** This combined canine-human study provides the first cross-species evidence of microplastic accumulation within mammalian male reproductive tissues. The findings demonstrate that microplastics are widespread in both dog testes and human semen, encompassing multiple polymer types and concentration ranges. Elevated microplastic burdens were associated with increased oxidative stress and altered sperm motility in dogs, while universal detection in human semen highlights the pervasiveness of exposure. Together, these results suggest that environmental microplastics may represent a previously unrecognized risk factor for male reproductive dysfunction. Future research should integrate larger human cohorts, mechanistic *in vitro* assays, and exposure modeling to determine causal relationships, evaluate co-exposure effects with heavy metals, and inform strategies for reproductive health protection.

PS 3831 Co-exposure to Polystyrene Nanoplastics and Phthalate Metabolites Mixture Disrupts Ovarian Cell Cycle and Oxidative Balance in Neonatal Ovaries *In Vitro*: A DOHaD Perspective

P. Souza¹, R. Santacruz Márquez², M. Laws², J. Flaws², and W. Scarano¹. ¹São Paulo State University - UNESP, Botucatu, Brazil; and ²University of Illinois Urbana-Champaign, Urbana, IL.

Background and Purpose: The increasing production and pollution of plastics raise concerns due to their harmful effects on the environment and human health. In the environment, plastics degrade into microplastics (<5 mm) or nanoplastics (≤100 nm) that can reach humans and cause health effects. Plastic additives such as phthalates, classified as endocrine-disrupting chemicals (EDCs), are released into the environment and could attach to the hydrophobic surfaces of nanoplastics, leading to bioaccumulation and biomagnification. The ovary is essential for female reproduction, responsible for folliculogenesis, oogenesis, and hormone synthesis. Females are born with a finite number of primordial follicles, the follicular reserve, which determines fertility throughout life. Alterations in this reserve can lead to premature ovarian aging, characterized by a decline in fertility potential with age or premature ovarian failure. The Developmental Origins of Health and Disease (DOHaD) proposes that events occurring during early development determine susceptibility to diseases later in life. The establishment of the primordial follicle pool is closely related to the DOHaD concept, as it occurs during late gestation in humans and around post-

natal day (PND) 3 in mice. Establishment of the primordial follicle pool depends on tightly regulated cell cycle, oxidative stress, apoptosis, and hormonal signaling that ensures the survival of a reproductive reserve with optimal long-term fertility potential. Previous studies have demonstrated the effects of phthalates on reproductive health, highlighting the importance of investigating environmentally relevant doses and mixtures. Recent studies have also shown that nanoplastics can reach and accumulate in the ovary, inducing oxidative stress, apoptosis, and disrupting ovarian homeostasis. However, limited information is available regarding the effects of exposure to nanoplastics alone or in combination with phthalates on the neonatal ovary during follicular reserve establishment. **Methods:** Therefore, this study evaluated the effects of exposure to polystyrene nanoplastics (PS-NPs, nominal size 100 nm) alone or in combination with a phthalate metabolite mixture (MM) on neonatal mouse ovaries *in vitro*. Ovaries from CD-1 mice on PND4 were collected and cultured for 96 hours with vehicle control, PS-NPs (5 - 100 µg/mL), MM (0.01 - 10 µg/mL), or the combination of PS-NPs + MM at lowest and highest concentrations. Doses were based on follicular fluid levels and dose-response evaluation. The MM was based on the proportions of phthalate metabolites in the urine of pregnant women. After 96 hours, ovaries were collected (three pooled per replicate) and processed for RT-qPCR analysis ($n = 5-6$). **Results:** The exposure to PS-NPs or MM alone did not significantly affect the expression levels of the analyzed genes. However, co-exposure to PS-NPs and MM increased the expression of *Ccnd2* ($p = 0.001$) and *Cdk6* ($p = 0.038$) at the lowest combined dose compared with the control, indicating activation of cell cycle progression related to the G1/S phase transition and possibly enhanced activation of primordial follicle proliferation. Moreover, *Esr2* ($p = 0.03$) and *Amh* ($p = 0.03$) expression levels were also increased at the same combined dose, suggesting potential defects in follicular recruitment, as *Amh* is expressed by growing follicles and *Esr2* has been associated with the maintenance of the follicular reserve. At the highest combined doses, co-exposure to PS-NPs and MM decreased *Cdkn1c* ($p = 0.04$) and increased *Lamp1* ($p = 0.04$) expression compared with the control, suggesting facilitated cell cycle progression and alterations in lysosomal membrane integrity. Also, co-exposure to PS-NPs and MM decreased *Hmox1* ($p = 0.005$ and $p = 0.0009$) expression at both combined concentrations, indicating an impact on oxidative stress balance. **Conclusions:** These findings suggest that early-life co-exposure to PS-NPs and MM may disrupt ovarian development and compromise future reproductive health, which is consistent with the DOHaD concept.

PS 3832 Long term exposures to di(2-ethylhexyl) phthalate and diisononyl phthalate alter the Nrf2 signaling pathway in the mouse ovary

Z. C. Inman, T. Seaton, A. Fields, M. Laws, and J. A. Flaws. University of Illinois Urbana-Champaign, Urbana, IL.

Background and Purpose: Di(2-ethylhexyl) phthalate (DEHP) and diisononyl phthalate (DiNP) are plasticizers used in a wide range of consumer products including building materials, food and beverage containers, and children's toys. This is concerning because DEHP and DiNP can leach out of products and enter the human body. Furthermore, both short-term and long-term exposures DEHP and DiNP have been shown to exhibit endocrine disrupting abilities and lead to early reproductive aging in animal models. However, little is known about the mechanisms underlying phthalate-induced reproductive aging. Previous studies indicate that increased oxidative stress can accelerate the loss of ovarian follicles and lead to reproductive aging. Thus, this study tested the hypothesis that DEHP and DiNP increase oxidative stress in the mouse ovary. Specifically, this study focused on the effects of DEHP and DiNP on the Nrf2 signaling pathway because Nrf2 is a transcription factor that is responsible for regulating the expression of antioxidant proteins such as glutathione peroxidase, glutathione S-transferases, NAD(P)H quinone dehydrogenase 1, and peroxiredoxin-1. **Methods:** To test this hypothesis, female CD-1 mice aged 39-40 days were dosed through the chow with either vehicle control (corn oil), DEHP (0.15, 1.5, 1500 parts per million (ppm)), or DiNP (0.15, 1.5, 1500 ppm) for 1, 6, 9, 12, and 15 months. The ovaries from these mice were then collected immediately post-dosing and subjected to quantitative polymerase chain reaction analysis of the expression of factors in the Nrf2 signaling pathway. **Results:** At 1 month post exposure, DEHP and DiNP at 1500 ppm significantly decreased the expression of NFE2 like bZIP transcription factor 2 (*Nfe2l2*), the gene that encodes the protein NRF2, when compared to control. At 6 months post exposure, DEHP and DiNP at 1500 ppm significantly increased the expression of *Nfe2l2* when compared to control. At 9 months post exposure, DEHP at 0.15 ppm and 1.5 ppm and DiNP at 1.5 ppm and 1500 ppm significantly increased the expression of *Nfe2l2* when compared to control. At 15 months post exposure, DEHP at 0.15 ppm and 1.5 ppm and DiNP at 1.5 ppm and 1500 ppm significantly increased the expression of *Nfe2l2* when compared to control. **Conclusions:** Collectively, our data indicate that DEHP and DiNP exposure significantly affect the Nrf2 signaling pathway in the ovary. Given that the Nrf2 signaling pathway is crucial for regulating oxidative stress in the ovary, these data suggest that long term exposure to DEHP and DiNP can significantly affect oxidative stress pathways in the ovary.

PS 3833 **Febuxostat Has A Protective Effect On Maternal Nano-Titanium Dioxide Inhalation Induced Placental Glycogen Changes in Female Pups**

A. Dunn. West Virginia University, Morgantown, WV.

Background and Purpose: Increased placental glycogen content during pregnancy is linked to gestational complications such as diabetes, preeclampsia, and intrauterine growth restriction in humans. Previously, we have shown that maternal inhalation exposure to nano titanium dioxide (nano-TiO₂) during gestation in rats impacts litter size, pup and placental mass, and increases labyrinth zone area and decreases junctional zone area. Additionally, we have investigated the role of xanthine oxidase (XO) in these mechanisms, and found that XO inhibition via febuxostat (FBX) has some protective effects against nano-TiO₂. Thus, we wanted to explore the possibility that glycogen storage is affected by FBX treatment during critical periods of placental development. We hypothesized that placental glycogen content would be elevated in the nano-TiO₂ exposed placentas compared to controls, and that FBX-treatment would restore glycogen levels to resemble control dams. **Methods:** Pregnant Sprague Dawley rats were randomly assigned to either sham-control or nano-TiO₂ groups. Dams were exposed (nano-TiO₂ concentration = 12 mg/m³; HEPA-filtered air 25 ml/min) for 6 hrs/d for 6 d between gestational day (GD) 10-19 before sacrifice on GD 20. Within those groups, rats were further assigned to early gestation FBX treatment (50 mg/L; GD 1-19), mid-gestation FBX treatment (50 mg/L; GD 13-19), or no FBX treatment. One male and one female placenta was taken from each dam fixed with paraformaldehyde, frozen, sectioned via cryostat at 10µm, and stained with Periodic acid-Schiff (PAS). ImageJ analysis was used to identify the following four parameters; average glycogen deposit area, average number of glycogen deposits, total glycogen area, and percent glycogen area by total tissue area. **Results:** Average glycogen deposit area was significantly increased in the female nano-TiO₂, mid-FBX exposed group compared to the female nano-TiO₂, early-FBX group (46144.11 ± 17406.69 AU vs. 11865.15 ± 1513.78 AU). Average number of glycogen deposits was also significantly increased in the female nano-TiO₂, no FBX treatment exposed placentas compared to female sham-control, no FBX treatment group (6.44 ± 3.42 vs. 1.78 ± 0.76). Finally, total glycogen area was significantly increased in the female nano-TiO₂, no FBX treatment group, compared to the female sham-control, no FBX treatment group (169372.67 ± 85206.07 AU vs. 58334.56 ± 14645.05 AU). **Conclusions:** These results highlight that nano-TiO₂ increases placental glycogen levels at a critical time point during the end of gestation, and FBX plays a modestly protective role, especially in female pups. The cellular mechanisms by which increased glycogen affects maternal and fetal health, specifically fetal growth, and how FBX modulates this response warrants further investigation.

PS 3834 **Alterations in early embryonic development by exposure to the pesticide temephos in male rats.**

A. Curbelo-Valiente¹, G. M. Moreno-Bustamante¹, M. J. Solis-Heredia¹, F. O. Casillas², and B. Quintanilla-Vega¹. ¹Cinvestav, Mexico City, Mexico; and ²Metropolitan Autonomous University (UAM) Iztapalapa Unit, Mexico City, Mexico.

Background and Purpose: Temephos is an organophosphate pesticide widely used in Mexico and worldwide to control mosquito larvae that carrier diseases such as dengue, Zika, and chikungunya. The World Health Organization (WHO) classifies temephos in Category III (slightly toxic) and considers its use in drinking water safe. The Environmental Protection Agency (EPA) classifies temephos as moderately toxic. However, several studies have reported that temephos causes reproductive adverse effects in males, including decreased fertilization rate. This study aimed to evaluate the effect of temephos exposure in male rats on early embryonic development. **Methods:** Male Wistar rats were exposed to doses of 10 or 100 mg/kg/day/5d by gavage (WHO-NOAEL and LOAEL, respectively). Temephos was emulsified with saline solution (0.9% NaCl; vehicle). The euthanasia was performed 24 h post-treatment and spermatozoa were collected from the cauda epididymis by deferens. Female rats not exposed to temephos were used and superovulated by intraperitoneal injection of 30 IU of eCG hormone, followed by 50 IU of hCG hormone 50 h later. Euthanasia was performed 24 h after the hCG injection, the ovaries were retrieved, and the cumulus-oocyte complexes were collected. Fertilization was performed under *in vitro* conditions (in HTF medium supplemented with 4% BSA/37 °C/5% CO₂/5 h); for embryo development, the cells were transferred to KSOM medium + 4% BSA for 120 h under similar incubation conditions. **Results:** The dose of 10 mg/kg/d/5 d did not cause changes in the fertilization rate compared with the control group; however, it showed an increase in the number of cells arrested at the 8-cell stage. While exposure to 100 mg/kg/day for 5 days of temephos reduced the fertilization rate by 25%, showing a significant increase in undivided cells and a 74% decrease in morula stage cells. Embryos from the control group reached the blastocyst stage with a median value of 8.12%; however, embryos from the treated group (100 mg/kg/day) did not show blastocysts. **Conclusions:** These results suggest that exposure of male rats to doses corresponding to the NOAEL and LOAEL affect early embryonic development. Further studies are needed to elucidate the mechanism by which the larvicide temephos causes these developmental effects.

PS 3835 **Exposure to a Phthalate Mixture Decreases Ovulation Rates, Impairs Steroidogenesis, and Alters Angiogenesis In Vivo**

B. A. Williams, S. M. Ghuneim, K. L. Land, C. V. Harper, E. T. Hayden, S. S. Sherlock, M. M. Wilson, and P. R. Hannon. University of Kentucky, Lexington, KY.

Background and Purpose: Phthalates are ubiquitous, endocrine-disrupting chemicals that people are exposed to daily. They are rapidly metabolized to monoester metabolites, which are distributed throughout the body and have been shown to reach the ovary. Previous work in our laboratory and others have shown that exposure to phthalates impairs steroidogenesis, alters angiogenesis, and decreases ovulation rates in cultured mouse antral follicles *in vitro*. Because of this, we hypothesized that mice exposed to phthalates *in vivo* would have decreased ovulation rates via potential mechanisms involving disrupted steroidogenesis and angiogenesis. **Methods:** For these experiments, we utilized a mixture of six phthalate metabolites (MPTmix) that was derived using urinary phthalate levels in women. Mice were injected intraperitoneally (IP) with MPTmix (10 or 100µg/kg) or DMSO (vehicle control) beginning at postnatal day 22. IP injection of metabolites was prioritized to replicate the composition of phthalate metabolites that reach women's ovaries. On day 3, the mice were injected IP with 5IU pregnant mare serum gonadotropin to induce ovarian follicular development ± MPTmix. 48 hours later, animals were injected IP with 2.5IU human chorionic gonadotropin (hCG) to induce ovulation ± MPTmix. Animals were euthanized prior to hCG administration or at 18 hours post-hCG treatment. At collection, ovulation rates were assessed, serum were collected for hormone measurements, one ovary was flash frozen in liquid nitrogen for qPCR analysis, and the other ovary was fixed in 4% formaldehyde overnight before being paraffin embedded for histology. Tissue sections were mounted and stained with hematoxylin and eosin (H+E) for follicle/corpus lutea (CL) counting, and subjected to CD31 immunohistochemistry, a marker of endothelial cells for ovulatory vascular visualization. ImageJ was used to measure average CD31 integrated density, a measurement that assesses stain intensity and area. **Results:** Animals that received hCG had increased ovulation rates (mean=16.5) and fewer preovulatory follicles compared to DMSO 0hr controls (n=8-16; p<0.05); however, animals treated with hCG+100µg/kg had decreased ovulation rates (mean=8.33) relative to hCG controls (n=12; p<0.05), and 6/12 animals had <2 ovulations. Consequently, these animals had significantly fewer CLs per ovary section than hCG controls. Animals that received hCG+100µg/kg had lower but not significantly decreased ovulation rates (mean=10.17) and numbers of CLs, and 4/12 animals had <2 ovulations. Additionally, these animals had significantly more preovulatory follicles than those treated with hCG alone (n=8-12; p<0.05). Treatment with hCG increased serum levels of progesterone compared to DMSO 0hr (n=7-14; p<0.05), but progesterone levels were decreased in animals that failed to ovulate with hCG+100µg/kg compared to hCG (n=3-10; p<0.05). Additionally, animals that received hCG+100µg/kg had decreased serum estradiol levels and decreased expression of *Cyp11a1* and *Hsd3b1* relative to hCG (n=6-15; p<0.05). Immunohistochemistry staining revealed an increase in integrated density of CD31 staining with hCG treatment relative to DMSO; however, animals that received hCG+100µg/kg did not have this increase (n=7-11; p<0.05), suggesting impaired ovulatory angiogenesis and luteal formation. **Conclusions:** While hCG+10µg/kg did not have significantly decreased ovulation rates, the ovaries contained significantly more preovulatory follicles, and there were several animals that failed to ovulate. This suggests that this dose may still alter ovarian function, and more analysis is needed with this dose. Animals exposed to hCG+100µg/kg had decreased ovulation rates and fewer CLs. This may be due to vascular dysfunction, indicated by a decrease in integrated density of CD31 staining for blood vessels. Further, progesterone levels, estradiol levels, and expression of *Cyp11a1* and *Hsd3b1* were decreased in animals exposed to hCG+100µg/kg, suggesting dysregulation of ovarian steroidogenesis during ovulation. Supported by R01ES033767, P30ES026529.

PS 3836 **A weight-of-evidence review of the toxicological and epidemiological literature of the reproductive and developmental hazard of vinyl chloride monomer**

M. L. Kreider¹, H. L. Fairbanks¹, L. R. Lautermilch¹, R. D. Righter², A. M. Urban³, L. P. Marshall⁴, and O. A. Adebambo¹. ¹Stantec, Pittsburgh, PA; ²Stantec, Portland, ME; ³Stantec (formerly), San Francisco, CA; and ⁴Valeo Sciences, Pittsburgh, PA.

Background and Purpose: The United States Environmental Protection Agency (EPA) designated vinyl chloride monomer (VC) as a High-Priority substance for risk evaluation under the Toxic Substances Control Act (TSCA) with reproductive/developmental outcomes as a health hazard of interest. The objective of this review was to independently assess the quality of available epidemiological and toxicological literature to determine the current weight-of-evidence for the relationship between VC exposure and reproductive/developmental outcomes. **Methods:** A review of English-language literature was conducted in PubMed and Scopus databases through October 7, 2024, and compared with reference lists from Agency for Toxic Substances and Disease Registry, Texas Commission on Environmental Quality, and EPA's Integrated Risk Information System assessments of VC. Inclusion criteria were met when the study included relevant population (e.g., animal, human), exposure (e.g., VC via oral, inhalation, or dermal route), comparator (e.g., sham or vehicle control, unexposed epidemiological controls), and outcome (e.g., reproductive/developmental). The quality of each included study was evaluated using the Draft Systematic Review Protocol Supporting TSCA Risk Evaluations for Chemical Substances. Studies were numeri-

cally scored from 1 to 4 (score of 1 indicating highest quality) on methodological and analytical characteristics, including study participation, exposure characterization, outcome assessment, potential confounding, and statistical analysis for epidemiological studies, as well as test substance, test design, exposure characterization, test organisms, outcome assessment, confounding control, and data presentation and analysis for toxicological studies. Individual metric scores were averaged to provide an overall ranking of *high* ($1 \leq X < 1.7$), *medium* ($1.7 \leq X < 2.3$), *low* ($2.3 \leq X < 3$), or *critically deficient* (score of 4 on any metric). **Results:** Ten toxicological and three epidemiological studies that assessed reproductive/developmental outcomes among VC-exposed subjects were reviewed. Of the animal studies, one was determined to be of high quality, four were of medium quality, and three of low quality. Two studies were critically deficient. High- and medium-quality studies demonstrated lack of statistically significant reproductive and developmental toxicity following VC exposure, although delayed ossification in offspring coincident with maternal toxicity was noted in mice. Though lower quality toxicological studies suggest potential for developmental toxicity in both mice and rats, effects were either not dose-dependent or occurred at doses that caused maternal toxicity evidenced by maternal mortality and reduced maternal body weight and food consumption. Of the human studies, two occupational case-control studies of women in PVC processing operations were of medium quality, and one ecological study was critically deficient due to likely exposure misclassification. In the medium-quality studies, odds of involvement in processing or heating of PVC were slightly elevated, though not statistically significant, among women who had spontaneous abortions compared to women who had successful births, as well as statistically significantly elevated among women with adverse birth outcomes compared to women with healthy births. Results of the reviewed epidemiological studies are limited by the small number of evaluated endpoints, small sample size, and lack of VC exposure characterization. **Conclusions:** Because of the limited nature of the available epidemiological studies, the epidemiological findings do not contribute significantly to a weight-of-evidence conclusion on reproductive or developmental toxicity studies for VC. However, the weight of evidence for reproductive/developmental toxicity from the available animal studies suggests that VC is neither a reproductive nor a developmental toxicant. Additional high-quality reproductive/developmental studies, particularly those assessing human VC exposure, would bolster confidence in the weight of evidence.

PS 3837 Environmental pollutants during pregnancy: phthalates and nanoplastics alter gut microbiota and intestinal morphology in pregnant rats

N. Magosso, I. Fávoro, P. Souza, M. Moreira, V. Rocha, M. Fioretto, and W. Scarano. São Paulo State University - UNESP, Botucatu, Brazil.

Background and Purpose: Between 1950 and 2017, global plastic production reached approximately 9 billion tons, of which only 23.9% were properly disposed of. The remaining 76.1% accumulated in the environment, fragmenting into micro and nanoplastics (MNP), which constitutes a public health problem. Furthermore, a group of chemical compounds, phthalates, is continuously used as additives to confer flexibility and malleability to plastic products, such as hospital equipment, building materials, toys, food containers, etc. However, due to their chemical instability, they are easily released into the environment, causing toxic effects, and are classified as endocrine disruptors (EDs). Evidence indicates that both MNPs and phthalates can cross biological barriers and compromise the integrity of the gastrointestinal tract, altering the microbiota and impacting metabolic, immunological, and developmental functions. Considering that ingestion is the primary route of exposure to these substances, it becomes fundamental to understand their effects during critical developmental phases, such as gestation. This study aimed to evaluate the effects of gestational exposure to polystyrene nanoplastics (PS-NPs, nominal size 100 nm) alone or in combination with phthalate mixture (PM) on the composition of the microbiota and histology of colon tissue in pregnant rats. **Methods:** Pregnant rats (CEUA 1174020523) were distributed randomly into 4 groups: CTR: (control; vehicle); T1: 20 µg/kg/day phthalate mixture (PM); T2: 1 mg/kg/day of polystyrene nanoplastics (PS-NPs - 100nm); T3: 20 µg/kg/day PM + 1 mg/kg/day PS-NPs (100 nm). Doses were based on previous studies on environmentally relevant exposure. Treatment was administered orally from gestational day 5 (GD5) to GD20. At GD20, 6-8 pregnant rats from each group were anesthetized and euthanized for analysis. Feces were collected from the cecal region for analysis of the microbiome composition through sequencing. The colon region was collected for histological analysis, such as morphometry by hematoxylin and eosin (HE) staining, and goblet cell counting by periodic acid-Schiff (PAS) staining. The statistical test used was ANOVA, followed by Tukey, with $p < 0.05$ considered statistically significant. **Results:** The microbiome analysis showed an increase in class *Bacilli* ($p = 0.02$) and order *Lactobacillales* ($p = 0.04$) was observed in T2 and T3 vs. CTR, while class *Clostridia* ($p = 0.04$) and order *Clostridiales* ($p < 0.06$) decreased in T1 vs. CTR. Nanoplastics may trigger an inflammatory response favoring *Bacilli* growth while partially preserving *Clostridiales*, and may indicate impaired trophic functions and maintenance of the intestinal barrier, since this group is essential for the production of short-chain fatty acids. A lower Shannon index (diversity and equity of species) was observed in group T1 vs. CTR ($p = 0.04$), indicating lower richness and uniformity of the intestinal microbiota in this group. Morphometric analysis, through the quantification of colon areas by the *imageJ* program, indicated a reduced muscular layer in T3 ($p = 0.03$) vs. CTR, suggesting compromised intestinal motility. Using PAS staining, it was possible to count goblet cells in the colonic mucosa, and an increase in the number of

cells was observed in groups T1, T2, and T3 ($p = 0.01$) vs. CTR, and an increase in T3 ($p = 0.01$) vs. T1. This suggests a compensatory or adaptive response of the epithelium to protect the tissue, an initial defense process against short-term exposure by increasing mucin production. **Conclusions:** These findings suggest that the effects of phthalates on the gut microbiota may be modulated by the presence of nanoplastics, which may lead to alterations in gut integrity and metabolism, influencing critical metabolic functions in the host.

PS 3838 Single-Nucleus RNA-seq Reveals Cell-Type-Specific Transcriptional Alterations in the Ovary After Adolescent Per- and Polyfluoroalkyl Substances (PFAS) Mixture Exposure

R. A. Ghorab¹, B. Nolan¹, C. Lee¹, J. W. George², M. Rowley¹, and K. L. Clark^{1,3}. ¹University of Nebraska Medical Center, Omaha, NE; ²University of Minnesota Genomics Center, Minneapolis, MN; and ³Veterans Affairs Nebraska-Western Iowa Health Care System, Omaha, NE.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are highly persistent synthetic chemicals widely used in consumer products, leading to extensive environmental contamination. PFAS exposure has been associated with altered menstrual function, premature ovarian insufficiency, and disruptions in steroidogenesis in both humans and animal models. Although legacy PFAS such as perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) have been phased out, they remain detectable, and newer short-chain alternatives including undecafluoro-2-methyl-3-oxahexanoic acid (GenX/HFPO-DA) and perfluorobutanesulfonic acid (PFBS) are now common in environmental mixtures. Despite this, the effects of PFAS mixtures on ovarian biology are still not well characterized. Our prior work showed that adolescent PFAS mixture exposure impairs ovarian function in adulthood through reduced ovarian reserve, endocrine disruption, Hippo pathway alterations, and increased fibrosis, though the timing of these effects remained unclear. We therefore hypothesized that PFAS mixture exposure initiates ovarian changes during the exposure window rather than only later in adulthood. **Methods:** Female CD-1 mice (postnatal day 30) received daily oral dosing via pipette delivery to the cheek pouch with either vehicle (distilled water containing 1% DMSO; $n = 10$) or a PFAS mixture (0.1 mg/kg each of PFOA, PFOS, GenX, and PFBS; $n = 10$) for a 15-day exposure period ending at PND45. The selected dose was selected based on previously published LOAEL values for developmental toxicity in juvenile mouse models. Body weight was monitored weekly, and vaginal cytology was assessed for 10 days prior to tissue collection. At PND45, serum reproductive hormone concentrations were quantified by ELISA. Ovaries from a subset of animals ($n = 3$ per group) were processed for snRNA-seq to characterize cell-type-specific transcriptional responses to PFAS exposure. **Results:** Adolescent exposure to the PFAS mixture did not alter overall body mass or the weights of reproductive organs; however, liver weight was significantly elevated ($P < 0.05$). PFAS-treated females exhibited notable disruptions in estrous cyclicity, characterized by an increased proportion of time spent in estrus ($P < 0.05$) and a reduction in time spent in metestrus/diestrus ($P < 0.05$) compared with controls. These animals also experienced more frequent cycle transitions ($P < 0.05$). Despite these alterations in cyclicity, circulating concentrations of progesterone, estradiol, testosterone, and luteinizing hormone remained unchanged. snRNA-seq identified distinct ovarian cell clusters, including granulosa (mitotic, antral, atretic, and preantral), theca, luteal, stromal, epithelial, immune, and endothelial cells. Further, snRNA-seq revealed widespread transcriptional changes across ovarian cell populations after PFAS mixture exposure. The most pronounced alterations occurred in luteal and thecal cells, where genes involved in cholesterol/steroid biosynthesis and cell survival were robustly upregulated. Notably, Hippo pathway effector *Yap1* re-emerged among top differentially expressed genes, reinforcing its role in PFAS-mediated follicle activation and ovarian remodeling. **Conclusions:** The effects of environmental toxicants on female reproductive health depend heavily on the developmental window of exposure, as well as the dose and duration. Defining when PFAS-induced reproductive impairments first emerge is essential for evaluating long-term fertility consequences. Our findings of disrupted estrous cyclicity, coupled with cell-type-specific transcriptional shifts in ovarian steroidogenic pathways, point to early-onset reproductive disturbances. These results underscore the need to further dissect the mechanisms underlying these initial alterations.

PS 3839 Chronic Exposure of Mice to Propylparaben Disrupts Hormone Signaling and Promotes Fibrosis in the Uterus

P. Voley, A. Kannan, M. Arshee, R. Shukla, J. Li, A. Chandola, M. K. Bagchi, A. Ziv-Gal, and I. C. Bagchi. University of Illinois at Urbana-Champaign, Champaign, IL.

Background and Purpose: Parabens are a class of widely used synthetic preservatives. Their ability to prevent microbial growth and extend product shelf life leads to their widespread usage, particularly in cosmetics and personal care products. Propylparaben (PP), one of the most common parabens, is frequently detected in women due to higher product use. Studies have shown that women tend to have higher levels of paraben exposure compared to men, likely due to greater use of these paraben containing products. Parabens possess estrogen-mimicking properties and are considered endocrine disruptors, raising concerns about their long-term effects on reproductive health. However, the impact of chronic PP exposure

on uterine function remains poorly understood. **Methods:** Adult female CD-1 mice were orally dosed with corn oil (vehicle control) or PP (2, 20, or 200 µg/kg/day) for six months. Uteri were subjected to histology, immunohistochemistry (IHC), RNA expression analysis, Picrosirius Red staining for fibrosis, F4/80 staining for macrophage infiltration, and p-SHG for collagen organization. **Results:** Chronic propylparaben (PP) exposure led to myometrial thickening in the 2 µg/kg/day treatment group. Further analysis revealed that exposure to PP caused marked upregulation of estrogen receptor (Esr1/Erα) expression, particularly in the luminal epithelium and subepithelial stroma, as confirmed by IHC. In contrast, progesterone receptor (Pgr) expression was starkly reduced in the luminal epithelium, while stromal PGR expression remained largely unchanged. Consistent with these receptor changes, PP exposure downregulated multiple *Pgr*-regulated genes (e.g., Sox17, Ihh, Csf1, Cd44) and upregulated *Erα*-regulated targets (e.g., Ezh2, Hif2α, cFos, Tgfb1, Muc1). Additionally, inflammatory markers (e.g., Stat3, Il1b, Ccl2, Ccl12, Ccl17, Ccl21, Tnfα, Tnfr1, Nfkb) were elevated. Our studies revealed a significant increase in the population of macrophages in the uteri of mice exposed to PP, indicating heightened inflammation in response to this chemical. Fibrosis-related genes (Col1a1, Col3a1, Tgfb1, Tgfb1r) were significantly induced, and Picrosirius Red staining confirmed significantly enhanced collagen deposition in PP-exposed uteri. Second Harmonic Generation further delineated the character of collagen deposition in the endometrial layer. Our findings indicate that chronic PP exposure disrupts the estrogen-progesterone signaling balance by enhancing *Erα* activity while diminishing luminal epithelial PR expression. This hormonal imbalance is associated with transcriptional changes promoting inflammation, immune cell infiltration, and fibrotic remodeling of the uterus. **Conclusions:** Chronic exposure to PP induces uterine changes characterized by enhanced *Erα* signaling, loss of luminal PR, inflammation, and fibrosis. These alterations highlight potential risks for reproductive health in individuals with sustained paraben exposure. These findings may have significant implications for reproductive health, particularly for individuals with long-term exposure to parabens through the use of personal care products.

PS 3840 From *In Silico* Prediction to *In Vitro* Validation: Kaempferol Mitigates Perfluorodecanoic acid (PFDA)-Induced Granulosa Cell Toxicity

C. Lee¹, R. A. Ghorab¹, K. E. Taylor¹, and K. L. Clark^{1,2}. ¹University of Nebraska Medical Center, Omaha, NE; and ²Veterans Affairs Nebraska-Western Iowa Health Care System, Omaha, NE.

Background and Purpose: Perfluorodecanoic acid (PFDA), a long-chain per- and polyfluoroalkyl substance (PFAS), has been implicated in ovotoxicity, but granulosa-cell mechanisms and tractable countermeasures remain uncertain. We implemented an *in silico* to *in vitro* workflow that first predicted PFDA injury nodes and kaempferol (KA) response pathways from network pharmacology and then experimentally tested those predictions in human granulosa (HGrC1) cells. **Methods:** Putative targets for PFDA and KA were integrated from public resources (e.g., CTD, ChEMBL, STITCH, PubChem) and intersected with ovotoxicity gene sets (GeneCards, OMIM). Protein-protein interaction (PPI) networks (STRING) were prioritized in Cytoscape using centrality metrics (MCC, MNC, degree, EPC, closeness). GO/KEGG enrichment (clusterProfiler; adjusted $p < 0.05$) predicted PFDA-evoked oxidative/inflammatory programs and KA-linked Nrf2-PPAR γ cytoprotection, which pre-specified readouts and dosing. HGrC1 cells were exposed to PFDA (20 µM) $\pm$ KA (3 or 10 µM) for 24-72 h. Outcomes included viability (MTT), intracellular reactive oxygen species (ROS; DCFDA), qPCR of antioxidant (CAT, GPX1, SOD2) and steroidogenic (PPARG, STAR, HSD3B1, HSD17B1) transcripts, and immunoblot of Nrf2-responsive proteins (HO-1, NQO1). One-way ANOVA with Dunnett's post-test compared treatments to vehicle controls. **Results:** Computational intersections yielded overlapping PFDA-ovotoxicity ($n=131$) and KA-ovotoxicity ($n=236$) genes. Networks/enrichment predicted activation of inflammatory (IL6, NFKB1, RELA) and oxidative-stress/xenobiotic pathways with PFDA and Nrf2-centered antioxidant and PPAR γ -linked cytoprotective programs with KA. Bench validation corroborated these predictions: PFDA (20 µM) decreased HGrC1 viability in a time-dependent manner, increased ROS, and downregulated PPARG and steroidogenic transcripts (STAR, HSD3B1, HSD17B1). Co-treatment with KA (3-10 µM) partially restored viability, reduced ROS, recovered antioxidant transcripts (CAT, GPX1, SOD2), and increased HO-1/NQO1 proteins consistent with Nrf2 activation, while rescuing PPARG and steroidogenic transcripts under PFDA stress. Thus, *in vitro* phenotypes aligned with *in silico* network predictions, nominating an Nrf2-PPAR γ protective axis. **Conclusions:** PFDA compromises granulosa-cell function through oxidative/inflammatory stress and disruption of steroidogenic/nuclear-receptor signaling. Guided by *in silico* predictions, KA mitigated these injuries by restoring antioxidant defenses and PPAR γ -linked transcription, experimentally validating a predicted Nrf2-PPAR γ axis. This prediction-driven network-to-bench approach identifies KA as a candidate modulator of PFAS-associated ovotoxic risk and yields mechanism-anchored entry points for *in vivo* studies.

PS 3841 Reproductive and Developmental Toxicity Assessment of Fragrance Ingredients: Considerations for Reprotoxic Classification in the Context of Maternal Toxicity

K. Assanome¹, I. Brown², V. Rocha¹, and G. Adamson¹. ¹Givaudan Fragrances Corporation, East Hanover, NJ; and ²Department of Pharmacology and Toxicology, Michigan State University, East Lansing, MI.

Background and Purpose: Reproductive and developmental toxicity is a key aspect in toxicological risk assessment, particularly for fragrance ingredients with generally low human exposure. While real-world exposure is low, high-dose animal testing required for regulatory compliance may report adverse effects even for low-exposure substances. A central challenge is distinguishing true developmental toxicity from effects secondary to maternal toxicity. This review evaluates published reproductive and developmental toxicity data for two fragrance monoterpenoids, focusing on how maternal toxicity may influence developmental outcomes. Maternal and fetal no-observed-adverse-effect levels (NOAELs) were compared to identify patterns indicating secondary effects. The findings indicate that developmental outcomes are more likely driven by maternal toxicity than direct fetal effects, improving the scientific basis for classification under the European framework. **Methods:** Representative monoterpene fragrance compounds were analyzed using studies conducted according to OECD Test Guidelines 414 (Prenatal Developmental Toxicity Study), 421 (Reproductive/Developmental Toxicity Screening Test), 422 (Combined Repeated Dose with Reproduction/Developmental Screening), 443 (Extended One-Generation Reproductive Toxicity Study), 407 (Repeated Dose 28-Day Oral Toxicity Study), and 408 (Repeated Dose 90-Day Oral Toxicity Study). Studies selected included published, well-defined systemic, maternal, and developmental NOAELs, with reproductive and/or developmental toxicity indicators. Systemic, reproductive, and developmental parameters were compared, focusing on maternal endpoints and offspring outcomes. Maternal analysis included body and organ weights, food intake, biochemistry, histopathology, and thyroid hormones. Reproductive parameters included estrous cycle, mating performance, pregnancy rate, and implantation loss. Developmental parameters included fetal viability, pup weight, malformations, skeletal variations, among other parameters. **Results:** For the first monoterpene, dose-dependent maternal toxicity was observed, including reduced body weight, decreased food intake, and biochemical alterations, particularly at ≥ 600 mg/kg/day. Elevated bile acids indicated liver dysfunction, while creatinine and urea elevations suggested renal stress, contributing secondarily to developmental effects. Male reproductive toxicity at 750 mg/kg/day included testicular degeneration and absence of spermatozoa. Developmental effects, such as reduced fetal and placental weights, occurred only at high doses of 600 mg/kg/day in the presence of maternal systemic stress and undernutrition, with no evidence of direct teratogenicity. For the second monoterpene, maternal toxicity was pronounced at ≥ 720 mg/kg/day, including reduced gestational weight gain, decreased food intake, liver hypertrophy, altered biochemistry (elevated bile acids, cholesterol, creatinine kinase, and reduced potassium), and hormonal changes (reduced T4 at ≥ 800 mg/kg/day). Developmental effects, including reduced viability at starting at 300 mg/kg/day, lower pup weights at 1000 mg/kg/day, delayed sexual maturation, and increased post-implantation loss, appeared secondary to maternal toxicity. Paternal toxicity at ≥ 720 mg/kg/day included liver and kidney changes, abnormal sperm, and reduced spermatid counts, potentially affecting early embryonic development. At the dose of ≥ 800 mg/kg/day, a decrease in circulating T4 levels was also observed. These changes correlate with liver enzyme induction and are relevant because reductions in T4 may cause effects on pups. **Conclusions:** Adverse developmental outcomes for both fragrance monoterpenoids were primarily associated with high-dose maternal toxicity. Effects in offspring were observed only alongside maternal stress, making unclear the attribution to direct fetal toxicity. These findings emphasize maternal health as an early, sensitive indicator of reproductive risk. Integrating mechanistic understanding and human-relevant exposure data can refine hazard assessments, guide regulatory decisions, and improve safety characterization of fragrance ingredients.

PS 3842 Sex differences in gonadal toxicity of exposure to fine particulate matter (PM_{2.5})

J. Lim, C. Nealon, S. Kotthru, F. Luna, C. Lim, D. Herman, M. Kitazawa, M. T. Kleinman, and U. Luderer. University of California Irvine, Irvine, CA.

Background and Purpose: Open burn pits were widely used to dispose of waste in American military bases in Iraq and Afghanistan. As combustion sources, burn pits emit PM_{2.5}. Many studies investigating the effects of PM_{2.5} have focused on exposure to males. Since women make up increasing proportions of the armed forces, it is important that experimental studies include both males and females. Previous studies have reported that exposure to ambient PM_{2.5} decreased epididymal sperm counts in male mice; sperm counts are expected to recover due to the presence of germine stem cells. In contrast, the post-natal ovary lacks germine stem cells. We hypothesized that PM_{2.5} exposure permanently depletes the ovarian follicle reserve and has reversible effects on testicular sperm production. **Methods:** We exposed 2-months old, late adolescent, male and female wild type (WT) C57BL/6J mice and mice that express the wildtype human amyloid- β sequence (hA β -KI mice) to concentrated ambient PM_{2.5} (average concentration 169 ± 113 µg/m³) or filtered air (1.9 ± 1.2 µg/m³) for 5h/day, 4d/wk for 12 weeks. Mice were euthanized 24 h after the last exposure at age 5 mos or 9 months after the last exposure at age 14 mos. In a

separate experiment, 5 mos old adult female and male hA β -KI mice were exposed to concentrated ambient PM_{2.5} (average concentration 85.2 μ g/m³) or filtered air (9.1 μ g/m³) for 5h/day, 4d/wk for 12 weeks and were euthanized 24h after the last exposure at age 8 mos. In both experiments, females were euthanized on a day of the estrous cycle with vaginal cytology showing cornified epithelial cells, characteristic of estrus. Ovaries were cleared and processed for wholemount imaging with antibody against oocyte cytoplasmic-specific protein MSY2 and automated follicle counting based on oocyte diameter using Imlaris software. Immunostaining or immunofluorescence was performed on contralateral ovaries to identify effects of PM_{2.5} exposure on ovarian follicle cell proliferation (Ki67), apoptosis (activated caspase 3), and autophagy (LC3B). **Results:** There were no statistically significant effects of exposure on estrous cycle length in mice euthanized at age 5 mos, 8 mos, or 14 mos. Females of both strains exposed to PM_{2.5} and euthanized at age 5 mos had statistically significantly decreased total number of ovarian follicles/ovary (P<0.001, effect of exposure), primordial follicles (P=0.002) and antral follicles/ovary (P=0.004), while the decrease in primary follicles approached significance (P=0.089). Female hA β -KI mice exposed to PM_{2.5} as adults and euthanized at age 8 mos also had statistically significantly decreased primordial, antral, and total follicles/ovary (P=0.022, 0.020, and 0.046, respectively), as well as significantly increased percentages of primary follicles with Ki67-positive granulosa cells (P=0.019) and significantly increased percentages of LC3B-positive secondary and antral follicles (0.043 and 0.010, respectively). The percentage of ovarian secondary and antral follicles positive for activated caspase 3 approached significance (P= 0.076 and P=0.065, respectively). By contrast testicular sperm counts and seminiferous tubule pathology were not significantly altered by exposure to PM_{2.5} in either strain at age 5 months, in hA β -KI mice at age 8 mos, nor were cauda epididymal sperm counts at age 14 months. **Conclusions:** Exposure to concentrated ambient PM_{2.5} significantly decreased ovarian follicle numbers and this was associated with evidence of increased activation of primordial follicles and increased autophagy and apoptosis in follicles at later stages of development. By contrast, there were no statistically significant effects of PM_{2.5} exposure on testicular or epididymal sperm counts or testicular histopathology.

PS 3843 Perinatal E-Cigarette Exposure and Maternal-Fetal Distribution of Nicotine and Its Metabolites

G. Chandan¹, C. Yu¹, R. Sakurai¹, J. Liu¹, D. Hatai¹, Y. Wang¹, A. Gour², A. Sharma², and V. K. Rehan¹. ¹Lundquist Institute, Torrance, CA; and ²University of Florida, Gainesville, FL. Sponsor: D. Hatai

Background and Purpose: Perinatal exposure to nicotine from electronic cigarettes (e-cigs) continues to raise concerns regarding fetal susceptibility to nicotine and its bioactive metabolites. The impact of gestational e-cig exposure is reported, but limited studies target the metabolite quantification. In the current study, we quantified maternal-fetal nicotine transfer by measuring nicotine and key metabolites in biological samples from e-cig-exposed pregnant mothers and their offspring. **Methods:** Using a well-established E-Cigarette Nicotine Delivery System (ENDS), pregnant Sprague Dawley rat dams (200-250-gram body weight) were exposed to nicotine (E- blue cigarette 2.4% with 50/50 propylene glycol and vegetable glycerol, 144 puffs over 12h daily) from embryonic day 6 (E6) until weaning at postnatal day 21 (PND21). Control dams were exposed to either filtered air or vehicle PG/VG. On E21, some mothers (control and nicotine exposed) were sacrificed for amniotic fluid, placenta and serum collection for the measurement of nicotine and metabolites (cotinine, norcotinine, trans-hydroxycotinine, and cotinine-n-oxide) concentrations via Liquid Chromatography-Mass Spectrometry (LC-MS). Postnatally, pups (N=8-10) were studied for these metabolites at PND1 and PND21 in the serum. **Results:** LC-MS quantification showed significant concentrations of cotinine, norcotinine, trans-hydroxycotinine, and cotinine-n-oxide in maternal serum, confirming systemic nicotine absorption during gestation. Similarly, pups' serum contained increased levels of the same metabolites at PND1, demonstrating efficient placental transmission. Elevated concentrations of nicotine metabolites were also identified in placental tissue (100-200 ng/g tissue) and amniotic fluid (358.22 $\pm$ 56.42 ng/ml), indicating fetal exposure throughout gestation and highlighting nicotine delivery to the developing fetus via these compartments. Substantial levels of these metabolites were detected in offspring serum at PND21 (56.80 $\pm$ 16.42 ng/ml), corroborating neonatal exposure to nicotine during development. Surprisingly, the serum nicotine levels of were significantly higher in female pups as compared to male pups at PND21. **Conclusions:** Taken together, these findings reveal that perinatal e-cigarette exposure results in significant fetal and neonatal accumulation of nicotine metabolites across maternal, placental, and fetal compartments highlighting the potential for adverse developmental effects and long-term health consequences. **Grant Support:** HL151769 (NIH); T32IP5044, T32IR5048, T32IR5365, T291R0737, T34IR8406 (TRDRP); and EDUC4-12837 (CIRM)

PS 3844 Chronic PFUnA exposure induces liver hypertrophy in CD-1 mice

M. A. Watt, O. Avenbuan, E. Mattingly, T. Tzendzalian, F. Li, and R. C. Fry. University of North Carolina- Chapel Hill, Chapel Hill, NC.

Background and Purpose: Exposure to per- and polyfluoroalkyl substances (PFAS) during pregnancy is associated with several adverse outcomes including preterm birth, low birth weight, and preeclampsia. PFAS are found in thousands of prod-

ucts, are extremely long-lasting, and are ubiquitous in the environment. Of specific concern to pregnant populations, PFAS have been shown to cross the placental barrier, accumulate in the placenta, and have been detected in cord blood of infants. Prior work has shown that perfluoroundecanoic acid (PFUnA) is significantly associated with adverse pregnancy outcomes, including preeclampsia, yet the mechanisms underlying these effects remain understudied. PFUnA has never been studied in the context of pregnancy outcomes in mice, specifically preeclampsia. The objective of this study was to assess multiple maternal, fetal, and placental endpoints after chronic exposure to PFUnA in drinking water in mice. **Methods:** CD-1 outbred mice were exposed to 0, 0.1, 0.5, or 2.5 mg/kg/day of PFUnA in drinking water from the day of weaning (23 days old) until gestational day (GD) 17.5 of their pregnancy. All mice were mated between 8-9 weeks of age to minimize any differences in exposure length. At GD 17.5, several organs and endpoints were recorded for the dams, including liver, kidney, and aorta. Pups and placentas were collected on GD17.5 with weights and morphological abnormalities recorded. Mass spectrometry was utilized to verify PFUnA accumulation in placental samples. Statistical analyses such as Anova or t-tests were performed between the two exposure groups and the control. **Results:** PFUnA in drinking water was associated with a significant decrease in body weight for the 2.5mg/kg/day group. Within 15-20 days of exposure, mice had lost 20% or more of their body weight, making them no longer eligible for the continuation of the study and subsequent pregnancy assessments. However, upon collection, their livers had visible signs of damage. Liver to body weight ratios at ~5 weeks old averaged 8.66 compared to 20.2 in the 10-week non-pregnant control mice. This shows a significant decrease in liver efficiency and increase in hypertrophy. Body weights for the control, 0.1, and 0.5 mg/kg/day exposure groups showed no significant differences at the end of pregnancy or in the non-pregnant mice at 10 weeks of age. Liver weights were significantly larger in the exposed mice. Body weight adjusted liver weights were on average 46.8% larger in the 0.5mg/kg group and 11.6% larger in the 0.1mg/kg group in comparison to the control. Assessments of PFUnA quantification in the placenta showed 1,321.2 ng/g in the 0.1 mg/kg group and 1.65 ng/g in the control. While there was no significant difference between the placenta weights, mean values show a trending increase as PFUnA exposure increases. **Conclusions:** In this study, PFUnA exposure at 2.5mg/kg/day was shown to be too high for the general health of the mice. This can be informative on the potency of this chemical, as there are several other chronic PFAS studies that utilize this dose. Additionally, our results show that there is a significant effect on the liver, suggesting an attempt to metabolically protect against the effects of this exposure. Lastly, PFUnA has a large potential to accumulate in the placenta, providing evidence that it can efficiently cross the placental barrier and have potential effects on the developing fetus. Future directions for this study include albumin creatinine ratios from GD17.5 to assess proteinuria, which is representative of kidney damage. Renal and liver abnormalities will also be characterized by immunohistochemistry. ELISA assays will be utilized to measure serum levels of placenta growth factor (PLGF) and soluble FMS-like tyrosine kinase-1/ vascular endothelial growth factor receptor (sflt-1/ VEGFR). Understanding the implications of PFUnA in drinking water can give insights on the effects this chemical may be having in the body. Specifically, as this PFAS has been associated with adverse pregnancy outcomes such as preeclampsia, testing for those same associated symptoms can give information on the mechanisms PFUnA uses to dysregulate systems within the body. This work has direct importance and translatability to the UNC-based high risk pregnancy cohort where PFUnA was detected in approximately 50% of placentas. This study may also help to elucidate future biomarkers, pathways, or processes that get altered in relation to PFAS exposure.

PS 3845 CONFOUNDING OF REPRODUCTION ENDPOINTS BY UNDERNUTRITION: A CASE-STUDY

M. McMahon. Penman Consulting Limited, Wantage, United Kingdom.

Background and Purpose: It is well-understood that undernutrition lowers fertility of female rodents and retards the development of their offspring. However, the extent to which this phenomenon confounds the interpretation of reproductive findings in regulatory toxicology studies remains controversial. Here, we present a case study (taken from an ongoing regulatory assessment under EU REACH) exemplifying this problem and providing some answers. **Methods:** A comprehensive programme of GLP-compliant OECD 422 test guideline studies with Han-Wistar rats were conducted via the dietary route on a set of 15 related Rosin (CASRN 8050-09-7) and derivatives substances. Extensive Multiple Linear Regression analyses were conducted across these regulatory studies to reveal relationships between undernutrition and reproductive parameters. Subsequently, bespoke GLP-compliant mechanistic studies based on the OECD 421 test guideline, including a pair-feeding study, were conducted to test whether the relationships had a causal basis. **Results:** The regulatory studies revealed that dietary exposure of rats to several Rosin and derivatives substances lowered mean *Corpora Lutea* counts (reduced ovulation rate). Other sexual function and fertility findings included changes in absolute weight of some sex organs, including ovaries. The only consistent developmental finding was of a retardation of offspring growth, sometimes accompanied by delayed ossification. In these studies, the test substances proved unpalatable and food consumption during the first week of the pre-pairing period was transiently, but severely, restricted in animals administered treatment diet. Consequently, treated rats were undernourished at the point of mating and remained underweight throughout gestation. Multiple Linear Regression analyses revealed highly significant correlations between all the aforementioned

reproductive findings and undernutrition. A subsequent mechanistic OECD 421 pair-feeding study confirmed that growth retardation seen in offspring of dams exposed to Rosin in the diet was caused by the undernutrition and is unrelated to any intrinsic property of the substance *per se*. Surprisingly, no effect of Rosin on sexual function and fertility was seen under pair-feeding conditions. **Conclusions:** The impaired development of rat offspring seen in dams exposed to dietary Rosin and derivatives substances is a non-specific secondary consequence of maternal under-nutrition. Further work is required to establish whether the fertility effects of these substances too are caused by undernutrition. More generally, the data presented here may be of considerable general interest because they clearly demonstrate that undernourishment at levels not uncommonly seen in toxicology studies does indeed affect reproduction in a common regulatory study design.

PS 3846 Overcoming the DART Assessment Bottleneck in Transgenic Mice: Study Design Strategies Informed by Historical Control Data

Y. Hu, Y. Zhang, L. Zhang, and J. Ma. JOINN Laboratories, Suzhou, China.

Background and Purpose: Following ICH S6(R1) and ICH S5(R3) guidelines, transgenic mice are now a critical relevant species for the developmental and reproductive toxicity (DART) assessment of biotherapeutics, often as an alternative to non-human primates (NHPs). However, a major limitation is the paucity of practical data on their reproductive and developmental performance. This study aims to conduct a systematic review of the historical control data from DART studies accumulated at our facility involving various transgenic mouse models, and to evaluate the utility, inherent challenges, and critical design elements for DART assessment in these models. **Methods:** A retrospective analysis was conducted on 26 DART studies performed at our facility that utilized transgenic mouse models on C57BL/6N background for biopharmaceuticals. The dataset included 6 Fertility and Early Embryonic Development (FEED), 15 Embryo-Fetal Development (EFD), and 5 Pre- and Postnatal Development (PPND) studies. Models targeted key molecules such as IL-1 β , IL-17A, CD22, and hIL6/hIL6R, among others. Reproductive performance parameters—including mating rate, pregnancy rate, early embryonic development, intrauterine embryo-fetal survival, and F1 generation litter size were evaluated in control animals to assess the robustness of these models for DART testing and to inform optimal study design. **Results: Variable Reproductive Performance in Transgenic Mice** Analysis of mating and pregnancy data from 6 FEED and 15 EFD studies revealed that transgenic mice exhibited normal mating behavior at sexual maturity (8-11 weeks of age), with a high mean mating rate (98.02%) and most pairs cohabiting successfully within one estrous cycle (4-5 days). The mean pregnancy rate was 85.90% in FEED studies, which declined to a mean of 72.78% in the larger dataset of EFD studies, with considerable inter-study fluctuation (as low as 37.5%). Consequently, study designs must incorporate an increased number of initial mating pairs to ensure a sufficient number of pregnant animals for a robust evaluation. **Analysis of Early Embryonic and Embryo-Fetal Survival in FEED and EFD Studies.** FEED studies (GD18) identified post-implantation loss (range: 8.58%-18.14%; Mean $\pm$ SD: 12.09% $\pm$ 4.08%) as the primary factor reducing live litter size, substantially exceeding pre-implantation loss rates (mean: 9.79%). Data from EFD studies (GD 18) were consistent, showing post-implantation loss rates from 4.85% to 27.27% (Mean $\pm$ SD: 13.75% $\pm$ 6.6%), primarily driven by early resorptions (mean: 12.15%), with notable variability across studies. Although the incidence of late resorptions and dead fetuses was low (combined mean: 1.11%), it was present in individual studies. Consequently, the mean number of live fetuses per litter in EFD studies ranged from 4.3 to 9 (Mean $\pm$ SD: 7.37 $\pm$ 1.24). **PPND Studies are Challenged by Insufficient and Variable Offspring Numbers.** Data from six PPND studies showed that the mean litter size for transgenic mice at birth (litter size) ranged from 5.9 to 8.5 pups (Mean $\pm$ SD: 7.6 $\pm$ 1.02). While individual litter sizes were highly variable (range: 1-12 pups), frequently accompanied by sex ratio bias. This situation aligns with the challenges reported for the PPND study of the approved drug UPLIZNA (Inebilizumab, an anti-CD19 monoclonal antibody), where a CD19 transgenic mouse model used characterized by "low pregnancy rate, low fecundity, and small litter size" resulting in an insufficient number of F1 offspring and leading regulators to deem the neurobehavioral assessment inadequate. This case underscores the critical need to: 1) Increase the number of initial mating pairs; 2) Implement litter standardization to a lower size (e.g., 6 pups/litter); and 3) Carefully plan the allocation of animals to various postnatal subgroups and assessments. **Conclusions:** The systematic collection of historical control DART data for transgenic mice is a cornerstone for their reliable use in DART assessment. Our data identify inherent limitations, including variable reproductive performance and limited offspring numbers, which must be proactively integrated into study design through optimized mating strategies, increased cohort sizes, and adjusted litter standardization practices. We recommend early regulatory engagement as a prudent strategy to align study designs with scientific and regulatory expectations for DART assessment using transgenic mice.

PS 3848 The Importance of Species Selection in Drug Discovery and Development

M. Nedelman¹, and B. Collier². ¹ANEWCRO, LLC., Fort Myers, FL; and ²Rockefeller University, New York City, NY. Sponsor: G. Gagnon

Background and Purpose: Species selection in the discovery and development of a drug is often trivialized. To evaluate the safety profile and toxicology for zalunfiban, a novel small molecule inhibitor of the platelet α IIb β 3 receptor, for use as the first point of medical contact treatment for ST segment elevation myocardial infarction (STEMI), its relative potency was tested across commonly used models in preclinical development to determine which species provided the most translatable data. **Methods:** Platelet aggregation and determination of the zalunfiban IC₅₀ was performed using light transmission platelet aggregation studies at 37°C with stirring using ADP to induce aggregation. **Results:** Zalunfiban caused inhibition of aggregation of platelets in human citrated platelet-rich plasma induced by adenosine diphosphate (ADP) (5 μ M) with an IC₅₀ of 0.057 $\pm$ 0.010 μ M. Approximately 14 times more drug was required to achieve comparable inhibition of the platelet aggregation of cynomolgus monkeys (*Macaca fascicularis*). Approximately 47 times as much zalunfiban was required to inhibit the aggregation of platelets from beagle dogs compared to human platelets. Moreover, because beagle dog platelets have variable responses to ADP alone, the studies with these animals required a combination of epinephrine (10 μ M) followed by ADP (25 μ M). Inhibition of rat platelet aggregation induced by 5 μ M ADP required more than 1,000 times as much zalunfiban compared to human platelets, whereas inhibition of mouse and rabbit platelet aggregation required approximately 200 times as much zalunfiban. Zalunfiban's hepatocyte stability was similar among species evaluated, as were the zalunfiban metabolite identification studies, with all species showing the des-glycine hydrolysis derivative of zalunfiban as the major metabolite. **Conclusions:** Based on the relative potency and translatability of zalunfiban to humans, the mouse and NHP were selected as the rodent and non-rodent nonclinical species for development.

PS 3849 Timing of Artifactual Erythrocyte Morphologic Changes Associated with Storage of Blood in Common Laboratory Animal Species

L. Wiczorkiewicz, M. Mogenson, A. Haldeman, and M. Meindel. Labcorp, Madison, WI. Sponsor: B. Chanas

Background and Purpose: Artifactual changes in hematologic parameters due to prolonged storage of potassium ethylene diaminetetraacetate (EDTA) blood have been well documented in many species. Corresponding blood smears often yield cellular morphologic changes that could result in misinterpretation of a pathologic condition. Prompt sample processing and proper storage conditions can reduce artifactual morphologic alterations; however, sample stability varies between species and should be considered when establishing laboratory operating procedures. Cellular morphologic changes were evaluated at multiple time points for macaques, dogs, rats, and rabbits in conjunction with the Siemens Advia® 2120i sample stability assessment conducted at Labcorp. **Methods:** Five whole blood EDTA samples were obtained from each of the following species: cynomolgus macaques, dogs, rats, and rabbits. A baseline blood smear slide was prepared for each sample within an hour of collection. Samples were divided into two aliquots; one aliquot was stored at room temperature and one stored refrigerated (2-8°C). A slide was prepared from each aliquot at approximately 4, 6, 24, 30, 48, and 72 hours from time of collection. All slides were stained and changes in leukocyte, erythrocyte and thrombocyte morphology were evaluated by comparison with the baseline slide. Slides were graded by a single technician as either changes seen or no changes seen. Analysis of the Siemens Advia® 2120i instrument stability occurred in conjunction with the slide stability assessment. **Results:** The slide evaluation revealed significant erythrocyte crenation preceded morphologic changes in leukocytes and thrombocytes; therefore, leukocyte and thrombocyte morphology were not assessed. At room temperature, macaque samples showed the longest stability, with no visible erythrocyte changes up to 6 hours. Dog samples maintained cell integrity for up to 4 hours. Rat and rabbit samples began showing changes by 4 hours, with more prominent alterations in rats. Refrigeration consistently improved cell preservation across all species. Rat samples remained the least stable, with erythrocyte changes evident by 6 hours. By 24 hours, all species exhibited notable cellular changes. Erythrocyte morphologic changes aligned with instrument sample stability at room temperature for macaques and rats, while instrument sample stability exceeded slide stability for dogs and rabbits. Refrigerated sample stability for the instrument was longer for macaques and rabbits but was comparable to slide stability for rats and dogs. **Conclusions:** The data demonstrated that blood smear slides should be prepared as soon as operationally possible upon arrival in the lab and within the accepted instrument stability in order to maintain optimal integrity of erythrocyte morphology. Sample refrigeration prolonged erythrocyte stability. In addition, since species were affected at different rates, priority for slide generation should be given first to rats, second to rabbits and dogs, and then third to macaques.

S. Iwabe, B. Ossont, N. Jordan, and M. Bacellar-Galdino. Altasciences, Scott Township, PA. Sponsor: N. Makori

Background and Purpose: The aim of this study was to localize and measure lacrimal glands (LG) from laboratory animals. **Methods:** Both LGs were collected from Sprague Dawley (SD) rats (n=12), New Zealand White (NZW) rabbits (n=8), Beagle dogs (N=8) and Cynomolgus Macaques (CM) (n=20). LGs were dissected, weighed (mg) and measured (width x length in mm). **Results:** Exorbital LG in SD rats was localized over the masseter muscle, mean weight of 117.4±3.1 mg, and measured 7.9 mm ±0.14 mm by 12 mm ±0.31 mm. Intraorbital LG underneath the lower temporal part of the orbit, mean weight was 13.5±1.9 mg, and measured 7.6 mm ±0.27 mm by 3.3 mm ±0.06 mm. In NZW rabbits the LG was embedded posteriorly in the superotemporal part of the orbit, mean weight was 328.4±23 mg, and measured 8.4 mm ±0.17 mm by 20.2 mm ±0.09 mm. In Beagle dogs the LG was in the superotemporal aspect of the globe and underneath the orbital ligament, mean weight was 337.9±89.5 mg, and measured 11.1 mm ±0.16 mm by 4.59 mm ±0.23 mm. LG in CM were located superotemporal aspect of the globe and was easily assessed by rotating the eye nasally and elevating the superior palpebra. The mean weight was 50.4±2.6 mg and measured 11.73 mm ±0.41 mm by 4.25 ±0.12 mm. **Conclusions:** LG location and measurements are essential information as new therapies and administration routes are being explored for treatment of dry eye disease.

PS 3851 Histopathological Assessment of Purkinje cells in the Cerebellum of Japanese Medaka (*Oryzias latipes*) Fish Exposed to Graphene Oxide

A. K. Dasmahapatra¹, and P. B. Tchounwou². ¹University of Mississippi, University, MS; and ²Morgan State University, Baltimore, MD.

Background and Purpose: Previous studies from our laboratory have demonstrated that graphene oxide (GO), a widely used carbon-based nanomaterial, exhibits minimal endocrine-disrupting effects in Japanese medaka (*Oryzias latipes*). The observed alterations in reproductive organs, interrenal glands, endocrine pancreas, and thyroid appear to result primarily from the physical aggregation and accumulation of GO rather than from direct endocrine interference. Although some histopathological changes, such as agglomeration in the gonads, liver, and kidney, have been reported, these are largely attributed to the physical characteristics of GO, not its endocrine-disrupting potential. In the present study, we extended our investigation to the central nervous system, focusing specifically on the cerebellum of adult Japanese medaka. Our objective was to examine the potential effects of GO exposure on Purkinje cells (PKCs), a critical neuronal population involved in cerebellar function and motor coordination. **Methods:** Adult Japanese medaka were exposed to GO *in vivo* via two routes: immersion (IMR; 20 mg/L GO in balanced salt solution, BSS) and single intraperitoneal (IP) injection (100 µg/g body weight). Control groups were maintained in BSS (for IMR) or injected with nanopure water (for IP). Following exposure, brains were dissected and processed for histological analysis. Paraffin-embedded brain sections were stained with hematoxylin and eosin (H&E), and the cerebellum was visualized using an Olympus CKX53 inverted microscope equipped with a DP22 camera and CellSens imaging software. A minimum of two cerebellar images per fish were analyzed using ImageJ software. **Results:** Purkinje cells (PKCs) were readily distinguishable from other cerebellar layers due to their large, drop-like morphology and localization within the Purkinje layer—situated between the molecular and granular layers. In Japanese medaka, the cerebellum is anatomically divided into three main lobes: valvula cerebelli (VC), corpus cerebelli (CC), and lobus caudalis cerebelli (LC). PKCs were exclusively distributed in the VC and CC, with no detectable presence in the LC. The Purkinje cell zone was observed to originate at the caudal end of the VC, extend through the CC, and terminate at the ventral margin of the CC. PKC density varied depending on the sectioning plane (dorsoventral, rostrocaudal, and lateral), with the highest concentration located in the central region of the CC and fewer PKCs found at the dorsal and ventral extremes. Exposure to GO via IP injection significantly reduced the number of PKCs in the CC of both male and female fish. In contrast, immersion exposure to GO did not elicit any measurable effect on PKC numbers in either sex. Additionally, morphometric analyses of the nucleus and soma of PKCs, including their area and nucleus-to-soma ratios, revealed inconsistent patterns of alteration, dependent on both the route of exposure and sex of the fish. **Conclusions:** These findings suggest that GO has the potential to alter brain morphology in Japanese medaka, likely through penetration of the blood-brain barrier and subsequent disruption of cerebellar structure. The observed reduction in PKC numbers, particularly following IP exposure, indicates a route- and sex-specific neurotoxic effect that may impair cerebellar function. Further studies are warranted to elucidate the mechanistic basis of GO-induced neurotoxicity and its potential implications for vertebrate neurodevelopment and behavior.

PS 3852 Risks of Microplastic Exposure for Vertebrate Immunity: Insights from *Xenopus*

J. Robert, F. De Jesus Andino, R. Lombardo, A. Gurcan, J. L. McGrath, E. Najafi-Majd, and R. Onuma. University of Rochester School of Medicine & Dentistry, Rochester, NY.

Background and Purpose: Small plastic debris, or microplastics (MPs; 1 µm-5 mm), have become ubiquitous in the environment and within animal and human tissues, including the brain, liver, placenta, and breast milk. However, their specific health effects remain poorly defined. Using tadpoles of the amphibian *Xenopus laevis*, we applied a comparative biology approach to investigate how early-life exposure to microplastics affects macrophage homeostasis, activation, and defense against pathogens such as nontuberculous mycobacteria (NTMs) commonly found in plastic-associated biofilms. *Xenopus* tadpoles offer an excellent model because their external post-embryonic development—including the immune system—makes them highly sensitive to waterborne pollutants, while their immune architecture shares strong conservation with mammals. Instead of using uniform microspheres at unrealistically high concentrations, we exposed tadpoles to low concentrations (0.1-10 mg/L) of environmentally relevant irregular microplastics (I-MPs; 1-20 µm), including polyethylene terephthalate (PET) and nylon. **Methods:** The biodistribution of fluorescently labeled I-MPs (Nile Red) was assessed by fluorescence microscopy on whole-mount tissues and isolated peritoneal macrophages, as well as by enzymatic digestion and silicon nanomembrane filtration. Tadpole colonization and immune responses to ranavirus (FV3) and NTMs were quantified by qPCR. **Results:** Even at concentrations as low as 0.1 mg/L, I-MPs accumulated rapidly in tadpole intestines, liver, kidneys, brain, and peritoneal macrophages, where they persisted for over a week. This accumulation led to macrophage dysfunction, impaired antiviral responses, and decreased resistance to FV3 infection, without inducing overt inflammation. Moreover, we found that mycobacteria pathogens detected in biofilms associated with environmental MPs such as *M. marinum*, can tightly bind to I-MPs *in vitro*, which may promote their colonization into tadpoles. **Conclusions:** Environmentally relevant microplastics accumulate and persist in *Xenopus* tissues at low concentrations, disrupting macrophage function and compromising immunity. The association of NTMs with I-MPs may further enhance pathogen colonization, highlighting potential immunological risks of microplastic exposure in vertebrates.

PS 3853 Insights into Sleep Architecture and EEG Spectral Profiles During Postoperative Recovery in Group-Housed Mice

M. Girand, T. Velie, J. Van Hee, K. Nichols, K. White, and J. Alvarez. Harvard Bioscience, Holliston, MA. Sponsor: M. Girand, Safety Pharmacology Society

Background and Purpose: Studying physiological parameters during post-surgical recovery is critical for gaining insights into animal health. However, technological restrictions pose practical challenges when conducting experiments with group-housed animals. **Methods:** To address this, we developed a telemetry system, SoHo™, capable of simultaneously collecting electroencephalogram (EEG), electromyogram (EMG), temperature, and activity in group-housed small animals. This study evaluates the efficacy of the SoHo™ to wirelessly monitor these parameters in group-housed mice. C57BL/6 female mice (22 weeks old; N=5) were surgically instrumented (subcutaneously) with the SoHo™ telemetry transmitters (model X02) and group-housed under a standardized 12-hour dark/light cycle. Synchronized EEG, EMG, body temperature, gross locomotor activity, and video data were continuously collected during 12 days of post-operative recovery. **Results:** Following surgery (day 0), the average percentage of slow wave sleep (SWS) was 32.9±15.5% and paradoxical sleep (PS) was 11.2±6.1%. By day 12, SWS decreased to 26.2±9.7% and PS decreased to 5.2±0.9%. EEG Delta power was 4693±276 µV2 (dark) and 3843±742 µV2 (light) post-surgery and decreased by 45% (dark) and 21% (light) on day 12. Post-surgery, the subcutaneous temperatures were 35.9±0.4 °C (dark) and 35.7±0.2 °C (light) and did not change on day 12. Average gross locomotor activity (calculated as counts per minute; cpm) was 13181±509 cpm (dark) and 81707±8161 cpm (light) post-surgery and increased by 1360% (dark) and decreased by 29% (light). **Conclusions:** The data demonstrates that SoHo™ telemetry is a robust tool for evaluating EEG, EMG, temperature, and activity in group-housed mice. Future studies are needed to further characterize EEG dynamics during recovery.

PS 3854 Evaluation of blue light exposure from LED lighting on lifespan and sleep in mice

K. Okamura, M. Sato, and K. Nohara. National Institute for Environmental Studies, Tsukuba, Japan.

Background and Purpose: LED lighting is widely used because its lifespan is more than three times longer than that of fluorescent lighting, and it consumes only one-third the power. LED lights emit a relatively high proportion of blue light (350-500 nm) compared to fluorescent lights, and nighttime exposure to blue light has been linked to sleep disturbances, although whether daily and lifetime exposure to blue light affects sleep is not well understood. Additionally, previous studies have shown that blue light exposure shortens lifespan in *C. elegans* and *Drosophila*. In this

study, we aimed to evaluate whether blue light exposure from LED lighting affects sleep or reduces lifespan in mice, as a representative mammalian model. **Methods:** Regarding evaluating the effect of lifespan by blue light exposure, senescence-accelerated mouse prone 8 (SAMP8) mice were used due to their short lifespan (approximately 1 year) and reported disruption of circadian rhythm, suggesting high sensitivity to blue light exposure. SAMP8 mice (N = 25 per group) were purchased at 3 weeks of age. After acclimation, mice were exposed to each light condition from 5 weeks of age: 1) 5,000K (high blue light component), 2) 3,500K (low blue light component), 3) blue light cut (no blue light component), and reared until the end of life. Room illuminance was maintained between 150 and 300 lux, and the lights were turned on from 7:00 AM to 7:00 PM. For measuring sleep parameters, we used SAMP8 and senescence-accelerated mouse resistant 1 (SAMR1) (as a control strain) (N = 8-10 per group). Each sleep parameter, including sleep duration (as a measure of sleep quantity), sleep episode duration (as a measure of sleep quality), and the circadian rhythm of sleep, was measured continuously using the non-invasive sleep monitoring system PiezoSleep at 27, 41, and 55 weeks of age. To ensure that changes in sleep parameters were due to light effects and not individual differences among groups, we measured sleep parameters at 4 weeks of age under a 5,000K light condition prior to exposure to specific light conditions. The data were analyzed using SleepStats v4 software. **Results:** The median life expectancy of SAMP8 mice was 50 weeks (5,000K), 71 weeks (3,500K), and 58 weeks (blue light cut). However, there were no significant differences among the groups. This result suggests that blue light exposure did not induce the severe shortening of lifespan reported in *C. elegans* and *Drosophila*, when tested in SAMP8 mice under standard rearing conditions. Regarding sleep, the duration of individual sleep episodes (sleep quality) showed age-dependent differences among strains. However, there were no significant differences among the light exposure groups. In terms of total sleep duration (sleep quantity), the data of SAMR1 mice showed that sleep during the dark period was significantly decreased in the 5,000 K group, which led to an increased light/dark (L/D) sleep ratio compared with the other groups at 27 and 55 weeks of age. Consistent with these observations, the circadian rhythm of sleep in SAMR1 mice differed between the 5,000 K group and the blue light-cut group, particularly at the beginning of the dark period. These changes were not observed in SAMP8 mice. **Conclusions:** In terms of evaluating the effect of blue light on lifespan, the current study using SAMP8 mice found no significant differences among groups with different blue light ratios. Regarding the effect of blue light on sleep, the sleep response to blue light exposure varied among strains. Blue light exposure reduced sleep duration at the beginning of the dark period and increased the L/D sleep ratio in a particular strain, suggesting that blue light exposure affects sleep patterns in certain populations.

PS 3855 Investigating the Role of the Aryl Hydrocarbon Receptor in Diet-Modulated Energy Metabolism and Weight Regulation in Male Mice

A. Bathina¹, J. Hakanen¹, A. Doka¹, J. Linden¹, S. Unniappan², A. Raasmaja¹, and R. Pohjanvirta¹. ¹University of Helsinki, Helsinki, Finland; and ²University of Saskatchewan, Saskatoon, SK, Canada. Sponsor: R. POHJANVIRTA, EUROTOX

Background and Purpose: Obesity is a major global health issue and a key risk factor for cardiovascular disease, type 2 diabetes, and cancer. However, many of the molecular mechanisms regulating body weight remain poorly understood. The aryl hydrocarbon receptor (AHR) has recently emerged as a contributor to energy balance. AHR is a ligand-activated nuclear receptor initially identified for mediating the toxicity of dioxins and polycyclic aromatic hydrocarbons, but it also regulates numerous genes with critical physiological functions. Emerging evidence suggests that AHR may influence energy metabolism, yet its precise role and significance remain unclear. The present study aimed to shed further light on the role of AHR in energy balance by examining the effects of global AHR deficiency in mice fed with either a standard diet (SD) or a high-fat diet (HFD). Previous studies have shown that a 30 % reduction in dietary tryptophan (TRP) increases energy expenditure in obesity-prone rats fed on a HFD, without affecting body composition. We hypothesized that this effect might be mediated by reduced AHR activity. To test this, we included a modified HFD with a 30 % lower TRP concentration (HFDtrp) in our study design. **Methods:** A total of 56 male AHR knockout (AHRKO; on C57BL/6J background) or wildtype (WT) mice (derived from C57BL/6J × AHR^{-/-}). These mice were fed either SD (10% of energy from fat), HFD (60% of energy from fat), or HFDtrp (60% of energy from fat), and were randomly assigned to six groups: WT-SD, AHRKO-SD, WT-HFD, AHRKO-HFD, WT-HFDtrp, and AHRKO-HFDtrp. All diets were purchased from Research Diets (USA), and the exposure lasted for 24 weeks. During weeks 16-17, the mice were subjected to glucose and insulin tolerance tests (GTT and ITT, respectively), and during weeks 18-20, their energy expenditure was determined by an indirect calorimetry. Whole-body composition measurements were carried out by a mini-spec analyzer on week 20. Upon study termination, total RNA was extracted from relevant tissues and reverse-transcribed to cDNA for real-time RT-qPCR analysis. **Results:** Body weight analysis showed no significant differences between genotypes on the same diet. AHRKO-HFD mice did not resist weight gain, similar to WT-HFD mice. Interestingly, the AHRKO-HFDtrp group showed the greatest weight gain, although no significant differences were observed among the HFD-fed groups. Relative liver weight was lower in AHRKO mice compared to WT, while epididymal white adipose tissue (EpiWAT) weights did not differ. Minispec analysis revealed no differences in body fat percentage among the HFD groups. Energy expenditure measured by

indirect calorimetry was also comparable across HFD-fed mice. Plasma chemistry analysis showed that all AHRKO groups had lower cholesterol and glucose levels than their WT counterparts. In liver tissue, *PPARα* expression was relatively lower in AHRKO mice compared with WT, and a similar trend was observed for brown adipose tissue *Ucp1* (uncoupling protein 1) expression. Histological analysis showed no significant differences in hepatic steatosis among the HFD-fed groups in either genotype. As expected, hepatic *Cyp1a1* mRNA abundance an index of AHR activity was significantly higher in WT compared with AHRKO mice. **Conclusions:** In contrast to previous reports, AHRKO mice did not resist weight gain when fed with HFD. Reduced dietary tryptophan also failed to attenuate weight gain. Energy expenditure was similarly unchanged across genotypes and diets. Hepatic steatosis levels were comparable across all HFD groups, indicating no genotype- or diet-specific effects. As expected, hepatic *Cyp1a1* expression was markedly lower in AHRKO mice, confirming reduced AHR activity. Together, these findings indicate that AHR deficiency does not protect against diet-induced weight gain under the present conditions and highlight a complex interaction between AHR signalling, dietary tryptophan, and metabolic regulation. Further investigation is needed to better understand the underlying mechanisms.

PS 3856 Loss of the Suppressor of Cytokine Signaling 1 (SOCS1) leads to progressive systemic inflammation in a SOCS1 inducible knockout adult mouse model

S. Moore, S. Zhu, C. Zhang, J. Price, V. Bhaskaran, I. Kim, R. Smith, and K. Augustine. Bristol Myers Squibb, Lawrenceville, NJ.

Background and Purpose: The Suppressor of Cytokine Signaling 1 (SOCS1) is a negative regulator of the immune system constraining the response of IFN γ signaling making it a potential target for therapeutic strategies aimed at immunomodulation. SOCS1 constitutive knockout mice are normal at birth but exhibit stunted growth and die within three weeks after birth, with a syndrome characterized by severe lymphopenia, activation of peripheral T cells, fatty degeneration and necrosis of the liver, and macrophage infiltration of major organs. Furthermore, SOCS1 haploinsufficiency is associated with patients presenting immune dysregulation with multisystem autoimmunity and autoimmune disease such as systemic lupus erythematosus. To evaluate potential liabilities related to postnatal loss of SOCS1, we conducted 1- and 4- month long phenotype studies in a tamoxifen inducible SOCS1 knock-out adult mice. **Methods:** Mice carrying floxed SOCS1 gene, either in one allele (HET SOCS1) or in both (HOM SOCS1) were treated with tamoxifen (75 mpk) daily for 5 consecutive days to induce excision of SOCS1. Vehicle-treated mice with same genotype or tamoxifen-treated mice not carrying the Rosa26-CreERT2 transgene were used as negative controls. Groups contained 4-10 mice each, both females and males. Mice were terminated either 1 month or 4 months after tamoxifen administration. Study endpoints included clinical observations, body weight, blood chemistry and hematology, histopathology, T-cell activation by flow cytometry, serum cytokines and anti-dsDNA autoantibody levels measurement. **Results:** Phenotypic evaluation of HOM SOCS1 mice at 1 and 4 months revealed a progressive organ inflammation, with HET SOCS1 mice exhibiting only minimal findings, supporting a gene dosage effect. At 1 month, in the HOM SOCS1 mice, severe histopathological changes were primarily confined to the gastrointestinal tract, however, by 4 months, the pathology extended to multiple organs with mixed-cell and/or mononuclear cell infiltrates observed in bone marrow, spleen, liver, and skeletal muscle. HOM SOCS1 mice showed lack of body weight gain or mild weight loss 4 months post-tamoxifen, consistent with gastrointestinal inflammation. Clinical blood pathology profiles supported inflammatory histopathology findings, showing decreased A/G ratios, elevated neutrophils and eosinophils and reduced lymphocytes. HOM SOCS1 mice showed also increased T-cell activation both at 1 and 4 months post-tamoxifen. Cytokine analysis indicated progressive increases of IFN γ levels, a negative regulator of SOCS1, IL6 and TNF α . Additionally, a modest elevation in dsDNA autoantibody levels was observed in HOM SOCS1 mice at 1 month and in both HET and HOM SOCS1 mice 4 months post-tamoxifen. Metabolic changes were also evident, with sustained reductions in glucose levels and transcriptional alterations in insulin signaling, including decreased expression of the liver gluconeogenic rate-limiting enzyme phosphoenolpyruvate kinase (PCK1), potentially related to liver inflammation. Overall, HET SOCS1 iKO mice displayed only minor changes compared to the pronounced phenotypic and metabolic alterations observed in HOM SOCS1 iKO mice. **Conclusions:** In this study, postnatal SOCS1 knockout demonstrated a gene-dosage effect: homozygous mice exhibited progressive multi-organ inflammation, with the gastrointestinal tract showing the earliest onset and increasing regional spread and severity, whereas heterozygous iKO mice displayed only minimal changes.

J. Maye¹, R. Smith¹, I. Kim¹, K. Granaldi¹, X. Li¹, X. Huang², J. Burns¹, J. Augusma¹, V. Bhaskaran¹, K. DiPetrillo³, J. Loy⁴, L. Armstrong¹, P. Levesque¹, and A. Rizzolo¹.
¹Bristol Myers Squibb, Lawrenceville, NJ; ²Bristol Myers Squibb, San Diego, CA;
³Bristol Myers Squibb, New Brunswick, NJ; and ⁴Bristol Myers Squibb, Cambridge, MA.

Background and Purpose: B lymphocyte-induced maturation protein-1 (BLIMP-1) is a transcriptional repressor that plays a pivotal role in the differentiation and homeostasis of immune cells. Given its central function in regulating B cell maturation, toxicological liabilities associated with lymphoma development were a significant concern. Notably, research suggests that loss of BLIMP-1 function may contribute to the pathogenesis of diffuse large B-cell lymphoma. In addition to its immunological roles, BLIMP-1 has been implicated in ocular development, specifically in the formation of the retina and the shaping of the corneal lens. However, its function in adult tissues remains largely unexplored. In light of these potential toxicities, we utilized a BLIMP-1 inducible knockout mouse model to systematically investigate the consequences of sustained loss of BLIMP-1, with a particular focus on lymphomagenesis and ocular pathology. **Methods:** To investigate on-target toxicities resulting from chronic BLIMP-1 suppression, a tamoxifen-inducible BLIMP-1 knockout mouse model was utilized. This model, obtained from the Walter and Eliza Hall Institute, enables conditional deletion of the floxed BLIMP-1 gene upon tamoxifen administration. Mice (n=10-20 mice/group/sex) at approximately 7 weeks old received daily tamoxifen dosing for five consecutive days. Clinical observations for all mice were recorded daily, and body weights were measured every other week. Due to declining animal health, humane euthanasia was performed between 5- and 7-months post tamoxifen-induction. At necropsy, blood samples were collected for flow cytometric analysis and target organ tissues were collected for gross and histological examination. **Results:** Female homozygous inducible knockout mice began exhibiting adverse clinical signs—including corneal ulcers, cervical lymphadenopathy and impaired weight gain—approximately 10 weeks after tamoxifen administration, and males showed similar signs beginning at week 19. Histopathological analysis revealed corneal lesions characterized by inflammation and squamous metaplasia. Neoplastic lesions were identified in the liver, lungs, mesenteric and mandibular lymph nodes, and spleen. Immunohistochemistry confirmed the presence of metastatic B-cell lymphoma and correlated with significant reductions in circulating B cells in both male and female inducible knockout mice. **Conclusions:** Histological findings corroborated the clinical observations, demonstrating that sustained loss of BLIMP-1 expression in adult mice was not tolerated and results in the development of metastatic B-cell lymphoma and ocular pathology that would likely result in blindness in humans. *All procedures were conducted in accordance with Bristol Myers Squibb institutional animal care and use protocols.*

PS 3858 Establishment of a mouse model of ischemic stroke and recurrence for preclinical studies

C. Wu¹, S. Liu², and C. Chen². ¹China Medical University, Taichung, Taiwan; and ²National Taiwan University, Taipei, Taiwan.

Background and Purpose: Stroke is the second largest cause of death in the world. It is one of major diseases to cause a long-term disability of work. It has been estimated for stroke patients that about eighty percent of patients are ischemic stroke and the others are hemorrhagic stroke or other type. The economic costs or social burden are very huge after stroke. For three out of four patients a stroke is the first event, while one in four patients can experience a recurrent stroke. The preclinical and clinical data showed the potential contribution of environmental toxins to an increased risk of stroke. Several performed ischemic or hemorrhagic stroke animal models have been established. However, few animal models of recurrent ischemic stroke have been established because of their complicated procedures and high mortality rate. The aims of this study were to establish an improved two-stage middle cerebral artery occlusion (MCAO) protocol for ischemic stroke and recurrence. We also provided an example for investigating the effect of non-invasive low-intensity pulsed ultrasound (LIPUS), a therapeutic ultrasound, combined with aerobic exercise on ischemic recurrent stroke. **Methods:** Male C57 BL6J mice with six-week-old were used. An intraluminal filament technique was used to determine transient focal cerebral ischemia induced by MCAO. Mice were anesthetized. The common carotid artery (CCA), external carotid artery (ECA), and internal carotid artery (ICA) were carefully exposed in the neck region. A 6-0 nylon filament was then inserted through the CCA into the ICA and advanced to the origin of the middle cerebral artery (MCA). The filament was left in place for about 40 min to block blood flow in the MCA. A second stroke surgery was performed 14 days after the first MCAO. A 6-0 nylon filament was reinserted through the external carotid artery into the MCA via the original CCA opening. This procedure could significantly reduce the mortality rate. The filament was again left in place for approximately 40 min to induce MCA occlusion, during which laser Doppler was used to monitor blood flow. LIPUS (100 mW/cm², 20 min daily to the cortical of brain) + exercise (treadmill aerobic training, 10-20 m/min, 10 min/2 times/day) were applied for 12 days after the first MCAO, and then the 2nd MCAO operation was carried out. All mice were euthanized on day 16 after initial MCAO. **Results:** We first observed mortality rates. In 1st MCAO, the survival rate was 80-100% at day 4 (n=10; two repeats). The survival rate reaches

up to 90% after the 2nd MCAO at day 16 (n=10). In 1st and 2nd MCAO mice, open field testing revealed marked reductions in movement patterns and exploratory behavior, and exhibited significantly decreased total travel distance and movement speed compared to original controls (n=8-10, p<0.05). The brain pathological changes in 1st and 2nd MCAO mice displayed a slight to moderate local neuronal cell necrotic loss with neuropil vacuolation, especially observed in the hippocampus and cortex areas; these severe lesions with hemorrhage were observed in 2nd MCAO (recurrent) mice (n=8-10, p<0.05). Moreover, we tested the effect of combined LIPUS with aerobic exercise rehabilitation on ischemic recurrent stroke. LIPUS + exercise significantly improved post-stroke mobility loss and significantly improved brain damage scores, including neuronal damage, vascular changes, and immune inflammatory infiltration (n=5, p<0.05). **Conclusions:** A two-stage MCAO mouse model for recurrent ischemic stroke, which significantly reduced locomotor activity, decreased movement speed, and diminished neurobehavioral scores compared to the first-time stroke and control, was established that may be applied to investigate the contribution of environmental toxins to an increased risk of stroke/recurrence or pharmacological studies for stroke/recurrence therapy. Using this model, we demonstrated that LIPUS + aerobic exercise rehabilitation offered potential benefits for ischemic stroke and its recurrence, laying the groundwork for future clinical applications.

PS 3859 Development and validation of a repeated exposure elastase-induced murine model for COPD and acute exacerbation of COPD

M. P. Cooper¹, Y. Li², C. Monge², A. Razazan², O. Oyewole², and S. Hussain^{2,3}.
¹Department of Microbiology, Immunology and Cell Biology, WVU, Morgantown, WV;
²Department of Physiology, Pharmacology & Toxicology, WVU, Morgantown, WV;
and ³Centre for Inhalation Toxicology (ITOX), West Virginia University, School of Medicine, Morgantown, WV.

Background and Purpose: Despite being a leading cause of death internationally, targeted treatment options for Chronic obstructive pulmonary disease (COPD) are limited. The long-term objective of this research is to evaluate the role of pathogen recognition receptors (PRRs) in COPD and acute exacerbation of COPD (AECOPD) to test a new therapeutic approach. To achieve this goal, this study aimed to establish and validate single-dose versus repeated-dose porcine pancreatic elastase (PPE)-induced murine models of COPD and AECOPD. Viral infections are among the most observed etiologies for AECOPD. A successful model is expected to exhibit an emphysematous phenotype, as evidenced by changes in lung function, increased lung immune cell infiltration, and alterations in lung gene and protein expression related to inflammation and extracellular matrix remodeling. **Methods:** Three different experimental designs of PPE exposure in C57BL6 mice were tested. Group 1 received 2IU PPE intranasally once per week for 3 weeks, followed by 3 weeks of rest. Group 2 received a single intratracheal dose of 1IU PPE and was sacrificed 3 weeks later. Group 3 received 0.2IU PPE intratracheally once per week for 4 weeks and was given two weeks of rest after the final dose. A portion of Group 3 also received 4mg/kg of TLR7 agonist, imiquimod, intranasally 24 hours prior to sacrifice. Healthy, unexposed mice were used as controls. Lung function was monitored over time with Whole Body Plethysmography. At the end of the experimental period, detailed lung function assessments were performed using FlexiVent Systems that included both forced oscillation-based and negative pressure-driven forced expiratory assessments. Cytology of bronchoalveolar lavage (BAL) was performed on all mice, and lung tissue was collected for mRNA expression analysis by qPCR. **Results:** Mortality within 48 hours following a PPE exposure occurred in 45.8% and 72.2% of mice exposed to 2IU of PPE or 1IU of PPE, respectively. No mortality was observed in mice receiving 0.2IU PPE with or without imiquimod. In all exposure schemes, PPE increased the number of macrophages, neutrophils, and lymphocytes in the BAL. Relative to controls, respiratory elastance and the ratio of forced expiratory volume to forced vital capacity (FEV:FVC) significantly decreased in mice exposed to 2IU PPE and 0.2IU PPE. Additional exposure to imiquimod in 0.2IU PPE-exposed WT mice further decreased the FEV:FVC ratio. **Conclusions:** The dosing schemes using 2IU PPE and 0.2IU PPE induced a COPD-like phenotype by pulmonary immune infiltration and respiratory dysfunction. However, the dosing scheme of four intratracheal exposures to 0.2IU PPE is a better model for our experimental needs due to animal mortality. Following imiquimod exposure in PPE-exposed mice, the further decrease in lung function by the FEV:FVC ratio suggests that this may be a promising model for AECOPD. Going forward, this model will be helpful for mechanistic assessment of the role of PRRs on COPD and AECOPD.

PS 3860 Identification of Liver-Specific Extracellular Vesicle (EV) RNAs as Biomarkers of Hepatotoxicity in CD9-EGFP Reporter Mice

R. Ono¹, M. Naruse², M. Kuwagata¹, Y. Yoshioka³, S. Kitajima¹, Y. Hirabayashi¹, T. Ochiya³, M. Ikawa⁴, and T. Yamada¹. ¹National Institute of Health Sciences (NIHS), Kawasaki, Japan; ²National Institute of Infectious Diseases, Tokyo, Japan; ³Tokyo Medical University, Tokyo, Japan; and ⁴Osaka University, Suita, Japan.

Background and Purpose: Extracellular vesicles (EVs), including exosomes, are secreted from cells and circulate in the bloodstream. EVs contain nucleic acids such as mRNA, microRNA (miRNA), and DNA, and function as mediators of inter-cellular communication. In recent years, miRNAs derived from human tumor-spe-

cific EVs have been reported as biomarkers with diagnostic accuracies exceeding 90%. Furthermore, we and others have demonstrated that EV-derived miRNAs in body fluids are useful biomarkers of chemical-induced toxicity [1,2]. We generated a Cre-inducible CD9-EGFP knock-in mouse line targeting the Rosa26 locus and established a mouse model that expresses human CD9-EGFP specifically in the liver. The aim of this study was to isolate liver-derived EVs using this model and to characterize the liver-specific EV miRNA profile by transcriptomic analysis. **Methods:** Male CD9-EGFP knock-in (flox/WT) mice were crossed with female Alb-Cre mice to generate flox/Alb-Cre (liver-specific CD9-EGFP expression) and WT/Alb-Cre mice. At 10 weeks of age, mice were administered a single oral dose of carbon tetrachloride (CCl₄, 70 mg/kg) or vehicle (corn oil). Twenty-four hours after dosing, serum was collected and liver-derived EVs were isolated by immunoprecipitation using an anti-human CD9 antibody. Total RNA was extracted from these EVs and subjected to transcriptomic analysis. **Results:** By using an CD9-EGFP knock-in mouse, we successfully isolated EVs restricted to those secreted from the liver, enabling us to determine whether the candidate biomarker EV RNAs truly originate from hepatotoxic injury or instead from other organs. Furthermore, RNA-seq-based expression profiling of liver-derived EVs allowed us to identify 20 highly sensitive biomarkers of hepatotoxicity. **Conclusions:** By using this mouse line, we successfully isolated EV RNAs that serve as bona fide liver-derived biomarkers of hepatotoxicity. These findings are expected to greatly contribute to the refinement of toxicity testing and to the 3Rs (replacement, reduction, and refinement) of animal welfare. Furthermore, by crossing this animal model with other organ-specific Cre driver mice, the same strategy can be used to efficiently isolate toxicity biomarkers for a variety of organs. **References:** [1] Ono R., et al. : Novel hepatotoxicity biomarkers of extracellular vesicle (EV)-associated miRNAs induced by CCl₄. *Toxicol Rep.* 2020; 7: 685-692. PS 3861 A Machine-Learning Virtual Histology Tool Reduces Animal Use and Captures Injury Dynamics in Toxicology Studies

C. Humphries, J. A. Cartwright, S. J. Forbes, and J. W. Dear. University of Edinburgh, Edinburgh, United Kingdom.

Background and Purpose: Heterogeneity in preclinical toxicology studies produces noisy data requiring large sample sizes and the desired endpoint histology can often only be obtained by terminal cull. Serial histology without sacrifice would reduce variability and animal use. We hypothesized that circulating biomarkers quantitatively correlate with tissue injury severity over time, enabling non-invasive histological injury quantification. However, biomarker-injury relationships are often non-linear and time-dependent, requiring flexible modelling approaches **Methods:** Under local ethical approval (093-LFR-24), fifty 12-week male C57BL6/J mice (Charles River, UK) received 350mg/kg intraperitoneal acetaminophen. Serial 40microl tail-vein microsamples (n=6 timepoints over 48h) were obtained to quantify alanine aminotransferase (ALT) and microRNA-122 (miR-122). Pre-defined groups were culled for tissue correlates at each timepoint. A necrosis prediction model was derived using Generalized Additive Modelling with Leave-One-Out Cross-Validation to integrate time and biomarker kinetics to predict individual mouse hepatic necrosis fractional area. **Results:** Cull hepatic necrosis ranged from 0.02-0.80 (median 0.32, IQR 0.23-0.48). The serial microsampling group showed consistent variability across timepoints (mean longitudinal ALT AUC CV 35.6±1.8%). In contrast, terminal sample necrosis showed high inter-timepoint variability (mean CV 38.7±28.9%), reflecting between-animal heterogeneity that serial cull designs cannot capture. Virtual histology derived from longitudinal biomarker kinetics achieved a Mean Absolute Error (MAE) of 7.88% (ALT) and 9.41% (miR-122). Power analysis demonstrated that use of the ALT model would allow equivalent statistical power to be achieved with 64-89% fewer animals depending on sampling frequency and desired effect size. Use of a machine learning approach improved the MAE by 13.6% compared to linear regression approaches. **Conclusions:** This virtual histology approach enables non-invasive, serial quantification of hepatic necrosis in individual mice, directly supporting 3Rs principles. The approach is potentially applicable to any frequently used animal model where there is a tissue injury of interest and a known tissue biomarker. Replacing terminal culls with longitudinal monitoring provides a more ethical, efficient, and statistically robust framework for preclinical toxicity and efficacy testing, without loss of the biological complexity captured by animal models. Additionally, capturing the injury trajectories from onset to resolution provides crucial insights into individual response heterogeneity and builds a clearer translational bridge to the serial monitoring designs used in clinical practice. The high-resolution datasets produced also provide a more confident basis for critical 'go/no-go' decisions in preclinical development, de-risking candidate selection and accelerating timelines.

PS 3862 Modulatory effects of glutamate transporter enhancers in alcohol-related liver injury in alcohol preferring rats

A. Alotaibi¹, K. Bhowmik¹, V. Kumar¹, M. AbouGharbia², W. Childers², and Y. Sari¹.

¹The University of Toledo, College of Pharmacy and Pharmaceutical Sciences, Toledo, OH; and ²Temple University, Philadelphia, PA. Sponsor: J. Wise

Background and Purpose: Prolonged ethanol use can induce behavioral and physiological alterations, along with affecting liver's capacity to metabolize ethanol, leading to injury and damage to hepatocytes. MC-100093, a beta-lactam non-antibiotic compound, possesses glutamate transporter-1 (GLT-1) modulatory capabilities, and demonstrated a reduction in ethanol consumption. **Methods:** Male and female P rats were exposed to ethanol for six weeks and were divided into four groups. On week six, rats received intraperitoneal injections of saline or MC-100093 (100 or 150 mg/kg) for five days consecutively. **Results:** MC-100093 effectively attenuated ethanol-induced liver injury by decreasing ethanol consumption and normalizing the expression of GLT-1, cystine/glutamate antiporter (xCT) and lipid and collagen type 1 (COL-1) in liver of male and female rats. Moreover, MC-100093 reversed ethanol-induced inflammation, and reduced triglyceride contents in the liver. **Conclusions:** Our data demonstrate that MC-100093 is effective in mitigating ethanol-induced liver injury.

PS 3863 Cytological Composition of Bone Marrow in Athymic Nude RH-FoxN1^{tmu} Rats

M. Defontis¹, R. Fares², and A. Bidauf². ¹Tox and Diag, St Germain Nuelles, France; and ²ERBC, Baugy, France. Sponsor: R. Fares, American College of Toxicology

Background and Purpose: Long-term pharmacology and safety evaluation of innovative human-derived cell therapy products require the use of immunocompromised animals to avoid immune-mediated destruction of injected human-derived cells. Athymic Nude rats represent an interesting alternative to broadly used Nude mice, particularly when implantation surgery is required and animals of larger size are preferred. **Methods:** Cytological composition of the bone marrow of 28 clinically healthy RH-FoxN1^{tmu} nude rats (11 males, 17 females) was determined as follows: complete differential counts, morphological assessment and calculation of myeloid:erythroid ratios. **Results:** Percentages of each cell type were obtained and myeloid:erythroid ratios were calculated (0.66 to 3.16, mean 1.62). Morphological characteristics of erythroid, granulocytic and lymphoid populations were obtained. **Conclusions:** Increase in the proportion of eosinophils (all stages), increase in emperipolesis of neutrophils on megakaryocytes and decrease in lymphocyte proportion were observed, in comparison to other commonly used rat strains. These results provide preliminary data of cytological bone marrow findings in athymic nude RH-FoxN1^{tmu} rats.

PS 3864 Interaction between pyrethroid exposure and Shank3 genotype on neurodevelopmental disorder-relevant behaviors in prairie voles

R. Shah. University of Toledo College of Medicine and Life Sciences, Toledo, OH.

Sponsor: J. Burkett

Background and Purpose: Developmental pesticide exposure has been linked to an increased risk of neurodevelopmental disorders such as autism spectrum disorder and attention deficit hyperactivity disorder (ADHD). Developmental pyrethroid pesticide exposure in mice and prairie voles causes a broad behavioral phenotype relevant to autism and ADHD. SHANK3 is among the strongest candidate genes for autism, with brain mechanisms overlapping with the effects of developmental pyrethroid exposure in animal models. Whether SHANK3 genotype interacts with developmental exposure is unknown. **Methods:** In this study, prairie vole mothers were administered one of four doses of the pyrethroid deltamethrin (0, 0.3, 1, or 3 mg/kg Q3D PO) throughout pre-conception, gestation, and lactation. We used a litter-based design with heterozygous breeding to produce one wild-type and one Shank3 +/- mutant offspring per litter. Adult offspring were assessed in hyperactivity, repetitive behaviors, and circadian rhythms. **Results:** Results related to differences in dose-response between siblings of different genotypes will be interpreted to evaluate both direct pesticide effects and genotype-by-environment interactions. **Conclusions:** These findings have the potential to inform on genetic susceptibility to developmental pesticide exposures that are a risk for autism and ADHD.

PS 3865 A comparative study of ocular anatomy in 3 different laboratory Swine strains

M. Bacellar-Galdino¹, N. Jordan¹, B. Ossont¹, D. Brocksmith², G. Bouchard², A. Walz¹, and S. Iwabe¹. ¹Altasciences Preclinical, Scott Twp, PA; and ²Sinclair Bio Resources LLC, Auxvasse, MO. Sponsor: N. Makori

Background and Purpose: The use of laboratory swine in ophthalmic research has grown considerably due to their anatomical and physiological similarities to humans. This study was designed to confirm quantitatively the similarity of ocular structures,

both in size and weight, between Sinclair Nanopigs (SN) comparable to those of the well-established Gottingen Minipigs (GM) and Yucatan pigs (YP). **Methods:** A total of 32 animals (15 SN, 12 GM, and 5 YP), with ages ranging from one- to thirty-months old, were used in this study. Eyes were either dissected (24 SN eyes, 10 GM eyes, and 6 YP eyes) or fixed in 10% formaldehyde (6 SN eyes, 14 GM eyes, and 4 YP eyes) overnight for evaluation. Dissected eyes had the following tissues collected and weighed: aqueous and vitreous humor volumes, cornea, iris/ciliary body, lens, trabecular meshwork, retina, choroid/RPE and sclera. Fixed eyes were sectioned sagittally for measurement of anteroposterior (axial) and transverse (horizontal) globe lengths, cornea diameter, anterior and posterior segment depths, and lens (thickness and diameter). All measurements were analyzed using ANOVA and Tukey-Kramer Test. **Results:** Within our preliminary results, no significant differences were observed in axial globe length, lens width/depth, and anterior segment depth between SN, GM, and YP. Although minimal, statistically significant differences were observed in transverse globe length (21.9 ± 2.22 mm SN, 20.3 ± 0.74 mm GM, 23.3 ± 0.82 mm YP), corneal diameter (13.0 ± 1.46 mm SN, 13.4 ± 0.67 mm GM, 15.3 ± 0.52 mm YP), and posterior segment depth (9.3 ± 0.82 mm SN, 10.5 ± 0.85 mm GM, 11.0 ± 0.82 mm YP). **Conclusions:** In conclusion, while statistically significant differences were observed in some globe measurements among all 3 species, eyes from all 3 species are comparable in weight and size and equally suitable for use in ocular studies.

PS 3866 Comparative Assessment of Oral Gavage, Intravenous, and Subcutaneous Dosing Routes on Maternal Body Weight and Food Consumption in Rabbit Embryo-Fetal Development Studies

Y. Pu, D. Harischandra, and P. Bushdid. Labcorp, Greenfield, IN. Sponsor: S. Xiao

Background and Purpose: The rabbit embryo-fetal development (EFD) study is a cornerstone of reproductive toxicology assessment, yet its execution is often complicated by the rabbit's intrinsic sensitivity to handling and dosing procedures. Although oral gavage (PO), intravenous (IV), and subcutaneous (SC) administration are the most commonly employed dosing routes, systematic comparisons of their impact on maternal body weight (BW) and food consumption (FC) - two critical indices of maternal tolerance - are limited. **Methods:** To address this gap, we retrospectively analyzed aggregated data from 172 rabbit EFD studies (2,390 animals), focusing on control group animals dosed via PO, IV, or SC routes. Dosing occurred during gestational days (GD) 6-19, followed by an undosed observation period (GD20-29). **Results:** Results demonstrated no statistically significant differences among dosing routes in maternal BW or FC during either the dosing (GD6-19) or post-dosing (GD20-29) periods. Across all routes, BW exhibited an upward trajectory from GD6-29, with PO animals showing the smoothest BW profile during the dosing period, followed by SC and IV. Mean daily FC followed a "U-shaped" pattern during GD6-20, with the nadir at GD12-16. SC-dosed animals exhibited the highest mean FC, while PO-dosed animals had the lowest. During GD20-29, mean daily FC declined progressively across all routes, reaching the lowest levels at GD25-29. Median FC trends paralleled the means, while PO-dosed animals demonstrated lower values with sharper mid-gestation (GD11-17) declines. **Conclusions:** In conclusion, these dosing routes did not materially influence maternal BW outcomes in rabbit EFD studies. However, FC was modestly affected, with PO exerting the greatest impact, followed by IV and SC. These findings support the interpretation that dosing route exerts minimal influence on maternal tolerance parameters and reinforce the robustness of rabbit EFD studies across standard administration routes.

PS 3867 Cytological Bone Marrow Cell Differential Counts and Morphological Findings in the Common Marmoset (*Callithrix jacchus*)

M. Defontis¹, A. Bidaut², and R. Fares². ¹Tox and Diag, St Germain Nuelles, France; and ²ERBC, Baugy, France.

Background and Purpose: Cytological bone marrow evaluation is performed in nonclinical toxicological studies to identify potential effects of tested compounds on hematopoiesis. The common marmoset (*Callithrix jacchus*) is a non human primate species used in biomedical research for over 30 years. Due to its small size and limited supply of other NHP species, the number of marmosets used in toxicological studies is expected to increase. The purpose of this poster is to present baseline bone marrow cytological quantitative and qualitative preliminary data. **Methods:** Bone marrow smears were prepared from the proximal femur from 26 healthy control marmosets (13 males and 13 females, 2-4 years old). Total population numbers and percentages of each individual cell type and myeloid:erythroid ratios were obtained and calculated following microscopic examination. **Results:** Bone marrow smears were of high quality. M:E ratios ranged from 0.61 to 1.77. Percentages of granulocytic (31% to 58%), erythroid (32% to 58%) and lymphocyte (5%-22%) series were obtained. Morphologic characteristics of each series were described and included: large to giant neutrophilic metamyelocytes and band neutrophils and very rare ring-shaped nuclei in the granulocytic series, and nuclear blebbing or lobulation with variable number of shapes and binucleated metarubricytes in erythroid series. Quantitative and morphological findings were similar to those observed in Cynomolgus monkeys. **Conclusions:** Bone marrow smears from the proximal femur are adequate for cytological bone marrow assessment in marmo-

sets. These results demonstrate technical and scientific appropriateness of cytological bone marrow evaluation in the common marmoset and provide preliminary data regarding background morphological findings.

PS 3868 Comparison of baseline levels of biomarkers commonly used to assess drug candidate safety, efficacy, and mechanism of action in Cynomolgus Monkeys of Cambodian, Chinese, or Cambodian-Chinese Mixed Origin bred in a US-based Research Facility

A. K. Mahoney¹, M. Strenge², T. Arndt², R. Matteo¹, F. Barone¹, and N. Makori². ¹ALTASCIENCES, Sacramento, CA; and ²ALTASCIENCES, Seattle, WA.

Background and Purpose: Cynomolgus monkeys (*Macaca fascicularis*) are a commonly used nonhuman primate model in preclinical toxicology research. Preclinical drug programs predominantly utilize cynomolgus monkeys of a single origin (Southeast Asian or Mauritian) to reduce experimental variability; however, a restriction in origin poses supply challenges. Here, we explore the use of mixed origin cynomolgus monkeys born at a US breeding facility by (1) characterizing standard biomarkers used to evaluate drug candidates' effects (clinical pathology, peripheral blood lymphocytes [by immunophenotyping], complement protein fragments, and cytokines) in Cambodian-Chinese cynomolgus monkeys, and (2) comparing the biomarkers to cynomolgus monkeys of Cambodian alone or Chinese alone origin. **Methods:** A total of thirty, research naïve, juvenile cynomolgus monkeys (n=10 per origin) were sampled. Clinical pathology parameters were quantified using standard diagnostic equipment; and peripheral blood lymphocytes, complement protein fragments, and cytokine levels were quantified using immunoassays. **Results:** Preliminary data suggests that there are no significant differences in baseline levels of biomarkers between cynomolgus monkeys of Cambodian, Chinese, or Cambodian-Chinese mixed origin bred in a US-based Research Facility. **Conclusions:** These findings are important because they support the use of mixed-origin cynomolgus monkeys born at a US breeding facility in preclinical toxicology research.

PS 3869 African Green Monkey Nonhuman Primate Periodontal Exam Scoring System (NHP-PESS)

K. Cruz¹, M. Lawrence¹, A. Pemberton¹, S. Korte¹, and A. Murti². ¹Virscio, New Haven, CT; and ²Research Animal Resources John's Hopkins University, New York, NY.

Background and Purpose: Comprehensive assessment of the periodontium is essential for accurate evaluation of oral health and disease progression. In translational research, nonhuman primates (NHPs) allow modeling of periodontal pathology and interventional testing given clinically relevant anatomy and physiology and naturally incident periodontitis. The St. Kitts African green monkey (*Chlorocebus sabaeus*) represents a particularly valuable species for this purpose, offering accessibility and limited genetic diversity. **Methods:** To establish a standardized approach periodontal scoring a "Nonhuman Primate Periodontal Exam Scoring System" (NHP-PESS) was developed by adapting the human "Periodontal Screening and Recording" (PSR) system. The scoring relies on a color-coded periodontal probe with 3 - 6 - 8 - 11 mm reference bands, as described by Miller [1950, Textbook of periodontia (oral medicine). Blakiston], allowing rapid visual assessment of periodontal pocket depth. Additional criteria were incorporated to increase precision and cross-study comparability, including the modified Gingival Index (MGI) for inflammation, Rustogi Plaque Index (RPI) for plaque distribution, and mobility classification. **Results:** The NHP-PESS employs a five-code structure (Codes 0-4) derived from the PSR methodology. Each code corresponds to specific ranges of probing depths, gingival bleeding, calculus presence, gingival inflammation, and tooth mobility, providing a rapid visual and concrete scoring framework: Code 0: Probing depth 1-3 mm, no calculus, healthy gingiva (MGI 0), mobility 0. Code 1: Probing depth 1-3 mm, mild inflammation, bleeding after probing, mobility 0. Code 2: Probing depth 1-3 mm, supragingival or subgingival calculus, mild to moderate inflammation, mobility 0. Code 3: Probing depth 3-6 mm, calculus present, moderate inflammation, mobility I-II. Code 4: Probing depth ≥ 6 mm, calculus present, severe inflammation, mobility II-III. The NHP-PESS framework provides an efficient method for classifying periodontal health and disease states in nonhuman primates. By prioritizing clinically relevant parameters and alignment to human PSR methodology, the system supports rapid disease staging while maintaining inter-observer consistency for translationally relevant data development. Incorporating the MGI and RPI further supports the integration of standard oral evaluation measurements in translational oral health outcome focused studies. The structured coding minimizes the need for extensive charting and reduces examination time per subject, improving reproducibility and workflow standardization. **Conclusions:** The "Nonhuman Primate Periodontal Exam Scoring System" provides a concise, objective, and reproducible framework for assessing periodontal health in different preclinical studies settings, bridging the gap between veterinary and clinical periodontal diagnostics. This method enhances welfare monitoring, supports longitudinal assessments of disease progression, and establishes a foundation for integrating clinical, histopathological, and molecular endpoints in translational research. Future validation will focus on correlating NHP-PESS scores with systemic inflammatory biomarkers and histopathological outcomes.

E. Sinopoulou¹, M. Lawrence², S. Korte², E. Oyarzabal², R. Hancock², R. Pike², C. Anselm², M. O'Connor², M. Tuszynski¹, and C. Sparrey³. ¹Center for Neural Repair, Biomedical Research Facility 2, University of California San Diego, La Jolla, CA; ²Virscio, New Haven, CT; and ³Mechatronic Systems Engineering, Neurospine Lab, Simon Fraser University, Surrey, DC, Canada.

Background and Purpose: Approximately 18,000 individuals in the US sustain a spinal cord injury (SCI) every year (National Spinal Cord Injury Statistical Center - NSCISC) with over 300,000 people living with long-term impairments. Despite medical advances there are no effective treatments for SCI. This highlights the importance of a clinically relevant nonhuman primate for translational research. Such a model is essential for bridging the gap between rodent studies and human trials, as it more accurately replicates the complexities of human SCI. African green monkeys (AGM) provide a better test system for spinal injury preclinical studies as they better approximate human SCI than rodent models, and they accommodate assessment of multiple recovery variables and rehabilitative therapy. The current contusion devices on the market provide standardized impact forces that may be sufficient for rodent models due to their relatively uniform spinal cord dimensions; however, this approach is inadequate for larger species like nonhuman primates (NHP), which exhibit significant variability in spinal cord size and anatomy. Here, we present a novel SCI cervical hemiconusion model to accurately mimic human SCI using the novel *High-precision in vivo tissue test system* (HITT) developed by the Neurospine lab (SFU). This system allows for individualized impact parameters based on pre injury MRI measurements of each subjects spinal cord. **Methods:** Twenty-six African Green Monkey (4 - 12 years, 5-8 kg for males; 3.5-7 kg for females) underwent a pre injury MRI one week before contusion. The subjects were placed in two different cohorts based on preclinical safety assessment timelines. Cohort 1 (n=11, 6 males and 5 females), three months recovery, and cohort 2 (n=15, 7 males and 8 females) nine month recovery. The subjects received a cervical spinal cord hemiconusion at the C5 vertebral level (C7 spinal level) on the right side. During the injury surgery we performed a C5 laminectomy to expose the spinal cord. The spinal column was then stabilized by clamping the C3/4 and C6/7 spinous processes (Large Animal Spinal Clamps, Kopf Scientific) to isolate the mechanical loading to the spinal cord. The impactor rod was placed on midline and moved from 0.1 to 0.5 mm over the midline (depending on spinal cord size). The impactor rod was lowered to displace the dorsal and ventral CSF and to trap the spinal cord at the bottom of the spinal canal. Then a controlled hit with set displacement was achieved. Post injury, an acute intraoperative ultrasound was performed to visualize the unilaterality and extent of the injury. The animals underwent recovery for 3 and 9 months post injury as part of a GLP, IND-enabling study. **Results:** All animals survived the contusion surgery and underwent post-surgery recovery. Of the 26 animals studied, 24 exhibited rapid post-operative recovery, sitting upright within hours of surgery and presenting with a contained uniform motor deficit localized to the right arm and hand. In contrast, two animals remained recumbent for approximately 48 hrs: in one monkey this was due to more severe impact forces that delayed but did not prevent their ability to sit upright, and in the second case preference for the recumbent position despite a mild impact (the monkey subsequently sat up). All of the lesions were restricted to the right side, as unilateral injuries are important for monkey well-being and long term care. Measurements from the acute intraoperative ultrasounds revealed that injury extent ranged from 35.1% ± 2.5% (SE) to 44.0% ± 2.2% of the entire spinal cord width. Functional observations showed a consistent deficit in all animals at 14 days post injury, with a right flaccid hand held in a flexed posture with minimal to no voluntary movement two weeks post-injury. **Conclusions:** Here we present a novel NHP primate hemiconusion injury model in the African green monkey population. Subject-specific injury parameters that are based on MRI measurements of lesion laterality and extent lead to a functional deficit that is consistent. This rigor and consistency of this model is useful for developing and testing candidate therapeutic interventions for SCI.

PS 3871 Spondylosis and intervertebral disc degeneration in African green monkeys (*Chlorocebus sabaeus*)

E. Hines, S. Korte, M. Lawrence, and I. Mikaelian. Virscio, New Haven, CT.

Background and Purpose: Intervertebral disc degeneration (IVDD) is a major cause of lower back pain in aged individuals and has significant negative impact on quality of life and productivity. Over one hundred million lost workdays and over 100 billion total costs are estimated per annum in the United States due to low back pain, making it a major clinical and public health problem with significant economic consequences. While the entire pathogenesis is unclear, IVDD in humans is multifactorial with age, gender, smoking, and nutrition being contributing factors. Disc degeneration also occurs naturally in the rhesus macaque (*Macaca mulatta*) in the thoracolumbar region, mimicking many aspects of human IVDD; in rhesus as well as humans, age is an important factor for lesion development and typical lesions include disc narrowing, degeneration, and osteophytosis. We have defined similar findings in African green monkeys (AGMs, *Chlorocebus sabaeus*). **Methods:** Three aged female AGMs (all greater than 17 years old) from our colony were incidentally noted to have lesions consistent with spondylosis and intervertebral disc disease at necropsy (e.g. thickened/enlarged and bridging bone at the ventral aspect of

thoracolumbar vertebral bodies), supporting relevance as a translational species for age associated pathologies and significant overlap with human and other NHP models in anatomy and pharmacology. One of these three was reportedly kyphotic, and another had experienced an episode of difficulty ambulating three years prior to necropsy. Otherwise, there were no relevant clinical signs or findings. The spinal columns were collected, fixed, decalcified, sectioned, and stained with hematoxylin and eosin (H&E). **Results:** Microscopic examination of two animals confirmed the gross findings of bridging ventral osteophytosis and dense fibrous connective tissue (spondylosis), as well as degeneration of the intervertebral disc with characteristic disc thinning, disc tears, and bulging. **Conclusions:** Aged AGMs represent a potential naturally occurring model of spondylosis and intervertebral disc disease, with similar gross and microscopic findings to those reported in humans and other NHPs. Further characterization will focus on the incidence and spectrum of disease in this population, with attention to age and sex, as well as MRI evaluation of, and screening for, IVDD in this species.

PS 3872 Male rhesus macaques fed a Western diet are susceptible to bone loss caused by both chronic binge alcohol and infection with simian immunodeficiency virus with subsequent antiretroviral therapy

M. Ronis¹, K. Pedersen¹, L. Suva², M. Bordelon¹, L. Simon¹, and P. Molina¹. ¹Louisiana State University Health Sciences Center, New Orleans, LA; and ²Texas A&M University, College Station, TX.

Background and Purpose: People living with HIV (PWH) are at an increased risk of low bone mineral density (BMD), osteoporosis, and bone fractures. HIV infection, antiretroviral therapy (ART), and high alcohol consumption are factors negatively affecting bone health. We and others have established that alcohol exerts a plethora of toxic effects on the skeleton by inhibiting bone formation and stimulating bone resorption, resulting in diminished BMD and bone strength. A further confounding effect on the skeletal health of PWH is the impact of diet, such as a high-fat Western diet. In this study, the aim was to address how these factors interact on parameters of bone health in a non-human primate model. **Methods:** Adult male rhesus macaques (*Macaca mulatta*) were fed a high-fat Western diet (42% carbohydrates (27% sucrose), 42% fat, 16% protein in % kcal) throughout the length of the study. After 4 months on the Western diet, chronic binge alcohol (CBA) at 13 - 14 g ethanol/kg/week or vehicle (VEH) were administered via intragastric catheters and continued for the remainder (1 year) of the study. 4 months after initiation of CBA/VEH infusion, macaques were either infected with simian immunodeficiency virus (SIV) or mock infected. All SIV-infected macaques received ART at a daily intragastric dose of 50 mg bictegravir, 200 mg emtricitabine, and 25 mg tenofovir alafenamide, starting 10 weeks after SIV infection. There were four experimental groups: VEH/SIV-; VEH/SIV+, CBA/SIV- and CBA/SIV+ (N = 7, 5, 5, and 6, respectively). The macaques were sacrificed after an additional 6 months. BMD of the whole body, humerus, thigh, and abdominal area was measured by DXA at four time points (pre-alcohol, pre-SIV infection, pre-ART, and at sacrifice). Whole body bone turnover was assessed by ELISA of serum bone formation marker P1NP and bone resorption marker CTX-1. The tibiae were collected at necropsy, and bone microstructure and geometry determined by microcomputed tomography (μCT). Gene expression in the fibula shaft was analyzed by qRT-PCR. **Results:** Over the course of the experiment, DXA revealed a significant decrease in BMD with time (P < 0.001 for all regions). The decrease was smallest for the VEH/SIV- group, especially between the pre-SIV and necropsy time point, for which the BMD decrease of the thigh area was significantly lower (P < 0.05) in the VEH/SIV- group than in the VEH/SIV+ group. μCT of the tibia revealed a significant decrease in the relative bone volume of the trabecular compartment (BV/TV) by both CBA and SIV+/ART (P < 0.001) without any apparent additive effects. The differences in BV/TV were explained, in part, by increased trabecular separation induced by CBA in non-infected macaques (P < 0.01) and the small but not significant changes in trabecular number. The changes measured by μCT were limited to the trabecular compartment, since no cortical bone parameters were changed by any treatment. The between-subject variation in serum concentrations of P1NP and CTX-1 was too large to yield statistically significant group differences. Gene expression measured in the midshaft area of the fibula showed a significant increase in RANKL mRNA expression by both CBA and SIV+/ART (P < 0.05) without additive effects, and a trend of increased expression of the osteoclast marker Ocstamp by SIV/ART (P = 0.07 for the main effect). **Conclusions:** Both CBA and SIV/ART contributed to decreased bone mass in the trabecular compartment of the tibia. Increased expression of RANKL by both CBA and SIV/ART likely increased osteoclast activation and bone resorption contributing to loss of bone mass. No clear additive or synergistic effects of CBA and SIV/ART were observed on any of the measured parameters. Support: NIH P60AA009803 (PM), R37 AA018282 (MR).

PS 3873 Perfluorooctanesulfonamide-induced epiboly delay is associated with decreased ATP production within zebrafish embryos

J. Hoang, N. Jimenez, K. Faizi, Q. Xiang, E. Fencel, R. Yates, J. Gan, and D. Volz. University of California Riverside, Riverside, CA.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) have been widely used within various industrial processes and consumer products, such as food packaging and fire-fighting foams. PFAS persistence within environmental media has led to ubiquitous exposure within humans and wildlife. We previously conducted a high-content toxicity screen of 38 different PFAS within the first 72 h of zebrafish development. This screen identified perfluorooctanesulfonamide (PFOSA) as the most potent developmental toxicant among the 38 PFAS tested. At non-lethal concentrations, exposure to PFOSA from 0.75 to 6 h post-fertilization (hpf) - a developmental window that includes cleavage, blastulation, and early-gastrulation - resulted in a concentration-dependent delay in epiboly (blastoderm migration and spreading) by 6 hpf. Therefore, for this study, we determined whether 1) PFOSA delays epiboly by inhibiting actin polymerization within the yolk, as epiboly progression is reliant on yolk-associated actin networks, and/or 2) PFOSA-induced effects are associated with a decrease in embryonic ATP, as PFOSA is a potent uncoupler of oxidative phosphorylation *in vitro*. **Methods:** To accomplish this objective, we first tested whether there was an association between the uptake of PFOSA into the developing embryo, and whether the timing and magnitude of PFOSA-induced epiboly delay were similar to CCB-induced epiboly delay. Next, we employed phalloidin-based staining of F-actin and high-resolution laser-scanning confocal microscopy to determine if CCB and PFOSA inhibited yolk-associated actin polymerization throughout the entire embryo. Third, using mRNA-sequencing, we tested whether the potential impacts of PFOSA on the transcriptome were similar to CCB during epiboly progression. Finally, we determined whether 1) PFOSA-induced epiboly delay was associated with a decrease in embryonic ATP and 2) co-exposure to exogenous ATP mitigated PFOSA-induced delayed epiboly. **Results:** Although PFOSA and CCB induced a similar magnitude of epiboly delay beginning at 4 hpf following initiation of exposure at 0.75 hpf, PFOSA did not, contrary to CCB, significantly decrease yolk-associated actin within embryos. Using mRNA-sequencing, we also found that, consistent with chemical-specific differences in effects on actin polymerization, PFOSA-exposed embryos were also transcriptionally different from CCB-exposed embryos. Moreover, phenotypically matched, PFOSA-exposed embryos at 6 hpf were transcriptionally similar to vehicle-exposed embryos at 5 hpf, and PFOSA delayed the maternal-to-zygotic transition (MZT) beginning at 5 hpf. Finally, PFOSA-induced delayed epiboly was associated with decreased ATP levels *in vivo*, an effect that was partially mitigated by co-exposure to exogenous ATP. **Conclusions:** Overall, our findings suggest that PFOSA exposure during early embryonic development decreases ATP production in the absence of effects on actin polymerization *in vivo*, an effect that is associated with PFOSA-induced delays in epiboly and the MZT.

PS 3874 Perfluorononanoic acid (PFNA) causes hepatomegaly while inhibiting hepatocyte proliferation independently of PPAR α and CAR in mice

X. Yu, X. Cheng, and P. Bu. St. John's University, Jamaica, NY.

Background and Purpose: Per- and polyfluoroalkyl substances (PFASs), including perfluorononanoic acid (PFNA, C₉), are a group of synthetic chemicals once widely used for industrial purposes and in consumer products. Because of their extraordinary resistance to degradation, PFASs are universally detected in the environment and human body, thus posing toxicological concerns. Once inside the body, PFASs accumulate in the liver, interrupting hepatic functions. Among PFASs, PFNA causes hepatomegaly in the mouse liver, but the underlying mechanism is not well understood. The present study aimed to investigate how PFNA affects liver homeostasis with respect to hepatocyte proliferation by employing PPAR α -null and CAR-null mouse models. **Methods:** A single dose of PFNA (0.1 mmol/kg) was intraperitoneally administered to WT, PPAR α -null, and CAR-null mice (n = 5/treatment/genotype). Two weeks later, mouse livers were collected for gross assessment, histology, gene expression analysis, and immunoblotting. In addition, human Huh7 hepatocellular carcinoma (HCC) cells were chosen as the *in vitro* model to complement the *in vivo* mouse studies. Huh7 cells, in quadruplicates, were treated with 10, 30, and 100 μ M PFNA for 7 days, followed by assessment of cell viability, proliferation state, cell size, gene and protein expression. **Results:** PFNA increased the liver-to-body weight ratio by 2.6-, 2-, and 1.8-fold, respectively, in WT, PPAR α -null, and CAR-null mice. The H&E staining analysis of liver sections showed that PFNA increased the size of hepatocytes (WT, 1.4-fold; PPAR α -null, 2.9-fold; CAR-null, 2-fold; of respective controls) but decreased the number of hepatocytes within the same microscopic field (WT, 52%; PPAR α -null, 49%; CAR-null, 67%; of respective controls). The hepatomegaly effect seemed to be due to cellular hypertrophy rather than hyperplasia of hepatocytes in all three genotypes of mice. Such a hypertrophic effect was also observed in PFNA-treated Huh7 cells. PFNA concentration-dependently decreased Huh7 cell number, with more than 70% decrease at 100 μ M, but increased cell size (10 μ M, 1.2-fold; 30 μ M, 1.8-fold; 100 μ M, 2.7-fold; compared to control). In addition, in the mouse liver, PFNA altered the expression of genes involved in the regulation of hepatocyte proliferation and/or hypertrophy. Specifically, PFNA induced the mRNA expression of growth arrest and DNA damage-inducible beta (Gadd45b) by 3.5-, 5.9-, and 5.4-fold, respectively, in WT, PPAR α -null, and CAR-null mouse livers.

PFNA increased the mRNA expression of cyclin-dependent kinase inhibitor 1 (p21) by 1.4-, 4.2-, and 3.6-fold, respectively, in WT, PPAR α -null, and CAR-null mouse livers. Both Gadd45b and p21 inhibit cell cycle progression. Furthermore, PFNA decreased the mRNA expression of yes-associated protein 1 (Yap1) (WT, 40%; PPAR α -null, 70%; CAR-null, 82%; of respective controls) and increased phosphorylated Yap1 protein (WT, 2.1-fold; PPAR α -null, 1.1-fold; CAR-null, 2.2-fold; of respective controls). This suggests that PFNA reduced Yap1 level, inhibited Yap1 activity, and thus contributed to suppressed cell proliferation. High-mobility group protein B2 (Hmgb2) regulates the cell size of hepatocytes. PFNA decreased the Hmgb2 mRNA expression by 17%, 54% and 93%, respectively, in WT, PPAR α -null, and CAR-null mouse livers. **Conclusions:** Our findings indicate that PFNA inhibits hepatocyte proliferation by modulating the expression of Gadd45b, p21, and Yap1, and PFNA increases hepatocyte hypertrophy, which is mediated, at least partially, by Hmgb2 suppression in a manner independent of PPAR α or CAR.

PS 3875 Preserved but Not Lost: Quantifying PFAS in Formalin-Fixed and Paraffin-Embedded Tissues for Retrospective Exposure and Dose Assessment

K. Biswas¹, J. Schlezinger², A. Bello¹, and D. Bello¹. ¹University of Massachusetts Lowell, Lowell, MA; and ²Boston University, Boston, MA.

Background and Purpose: Formalin-fixed (FFT) and formalin-fixed paraffin-embedded (FFPET) tissues represent an immense, underutilized resource for reconstructing historical chemical exposures. For persistent contaminants such as per- and polyfluoroalkyl substances (PFAS), these archived specimens could enable retrospective biomonitoring and tissue-level dosimetry, linking exposure history to disease outcomes. However, fixation and embedding may alter analyte stability and recovery, creating uncertainty in quantification. **Methods:** We developed and validated a liquid chromatography-electrospray tandem mass spectrometry (LC-ESI-MS/MS) method to quantify six environmentally relevant PFAS (PFHxS, PFOA, PFOS, PFNA, PFDA, PFUnA) in mouse liver, kidney, ileum, and brain. Tissues from exposed mice were divided into matched sets of cryopreserved (FT), formalin-fixed (FFT), and formalin-fixed paraffin-embedded (FFPET) tissue samples. PFAS recovery and loss were tracked through fixation, storage, and deparaffinization steps. **Results:** All PFAS were detectable in each matrix. The total tissue load quantified in the cryopreserved liver tissue was 22.6 μ g/g; in the kidney, 2.69 μ g/g; in the ileum, 1.05 μ g/g; and in the brain, 0.28 μ g/g. Formalin fixation largely preserved analytes, with recoveries of 77-84% relative to cryopreserved tissue, although 12-20% of PFAS were detected in the storage solution. Paraffin embedding resulted in further losses, yielding 57-75% recovery, with 6-16% loss during xylene and ethanol processing. Long-chain PFAS (PFNA-PFUnA) exhibited greater retention than short-chain species (PFHxS, PFOA), and tissues with higher PFAS burdens, such as liver, showed better recovery than low-burden tissues like brain and ileum. **Conclusions:** This work demonstrates the feasibility of quantifying PFAS in archived tissues and provides the first systematic insight into compound- and matrix-specific recovery patterns. Further validation is needed for short and ultrashort PFAS (C1-C4). Human tissues with much lower PFAS loads may experience proportionally greater analytical losses, requiring higher analytical sensitivity and application of correction factors for accurate dose estimation.

PS 3876 Perfluorooctanoic Acid and Trifluoroacetic Acid Exposure Impacts Doxorubicin Uptake and Doxorubicin-Induced DNA Damage Repair in Mammalian Liver and Ovary Cells

E. E. Tobin¹, S. Gaddameedhi^{1,2}, and N. Kotlarz^{1,2,3}. ¹Toxicology Graduate Program, North Carolina State University, Raleigh, NC; ²Center for Human Health and the Environment, Raleigh, NC; and ³Civil, Construction, and Environmental Engineering Dept, North Carolina State University, Raleigh, NC.

Background and Purpose: Our genomes are under constant threat of DNA damage from exogenous and endogenous sources. If DNA repair is disrupted by environmental chemical exposures, then the risk of cancer-driving mutations is heightened. Per- and polyfluoroalkyl substances (PFAS) are a widely distributed class of synthetic fluorinated chemicals. Exposure to some PFAS is associated with cancer development, yet PFAS impacts on DNA damage repair remains unclear. Given that human exposure to PFAS is widespread, understanding the dynamics of DNA repair under a PFAS + exogenous carcinogen co-exposure scenario is critical. Limited prior studies suggest exposure to perfluorodecanoic acid (PFDA) or perfluorooctanoic acid (PFOA) inhibits double strand DNA break repair, but this work is limited in scope - assessing effects of individual PFAS only and not considering the impact of PFAS exposure on DNA damaging agent uptake. We investigated whether exposure to two PFAS, perfluorooctanoic acid (PFOA) and trifluoroacetic acid (TFA), impacts the repair of DNA breaks induced by the chemotherapeutic doxorubicin. We hypothesized; if PFAS exposure interferes with baseline DNA repair processes, then exposing mammalian cells to PFAS prior to and during DNA damage will result in reduced DNA damage repair rate. **Methods:** We exposed human hepatoblastoma cells (HepG2) and Chinese hamster ovary cells (CHO-K1) to PFOA (0.78 μ M or 100 μ M), TFA (6 μ M or 200 μ M), or vehicle control (water) for 24 h, then co-exposed cells to vehicle control or PFAS + Doxorubicin (0.125 μ M - 1 μ M) for 24 hours. Cells were then maintained in vehicle control or PFAS and collected over a 0-24 h recovery period. DNA damage

(comet tail intensity, TI) was quantified using the 96-well HT alkaline Comet Chip assay (CellArray™) and Comet Analysis Software (Trevigan). Doxorubicin uptake after 24 h PFAS exposure was assessed by fluorescence spectroscopy of cell lysate using a microplate reader at 470/560nm ex/em. PFAS stock concentrations were quantified using liquid chromatography-mass spectrometry. **Results:** Exposure to PFOA or TFA alone at tested concentrations did not induce DNA damage in CHO-K1 or HepG2 cells. CHO-K1 cells exposed to PFOA or TFA prior to and throughout doxorubicin (1 µM) treatment exhibited increased initial doxorubicin-induced DNA damage (i.e. at recovery timepoint 0 h). At 0 h recovery the median TI of vehicle control + doxorubicin exposed cells was 40.5%, while the median TI after PFOA (0.78/100 µM) + doxorubicin co-exposure was 59.4%/64.5% and median TI after TFA (6.5/2000 µM) + doxorubicin co-exposure was 59.1%/70.0%. After 24 h, TFA-exposed CHO-K1 cells reduced TI less efficiently than vehicle control or PFOA treated cells. The median TI of vehicle control + doxorubicin exposed cells was 20.1%, median TI of PFOA + doxorubicin exposed cells was 20.9%/23.5%, while median TI of TFA + doxorubicin exposed cells was 32.3%/35.4%. HepG2 cells exposed to PFOA prior to and throughout doxorubicin treatment exhibited higher TIs at recovery timepoint 0 h compared to vehicle control exposure, but the effect was less pronounced than in CHO-K1 cells (9.7% to 19.4%/19.1% with PFOA, 9.7% to 13.3%/8.4% with TFA). After 24 h, PFOA and TFA exposed HepG2 cells recovered to vehicle-control TI levels. As DNA repair fidelity may vary even if TI is similar, follow up mechanistic assessments of repair pathways utilized in PFAS-exposed cells are needed. Experiments assessing PFAS impacts on doxorubicin uptake are ongoing. **Conclusions:** This study assesses whether PFOA and TFA exposure alter DNA repair in mammalian cells. Our results show two PFAS (TFA and PFOA) enhance initial doxorubicin-induced DNA damage and TFA impairs DNA repair efficiency in mammalian cells. Incorporating doxorubicin uptake measurements will clarify potential mechanisms and improve translatability of this work. We will expand this experimental framework to additional individual PFAS and PFAS mixtures [hexafluoropropylene oxide dimer acid (HFPO-DA), perfluoro-3,5,7,9,11-pentaaxadodecanoic acid (PFOSDoA), and perfluoro-2-methoxyacetic acid (PFMOAA)], and to other DNA-damaging agents to investigate environmentally relevant co-exposure scenarios.

PS 3877 Investigating the neurodevelopmental effects of PFAS mixtures in a chicken embryo model

J. Vo, and S. McLarnan. Hamline University, St Paul, MN.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are a large class of synthetic compounds widely used in manufacturing, firefighting foams, nonstick coatings, and many consumer products. Their strong carbon-fluorine bonds make these pollutants persistent in the environment, allowing them to accumulate in water, soil, and living organisms. In Minnesota, PFAS contamination has been detected in drinking water across multiple communities, where individuals are often exposed to complex mixtures of individual compounds. While previous research has shown that individual PFAS compounds can affect growth and development, the effects of PFAS mixtures remain poorly understood. In this study, we use chickens (*Gallus Gallus*), which have a developmental pathway comparable to humans, to investigate the early developmental effects of exposure to environmentally relevant PFAS mixtures representative of those found in Minnesota drinking water (PFOA, PFOS, PFBA, PFBS, and PFHxS). **Methods:** Fertilized chicken eggs were incubated for 48 hours to reach Hamburger-Hamilton stage 15. At 48 hours the embryos were dissected, and neural tube sections were plated to isolate neural crest cells, which play an essential role in early embryonic development. After 24 hours of neural crest cell migration, we used fluorescence microscopy to analyze cell health and mitochondrial density. **Results:** Exposure to PFAS mixtures caused dose-dependent developmental effects on chick neural crest cells. Preliminary findings suggest that higher concentrations result in reduced neural crest cell survival and visible alterations in mitochondrial abundance. Qualitatively, we noticed visible differences in embryo growth, albumin consistency, and yolk fragility, suggesting general developmental stress at higher PFAS concentrations. **Conclusions:** These findings demonstrate that PFAS mixtures, at levels comparable to those found in Minnesota drinking water, can affect early embryonic development. The results highlight that evaluating single PFAS in isolation does not consider real-world exposure risks. Understanding how mixtures change cellular and mitochondrial processes is crucial for informing environmental health policies and supporting stronger regulations to protect both wildlife and human populations. Further work is necessary to determine the influence of PFAS mixtures on long-term developmental and health outcomes.

PS 3878 Evaluating the Effects of Environmentally Relevant PFAS Mixtures on Human Cell Viability and Mitochondrial Density

S. Mohamoud, and S. McLarnan. Hamline University, St. Paul, MN.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are synthetic, long-lasting compounds widely used since the 1940s in commercial and industrial products. Because of their strong carbon-fluorine bonds, PFAS persist in the environment and accumulate in living organisms, leading to contamination and associated health risks such as cancer, immune disruption, and hormonal imbalance. While most toxicological studies focus on individual PFAS, real-world exposure occurs as

mixtures. This study aimed to evaluate the toxicity of environmentally relevant PFAS mixtures on human cells, with a focus on cell viability and mitochondrial density, to better understand combined chemical effects. **Methods:** Human colorectal carcinoma (HCT 116) cells were exposed for 24 hours to seven treatment groups: two PFAS mixtures and five individual PFAS compounds (PFOA, PFOS, PFBA, PFBS, PFHxS) at environmentally relevant concentrations ranging from 0.1 nM to 1 µM. Mixture 1 consisted of equal proportions of the five PFAS, while Mixture 2 reflected realistic blood-level ratios based on Minnesota biomonitoring data. Cell death and mitochondrial density were quantified using fluorescence microscopy and analyzed with CellProfiler software to assess dose- and compound-specific toxicity. **Results:** Preliminary analyses show high variability in cellular responses across all exposures. Trends in mitochondrial density were variable by compound. PFBS and PFOS exposure led to the highest mitochondrial density at 100 nM. PFBA exposure led to the highest mitochondrial density at 0.1nM, whereas PFHxS exposure was associated with a reduction in mitochondrial quantity at 10nM. Exposure to both mixtures was associated with a reduction in mitochondrial density, with mixture 2 (Minnesota biomonitoring-based mixture) exhibiting a more pronounced effect at 10nM. **Conclusions:** While results were not significant, the variation in effect by compound mixture is indicative of the importance of studying biologically relevant exposure in addition to individual compounds and equimolar mixtures. Understanding these effects is critical for assessing potential risks to human health, particularly during sensitive periods of neurodevelopment. Further work is ongoing to resolve the high replicate variability and examine the effects of these exposures in neuroblastoma cells to assess their effects on neurodevelopmental health.

PS 3879 Impact of PFAS on Prostate Cancer Metabolism

C. R. Clayton^{1,2}, ¹University of Illinois Urbana-Champaign, Urbana, IL; and ²King University, Bristol, TN.

Background and Purpose: Prostate cancer is the second most frequent cause of cancer among men in the world. Prostate cancer progresses into metastatic castration-resistant prostate cancer (mCRPC) after resistance to treatment is acquired. Per- and polyfluoroalkyl substances (PFAS) are found in everyday items as they are designed to be resistant to water, stains, heat, and grease. Previous studies have investigated hundreds of different PFAS and their impact on the body but two PFAS that are more prevalent and the oldest are perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). The International Agency for Research on Cancer has listed these two as Class 2B carcinogens that are capable of increasing risks of kidney and testicular cancer which leads to the potential risk for other cancers such as Prostate Cancer. Preliminary data collected in our lab utilized RWPE-KRAS cells exposed to old, long chained PFOS or new, short chained perfluorobutane sulfonic acid (PFBS) with or without dihydrotestosterone (DHT) and found PFOS exposure alters regulation of metabolites in key metabolic pathways. PFOS was chosen as the primary PFAS for this study. This study aimed to examine the impact PFOS has on metabolic pathways associated with the activated nuclear receptor PPARα. **Methods:** Vehicle and PFOS groups were treated with media and 1x10⁻⁸ M PFOS respectively, then analyzed using Metabolomic profiling and Western blots. **Results:** Metabolic pathway analysis indicated disruptions in key metabolic pathways including TCA cycle and galactose metabolism, contributing to altered energy production and disease progression. Two-way t-tests revealed non-significant results (p>0.05) for both trials of the Western blots. **Conclusions:** These findings emphasize the need for further research on specific implications of PFAS exposure on metabolic pathways and overall increased risk of mCRPC through protein analyses and metabolite quantifications.

PS 3880 Per- and Polyfluoroalkyl Substances in Enterohepatic Bile Acid Homeostasis

T. Troncoso¹, B. Kong¹, S. Hong^{1,2}, V. Basaly¹, J. Zhang¹, S. Xiao¹, and G. L. Guo¹. ¹Rutgers, The State University of New Jersey, Piscataway, NJ; and ²Sun Yat-Sen University, Guangzhou, China.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS), or “forever chemicals,” are environmental pollutants with high resistance to degradation. An estimated 98% of the U.S. population has detectable levels of PFAS in their bodies (Coulson, 2024). Nuclear receptors, such as Farnesoid X Receptor (FXR), Peroxisome Proliferator-Activated Receptor α (PPARα), Constitutively Active Receptor (CAR), and Pregnane X Receptor (PXR), are ligand-activated transcription factors that play a crucial role in regulating lipid and bile acid synthesis, transport, and detoxification. The purpose of this study was to investigate the effects of PFAS on the activation of CAR, PPARα, FXR-FGF15/19 axis, and PXR in mice and their regulation of gene expression in lipid and bile acid homeostasis. **Methods:** Eight-week-old CD-1 female mice received 0, 0.4, 1.2, and 4 µg/mL of Perfluoronanoic acid (PFNA) via drinking water for 8 weeks. Gene expression at mRNA levels was quantified using RT-qPCR. **Results:** Ileal Fgf15 shows dose response inhibition; however, both classic and alternative bile acid synthesis pathways show no significant change. CYP2B10 and Cyp3a11 were dose-dependently induced, indicating activation of CAR- and PXR-mediated detoxification pathways. Cyp4a10, a PPARα target gene involved in fatty acid oxidation, showed up to 16-fold induction. Cyp36 and Fabbp1, PPARα target genes associated with lipid transport and metabolism, showed upward regulation,

indicating PFAS-induced PPAR α activation and increased intracellular lipid load. **Conclusions:** These changes imply PFAS exposure disrupts bile acid detoxification and hepatic lipid metabolism. This study offers insight into how forever chemicals disrupt lipid and bile acid homeostasis, potentially contributing to the pathogenesis of liver diseases.

PS 3881 Cardiac Remodeling as a Novel Target of Short-Chain PFAS Toxicity

E. C. Wittenborn, J. Roberson, A. Lopez-Ramirez, X. Wu, and T. L. Woodlief. East Carolina University, Greenville, NC.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are a class of 15,000+ synthetic chemicals that persist in environmental and human blood, urine, and drinking water. Long-chain PFAS, perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), are associated with immune dysfunction, metabolic disturbances, and cardiovascular toxicity. Cardiac macrophages are key regulators of tissue homeostasis and repair; these macrophages coordinate immune responses and extracellular matrix (ECM) turnover. However, their dysregulation contributes to chronic inflammation, oxidative stress, and myocardial fibrosis, hallmarks of diastolic dysfunction and heart failure with preserved ejection fraction. Short-chain PFAS, including pentafluoropropionic acid (PFPrA), are replacing long-chain PFAS compounds and are increasingly detected in surface and drinking water. Although considered less bioaccumulative, emerging data indicate that short-chain PFAS retain biological activity and immune and metabolic signaling. Despite growing concern, their impact on cardiac health, particularly macrophage-mediated inflammation and fibrosis, remains largely uncharacterized. Defining whether PFPrA promotes profibrotic cardiac remodeling is essential to evaluate cardiovascular risk from environmentally relevant exposures. We hypothesize that PFPrA activates cardiac macrophages and profibrotic signaling pathways, leading to ECM remodeling and early fibrosis. **Methods:** Male (M) and female (F) C57BL/6 mice were orally administered PFPrA (0, 0.5, 5.0, or 50 mg/kg/day) for 30 days. Livers were weighed, and frozen for assessment of peroxisome proliferation using acetyl-CoA oxidase-1 (ACOX-1) activity. Relative liver weight and ACOX-1 activity, biomarkers of PFAS exposure, were compared to PFOA (7.5 mg/kg/day; relative liver weight increases: ~210% F, ~138% M; peroxisome proliferation [ACOX-1]: ~200% M/F). Hearts were weighed, and the left ventricles were fixed in 4% paraformaldehyde for histological evaluation. For histological evaluation, Masson's trichrome staining will be used to assess collagen deposition and ECM remodeling. The remaining hearts were snap-frozen, for future analysis of inflammatory and fibrotic gene expression (IL-1 β , MMP-12, TGF- β 1, Nrf2, and PPAR γ). Macrophage pro-inflammatory M1 type will be characterized through CD11b immunohistochemistry staining. Macrophage infiltration will be quantified by F4/80 immunohistochemistry. Sex-specific differences will be evaluated across exposure groups. **Results:** PFPrA exposure did not alter terminal body or relative heart weights compared to controls. However, relative liver weights increased significantly in males at 5 and 50 mg/kg (~71%) and in F at 50 mg/kg (~69%). Peroxisome proliferation also increased in a dose-dependent manner (M: 82% at 5 mg/kg and ~230% at 50 mg/kg; F: 68% at 50 mg/kg), consistent with early hepatic response to PFAS exposure. We anticipate that cardiac macrophage proinflammatory polarization and infiltration will increase with PFPrA exposure. Our preliminary results indicate CD11b positive macrophage area increased in F heart ventricular epicardium tissue: 5 and 50 mg/kg/day, quantitative analysis is ongoing. Upregulation of IL-1 β , MMP-12, and TGF- β 1 is expected to indicate activation of ECM remodeling and early fibrotic signaling, even in the absence of overt myocardial damage. **Conclusions:** Although PFPrA did not induce systemic toxicity based on changes in body weight, early hepatic activation was evident through increased liver weight and peroxisome proliferation. These findings indicate sufficient internal exposure to PFPrA, such that we must evaluate downstream immunotoxic and cardiotoxic effects. This study addresses a critical gap in PFAS toxicology by defining whether short-chain PFAS such as PFPrA contribute to macrophage-driven cardiac remodeling and fibrosis. By linking immune activation to structural cardiac changes, this work advances understanding of PFAS-induced cardiovascular dysfunction and will inform risk assessment for exposed human populations. Future phases will incorporate echocardiography to evaluate cardiac function and enhance translational applicability to human health outcomes. Additional mechanistic studies are needed to characterize chronic exposure effects, interspecies variability, and long-term cardiovascular risk of emerging short-chain PFAS.

PS 3882 Comparative Effects of Per- and Polyfluoroalkyl Substances Exposure on Lifespan and DJR-1 Expression in *Caenorhabditis elegans*

J. Barkley, D. Payton, and C. A. Dodd. Fort Valley State University, Fort Valley, GA.

Background and Purpose: Parkinson's disease (PD) is a progressive neurodegenerative disorder marked by tremors, rigidity, and bradykinesia. Its primary pathology involves the loss of dopaminergic (DA) neurons in the substantia nigra, with elevated reactive oxygen species (ROS) playing a central role in neuronal death. Environmental contaminants that promote oxidative stress may contribute to the neurodegenerative processes. Among these are per- and polyfluoroalkyl substances (PFAS), a class of

synthetic chemicals used both industrially and commercially. These environmentally persistent organic compounds are associated with various health concerns. With over 14,000 existing variants, PFAS have become major contaminants, particularly in drinking water. In 2024, the Environmental Protection Agency (EPA) established drinking water regulations for six PFAS chemicals to reduce human exposure; in 2025, these only applied to two perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA). Prior research has shown that PFOS and PFOA reduce the lifespan of *Caenorhabditis elegans* (C. elegans) and may exacerbate oxidative stress, disrupting DA neuron function. This study investigates whether exposure to two previously regulated PFAS compounds, a short-chain perfluorobutanesulfonic acid (PFBS) and a long-chain perfluorononanoic acid (PFNA), alters the lifespan of C. elegans while also examining the impact of these substances on DJR-1 expression, a gene involved in the oxidative stress response. With this study, we aim to understand the influence of environmental PFAS contamination on aging and risks to human health. **Methods:** Age-synchronized populations of C. elegans were collected and exposed to 0 (control group), 1, 10, 50, and 100 μ M concentrations of PFNA and PFBS separately. Approximately 40 hours after treatment, lifespan assays were conducted to identify any changes in the longevity of C. elegans. Worms were monitored daily, their deaths scored, and mortality rates were analyzed over a 26-day period. To assess DJR-1 expression, worms were treated with 0 (control group), 50, 100, and 150 μ M concentrations of PFNA or PFBS, followed by real-time PCR analysis. **Results:** After 26 days of exposure, the lifespan assays indicate that the survival rate of C. elegans treated with PFNA began to decline at Day 9 post-treatment; the highest mortality rate of each concentration was reached between Days 20 and 23. Lifespan reduction in C. elegans exposed to PFBS was initiated on Day 10, revealing a similar trend to PFNA. Data collection and statistical analysis for these treatment groups are underway. Previously collected data on gene expression indicate that PFOS exposure modulates DJR-1 expression, suggesting a potential mechanism for PFAS-induced oxidative stress. Ongoing experiments are determining whether PFNA and PFBS elicit comparable or distinct effects on DJR-1 regulation, potentially linking lifespan reduction to oxidative stress dysregulation. Comparative analysis will clarify the differential impact of individual PFAS congeners on oxidative stress pathways in C. elegans. **Conclusions:** This study aims to elucidate the role of PFAS in modulating oxidative stress-related gene expression during neurodevelopment and reducing organismal lifespan. A connection between these environmental pollutants and their effects on a model organism is highlighted, and our findings contribute to a broader understanding of environmental risk factors in neurodegenerative disease etiology, particularly PD.

PS 3883 Assessment of Developmental and Endocrine Pancreatic Toxicity of Aqueous Film Forming Foams (AFFF) in Larval Zebrafish (*Danio rerio*) and its Potential Modulation by the Nrf2 Pathway

A. Lachapelle¹, K. M. Satbhai², and A. R. Timme-Laragy². ¹Department of Biochemistry and Molecular Biology, University of Massachusetts Amherst, Amherst, MA; and ²Department of Environmental Health Sciences, University of Massachusetts Amherst, Amherst, MA.

Background and Purpose: The use of aqueous film-forming foams (AFFF) as fire-fighting agents at military bases and fire training facilities is a well-documented source for drinking water contamination by per- and polyfluoroalkyl substances (PFAS). The major constituent of AFFFs are PFAS, a class of chemicals that are neither metabolized nor degraded and are known to persist in the environment. While the developmental and pancreatic toxicity of individual PFAS has been reported, the adverse effects of PFAS mixtures are less understood. Nfe2l2 (or Nrf2) is a transcription factor which regulates the cells' antioxidant responses and has been shown to modulate toxicity of some PFAS. In this study, we aim to assess the developmental and pancreatic toxicity of a mixture of 27 PFAS that were detected in legacy AFFF samples, in comparison to a mixture of 6 PFAS that are currently regulated, using transgenic zebrafish (*Danio rerio*) larvae. **Methods:** A mixture of 27 PFAS chemicals found in legacy AFFF and a mixture of 6 regulated PFAS chemicals, both comparable to the proportions present in 3% AFFF were synthesized by the Massachusetts Pesticide Analysis Lab. Homozygous Nrf2a wild-type and mutant (nrf2a^{th318}) Tg(ins:GFP) embryos were exposed to either mixture at 0.0005%, 0.001%, and 0.0025% AFFF, with 0.1% methanol as a solvent control at 3 hours post fertilization (hpf). Exposures were static up to 100 hpf when larvae were collected and imaged under brightfield and fluorescence microscopy. Images were blinded and fish length, yolk sac area, pericardial area, and islet area were measured using ImageJ. The toxicity of the PFAS mixtures was then compared to the most abundant PFAS in the mixtures, perfluorooctane sulfonate (PFOS), using previous data from our lab. **Results:** No difference was observed in morphology between the Danieau's control group and solvent control group (0.1% methanol). Our results for the 27 PFAS mixture show that fish length was significantly decreased in wildtype larvae exposed to 0.001% and 0.0025% AFFF, and all concentrations for mutant larvae. Yolk sac area and pericardial area were significantly increased in both wildtype and mutant larvae exposed to 0.001% and 0.0025% AFFF. Islet area was significantly decreased in wildtype and mutant larvae exposed to 0.001% and 0.0025% AFFF, but the effect was not as severe in the mutant larvae. The 6 PFAS mixture with comparable PFOS concentrations was markedly less toxic than the mixture of 27 PFAS, with impaired swim bladder inflation and a small decrease in growth, but no pericardial edema or overt deformities. Comparable exposures to PFOS alone at its concentration within the mixtures showed no morphological changes. **Conclusions:** Larvae exposed to

the 27 PFAS mixture showed developmental and pancreatic toxicity, with differences between Nrf2a mutant and wildtype larvae for fish length and yolk sac area, and a partial decrease in severity of islet toxicity in the Nrf2a mutant fish, as shown previously for PFOS. The Nrf2 pathway may therefore play a role in modulating PFAS mixtures toxicity and should be studied further. The results of this study show that the total sum of PFAS in a mixture exposure is more predictive of toxicity than either PFOS alone or PFOS in combination with five other commonly measured PFAS. This suggests current water monitoring and regulatory approaches for PFAS likely underestimate toxicity and risk. This work was supported by R01ES025748

PS 3884 The Effect of PFAS on Microbial Communities in South Carolina Estuaries of Varying Urbanization

R. Dotson, and Z. Padgett. Clemson University, Clemson, SC.

Background and Purpose: Estuaries are dynamic and biologically rich ecosystems that provide crucial ecological services such as nutrient cycling, contaminant filtration, and habitats for juvenile organisms. However, these ecosystems are threatened by anthropogenic pressures, especially pollution from coastal urbanization. Among the most concerning pollutants are per- and polyfluoroalkyl substances (PFAS), which are synthetic, heat- and water-resistant compounds that persist and bioaccumulate in the environment. PFAS contamination has been detected in water systems worldwide and locally, including South Carolina in urban estuaries such as Charleston Harbor (CH). Microbes play essential roles in estuarine health by driving biogeochemical cycling, yet PFAS exposure is disrupting these communities by reducing diversity, altering metabolic function, and interfering with key processes. Though it is thought some microbial taxa may possess the metabolic capacity to transform or degrade PFAS, offering a natural avenue for bioremediation. This study compares PFAS concentrations and microbial community composition between an urbanized (CH) and non-urbanized (St. Helena Sound, SHS) estuary to understand how contamination affects microbial diversity and function. We hypothesize that (1) PFAS concentrations in surface water and sediment are higher in CH than SHS and (2) microbial communities in PFAS-enriched sites will be dominated by taxa more resistant to PFAS or capable of transformation. **Methods:** Surface water and sediment samples were collected from three sites within each estuary between October 2024 and May 2025. High-performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS) quantified PFAS concentrations. Sediment components were characterized by pipette analysis to determine the relative proportions of sand, silt, and clay, given that finer sediments may facilitate PFAS sorption. 16S rRNA sequencing was used to characterize microbial community structure by assessing alpha diversity (Shannon index, Pielou's evenness), and beta diversity (Bray-Curtis and UniFrac distances). Statistical analyses tested for site and seasonal differences across PFAS profiles. **Results:** Preliminary data indicates that PFAS concentrations in sediment samples were not significantly different between CH and SHS, however overall PFAS concentrations were significantly higher in CH than SHS in water samples, supporting our hypothesis. These elevated concentrations in CH appear to be driven primarily by perfluorooctanesulfonic acid (PFOS), which was the most abundant compound detected in both sample types from CH. The total PFAS concentrations showed significant differences in both sediment and water samples, indicating that localized environmental factors influence PFAS concentration. Microbial community analyses revealed site- and season-specific differences in diversity and composition. CH exhibited lower microbial evenness and overall diversity relative to SHS, consistent with greater environmental stress in the more urbanized estuary. Alpha and beta diversity analyses showed clear clustering by estuary and season, suggesting that PFAS exposure, salinity, and sediment properties together shape microbial assemblages. Dominant phyla included taxa commonly linked to contaminant metabolism and stress tolerance. Although these findings highlight associations between PFAS concentrations and microbial community composition, controlled experiments will be explored in the future. **Conclusions:** To directly test microbial tolerance and transformation capacity, controlled culture experiments will be conducted using sediment-derived microbial communities under aerobic and anaerobic conditions. Cultures will be exposed to environmentally relevant and elevated PFOS concentrations (up to 10mM) for 30 days to monitor potential degradation and community shifts. Analytical techniques such HPLC-MS/MS will be used to quantify PFOS loss and detect transformation products. Concurrent 16S rRNA sequencing of these cultures will identify taxa that persist under PFOS stress, potentially capable of PFAS degradation. These experiments will clarify whether microbes from estuarine sediments can actively metabolize PFAS, provide microbially mediated bioremediation strategies, and further our understanding of how urban pollution alters microbial communities in coastal environments.

PS 3885 Unveiling PFAS-Induced Cardiovascular Endothelial Toxicity: Differential DNA Damage and Oxidative Stress Responses

N. Nguyen¹, S. Sharma², M. Meister², and C. Wright². ¹University of Massachusetts-Amherst, Amherst, MA; and ²Chemical Insights Research Institute, UL Research Institutes, Marietta, GA.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS), or "forever chemicals," are synthetic, persistent compounds widely used in consumer and industrial products, and PFAS exposure has been linked to vascular dysfunction and an increased risk of hypertension. Human coronary artery endothelial cells (HCAEC) are responsible for regulating vascular tone and endothelial integrity, and their functional disruption is marked by increased permeability and elevated reactive oxygen species (ROS). While most research has focused on their effects in hepatic, immune, and reproductive systems, the impact of PFAS on HCAEC remains largely unexplored. In particular, the individual and mixed effects of (i) legacy PFAS (e.g., PFOS, PFOA, PFNA, PFDA), and (ii) emerging short-chain PFAS (e.g., PFHxA, PFHpA) on genetic alterations in HCAEC have not been investigated. This study aims to evaluate selected PFAS (PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA, and their mixture) on HCAEC, specifically to 1) assess ROS formation and 2) determine the genotoxic potential of individual and mixed PFAS. **Methods:** HCAEC were treated with lower (10 nM) and higher (10 µM) doses of individual PFAS (PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA, and their mixture) for 24 hours. Following exposure, cell viability and ROS formation were measured to assess oxidative stress, while DNA damage biomarkers were evaluated to characterize genotoxicity. **Results:** At a low dose, 10 nM, PFAS activated the ATR-Chk1/Chk2 DNA damage checkpoint, upregulating stress response proteins p21 and p53. In contrast, high-dose PFAS (10 µM) induced cytotoxicity and increased ROS in HCAEC. The extent of toxicity correlated with chain length, with longer-chain PFAS (PFNA, PFDA, and the mixture) producing stronger cytotoxic effects and greater ATR pathway activation. **Conclusions:** PFAS exhibit both dose and structure-dependent effects on endothelial cells. Low-dose PFAS triggers a protective DNA damage response, leading to growth arrest rather than cell death. Conversely, longer-chain PFAS exacerbate oxidative stress and checkpoint activation, contributing to endothelial toxicity and genomic instability. Understanding how PFAS structure and exposure level influence these cellular responses is crucial for assessing cardiovascular toxicity risks.

PS 3886 Low-dose PFAS Exposure Disrupts ABC and OATP Transporter Activity in Human Cell-based Models

G. E. Collier, and R. Lavado. Baylor University, Waco, TX.

Background and Purpose: PFAS are bio accumulative chemicals which have been consistently detected in the serum of humans. Recent work has suggested relevant exposure to low doses of many common short chain PFAS alters the expression of the ABC transport protein ABCG2, one of many ABC implicated in drug resistance and critical metabolic processes. In this work, the protein expression of ABCG2 in commonly used cell lines, the gene expression of many ABC in HepaRG, and the functional ability of HepaRG liver cells to uptake and efflux prototypical fluorescent substrates, such as Hoechst, rhodamine, and fluorescein, has been investigated following PFAS exposure in order to understand the potential impact to overall human health following PFAS exposure, and the potential mechanisms involved. **Methods:** In this work, nine cell lines were first evaluated for ABCG2 protein expression treated with PFBS, PFHxA, PFHxS, 6:2FTOH, or DMSO control. Cells were grown on glass slides, dosed with 1 nM or 1 µM PFAS for 48 hours, and an anti-ABCG2 alexafluor antibody used to allow for confocal imaging and quantification of RFU per cell. For gene expression experiments, HepaRG cells were treated with 1 µM doses of PFAS in low serum media for 48 hours, and qPCR performed using TaqMan ABC array plates. For transport assays, HepaRG were pre treated for 48 hours with PFAS or control media. Cells were then changed to PFAS treated media containing fluorescent substrates CMFDA, Hoechst33342, Rhodamine 123, Bodipy Cholesterol, or fluorescein for 45 minutes. For fluorescein, a substrate of OATP uptake transporters, cells were then washed and fluorescence read on a plate reader. For ABC efflux substrates, cells were washed and changed to plain media for 45 minutes to allow for efflux. Cells were then washed and read to determine remaining retained fluorescence per well. **Results:** All cell lines investigated here expressed ABCG2, with the highest expression seen in liver and kidney cell lines. HepaRG, which have robust transporter expression, were then evaluated further, demonstrating significantly increased protein expression following both 1 nM and 1 µM PFAS treatments. Likewise, 1 µM exposures in HepaRG significantly increased log fold gene expression of many ABC, including ABCA4, ABCB6, ABCB2, ABCG2, and ABCA1. ABCD2 displayed the largest relative change to expression, with PFBS, PFHxA, and PFHxS all leading to an 8 fold or greater increase. In addition to changes to the gene and protein expression of ABC, the ability of these transporters to move prototypical substrates was also significantly altered. For all substrates, short term 45 minute PFAS exposure caused little effect, while 48 hour PFAS pre-treatment significantly altered both ABC efflux, and OATP uptake. Relative to DMSO controls, fluorescein uptake was decreased by 12% or more for all 1 nM treatments, with the greatest decrease seen following exposure to 1 µM PFBS, with a 35% decrease in relative retained fluorescence. All ABC Substrates had significant decreases to retained fluorescence following PFAS exposures, indicating increased substrate efflux. Bodipy cholesterol was most significantly altered by PFAS exposure, with all 48 hour treat-

ments significantly decreasing relative retained fluorescence by 30% or more. The most significant change was seen with Bodipy cholesterol following exposure to 1 μ M PFHxA, with a 66% decrease in relative retained fluorescence, and a p value less than 0.0001. **Conclusions:** ABCG2 protein is expressed throughout the body, and is significantly altered by PFAS exposure, with a greater potential impact in the liver, where ABC play a major role. This effect was not limited to ABCG2, with many ABC being upregulated, and the overall ability of ABC and OATP to transport their substrates in a robust liver transport model ultimately being affected. These significant and widespread results suggest that exposure to short chain PFAS at concentrations currently found in the serum of the US population may alter the ability of cells to function normally, and impact human health. The notable changes to transport of the substrate Bodipy cholesterol were particularly alarming, highlighting the potential for low dose human PFAS exposures to alter cholesterol transport by ABC in the liver.

PS 3887 Integrative Multi-Scale Approach Using Zebrafish Transcriptomics and Molecular Docking to Determine the Sulfonamide-Specific Mechanisms of Developmental Toxicity of Four-Carbon PFAS

E. M. Cowan, S. J. Carrell, L. Truong, and R. L. Tanguay. Oregon State University, Corvallis, OR.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are a structurally diverse class of contaminants characterized by a hydrophilic headgroup and a fluorinated tail. Differences in chain length or headgroup influence biological uptake, protein binding, and gene expression, giving each PFAS a unique toxicity profile. As regulatory pressure against long-chain PFAS increases, production has shifted toward short-chain alternatives. However, evidence shows many short-chain PFAS still cause physiological effects, suggesting headgroup may impact biological activity beyond chain length. Understanding how structural variations drive protein interactions and downstream regulation is critical to predicting PFAS toxicity. In an embryonic zebrafish screen of four four-carbon PFAS, only perfluorobutane sulfonamide (FBSA) caused malformations. To investigate the molecular basis of this headgroup-specific activity, we performed transcriptomic, molecular docking, and miRNA analyses comparing FBSA to perfluorobutane sulfonate (PFBS), which has similar uptake but distinct outcomes. **Methods:** To examine the effect of headgroup in four-carbon PFAS, we compared two compounds, FBSA and PFBS. Embryonic zebrafish exposure started at 8 hours post fertilization (hpf) to each compound at identical concentrations (47 μ M); the morphological EC₅₀ for FBSA and a matching PFBS concentration for direct comparison. Morphological malformation was evaluated at 120 hpf, and transcriptomic profiling at 48 hpf to capture gene expression changes preceding visible effects. To investigate the molecular basis of the divergent outcomes, AutoDock was used to screen both compounds across a library of human ligand-binding sites to identify proteins uniquely predicted to bind FBSA. To test if FBSA-repressed transcriptional changes may be mediated by miRNA-based post-transcriptional regulation, genes downregulated by FBSA were cross-referenced with TargetScanFish potential miRNA targets. **Results:** At 48 hpf, FBSA and PFBS had similar uptake (11 $\pm$ 1.5 ng/mg and 8.9 $\pm$ 0.99 ng/mg, respectively), but only FBSA caused malformations at 120 hpf, while PFBS was inactive. Transcriptomic profiling revealed that FBSA misregulated 1,909 genes at its EC₅₀, compared to only 5 DEGs for PFBS. Molecular docking identified 114 proteins with zebrafish orthologs uniquely predicted to bind FBSA at $\leq$ -7.0 kcal/mol that may underlie the divergent transcriptional and morphological responses between the two compounds. Integration of transcriptomic and TargetScanFish analyses found several FBSA-downregulated genes also predicted as miRNA targets. **Conclusions:** By integrating developmental toxicity screening, transcriptomics, molecular docking, and miRNA prediction, this study reveals a mechanistic basis for divergent toxicity of short-chain PFAS with distinct headgroup chemistries. To investigate this divergence, we examined interaction potential across protein and post-transcriptional regulatory networks. Molecular docking identified proteins predicted to uniquely bind FBSA, indicating the sulfonamide headgroup enables interactions not accessible to the sulfonate. Integration of transcriptomic and miRNA analyses suggests that FBSA-responsive downregulation may involve both direct protein-ligand interactions and miRNA-mediated post-transcriptional regulation, providing a molecular explanation for the contrasting developmental outcomes of FBSA and PFBS.

PS 3888 PFAS Terminology and Fit-For-Purpose Risk-Based Grouping

B. J. Henry¹, and B. Ameduri². ¹Toxicology Consultant, Havre de Grace, MD; and ²ICGM, University Montpellier, Montpellier, France.

Background and Purpose: Accurate and consistent PFAS terminology is essential to ensure effective PFAS communication. But not all PFASs have the same risk. The tremendous diversity across 14,000+ PFASs complicates risk management communication. Recently, PFAS risk management actions globally illustrate this terminology-grouping debate: PFAS bills by Health Canada, some US states and the current proposed EU PFAS restriction exclude some substances (e.g. fluoropolymers or PFAS as pesticide active ingredients) meeting the terminology definition of a PFAS from risk management actions. Risk management actions are separate from the PFAS definition. These two concepts of *terminology* and *risk-based grouping* are not,

however, mutually exclusive. *Terminology* is essential to ensure consistent and accurate PFAS communication occurs. *Risk-based grouping* is essential to put the PFAS terminology into human and environmental protection perspective, beyond chemical and molecular structure. Agreement upon that PFAS terminology and diligent application thereof then enables the establishment of *fit-for-purpose working scopes* or *risk management-based grouping* of PFAS. **Methods:** Through two examples of polymeric PFASs, a fluoropolymer (polytetrafluoroethylene, PTFE) and a perfluoropolyether (PFPE, 1,1,1,2,2,3,3,3-heptafluoro-3-(1,1,2,2,2-pentafluoroethoxy) propane ether), the implementation of a consistent PFAS *terminology* is applied in five elements of risk management-based groupings: grouping by *hazard*, *exposure*, *risk* (as a function of hazard and bioavailable exposure), *socioeconomics*, and ultimately *risk management grouping*. Criteria are proposed for each *fit-for-purpose risk-based grouping* founded on already established and globally implemented consensus criteria such as the UNECE GHS categories, the U.S. TSCA, the EU REACH regulation, and the UNEP Stockholm Convention. **Results:** Fluoropolymers and PFPEs are distinctly different from non-polymeric PFASs such as perfluoroalkyl acids (e.g., PFOA), though the OECD 2021 *terminology* identifies them all as PFASs. But their *hazard-based grouping* across the life cycle differs (e.g., toxicity, molecular weight, vapor pressure, water solubility, bioaccumulation, environmental partitioning, etc.). *Exposure-based grouping* results in many uses across a wide range of high technology/high value products (e.g., defense, energy, communication, medical devices, lubricants to critical industrial processes, etc.) while highlighting control technology effectiveness and limitations. The potential for bioavailable exposure of the fluoropolymer and PFPE is low. *Socioeconomic-based grouping* illustrates the significant and broad impact of these polymeric PFAS informing risk management decision-making. Residual risks, identified after these fit-for-purpose groupings, are integrated into a *relative risk spectrum* from which risk management measures are proposed. The value of a relative risk versus the all-or-nothing "P-sufficient" approach is discussed. Risk management actions proposed focus on emissions control during manufacturing and use and highlight responsible end of life options for PTFE and the PFPE. **Conclusions:** While no risk assessment is ever without uncertainty, an overall PFAS risk management process using relative risk (based on hazard, bioavailable exposure and control technologies, and socioeconomic risk) is as comprehensive an approach as possible while consistently applying correct PFAS terminology. Public and environmental health protection, promotion of responsible manufacturing and innovation, and harnessing fluorinated chemistry to meet societal expectations within economic realities is achievable.

PS 3889 Environmental Monitoring of PFAS in Himachal Pradesh: Contamination Levels and Human Health Implications.

N. Verma, and N. Singh. Chitkara University, Himachal Pradesh, Baddi, India.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are contaminants of increasing concern owing to their persistence in the environment, their propensity to accumulate in living organisms, and their links with negative health outcomes. The current research is an analysis of the PFAS pollution in different water bodies in Himachal Pradesh with a particular focus on the potential health hazards. **Methods:** Thirty-one samples were taken in rivers, groundwater, and drinking water supply sources in five districts, Una, Kangra, Chamba, Solan, and Bilaspur and subjected to solid-phase extraction and LC-MS/MS in compliance with the USEPA Method 537.1. **Results:** PFOS and PFOA were found to be high, particularly in Solan and Una districts and some of the results exceeded the advisory levels set by the United States Environmental Protection Agency (70 ng/L) and the European Commission. Non-carcinogenic and carcinogenic risks attributed to Long-term exposure to contaminated drinking water were assessed using health risk assessment methods based on hazard quotient (HQ) and lifetime cancer risk estimates. Industrial areas like Baddi in the Solan district had a greater variety of both established and novel PFAS compounds, which led to an increase in the exposure risks. **Conclusions:** The paper points to a significant requirement of PFAS-specific components of controlling actions, systematic observation, and directing health care in India to reduce the long-term impact and ensure water purity. **Acknowledgement:** Financial support for this work was provided under the Core Research Grant (CRG) Scheme, Earth and Atmospheric Division, ANRF (Grant No: CRG/2021/007791), for the project titled "Initiative to estimate the presence of perfluoroalkyl substances (PFAS) in rivers and ground/drinking water in Himachal Pradesh: Emission and implications for human exposure."

PS 3890 Astrocyte Dysfunction as a Mechanism of PFAS-Induced Neurotoxicity: Implications for Neuroinflammation and Neurodegeneration

J. Xie, H. Zhao, S. Wu, J. L. Freeman, and C. Yuan. Purdue University, West Lafayette, IN.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS), including perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), are persistent environmental contaminants linked to multiple health effects. While neuronal toxicity has been well characterized, the impact of PFAS on astrocyte function remains poorly understood. Astrocytes play essential roles in maintaining neuronal homeo-

stasis, regulating glutamate clearance, modulating neuroinflammation, and supporting mitochondrial metabolism. This study aimed to elucidate how PFAS exposure disrupts astrocyte function and contributes to neuroinflammatory and neurodegenerative processes. **Methods:** Human iPSC-derived astrocytes were exposed to environmentally relevant concentrations of PFOA and PFOS. Transcriptomic and proteomic analyses were performed to assess PFAS-induced molecular alterations. Cytokine profiles were validated by ELISA, while glutamate uptake and phagocytosis assays were used to evaluate astrocyte functionality. Lipid peroxidation was quantified to assess oxidative stress responses. **Results:** PFAS exposure significantly altered cytokine expression profiles in astrocytes, with several key pro-inflammatory mediators upregulated and confirmed by ELISA. Functional assays revealed decreased glutamate uptake capacity, indicating impaired neurotransmitter regulation, along with increased astrocytic phagocytosis, suggesting maladaptive activation under stress. Elevated lipid peroxidation further indicated enhanced oxidative stress and mitochondrial dysfunction. **Conclusions:** These findings reveal that PFAS exposure induces astrocyte dysfunction characterized by disrupted glutamate regulation, oxidative stress, and heightened inflammatory signaling. The data highlight astrocytes as critical mediators of PFAS-induced neurotoxicity and suggest that astrocytic impairment may contribute to the pathogenesis of neuroinflammatory and neurodegenerative disorders. Targeting astrocyte pathways may therefore represent a promising strategy to mitigate PFAS-related neurological risks.

PS 3891 Impact of Developmental Exposure to Environmentally Relevant Levels of PFAS and PFAS Mixtures on Multi-tissue Transcriptomic Profiles in Adult Zebrafish

A. Meyers¹, D. Meyer¹, A. Haimbaugh^{2,3}, M. Connell^{1,2}, B. Vo¹, A. Guarino¹, E. Cavaneau¹, G. Winny¹, C. Wu², and T. Baker¹. ¹University of Florida, Gainesville, FL; ²Wayne State University, Detroit, MI; and ³University of Colorado, Aurora, CO.

Background and Purpose: Concern over the potential effects of per- and polyfluoroalkyl substances (PFAS) commonly present in the environment (including drinking water) have risen since the early 2000s. Although certain PFAS, including perfluorosulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) are no longer used in manufacturing in the United States, they are ubiquitous in the environment due to their strong carbon fluorine bonds rendering them effectively indestructible. PFOA and PFOS have been reported to induce immunotoxicity, endocrine toxicity, and developmental toxicity. Epidemiological studies have associated PFAS with multiple adverse health outcomes, including altered immune function, liver disease, lipid metabolism dysregulation, kidney disease, miscarriages, and cancer. **Methods:** In this study, we sought to determine the effect of an environmentally-relevant levels of exposure (70ng/L) of PFOA, PFOS (240 ng/L), and a mixture (35 ng/L of PFOA + 120 ng/L of PFOS) of each on larval zebrafish from 0-5 days post-fertilization (dpf) that were then raised to adulthood (~18 months). RNA-Seq (3' mRNA-seq) transcriptomic analyses was then used to analyze extracted RNA from brain, gonad, liver, and kidney tissue of male and female control and exposed fish (n=2-4/treatment; 4-8/respective control). Libraries were quantified using a Qubit 2.0 fluorometer and run on an Agilent TapeStation 2200 for quality control. The samples were sequenced on an Illumina HiSeq 2500 and analyzed using a combination of the Lexogen Bluebees Genomics Platform and Lexogen in-house data analysis. Readswere aligned to *D. rerio* (Build GRCz11). Differentially expressed genes (DEGs) were determined via DESeq2 and defined by absolute log2 fold change value $\geq |1|$; $p < 0.05$. DEGs were compared for overlap using UpSetR and were uploaded into Ingenuity Pathway Analysis (IPA). **Results:** Previously, we reported that developmental PFAS exposure altered lipid transcriptomics and light/dark swim distance in larval fish (5 dpf) and impacted fecundity in PFOA-exposed fish raised to adulthood (4-6 months). Comparisons between larval and adult-onset differential gene expression revealed significantly higher effect later in life. The number of DEGs was low (ranging from 1-106) in larval fish, whereas adult fish exposed during development were found to have anywhere from 2-9360 DEGs. IPA analysis of DEGs revealed significant enrichment of several disease pathways, including lipid metabolism disruption (p-value = 7.02×10^{-25} PFOS female liver), endocrine disruption (p-value = 6.11×10^{-85} mixture male gonad), organismal survival (p-value = 3.11×10^{-34} mixture female liver), cancer (p-value = 3.90×10^{-142} PFOA female liver), and reproduction (p-value = 4.12×10^{-66} PFOA male gonad) in PFAS exposed fish. Outcomes in the brain were highly elevated in the mixture exposure. More tissue-specific outcomes were identified including motor development (p-value = 1.35×10^{-66} mixture male brain) and seizure markers (p-value of up to 7.24×10^{-33} mixture male brain) in the brain and inflammation (p-value = 4.39×10^{-10} PFOS female liver), steatosis (p-value = 6.95×10^{-11} mixture male liver) and liver tumor (p-value = 1.19×10^{-18} PFOS male liver) in the liver. Several upstream regulators including beta-estradiol (p-value 7.02×10^{-57} mixture female gonad), BDNF (p-value = 2.71×10^{-25} mixture female liver), TGF β 1 (p-value = 1.74×10^{-14} PFOA male gonad), HNF4A (p-value of 8.01×10^{-35} mixture female gonad) and PPAR α (p-value - 1.99×10^{-33} PFOS female liver) were identified to be altered regulators of observed diseases. **Conclusions:** Early life PFAS exposure at environmentally relevant levels has multi-systemic effects months after the initial exposure. Ongoing studies are supporting the associated links of PFOA and PFOS in human populations with animal toxicology studies including zebrafish. Several theorized molecular mechanisms of PFAS were observed to be dysregulated, potentially leading to the diseases observed. Animal studies such as this are important for confirming findings of epidemiologic and cell line toxicology studies. This research is important to determining the effect of PFAS on public health and the relative safe level of PFAS in drinking water.

PS 3892 Characterization of PFAS in Vermont public water systems

A. Killius¹, and L. T. Covell². ¹ToxStrategies, Atlanta, GA; and ²ToxStrategies, Phoenix, AZ.

Background and Purpose: Per- and poly-fluorinated alkyl substances (PFAS) have gained considerable attention due to their persistence, widespread environmental detection, and frequent presence in drinking water systems. While certain regions are impacted due to local PFAS manufacturing facilities, the State of Vermont makes for an interesting case study because it has no known primary manufacturing sources of PFAS, yet many PFAS congeners are present in Vermont drinking water. The Vermont Water Supply Rule requires public water systems to routinely test for PFAS, including 18 individual congeners and the sum of PFHpA, PFNA, PFOS, PFOA, and PFHxS. Vermont regulations state that the sum of these 5 congeners must be below 20 ppt. Although the testing results are publicly available, the database format is not easily accessible for analysis. Here, we systematically transformed Vermont's public PFAS drinking water database into a usable format and conducted a quantitative analysis characterizing PFAS occurrence and temporal and spatial patterns across the state. This analysis provides insight into "background" PFAS drinking water concentrations in regions with no known primary PFAS sources. **Methods:** PFAS drinking water results were obtained from the Vermont Drinking Water Database on August 19, 2025. The PDF file was imported into RStudio to parse and extract data, and the resulting dataset was exported into Microsoft Excel for further manual data tidying and quality assurance due to the inconsistent formatting of the PDF output. Because the limit of detection (LOD) was not provided for results reported as non-detects, a value of 0.1 ppt was used for imputation to enable further quantitative analysis. Each town was mapped to its county for broader geographical analysis. Summary statistics were calculated for each congener, and the sum of the five Vermont-regulated PFAS was used to characterize temporal and geographical trends. **Results:** A total of 631 unique public water systems across 231 towns and all 14 counties were sampled between July 28, 2019, and August 4, 2025 (n=2,656). Most (94.1%) systems were sampled on at least 3 separate occasions. 503 systems (79.7%) and 148 towns (64.1%) exhibited no detectable PFAS in any sample. Six of the 18 congeners assessed were not detected in any sample. The long chain legacy PFOA and PFOS congeners were the most frequently detected analytes, observed in 16.3% and 13.6% of samples, respectively, and had the highest average concentrations among all congeners (1.15 and 1.59 ppt, respectively). They were primarily detected simultaneously, wherein 306 samples had detectable levels of both PFOA and PFOS, and only 186 samples resulted in concentrations of either compound alone. The detection frequencies of the shorter-chain replacement compounds were lower: PFHxS (12.2%), PFBS (8.6%), PFHxS (4.9%), and HFPO-DA (0.2%), indicating dominance of legacy long-chain PFAS. Years with the highest number of samples had the lowest average annual PFAS concentrations. The average sum of the 5 Vermont-regulated PFAS was 3.63 ppt, which is lower than the regulated sum of 20 ppt. Rutland County exhibited the highest average sum value (9.83 ppt). The ten highest sum concentrations were all observed in a single water system in Mount Holly, suggesting a potential localized secondary source of PFAS. Other towns with relatively elevated sum concentrations compared to the rest of the state included Barre Town, Arlington, and Killington. PFOS and PFHxS were the primary contributors to elevated sum concentrations. **Conclusions:** The majority of public water systems in Vermont do not have detectable levels of PFAS, which is consistent with the absence of primary point sources within the state. Although long-chain congeners were phased out more than a decade ago, they continue to persist in higher concentrations and detection frequency than the short-chain replacements, indicating historical legacy contamination rather than ongoing inputs. The annual average trend with sample size shows expanded monitoring found smaller overall statewide impacts. PFAS concentrations were elevated in several specific areas, possibly due to secondary sources that historically used PFAS in their production. Overall, the data show that PFAS detections in Vermont drinking water supplies are low and the congener profile is indicative of historical widespread use, rather than continued ongoing contamination.

PS 3893 Sex-specific hepatic mitochondrial and peroxisomal bioenergetic adaptations following PFOA (C8) exposure

A. Lopez-Ramirez, J. Roberson, E. Wittenborn, and T. Woodlief. East Carolina University, Greenville, NC.

Background and Purpose: Perfluorooctanoic acid (PFOA) is a persistent per- and polyfluoroalkyl substance (PFAS) that accumulates in the liver and is consistently associated with hepatotoxicity. In humans, elevated PFOA exposure correlates with increased liver enzymes, including ALT. Animal studies show PFOA induces hepatomegaly, peroxisome proliferation, altered fatty-acid oxidation, and triglyceride accumulation. Very-long-chain fatty acids (e.g., C24) undergo initial partial oxidation in peroxisomes before mitochondrial β -oxidation, whereas medium-chain (e.g., C8) and long-chain (C16) substrates follow primarily mitochondrial pathways with varying peroxisome-mitochondria interplay. Despite these mechanistic insights, sex-specific mitochondrial and peroxisomal bioenergetic responses to PFOA, especially in the context of chain-length-specific oxidation is poorly characterized. This study evaluated hepatic mitochondrial respiration across multiple substrate chain lengths and peroxisomal acyl-CoA oxidase-1 (ACOX-1) activity in male and female mice following sub-chronic PFOA exposure. **Methods:** Adult male and female C57BL/6 mice (n = 6/group) received oral PFOA (7.5 mg/kg/day) for 15 days. Liver tissue was

harvested, homogenized (tissue mg $\times$ 20 μ L buffer), and assayed for mitochondrial and peroxisomal bioenergetics. Mitochondrial oxygen consumption was measured using substrates selected to probe chain-length-specific oxidation: lignoceric acid (C24) for peroxisome-mitochondria coordination; palmitoyl-carnitine (C16) for long-chain mitochondrial β -oxidation; octanoyl-carnitine (C8) for medium-chain mitochondrial oxidation; glutamate/malate for TCA-linked respiration; pyruvate/malate for carbohydrate-linked oxidation; and pyruvate alone for anaplerotic (pyruvate carboxylase-driven) flux. Peroxisomal ACOX-1 activity was quantified as a biomarker of enhanced peroxisomal fatty-acid flux. Data were analyzed by two-way ANOVA (sex $\times$ exposure). **Results:** PFOA exposure induced significant substrate- and sex-specific hepatic bioenergetic alterations. Liver weight increased by approximately 116% in males and 142% in females versus controls. ACOX1 activity increased $\sim$ 254% in male PFOA-exposed mice and $\sim$ 194% in females, indicating enhanced peroxisomal fatty-acid flux. In male PFOA-exposed mice, liver homogenate C24 oxidation doubled; C16 oxidation increased $\sim$ 3.6-fold; C8 oxidation $\sim$ 2.7-fold; glutamate/malate-supported respiration $\sim$ 1.2-fold; pyruvate/carboxylase-stimulated (anaplerotic) respiration $\sim$ 3.2-4.7-fold; and pyruvate/malate (carbohydrate-linked) respiration $\sim$ 2-fold. In female PFOA-exposed mice, liver homogenate C24 and C8 oxidation increased $\sim$ 1.6-4.3-fold, with selective ADP + malate-stimulated respiration indicative of a shift toward fatty-acid-preferential β -oxidation. Glutamate/malate respiration nearly doubled, while pyruvate/malate and pyruvate/carboxylase responses were modest. Two-way ANOVA revealed significant main effects of sex and exposure and sex $\times$ exposure interactions for most substrates ($p < 0.0001$ to 0.05). **Conclusions:** Sub-chronic PFOA exposure drives sex-specific hepatic metabolic reprogramming, evidenced by elevated peroxisomal ACOX-1 activity and enhanced mitochondrial fatty-acid oxidation. In males, broad mitochondrial activation aligns with increased peroxisomal chain-shortening flux, whereas in females a selective fatty-acid-preferential oxidation pattern emerges. These findings underscore the functional interplay between peroxisomes and mitochondria in chain-length-specific fatty-acid metabolism and highlight the critical importance of including sex as a biological variable in mechanistic toxicology and PFAS risk-assessment frameworks.

PS 3894 PFOS toxicity in yeast cells: the upregulation and downregulation of genes by RNAseq

T. Sandul, and K. Kim. Missouri State University, Springfield, MO.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are characterized by their strong carbon-fluorine bonds, which makes it highly resistant to degradation. A notable member of the PFAS group is perfluorooctane sulfonate (PFOS), which is widely used in products like non-stick cookware. It is used because of its unique ability to repel water and oil. However, PFOS's high environmental persistence and long half-life poses significant risks to human health and natural biogeochemical processes. Several studies about PFOS and its toxicity to bacteria and certain eukaryotic cells have been reported; however, studies about PFOS and its toxicity within yeast cells remain to be accomplished. **Methods:** A budding yeast strain was cultured and grown in yeast extract peptone dextrose (YPD) media exposed to PFOS with varying concentrations. Cell viability and mitochondria structure alterations were examined to determine any proliferation rate changes and/or energy depletion within the cell. To determine which genes are being expressed differently when exposed to PFOS, an RNAseq analysis was performed where total RNA from control and treated cells were isolated. The RNA samples were converted to cDNA for the next generation sequencing. A bioinformatic approach was employed to reveal global gene expression in PFOS-treated cells, which was helpful in finding specific biological pathways that are being downregulated or upregulated in response to PFOS. **Results:** PFOS exposure decreased yeast cell viability in a dose-dependent manner. The treatment groups were as follows: no treatment (control), 8 μ M, 80 μ M, 160 μ M, 800 μ M, and 1600 μ M with 800 μ M being the inhibitory concentration (IC50). Due to decrease in cell viability, PFOS exposure impaired mitochondrial function in yeast by disrupting and decreasing energy production, leading to reduced cellular respiration and growth. Finally, PFOS exposure induced differential gene expression in yeast, particularly affecting genes involved in stress response, metabolism, and mitochondrial function. **Conclusions:** Showcasing the toxicity of PFOS in budding yeast cells will offer new insights into the underlying molecular mechanisms of PFOS-mediated toxicity in fungal cells in relation to mammalian and bacterial cells. It will also provide potential impacts in raising public awareness about the risk of PFOS exposure as well as strategies to decrease the presence of the toxic compound within the environment.

PS 3895 Mechanisms driving Per and Polyfluoroalkyl Substances (PFAS) Disposition in Human Breast Milk: Roles of Efflux Transporters, Permeability, and Binding

L. Geyer¹, G. Norman¹, J. Beckanova^{2,1}, S. Vojta^{2,1}, R. King¹, A. Slitt¹, S. Ryu¹, and F. C. Fischer¹. ¹University of Rhode Island, Kingston, RI; and ²Graduate School of Oceanography, Narragansett, RI.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are widespread environmental pollutants linked to neurodevelopmental disorders in children. Maternal transfer of PFAS through breastfeeding represents a critical exposure path-

way during early life. This study investigated the toxicokinetic mechanisms driving PFAS transfer into breast milk by evaluating interactions with the efflux transporter Breast Cancer Resistance Protein (BCRP), passive membrane permeability, and PFAS binding in human serum and breast milk. **Methods:** PFAS binding in human serum and breast milk was quantified using solid-phase microextraction with C18 fibers. Passive permeability and BCRP-mediated transport were assessed in trans-well *in vitro* assays using transporter knock-out and BCRP knock-in cell lines and the results were compared to molecular docking simulations using the Molecular Operating Environment (MOE) software. **Results:** PFAS binding in breast milk increased linearly with molecular weight for sulfonic acid and sulfonamide groups. In contrast, carboxyl and fluorotelomer PFAS followed this trend only up to 500 g/mol, after which binding declined. BCRP-mediated transport increased with molecular weight, with efflux ratios ranging from 10- to 50-fold higher in BCRP-expressing cells compared to inhibited controls, agreeing with molecular docking simulations. Similarly, passive permeability increased with molecular weight, with the highest permeability observed for PFAS above 500 g/mol. **Conclusions:** Our preliminary results show that molecular weight strongly influences PFAS transfer into breast milk, with higher molecular weight compounds exhibiting increased binding, greater passive permeability, and enhanced BCRP-mediated transport. The mechanistic data will be integrated into a physiologically based toxicokinetic model to simulate PFAS transfer into breast milk under human physiological conditions, accounting for inter-individual variability such as BCRP polymorphisms and hypoalbuminemia as potential risk factors for disproportionate transfer of PFAS to the breastfeeding infant during lactation.

PS 3896 Understanding the Molecular Impact of PFOS on Protein Structure and Function: A Biophysical and Functional Assessment

U. Sweetey, and M. Narayan. The University of Texas at El Paso, El Paso, TX. Sponsor: U. Sweetey, Society of Environmental Toxicology and Chemistry

Background and Purpose: Perfluorooctane sulfonate (PFOS), a widespread and highly stable perfluoroalkyl substance, persists in the environment and accumulates in biological systems, posing serious toxicological risks. Its molecular interactions with proteins are suspected to disrupt structural integrity and cellular processes, yet these mechanisms remain poorly defined. This study aimed to investigate how PFOS alters protein structure and function and to link these molecular alterations with cytotoxic and neurotoxic outcomes. **Methods:** Model proteins, including bovine β -lactoglobulin (BLG) and hen egg white lysozyme (HEWL), were incubated with PFOS under physiological conditions. Ultraviolet-visible (UV-Vis) absorption, fluorescence, and Fourier-transform infrared (FTIR) spectroscopy were employed to assess tertiary and secondary structural changes. Morphological and aggregation alterations were visualized by atomic force microscopy (AFM). Fibril formation kinetics were examined using thioflavin T (ThT) fluorescence assays. SH-SY5Y neuroblastoma cells were used to assess cytotoxicity and oxidative stress through cell viability and fluorescence microscopy analyses. Finally, *Caenorhabditis elegans* served as an *in vivo* model to evaluate behavioral and neurodevelopmental toxicity following different concentrations of PFOS exposure. **Results:** Spectroscopic analyses showed distinct PFOS-induced conformational changes, including reduced fluorescence intensity and red-shifted emission maxima, indicating partial unfolding of the protein. FTIR spectra revealed a shift from α -helix to β -sheet structures, consistent with aggregation confirmed by AFM and ThT assays. In SH-SY5Y cells, PFOS exposure caused concentration-dependent decreases in viability, increased reactive oxygen species (ROS) production, and morphological changes. In *C. elegans*, exposure led to reduced locomotor activity and delayed neurodevelopmental milestones, consistent with systemic neurotoxicity. Together, these findings demonstrate that PFOS destabilizes protein structure and function, leading to downstream cellular and organismal effects. **Conclusions:** PFOS exerts a dual molecular and biological impact by inducing protein misfolding and aggregation while impairing neuronal cell health and organismal behavior. The combined use of biophysical, cellular, and *in vivo* approaches establishes a mechanistic framework linking PFAS-induced structural perturbation to neurotoxicity. These results enhance our understanding of PFOS toxicity and highlight the importance of integrating molecular and functional endpoints to develop predictive biomarkers for environmental and human health risk assessment.

PS 3897 Persistent albuminuria in type 2 diabetes is associated with lower circulating PFAS levels: implications for kidney research

H. E. Sharkey¹, H. Wang¹, J. Bunis², B. Seo¹, A. Slitt², P. Bjornstad³, L. Pyle³, A. Ducatman⁴, L. Chatzi¹, M. Aung¹, D. Conti¹, J. Shaub⁴, J. W. Nelson¹, F. Fischer², and J. A. Goodrich¹. ¹University of Southern California, Los Angeles, CA; ²University of Rhode Island, Kingston, RI; ³University of Washington, Seattle, WA; and ⁴University of Michigan, Ann Arbor, MI.

Background and Purpose: The prevalence of diabetic kidney disease (DKD) in the US is rising, highlighting the importance of identifying modifiable risk factors that may accelerate DKD progression, such as exposure to per- and polyfluoroalkyl substances (PFAS). PFAS are nephrotoxic in animal models, yet some epidemiological studies on DKD have identified an inverse association with circulating PFAS levels, making PFAS appear protective against DKD. This unexpected relationship may be due to loss of albumin through the urine (albuminuria), a defining feature of

DKD. Albumin, the most abundant protein in blood, binds strongly with PFAS, and albuminuria has been associated with lower blood PFAS concentrations. We hypothesized that persistent albuminuria, driven by increasing diabetes duration and subsequent progression to DKD, leads to increased urinary PFAS clearance and a decline in circulating PFAS concentrations. **Methods:** The role of albuminuria on PFAS levels was explored through three analyses using data from 1773 participants with diabetes from the National Health and Nutrition Examination Survey 2005-2020 (NHANES) and 137 participants with chronic kidney disease from the Kidney Precision Medicine Project (KPMP). Serum PFAS were measured through liquid chromatography and mass spectrometry; albuminuria was assessed via urinary albumin-to-creatinine ratio (uACR). Analysis 1 used NHANES data to evaluate the relationship between diabetes duration, uACR, and PFAS concentration to test whether albuminuria mediates the association of diabetes duration with PFAS. Analysis 2 applied a one-compartment toxicokinetic model to the NHANES data, integrating physiological and biochemical data to separate albuminuria-mediated from baseline/estimated glomerular filtration rate (eGFR) associated clearance and quantifying the albuminuria-mediated contribution to PFOA variance. Analysis 3 used KPMP data to compare the uACR-to-PFAS association in chronic kidney disease (CKD) versus acute kidney injury (AKI) patients. **Results:** In NHANES, longer diabetes duration was associated with a statistically significant decrease in PFOA levels. Mediation analysis identified a significant negative indirect effect, indicating that some of the reduction in PFOA at longer diabetes durations was ascribed to differences in uACR; 54.3% of the variance in PFOA in people with diabetes was explained by uACR. The direct effect, indicating the remaining difference in PFOA between diabetes groups after accounting for uACR, was not statistically significant ($p > 0.05$). The toxicokinetic model indicated that a 10-fold increase in albumin clearance reduced PFOA levels by 30% across the observed range of albuminuria; when accounting for the range of albuminuria observed across people with diabetes, this translated to a projected 76% reduction in serum PFOA levels. In comparison, differences in estimated eGFR-associated PFOA clearance were not associated with differences in serum PFOA levels. Results were generally consistent across NHANES cycles. KPMP results indicated that lower circulating PFOA is associated with albuminuria in CKD (persistent albumin loss), but not in AKI (short-term albumin loss; interaction p -value = 0.019). **Conclusions:** Results suggest that progressive diabetic nephropathy, marked by persistent continuing albuminuria, increased urinary excretion of albumin-bound PFAS and decreased blood PFAS concentration. This decrease can be explained by the mediating role of albuminuria. These findings help explain the previously reported paradoxical protective association between blood PFAS and DKD risk. Results highlight concerns about the reliability of using blood PFAS measurements for assessing PFAS exposure in populations with albuminuria, particularly DKD.

PS 3898 A bioinformatics approach identifies emerging PFAS associated with amino acid and lipid metabolic pathways during early pregnancy

A. F. Pedersen¹, L. Petrick², K. Roth¹, Z. Yang¹, C. Carignan³, J. Goodrich⁴, J. M. Kerver³, and M. Petriello¹. ¹Wayne State University, Detroit, MI; ²Icahn School of Medicine at Mount Sinai, New York, NY; ³Michigan State University, East Lansing, MI; and ⁴University of Michigan, Ann Arbor, MI.

Background and Purpose: Exposures to dozens, if not hundreds/thousands, of environmental chemicals can occur during pregnancy, yet only a handful of chemicals, like some per- and polyfluoroalkyl substances (PFAS), are routinely biomonitored. For instance, although there are >14,000 different PFAS of known production, the exposures and associated toxic effects of only a handful (<1%) of PFAS are known. Some of these emerging PFAS are marketed as less toxic and bioaccumulative, yet they may have similar metabolism disrupting potential and impacts to maternal and child health as known legacy PFAS (e.g., PFOS and PFOA). Targeted approaches are routinely conducted to monitor some legacy PFAS, yet nontargeted high-resolution mass spectrometry (HRMS)-based approaches coupled with bioinformatics tools may hold benefits over these approaches. These HRMS approaches can simultaneously measure complex, real-world mixtures of both legacy and emerging environmental pollutants and metabolic products, offering to better determine disease risk during pregnancy and the breadth of chemical exposure. **Methods:** We aimed to use a nontargeted HRMS approach that monitors both endogenous metabolites and environmental pollutants to identify associations between mixtures of emerging and legacy PFAS with metabolic pathway in serum of 100 pregnant women from MARCH (Michigan Archive for Research on Child Health), a cohort of the Environmental influence on Child Health Outcomes (ECHO) program. A discovery-based bioinformatics approach, FluoroMatch 3.0, was used to identify nonlegacy/emerging PFAS in these same samples. Metabolic pathways of interest were determined using MetaboAnalyst software. Linear models adjusted for variables known to impact circulating PFAS levels and metabolic profiles during pregnancy (diet, alcohol consumption, maternal age, smoking, body mass index, income, and race/ethnicity) were used to assess associations between PFAS exposure and metabolic pathways. **Results:** 105 PFAS were identified with high identification confidence from matching retention time, exact mass, and fragmentation patterns to the library database, with 86 chemicals showing >90% detection across all maternal serum samples. Only 9 identified compounds can be considered a legacy or a routinely-monitored emerging PFAS, while the remaining are emerging PFAS with no previously reported detection or toxicity assessments in the current literature. Of the list of 105 FluoroMatch-identified PFAS, 51 showed significant associations with at least one metabolic

pathway at $FDR < 0.05$. 21 emerging PFAS also showed a significant positive ($p < 0.05$) association with legacy PFAS (e.g., PFOA, PFOS). Pathways significantly associated with these 21 emerging PFAS were largely similar as legacy PFAS and were near-exclusively related to amino acid metabolism, including taurine and hypotaurine metabolism, glycine, serine, and threonine metabolism, arginine and proline metabolism, and valine, leucine, and isoleucine biosynthesis (at $FDR < 0.05$). **Conclusions:** Dozens of emerging PFAS not previously reported in the current literature with potentially similar metabolism-disrupting potential as legacy PFAS were detected with high detection frequency in Michigan mothers during early pregnancy. These results will inform future biomonitoring studies that utilize targeted approaches to include and prioritize these additional PFAS of emerging concern. Moreover, these results may lead to potential new biomarkers of exposure and identify biomechanisms of toxicity to aid in early intervention and mitigate maternal-child health burdens.

PS 3899 Parkin regulates PFOS-induced apoptosis via BAX/BAK ubiquitination in rat dopaminergic neuronal cells

S. Narukkottil, and J. Cannon. Purdue University, West Lafayette, IN.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are a group of synthetic compounds known for their high chemical stability and resistance to degradation. Perfluorooctane sulfonate (PFOS) is one such PFAS that has been found to produce mitochondrial stress and neurotoxicity. Mitochondrial dysfunction is a critical early event in neuronal injury that may lead to apoptotic cell death. Despite growing evidence on the involvement of PFOS exposure in neurotoxicity, the precise molecular mechanisms governing this process remain incompletely understood. Parkin, an E3 ubiquitin ligase, has a central role in maintaining cellular homeostasis by ubiquitinating substrate proteins involved in crucial cellular processes, including protein catabolism, immune response, and cellular apoptosis. Dysregulation of parkin activity has been implicated in mitochondrial damage and neuronal vulnerability. Considering the critical role of parkin in mitochondrial quality control and apoptosis, this study aimed to test the hypothesis that PFOS-induced apoptosis in dopaminergic neuronal cells would be modulated through Bax, Bak, and Bcl-2 ubiquitination. **Methods:** N27 cells were exposed to 0-650 μ M of PFOS for different durations (0-72 hrs) to evaluate dose- and time-dependent effects. Cell viability was assessed using MTT. Mitochondrial ROS generation and mitochondrial membrane potential ($\Delta\Psi_m$) were assessed by MitoSOX Red and TMRM fluorescence, respectively, to assess mitochondrial function. Based on these results, toxic and subtoxic concentrations and corresponding time points were selected for further analysis of gene and protein expression of apoptosis- and mitochondrial-related markers. **Results:** PFOS exposure resulted in a dose- and time-dependent elevation of mitochondrial reactive oxygen species (ROS), accompanied by a marked reduction in TMRM fluorescence. During the early phase of stress, both parkin gene expression and protein levels were increased, suggesting an adaptive cellular response aimed at maintaining mitochondrial integrity and suppressing apoptosis. Increased parkin activity enhanced substrate ubiquitination, including Bax/Bak/Bcl2, leading to reduced expression of pro-apoptotic factors and a relative increase in anti-apoptotic Bcl-2 levels, indicating a transient protective effect. However, at higher PFOS concentrations and prolonged exposure, parkin expression declined, coinciding with a significant increase in Bax and caspase-3 expression and a reduction in Bcl-2 levels, consistent with the activation of the intrinsic apoptotic pathway and loss of mitochondrial homeostasis. **Conclusions:** Our data indicate that PFOS induces mitochondrial dysfunction and apoptosis in dopaminergic N27 cells, potentially through disruption of parkin-mediated ubiquitination of apoptosis-related proteins. The resulting imbalance between pro- and anti-apoptotic signalling may contribute to PFOS-associated neurotoxicity. The findings are expected to provide insight into how environmental toxins may disrupt parkin-dependent mitochondrial surveillance mechanisms and thereby contribute to dopaminergic neurodegeneration.

PS 3900 Environmental fate and behavior studies of polytetrafluoroethylene (PTFE) - results and application to risk assessment

B. J. Henry¹, and N. Timmer². ¹Toxicology, Risk Assessment, Scientific & Regulatory Consulting, Havre de Grace, MD; and ²Charles River Laboratories, Den Bosch BV, 's Hertogenbosch, Netherlands.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) may be non-polymeric (per- or polyfluoroalkyl substances) or polymeric (fluoropolymers, perfluoropolyethers, side-chain fluorinated polymers). Although peer-reviewed publications have demonstrated that PTFE has low toxicity, high stability, high chemical resistance, and is not bioaccumulative, the literature does not contain environmental fate and behavior testing. The environmental fate and behavior for a well characterized PTFE-FA (high molecular weight, fine powder, microparticulate PTFE meeting the ASTM D4895 specification) are presented here. Physicochemical properties, biotic and abiotic degradation (in air, water, soil and sediment), transformation, mobility, partitioning, long range transport potential, and application of this data to the state-of-the-science polymer risk assessment are discussed. This addresses what would happen to PTFE-FA if found in the environment: would it degrade to and subsequently release substances of concern like non-polymeric PFAS? **Methods:**

OECD test guidelines (TG) 100 (physical chemical properties) and 300 (environmental fate and behavior) series were performed at CRL utilizing validated analytical methods. An ultra-high molecular weight, fine powder PTFE (CAS no. 9002-84-2) that met the ASTM D4895-18 2018 specification for PTFE made from dispersion (referred to as PTFE-FA), with an average particle size (D 50) of 529 µm, was tested. Analytical methods, based on UPLC with MS/MS, were developed for the quantitative analysis of 33 PFAS in aqueous samples, natural sediment, natural soil, and activated sludge. Spike recovery was done in each matrix tested for all analytes resulting in acceptable values validating that they could be detected if they were present in these matrices above the LOD. These methods were validated with respect to specificity, calibration, accuracy and repeatability, limit of quantification, stability of analytical system as well as solutions, and storage stability of samples. These analytes and analytical method development were selected based on best available analytical methods (EPA Methods 533 and 537) in 2019 (study start), rigorous review, adherence to scientific principles and knowledge of fluoropolymer chemistry. **Results:** Using DSC (TG 102), the melt transition was observed at ~350°C. No further melting/decomposition below 400°C was observed. Thermal stability (TG 113) was confirmed by minimal weight loss (5%) at 549°C. The vapor pressure, $< 1 \times 10^{-10}$ of mm Hg at 20°C (TG 104) confirmed the lack of volatility and low likelihood of partitioning to air and long-range transport potential, as a gas or vapor. Although solubility prevented GPC testing (TG 118), molecular weight was $> 500,000$ through Standard Specific Gravity tests. Results of OECD TG 105, 120 and the published literature confirm PTFE-FA is insoluble in water and is highly unlikely to be a water-soluble contaminant or be mobile in water. PTFE-FA was not corrosive, caustic, or ionizable (TG 122). It was not readily biodegradable (TG 301B) and had no inherent biodegradability (TG 302C). Aerobic and anaerobic biodegradation testing in soil (TG 307) and aquatic sediment (TG 308) showed PTFE-FA to be completely stable. It was stable and non-inhibitory in aerobic sewage (TG 303A). It was completely photolytically stable (TG 316 and Phototransformation of Chemicals on Soil Surfaces). PTFE-FA was hydrolytically stable (TG 111). Insolubility prevented the performance of TG 105, 107, 117, 121, 306, Henry's Law Constant and log K_{ow} . **Conclusions:** These results demonstrate PTFE-FA's absence of mobility, degradation, adsorption to soil/sediment, partitioning to air (as a gas or vapor) from water or organic matter, long-range transport in air (as a gas or vapor), water or soil, transformation to and subsequent release of non-polymeric PFAS. Therefore, the persistence of PTFE-FA does not imply future degradation, transformation and subsequent release of substances of concern. As the EU PFAS restriction proposal evolves, this data reduces uncertainty in this fluoropolymer risk assessment based on the lack of degradation, transformation and subsequent release of substances of concern.

PS 3901 PFAS Exposures in Military Firefighters Enrolled in the Millennium Cohort Study

R. P. Rull¹, A. Morris², E. Richard^{1,3}, A. Rivera^{1,3}, C. Kolaja^{1,3}, C. Hall^{1,3}, L. Havens², K. Hartley², W. Culpepper⁴, A. Schneiderman⁴, and T. Vincent-Hall⁴. ¹Naval Health Research Center, San Diego, CA; ²Central Arkansas Veterans Healthcare System, Department of Veterans Affairs, Little Rock, AR; ³Leidos Inc., San Diego, CA; and ⁴Health Outcomes Military Exposures, Department of Veterans Affairs, Washington, DC.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are major constituents of aqueous film-forming foams used in firefighting operations, and previous research has found that firefighters have higher body burdens of PFAS compared with the general population. The objective of this study was to conduct a comprehensive analysis of PFAS congeners measured in existing serum collected from military firefighters and a comparison group of construction workers enrolled in the Millennium Cohort Study, a large prospective health study that has enrolled over 260,000 US service members since 2001. **Methods:** Existing serum specimens from the Department of Defense Serum Repository were analyzed to quantify short- and long-chain PFAS congener concentrations via a validated assay using UHPLC-coupled electrospray ionization tandem mass spectrometry. PFAS concentrations were compared among 830 firefighters and 616 construction workers. PFAS concentrations were log-transformed and the interquartile range was calculated. Multivariable logistic regression models were used to investigate associations between demographics, military characteristics, and interquartile range increase in log total PFAS concentrations and cardiometabolic conditions. **Results:** The geometric mean concentrations of total PFAS, total perfluorohexane sulfonic acid, perfluorooctanoic acid, perfluorooctanoic acid, and total perfluorooctane sulfonate were elevated among firefighters compared with construction workers (eg, total PFAS: 40.7 vs 26.3 µg/L; $p < .0001$). These differences mostly persisted in analyses stratified by service branch. By Service branch, Air Force personnel consistently had higher geometric mean concentrations of PFAS congeners than those in the Army (eg, total PFAS: 38.3 vs 22.7 µg/L; $p < .0001$). Cross-sectional analyses indicated a 30% higher risk of cardiometabolic conditions per interquartile range increase in log total PFAS concentration (OR 1.29; 95% CI, 1.04-1.60). **Conclusions:** Findings from this study are critical for establishing historical baselines for PFAS body burden among military firefighters. The observed association between total PFAS exposure and cardiometabolic conditions suggests the potential for long-term health consequences among exposed military personnel and veterans.

PS 3902 Perfluorooctanoic Acid (PFOA) Exposure Induces Oxidative and Inflammatory Stress Markers in C57/BL6 mouse Ocular Tissues

J. Roberson, N. Doctor, A. Bauer, A. Lopez-Ramirez, E. Wittenborn, J. Cooke Bailey, and T. Woodlief. East Carolina University, Greenville, NC.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) are persistent environmental contaminants linked to immune suppression, hepatotoxicity, and dysregulation of lipid metabolism. The prototypical PFAS, perfluorooctanoic acid (PFOA), structurally resembles fatty acids and interacts with lipid-binding proteins such as fatty acid-binding protein 1 (FABP1), potentially driving oxidative stress through lipid peroxidation pathways. The retina and optic nerve are particularly susceptible to such damage due to their high lipid content and oxygen consumption. Separately, high-fat diets (HFD) have been shown to disrupt retinal lipid metabolism and induce oxidative and inflammatory injury. Together, these findings suggest that chemical (PFOA) and dietary (high-fat diet) lipid stressors may compromise ocular health through similar mechanisms. We hypothesized that PFOA exposure increases oxidative and inflammatory stress while impairing ocular defense pathways, thereby contributing to an elevated risk for eye disease. **Methods:** Male and female C57BL/6 mice were administered PFOA (0 or 7.5 mg/kg/day) by oral gavage for 15 days. A separate cohort was placed on a 60% high-fat diet (HFD) without PFOA (no combined exposure group) to serve as a dietary lipid stress comparison group. Pre- and post-exposure serum and whole eyes (excluding the HFD group) were collected and stored at -80 °C. Ocular tissues were sonicated in RIPA buffer, and supernatants were analyzed by ELISA for Interleukin-6 (IL-6), 8-isoprostane, and Tumor necrosis factor-α (TNF-α) to assess inflammatory and oxidative stress responses. Remaining samples were prepared for future analyses. Ocular expression of apoptotic marker p53 and protective proteins pigment epithelium-derived factor (PEDF) and lactoferrin will be evaluated by Western blotting to assess cellular stress and defense mechanisms. Serum PFOA concentrations will be quantified by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Sex-specific differences will be evaluated using one-way ANOVA followed by Tukey's honestly significant difference (HSD) test. **Results:** Preliminary findings indicate a ~37% reduction in serum IL6 levels following PFOA exposure compared to pre-exposure levels, although, these differences between treatment groups were not statistically significant. No significant IL-6 changes were observed in ocular homogenates. Based on complementary assays, we anticipate elevated 8-isoprostane and TNF-α concentrations in both serum and ocular tissue, consistent with enhanced lipid peroxidation and proinflammatory signaling. Western blot analyses are expected to show increased p53 expression, reflecting oxidative stress-induced apoptosis, along with reduced PEDF and lactoferrin expression, indicating compromised ocular defense capacity. These findings suggest that PFOA suppresses systemic inflammatory signaling while promoting oxidative and apoptotic stress within ocular tissues. The observed IL-6 reduction may reflect PFOA-mediated immune suppression consistent with prior reports of lymphocyte inhibition. Ongoing integration of LC-MS/MS exposure data with biochemical and protein endpoints will clarify the link between PFAS burden, oxidative injury, and ocular health, providing mechanistic insight into early molecular indicators of PFAS-associated eye disease. **Conclusions:** Although changes in IL-6 were not statistically significant, the observed reduction in serum IL-6 levels may reflect PFOA-mediated immune suppression and lymphocyte depletion. Further quantification of oxidative stress (via 8-isoprostane) and inflammatory markers (TNF-α and lactoferrin) will further define the oxidative and inflammatory burden imposed by PFOA exposure. Assessing ocular expression of p53 and PEDF will provide mechanistic insight into how PFAS disrupt redox balance and compromise ocular defense pathways. Due to the structural similarities between PFOA and long-chain fatty acids, these studies may also help uncover shared mechanisms of action between PFAS exposure and high-fat diet-induced metabolic stress. Integrating these findings with serum PFOA concentrations will clarify the molecular cascade linking PFAS exposure to ocular oxidative and inflammatory injury and may identify early biomarkers of PFAS-associated eye disease.

PS 3903 Immuno-proteomic profiling of neural antigens links short- and long-chain PFAS exposure to neuropathological pathways in adolescents from Taranto, Italy

S. Marjan¹, A. Deoraj¹, R. Lucchini¹, H. Krishnamurthy², D. Placidi³, A. Patrono³, and Q. Felty¹. ¹Florida International University, Miami, FL; ²Vibrant Sciences LLC, San Carlos, CA; and ³University of Brescia, Brescia, Italy.

Background and Purpose: Per- and polyfluoroalkyl substances (PFAS) exposure has been linked to various neurological disorders, including neurodegenerative and neurodevelopmental pathologies. Early life and chronic exposure to PFAS among individuals born and living near contaminated industrial sites may elevate the risk of neurological disorders. However, the biological mechanisms and molecular pathways through which PFAS disrupt neurological function remain poorly understood. This study aimed to identify PFAS-associated alterations in circulating neural proteins among 286 adolescents living in different zones of exposures near a large steel plant in Taranto, Italy. **Methods:** Four long-chain (PFOS, PFOA, PFNA, PFHxS) and two short-chain (PFBA, PFHxA) PFAS were measured using liquid chromatography-mass spectrometry (LC-MS/MS) in the serum of the study participants. Serum antibodies specific to neural antigens were measured using a multiplex protein microarray. The microarray targeted 64 neuronal and glial antigens associated with

neuroinflammation and cognitive decline. Antibody reactivity was used to assess a targeted neural proteomic profile. Associations between PFAS exposure and neural antibody reactivity were evaluated using correlation heatmaps and volcano plots in RStudio. Functional enrichment of significantly ($p < 0.05$) altered proteins was performed using the STRING database to identify Gene Ontology (GO) pathways. **Results:** Distinct immuno-proteomic profiles of neural antigens associated with short- and long-chain PFAS exposures were observed among the study participants living in different exposure zones of the steel plant. Based on one-way ANOVA with Tukey's post hoc comparisons, short-chain PFAS showed significantly higher concentrations in zones closer to the steel plant (Zones 1 and 2), whereas long-chain PFAS (PFOS, PFOA, PFHxS, and PFNA) were significantly higher in the distal zone (Zone 3). Unlike the ubiquitous long-chain PFAS, the short-chain PFAS detected near the plant likely originate from facility-specific processes or waste streams, such as PFAS-containing industrial materials, or firefighting foams used during operational incidents. The top three proteins upregulated by long-chain PFAS were $\alpha 2B$ -adrenergic receptor (ADRA2B), Beta-Amyloid (25-35), and dopamine β -hydroxylase (DBH), while the most downregulated ones were 5-Hydroxytryptamine (5HT), amphiphysin (AMPH), and acetylcholine receptor. In contrast, short-chain PFAS exposure upregulated 5HT, AMPH, and glutamate decarboxylase 2 (GAD2), and downregulated Beta-Amyloid (25-35), heat shock protein 5 (HSPA5), and Neurofascin proteins. The functional analysis using the STRING database showed that proteins upregulated by long-chain PFAS were significantly enriched in pathways regulating neurotransmitter signaling and dopamine metabolism. Downregulated proteins linked to long-chain PFAS were primarily involved in dopaminergic signaling and synaptic function, indicating potential suppression of neurotransmitter receptor activity and postsynaptic processes that may impair neuronal communication. On the other hand, short-chain PFAS enhanced inhibitory synaptic signaling activity by upregulating proteins involved in inhibitory neurotransmission and postsynaptic receptor function. There was no significant enrichment for proteins downregulated by short chain PFAS. **Conclusions:** The findings reveal that short- and long-chain PFAS produce distinct immuno-proteomic signatures of circulating neural proteins in adolescents. Long-chain PFAS appear to disrupt dopaminergic and excitatory pathways, whereas short-chain PFAS enhance inhibitory neurotransmission. These contrasting molecular patterns suggest short- and long-chain PFAS-specific mechanisms that may alter synaptic balance and contribute to neurological dysfunction. Together, they provide preliminary molecular evidence that both individual PFAS and their mixtures exert type-specific neuropathological effects among adolescents living near the steel plant in Taranto, Italy.

PS 3904 Rapid Non-target Detection of Per- and Polyfluoroalkyl Substances (PFAS) in Artificial Turf

S. Martinez, C. De Oliveira-Cordova, M. Hassan, T. Yaroshuk, H. Chen, and G. Warner. New Jersey Institute of Technology, Newark, NJ.

Background and Purpose: Artificial turf (AT) fields are widely used across the United States, with over 130,000 fields and 1,200-1,500 new fields installed annually. This has raised toxicological concerns regarding potential exposure to per- and polyfluoroalkyl substances (PFAS), a diverse group of >14,000 anthropogenic compounds known for environmental persistence and bioaccumulative potential. PFAS are used in polymer coatings and plastic manufacturing associated with AT production. However, little is known about which PFAS are present, their sources within AT components, or their environmental transformation during AT lifetime. This study will identify multiple PFAS and their concentrations in AT fields to contribute to evidence-based environmental decision-making. **Methods:** AT field samples were collected, ranging from weathered to non-weathered synthetic grass fibers, traditional crumb rubber infill and "eco-friendly" alternative infill, and backing and shock pad materials. Following collection, we performed a non-target analysis using paper spray mass spectrometry (PS-MS), an innovative rapid ionization technique that enables direct analysis from minimal extraction to detect PFAS in each AT field component. After PFAS detection (i.e., presence/absence), tandem mass spectrometry was used to confirm the identity and structure of PFAS species. **Results:** PS-MS revealed multiple PFAS compounds distributed across different AT fields. Over twenty PFAS species were identified, including perfluoropentanoic acid (PFPeA) and perfluorohexanoic acid (PFHxA), in weathered and non-weathered samples, suggesting that PFAS is produced during manufacturing in addition to environmental transformation over AT lifetime. **Conclusions:** This study demonstrates that PS-MS provides rapid, highly sensitive, highly specific, and accurate analysis of PFAS in artificial turf fields. Overall, multiple PFAS were detected in synthetic grass fibers of AT fields, which may contribute to human exposure and environmental contamination. These findings highlight the importance of applying rapid analytical methods in exposure assessment and toxicological evaluation of artificial field components to better inform risk assessment and regulatory monitoring strategies.

PS 3905 PFOS induces cellular damage in HepG2 and THLE-2 cell models

P. Tran, and K. Kim. Missouri State University, Springfield, MO.

Background and Purpose: Perfluorooctane sulfonate (PFOS) is a persistent environmental pollutant that has posed potential hepatotoxic effects and associated health risks. Despite its widespread distribution, the underlying mechanisms remain poorly

understood. To investigate the molecular mechanisms behind toxicities of PFOS, our study utilized HepG2, and THLE-2 hepatic cell models to replicate conditions reflecting PFOS accumulating in the liver. **Methods:** Cell viability, cell stress, and cell death assays were conducted to assess the toxicological interactions of the chemical on both cell lines. Total RNA extraction was performed, followed by cDNA sequencing, quantification using rt-qPCR. **Results:** The XTT viability assay revealed a dose-dependent decrease in number of viable cells during treatments with increasing PFOS concentrations. The inhibitory concentration (IC50) values were approximately 100 micromolar, which elevated reactive oxygen species (ROS) production and apoptotic level in HepG2 cells. Based on the transcriptomic analysis for HepG2, mitochondrial genes involved in oxidative phosphorylation were downregulated, including COX, ND, and ATP synthase family. Additionally, there were about 30 up-regulated genes implicated in the cAMP signaling pathway. CYP7A1 and HSPA6 were chosen candidate genes for rt-qPCR validation. **Conclusions:** Our future goals involve exploration of mitochondrial damage under PFOS exposure, providing comprehensive insights into the chemical's toxic effects on hepatic cellular metabolism.

PS 3906 Subchronic 90-Day Oral Toxicity Study With Perfluoropentanoic Acid In Sprague Dawley Rats

M. J. DeVito¹, E. Mutlu¹, E. Kenyon¹, J. Blake², A. Watson³, G. Chappell⁴, and M. F. Hughes¹. ¹USEPA, Research Triangle Park, NC; ²RTI, Durham, NC; ³Inotiv, Morrisville, NC; and ⁴ICF, Research Triangle Park, NC.

Background and Purpose: Perfluoropentanoic acid (PFPeA) is a perfluorinated alkyl substance (PFAS) that is used in aqueous film forming foams and is also used as a surfactant and stain repellent. PFPeA has been found in surface and drinking water and biosolids in several countries. However, there is limited publicly available toxicity data for PFPeA. A subchronic 90-day oral toxicity study in Sprague-Dawley rats was performed to provide toxicity information. **Methods:** Subchronic (90-day) guideline (OPPTS 870.3100) studies were conducted in male and female Sprague Dawley rats ($n=10/\text{sex}/\text{dose}$) exposed to PFPeA via gavage in 100mM citrate buffer adjusted to pH 4.5 ± 0.2 (5 ml/kg). The dose range was based on repeat dose 14-day studies and were 62.5, 125, 250, 500 and 1,000 mg/kg/day. Ophthalmological examinations were performed after arrival but before dosing and again before termination. Body weights and clinical observations were performed weekly with daily cage-side observations. After ≥ 11 weeks of exposure, animals were screened for neurotoxicity with a functional observational battery (FOB). After ≥ 90 days of exposure, animals were humanely euthanized. Animals were fasted overnight before termination. A full screen necropsy with collection of selected tissues was performed. Tissues were fixed by appropriate methods and microscopically evaluated. Samples were collected for clinical pathology analysis. **Results:** Body weights were decreased at 1000 mg/kg/day in the male rats. No other changes in body weights were observed. There were no changes in food consumption or ophthalmic examinations. Decreases in forelimb strength was observed in males only at the 1000 mg/kg/day dose and were associated with changes in body weight. Increases in relative liver and kidney weights were observed at 1,000 mg/kg/day in males and females. Males also had increased relative brain and testes weights at the high dose. Absolute and relative pituitary weights were decreased in females at 62.5 and 125 mg/kg/day but not at other dose levels. In males, absolute pituitary weight was reduced at 62.5, 500, and 1,000 mg/kg/day, while relative pituitary weight was reduced at 125 mg/kg/day. There were no microscopic findings observed in any of the 1,000 mg/kg/day exposures. Gross observations were either not accompanied by microscopic findings or were considered incidental lesions. **Conclusions:** Since the changes in organ weights were not accompanied by consistent dose response trends or histopathological changes, these effects were deemed not adverse. The overall evaluation indicates that there were toxicological effects observed at the 1,000 mg/kg/day dose and the no observed adverse effect level for PFPeA is 500 mg/kg/day. (The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the U.S. Environmental Protection Agency)

PS 3907 Tire-Derived 6-PPDq Impairs Mitochondrial Function and Viability in Human Cardio-Pulmonary Cells.

P. Sharma¹, S. Islam², R. Hancock¹, S. Bolla³, B. Kosmider⁴, N. Marchetti³, G. Criner³, G. Andaluri², V. Garikipati⁵, and P. Sharma¹. ¹Department of Pathology and Laboratory Medicine, Lewis Katz School of Medicine, Temple University, Philadelphia, PA; ²Department of Civil and Environmental Engineering, College of Engineering, Temple University, Philadelphia, PA; ³Department of Thoracic Medicine and Surgery, Temple Lung Center, Temple University, Philadelphia, PA; ⁴Department of Thoracic Medicine and Surgery, Temple University, Philadelphia, PA; and ⁵Department of Cardiovascular Sciences, Temple University, Philadelphia, PA.

Background and Purpose: N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine quinone (6-PPDq), an ozone-derived transformation product of the tire antioxidant 6-PPD, has recently emerged as an airborne toxicant detected in particulate matter and aerosols. While human exposure likely occurs at nanogram-microgram levels, its impact on cardio-pulmonary health remains poorly defined. **Methods:** Lung tissue from individuals with chronic obstructive pulmonary disease (COPD) and healthy controls were analyzed for 6-PPDq using LC-MS/MS. Human lung epithelial (A549),

airway smooth muscle (ASM) and cardiomyocyte (AC16) cells were cultured as 2D monolayers and 3D spheroids using A549 cells. Cytotoxicity was quantified by MTT assay (1-1000 ng/ml). Mitochondrial function was assessed via extracellular flux analysis (Seahorse XF Cell Mito Stress Test), JC-10 dye assay for mitochondrial membrane potential. Cell injury and epithelial integrity were assessed by LDH release and transepithelial electrical resistance (TEER), respectively. Epithelial-mesenchymal transition (EMT) markers were analyzed by immunoblotting. **Results:** 6-PPDq accumulation was approximately twofold higher in COPD lung tissues compared to healthy samples (n=5). *In vitro*, 6-PPDq induced a concentration-dependent loss of viability in A549 and ASM cells after 48h ($p<0.001$) and in AC16 cells within 24h ($p<0.001$). Mitochondrial stress testing revealed impaired spare respiratory capacity and significant loss of membrane potential using after 12 hours ($p<0.05$), accompanied by elevated LDH release ($p<0.01$). TEER analysis demonstrated a -dependent decline in epithelial cell barrier integrity. In 3D epithelium spheroids, 6-PPDq exposure exhibited altered morphology and reduced viability, suggesting enhanced sensitivity of multicellular structures. EMT marker upregulation (N-Cadherin, Vimentin, and α -SMA) indicated a phenotypic shift towards mesenchymal characteristics. **Conclusions:** These data identify 6-PPDq as a cardiopulmonary toxicant that accumulates in human lung tissue, disrupts mitochondrial energy metabolism, impairs epithelial barrier function, and promotes EMT. The findings highlight a potential mechanistic basis for cardiopulmonary injury following environmental 6-PPDq exposure and underscore the need for further risk assessment.

PS 3908 Chemical-dependent Effects of Acute Wildfire Smoke Exposure on Shared Inflammatory Dysregulations in the Lung and Brain

D. You¹, H. Park², M. Malfatti¹, E. Ubick¹, S. McCloy¹, L. Nguyen¹, H. Enright¹, and B. Buchholz¹. ¹LLNL, Livermore, CA; and ²UC Davis, Davis, CA.

Background and Purpose: Health impacts of wildfire smoke have arisen as a public concern with the increase in global prevalence of wildfire. Epidemiology and animal studies have both shown negative respiratory health effects of wildfire smoke. More recently, the effects of wildfire smoke have been further assessed in its neurotoxic effects and have been associated with dementia and cognitive impairment. Wildfire smoke is a complex mixture of gases and particulate matter which vary in degree by the source of biomass, chemical composition, and combustion scale and phases. To untangle these complexities and investigate the effect of wildfire in the lung and brain, we exposed rats to woodsmoke extracts (WSE) reconstituted with different classes of chemicals commonly found in real-world wildfire. We hypothesize that chemicals reconstituted in WSE will differentially induce inflammatory molecular changes in similar ways in the lung and the brain, potentially acting through shared regulatory mechanisms. **Methods:** Male Sprague Dawley rats (n=7-10) were intranasally instilled with 50µg/kg of either ¹⁴C-palmitic acid (PA), ¹⁴C-benzo[a]pyrene (B[a]P), or ¹⁴C-catechol (CAT) reconstituted in 1mg/mL of smoldering eucalyptus WSE for 24h. Controls received equal volume of saline. The left-brain hemisphere and left lung lobe were fixed for histology. Paraffin sections were stained for cyclooxygenase-2 (COX-2), a biomarker of acute inflammation, COX-2 and heme oxygenase-1 (HO-1), an indicator of antioxidant response, using fluorescent immunohistochemistry (IHC). COX-2 and HO-1 were each co-stained with neuron (NeuN) on brain sections and macrophages (CD68) on lung sections. Quantitative IHC analysis was done for each biomarker using customized macros in Fiji. IHC image data were analyzed with linear mixed-effects regression for brain and simple linear regression for lung sections, followed by BH FDR correction, in R Studio. **Results:** In the lung, COX-2-positive cell density was significantly increased with B[a]P exposure, and interestingly, the same trend was observed in B[a]P-exposed hippocampal sections without reaching significance ($p_{adj}=0.109$). The number of HO-1-positive macrophages in the lung was reduced with PA exposure ($p_{adj}=0.068$). While a similar trend in HO-1-positive neuronal counts were observed in the hippocampus, changes were statistically insignificant with high variance. No notable changes were observed in astrocytes in the dentate gyrus brain region, while there was 4.2 fold increase in percent area of microglial expression in the B[a]P exposure group ($p_{adj}=0.056$). **Conclusions:** Our results indicate that WSE caused chemical-dependent inflammatory dysregulations in both the lung and brain. Similar patterns of chemical-induced changes in COX-2 and HO-1 expression in the lung and brain suggest either: (1) B[a]P and PA may act through shared molecular pathways upon entering lung and brain, or (2) that mediators originating in the lung circulate systemically to the brain and drive neuroinflammation. These findings warrant further mechanistic studies to delineate the temporal sequence of events to establish the lung-brain axis. Nevertheless, our results still indicate that the brain is affected by WSE-reconstituted chemicals in a manner similar to the lung. Moreover, these findings raise the importance of identifying main chemicals in wildfire to provide more tailored and effective medical care to exposed individuals. Supported by LLNL LDRD 23-ERD-020 and leveraged Fiji macro-driven automated IHC image analysis pipeline developed under NIH RF1 AG074709. This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-2013563.

PS 3909 Study of Neighborhood Air near Petroleum Sources (SNAPS): California's characterization of air quality and health risks in communities near oil and gas operations

L. D. Scanlan, H. M. Bolstad, and Á. Alvarado. Office of Environmental Health Hazard Assessment, Sacramento, CA.

Background and Purpose: California's Office of Environmental Health Hazard Assessment (OEHHA) and the California Air Resources Board (CARB) developed the Study of Neighborhood Air near Petroleum Sources (SNAPS) program to characterize air quality and corresponding health risks in communities near oil and gas operations in California. SNAPS is a first-of-its-kind, community-driven monitoring effort focused on communities living near oil and gas operations. Lost Hills, CA (Kern County) is the first SNAPS location. It is a small community downwind of oil and gas operations. It is close to an interstate, trucking route and agricultural activities. Lost Hills is a disadvantaged community with a CalEnviroScreen score in the 86th percentile and pollution burden in the 91st percentile. **Methods:** OEHHA and CARB used public engagement to develop the SNAPS Lost Hills program. Input and lived expertise from communities informed monitoring locations, mobile monitoring timing, and communication of complex data to a broad audience. Staff attended and led in-person and virtual community meetings to provide updates and incorporate feedback. SNAPS measured pollutants in Lost Hills from May 2019 through April 2020 using a suite of instruments housed in a stationary trailer and a mobile platform. CARB conducted monitoring according to a community-specific air monitoring plan and a quality assurance project plan and processed data to provide 1-hour and 24-hour pollutant concentrations. Using the collected monitoring data, OEHHA performed human health risk assessments using OEHHA's Air Toxics Hot Spots methods. We used hazard quotient and hazard index to assess individual chemical hazard and cumulative hazards, respectively. We estimated cancer risk with cancer slope factors and estimated cumulative risk as the sum of individual risks. We used the single highest 24-hour or 1-hour concentration for acute assessment and the annual average concentration for chronic and cancer assessment. SNAPS communicated data and results at public meetings and via posting on the SNAPS website. The final report was posted in October 2025. **Results:** In Lost Hills, SNAPS monitored close to 200 compounds, including criteria pollutants and toxic air contaminants. Concentrations of particulate matter (PM_{2.5}), ozone, carbon monoxide, lead, and hydrogen sulfide met ambient air quality standards. Pollution levels were similar to other Central Valley locations, with the exception that acrolein concentrations were higher. Source apportionment showed that oil and gas-related sources contributed 39-55% of benzene, toluene, ethyl benzene and xylene (BTEX) concentrations. Similarly, oil and gas-related sources contributed over 80% of other volatile organic compounds (VOC) analyzed. When wind came from the direction of the Cahn 3 Gas Processing Plant, increased hydrocarbons and VOCs were observed in Lost Hills. Black carbon was primarily from mobile sources. Noncancer health hazards of concern (hazard index or hazard quotient >1) were identified for the respiratory system (acute HI=4.5, chronic HI=6.6), eyes (acute HI=2.1), and nervous system (chronic HI=1.1). Acrolein (acute HQ=2.2, chronic HQ=5.5), dimethyl disulfide (acute HQ=2.0), metals and benzene levels contributed to these hazards. Most carcinogens were detected at concentrations similar to other areas of California not directly associated with oil and gas production. Key contributors to cancer risk were diesel particulate matter, carbon tetrachloride, formaldehyde, and benzene, with cancer risk estimates of 460, 67, 66 and 36 excess cases per million, respectively. Cumulative cancer risk was 760 excess cases per million. No health value was available to assess cancer risk from acrolein. **Conclusions:** SNAPS is a novel air monitoring program that aims to improve the understanding of pollutants that residents living near oil and gas production may be exposed to. Results in Lost Hills showed potential hazards to eyes, the respiratory system and nervous system. Monitoring showed elevated levels of acrolein compared to other parts of the state. Acrolein is a carcinogen but has no health guidance value available to assess cancer risk. In response, OEHHA is developing a cancer potency factor for acrolein.

PS 3910 Impaired efferocytosis by MerTK shedding in macrophages attributes to pathogenesis of cadmium induced emphysema

G. Mani, N. Castellanos-Sanchez, K. Patel, A. Pudhota, S. Bodduluri, M. Wells, and R. Suroli. University of Alabama at Birmingham, Birmingham, AL.

Background and Purpose: Cadmium (Cd) is a widely recognized toxic heavy metal that is commonly found as an occupational and environmental pollutant. Exposure to Cd accumulated in the lungs and other organs may inevitably affect intracellular signaling, resulting in chronic inflammation, COPD, and emphysema. In this study, we aimed to investigate the mechanisms underlying Cd-induced impairment of efferocytosis (phagocytic clearance of apoptotic cells), leading to chronic inflammation and emphysema. **Methods:** Mouse alveolar macrophage cells treated with Cd, and were assessed for their efferocytosis ability. The cell lysates were used for immunoblotting for the efferocytosis protein MerTK, pADAM17, and ADAM17. C57BL/6 mice (8-10 weeks old, both male and female), or MerTK^{-/-} were exposed to cadmium and evaluated for immunohistochemical analysis, lung functions, and lung injury at Day 21st. *Ex vivo* and *in situ* efferocytosis assays were performed to analyze efferocytosis function in alveolar macrophages of control and Cd-exposed mice. The effects of soluble Mer (sMer) treatments were analyzed in control and Cd-exposed mice. **Results:** Cadmium reduced the efferocytosis index in alveolar macrophages;

however, it upregulated MertK expression. Furthermore, we found that Cd treatment caused MerTK shedding through activation of ADAM17. Proteolytic cleavage of Mer produced an extracellular form of Mer (sMer), which acted as a decoy receptor by binding to Gas6 and inhibiting efferocytosis. *In vivo* studies showed that Cd increased sMer levels and ADAM17 activity and inhibited efferocytosis, leading to emphysema. Intratracheal administration of sMer was itself pathological, decreasing the efferocytosis index and increasing lung inflammation and emphysema. Co-treatment with sMer and Cd worsened inflammation and emphysema and further reduced the efferocytosis index. Additionally, we observed more severe emphysema in MerTK^{-/-} mice than in MerTK^{+/+} Cd-exposed mice. Interestingly, COPD plasma samples showed elevated sMer levels compared to control subjects. **Conclusions:** Cadmium increases levels of extracellular Mer and which then acts as decoy scavenger receptor, leading to defective efferocytosis. The anti-efferocytic activity of sMer perpetuates inflammation and causes emphysema.

PS 3911 Air Pollution Derived Fe-Oxide Inhalation Produces Persistent Sex-Specific Behavioral and Morphological Deficits in Mice

J. V. George¹, K. Hornburg², T. Covitz¹, M. Masten¹, E. Marvin¹, D. Chalupa¹, K. Cristillo¹, C. Galloway¹, K. Bentley¹, G. Johnson², G. Oberdorster¹, D. Cory-Slechta¹, and M. Sobolewski¹. ¹University of Rochester, Rochester, NY; and ²Duke University, Durham, NC.

Background and Purpose: Iron-overload, a hallmark and potential contributor to neurodegeneration, comprises a large portion of ultrafine particulate (UFP) matter of air pollution, with especially high concentrations in US subway systems. Previous research demonstrated that Fe-oxide nanoparticles can translocate along cranial nerves into the brain, form deposits within the brain, and associate with degenerating myelin. We hypothesize that the essential role Fe plays in myelination and the direct physical damage caused by Fe-oxide nanoparticle transport along axons can contribute to the sex-specific white matter dysregulation observed in neurodegeneration. **Methods:** To assess the impact of Fe-oxide nanoparticle inhalation and age-related increases in brain Fe content on white matter, two cohorts of 10-week-old C57BL/6 mice were randomly exposed to HEPA-filtered air or 1.5 ng/L iron-oxide UFPs for two hours daily for 20 days. An acute cohort was either acutely sacrificed followed by MRH or subjected to a behavioral battery. The other cohort aged undisturbed in their home cage until MRH, and a broad behavioral battery were performed at 12 and reassessed at 18 months. Micro-dissected corpus callosum from 18-month-old animals were sent for electron microscopy imaging. **Results:** Acutely, Fe-exposure produced sex-specific diffusivity differences in olfactory bulb, with Fe-exposed females exhibiting increases in diffusion indices and males decreases. At 12 months, significant increases, not decreases, in fractional anisotropy in both sexes were observed in caudal regions along the olfactory circuit. In Novel Object Recognition, Fe-exposed female mice had significantly lower recognition indices acutely and at 12 months indicating a persistent, female-specific memory deficit. No locomotor or motor changes were observed in either sex at 12 months of age, however, at 18 months, Fe-exposed male mice exhibited significant hypoactivity on a locomotor assay and significantly more footslips on a 2.5cm and 1.25cm balance beam on days 2 and 3, representing an emergent male-specific motor deficit after early adulthood Fe-oxide exposure. Ultrastructural 18-month corpus callosum myelin analyses demonstrated Fe-induced female-specific decreases in g-ratio and increases in axon, fiber, and myelin area indicating thicker myelin sheaths. However, Fe-exposed female mice were also found to have significantly more split myelin sheaths indicating significant myelin dysregulation in Fe-exposed females. Contrastingly, Fe exposure significantly increased total fiber and myelinated areas in males without concomitant decreases to g-ratio or increases in axonal area. Similar to Fe-exposure in females, Fe-exposed males also had significantly more split myelin area. However, when considering geometry of the axons, significant sex-specific changes to circularity index were observed with Fe exposure reducing circularity index in females but increasing the index in males. This change in axonal geometry could potentially underlie sex differences in diffusivity. **Conclusions:** Early adulthood Fe-oxide nanoparticle inhalation produces sex-specific behavioral and morphological differences that persist and even, emerge, with age. The observed behavioral differences indicate that Fe-exposures produces sex-specific behavioral alterations with females exhibiting persistent short-term memory deficits and males exhibiting emergent motor deficits at 18 months. Fe-exposure produced acute sex-specific differences in white matter in the olfactory bulb and these diffusivity differences moved caudally with age. At the ultrastructural level, Fe-exposure produced sex-specific changes in g-ratio and axonal geometry which could potentially underlie diffusion differences. These data suggest that Fe-oxide inhalation can cause sex-specific white matter dysregulation with concomitant behavioral deficits.

PS 3912 Simulated wildfire smoke particulate matter exposure elicits an inflammatory and oxidative response in RAW264.7 macrophage and C57BL6 mixed glia

S. Boland, Z. Fields, J. A. Moreno, and L. Montrose. Colorado State University, Fort Collins, CO.

Background and Purpose: Wildfire smoke (WFS) is a major source of ambient particulate matter (PM) exposure and has been associated with adverse respiratory and neurological outcomes, including increased inflammation. However, the cellular mechanisms linking WFS exposure to inflammatory signaling within the lungs and periphery and how this in turn affects the blood-brain barrier and finally the brain itself remains unclear. **Methods:** To better understand the lung-brain axis we established a lung and brain exposure model to begin to investigate the effects of PM_{2.5} generated from a 50:50 mixture of eucalyptus:manzanita (E/M)—a common wildfire smoke source in California and Australia, on macrophage activation using the murine RAW264.7 cell line and on glial activation, using primary C57BL/6 mixed glia. Macrophages or glia were exposed to a concentration range of 0.01-10 ug/ml WFS PM_{2.5}, and outcomes include mitochondrial superoxide via Mitosox, cytokine gene profiling (IL-1 β , TNF- α , IL-6, C3) via qPCR, NLRP3 inflammasome expression and p65 phosphorylation through western blotting. Data were analyzed using one-way ANOVA with appropriate multiple-test corrections. **Results:** Exposure to E/M WFS PM_{2.5} induced a dose and time dependent increase in proinflammatory cytokine TNF- α , within macrophages; glia exhibit the most consistent and significant upregulation of IL-1 β , TNF- α , and C3. Following exposure, RAW264.7 cells also exhibited a dose and time dependent increase in mitochondrial superoxide, highlighting a pro-inflammatory and oxidative cellular response. Importantly, cell viability remained largely intact at relevant exposure concentrations, indicating that the inflammatory activation was not driven by overt cytotoxicity. **Conclusions:** These findings demonstrate that WFS PM_{2.5} robustly activates macrophage and glial inflammatory pathways. Establishing RAW264.7 macrophages and murine primary glia as a tractable model for WFS-induced inflammation, this work lays the foundation for future studies investigating downstream effects on the blood-brain barrier and neuroinflammatory signaling.

PS 3913 Effectsof Diesel Exhaust onLipid Remodeling and Endocrine Regulation in Obese Mice

E. Scott¹, V. Lopez¹, A. Louie², R. Gupta², Z. Afsharnejad¹, T. K. Bammler¹, M. T. Kleinman³, J. A. Araujo², and J. L. Marsillach¹. ¹University of Washington, Seattle, WA; ²University of California, Los Angeles, CA; and ³University of California, Irvine, CA.

Background and Purpose: Obesity, whose incidence has tripled since 1975, is a major global health concern. Emerging evidence implicates air pollution, particularly ultrafine particles (UFP) and traffic-related air pollution (TRAP) as contributors to metabolic dysfunction. These pollutants can activate oxidative and inflammatory pathways, potentially influencing adipose tissue and endocrine regulation. We hypothesize that UFP/TRAP exposure alters lipid signaling through systemic oxidative stress and inflammation, impairing neuroendocrine regulation and metabolic homeostasis, particularly under high-fat diet (HFD) conditions. **Methods:** Adult male and female low-density lipoprotein receptor knockout (Ldlr KO) mice were exposed to UFP/TRAP emissions or filtered air while fed chow or HFD for 18 weeks. Exposure conditions mimicked ambient roadway air pollution using a diesel generator producing 250 μ g/m³ PM_{2.5} for 6 h/day, 5 days/week, while control mice received HEPA and carbon-filtered air. At sacrifice, blood was collected via orbital bleeding in heparinized tubes. After PBS perfusion, epididymal white adipose tissue was collected for untargeted lipidomics using liquid chromatography-ion mobility mass spectrometry. Lipid features were annotated against spectral libraries. Statistical analyses were conducted with LipidSigR package using two-group tests with FDR correction, and two-way ANOVA assessed exposure x diet interactions. Plasma thyroid markers (TSH, T3, T4) were quantified using multiplex assays. **Results:** Significant differences in lipid class abundance were identified between exposure groups using characteristic-level association analysis with FDR correction ($p < 0.05$). Diesel exhaust (DE) exposure strongly increased N-acyl ethanolamine (NAE) (log₂ FC 4.77), Lysophosphatidylglycerol (LPG) (2.89), Phosphatidylinositol-3,4,5-trisphosphate (PIP3) (2.21), and Glucosylceramide (GlcCer) (2.03), with rises in PIP, PG, TG, PI, MGDG, and DG. Pronounced reductions occurred in Hexosylceramide (HexCer) (-14.77), Ceramide (Cer) (-4.82), Lysophosphatidylcholine (LPC) (-3.70), Phosphatidylserine (PS) (-3.39), Phosphatidylcholine (PC) (-2.91), Digalactosyldiacylglycerol (DGDG) (-2.85), and Cardiolipin (CL) (-2.10), and smaller decreases in PE, PA, PIP2, LPE, and LPA. GATOM network highlighted arachidonoyl-CoA across multiple reactions. Chow vs. HFD comparison showed 11 classes with consistent directional changes under DE, including increases in PIP, PG, TG, PC and decreases in DGDG, PS, PI, Cer, DG, PE, PIP2. Four classes reduced under chow (LPE, LPC, CL, PA) increased under HFD, indicating diet-dependent regulation. Multiplex assay revealed elevated TSH in chow-fed Ldlr KO males under DE. HFD-fed mice had higher TSH overall with sex-dependent differences. Plasma T4 decreased in HFD-fed mice, while body weight rose with HFD but was not significant across exposures. **Conclusions:** DE exposure in chow-fed mice caused major lipid shifts, increasing signaling lipids (NAE, LPG, PIP3, GlcCer), and reducing sphingolipids and glycerophospholipids. Under HFD, similar patterns emerged, with some chow-decreased classes (LPE, LPC, CL, PA) increasing,

showing diet-dependent effects. Dysregulation of bioactive lipids tied to inflammation suggests DE could potentially trigger inflammatory pathways in adipose tissue. Disruption of TG, PC, PI, and structural lipids (PC, PE, PS, CL) could signify downstream impairments in cellular metabolism, systemic energy balance, and membrane structural integrity and function. Together, these lipidomic, network, and endocrine results indicate differences in metabolic and signaling pathways varying with exposure and diet.

PS 3914 Occupational Health Hazards: Aerosol toxicity and cardiopulmonary effects on a restaurant cohort

A. F. Saporito¹, T. Huynh¹, A. Aherrera², J. Balmes³, J. T. Zelikoff¹, and T. Gordon¹.

¹NYU Grossman School of Medicine, New York City, NY; ²University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; and ³University of California, Berkeley, Berkeley, CA.

Background and Purpose: Workers disproportionately exposed to air pollution have an increased risk for adverse health or cardiopulmonary outcomes. However, both toxicological and epidemiological data on cooking emissions exposure and their impacts on restaurant workers remains limited. **Methods:** We conducted a pre-post shift panel study among front-of-house (FoH) and back-of-house (BoH) for n = 39 non-smoking restaurant workers to assess acute changes in cardiopulmonary health associated with cooking-related PM_{2.5} exposure. Data were stratified by reported amount of time spent in kitchen ($\geq$ or $<$ 50%). Average PM_{2.5} concentrations were estimated using low cost-sensors. Clinical measurements including spirometry and oscillometry were conducted pre-post shift, along with blood pressure, O₂ saturation, and short-term health survey data (REDcap). Urine was collected for lipid peroxidation (TBARS) examination. Dried blood spots (DBS) and nasal epithelial lining fluid (NELF) were collected for pro-inflammatory cytokine (IL-1 β , IL-6, IL-8, and TNF- α) quantification via Meso Scale Discovery (MSD) plates. **Results:** Participants (n = 39) were 74.4% male and 25.6% female, with an overwhelming majority being Hispanic or Latino/a (66.7%) while 10.3% were Asian or Asian American, 15.4% Black or African American, and 12.8% White or European. Higher percentages of back pain and shortness of breath amongst workers were reported post-shift. Statistically significant baseline (pre-shift) blood pressure or O₂ saturation differences were not detected between BoH and FoH groups, particularly when controlling for average PM_{2.5} concentrations; however, post-shift systolic blood pressure was higher amongst BoH workers compared to their pre-shift values ($p \leq 0.05$). There were no significant differences for pre- and post-shift FEV₁ ($p = 0.071$), FEV₆ ($p = 0.49$), or FVC ($p = 0.34$) for all workers with acceptable spirometry (n = 20); additionally, neither BoH nor FoH showed significant short-term differences. For all acceptable pre-shift pulmonary function tests, 34.6% (9/26) indicated moderate obstructions or possible restrictive spirometry's. **Conclusions:** Restaurant employees are an understudied population, often facing 50-to-70-hour workweeks, high heat, stress, noise, and air pollution. These preliminary clinical findings may suggest adverse short-term health effects for BoH workers correlated with air pollution exposure, but further examination of a larger population is necessary.

PS 3915 Spatial single-cell transcriptomic analysis of benzene-exposed atherosclerotic plaque

B. Taylor, S. McFall, M. Malovichko, S. Srivastava, and I. N. Zelko. University of Louisville, Louisville, KY.

Background and Purpose: Chronic exposure to airborne pollutants, including benzene, has been linked to an increased risk of myocardial infarction, heart failure, and cerebrovascular events. Benzene is a pervasive environmental contaminant, ranking sixth on the Agency for Toxic Substances and Disease Registry's priority list. It ranks among the top 20 chemicals produced by industrial activities in the United States and constitutes a principal toxic component in vehicular emissions and cigarette smoke. Our recent studies have revealed that benzene exposure is sufficient to induce endothelial dysfunction, toxicity, and heart failure. Extensive research has examined the atherogenic potential of various environmental pollutants, including particulate matter, ozone, acrolein, arsenic, and cadmium. Nevertheless, the impact of benzene on vascular inflammation and the stability of atherosclerotic plaques remains poorly understood. The primary objective of this investigation is to delineate the molecular mechanisms underlying benzene-mediated plaque inflammation and attenuation of fibrous cap integrity. **Methods:** Atherosclerosis-prone low-density lipoprotein receptor knockout (LDLr-KO) mice were maintained on a Western Diet for 10 weeks to establish atherosclerotic lesions. Mice were then randomized to receive whole-body inhalation exposure to either 1ppm benzene or HEPA-filtered air (control) for 6 hours/day, 5 days/week, for 4 weeks, while remaining on Western Diet. Following the 4 weeks of exposure, innominate arteries were harvested, cleaned, sectioned, and analyzed using the Nanostring CoxMx™ Spatial Molecular Imager. A 1,000-plex gene panel was used to assess single-cell gene expression profiles *in situ*. High-resolution imaging datasets facilitated the delineation of three regions of interest (ROIs): the vessel wall, plaque core, and fibrous cap. Visualization and spatial segmentation of RNA transcripts were conducted utilizing the Napari software. Expression matrices, associated metadata, and field-of-view (FOV) files were imported and processed using the Seurat package in R. Cells exhibiting aberrant

gene counts (either excessively high or low) were excluded from further analysis. Inter-cellular communication was evaluated through receptor-ligand interactions using databases integrated into the NicheNet R package. **Results:** Using the Leiden clustering approach, six cell clusters were identified: Activated Endothelial Cells, Proliferating Endothelial Cells, Fibroblasts, Macrophages, and two distinct Vascular Smooth Muscle Cell populations. Significant downregulation of the major structural Col3a1 gene was identified in the fibroblasts residing in the fibrous cap and plaque areas of benzene-exposed animals compared to air-exposed controls ($p < 0.001$). Conversely, significant upregulation of atherogenic and inflammatory Psap and ApoE genes in macrophages localized to the same regions was observed ($p < 0.001$). In addition, a reduction in the number of fibroblasts was detected in benzene vs air fibrous cap areas. These data suggest that benzene and its metabolites compromised the integrity of the protective fibrous cap in the plaque. Next, we explored cell-cell interactions, focusing on endothelial cells as signal senders and macrophages as signal recipients. Several ligands with high target gene prediction ability were identified in endothelial cells (Csf1, Tgfb1, and Fgf7), which were expressed at higher levels in activated EC and were differentially regulated by benzene exposure. These ligands have a high probability of interacting with target genes, including Apoe, Ctsd, and Tgfb1, which are expressed in macrophages. **Conclusions:** Our data suggest that short-term benzene exposure alters the stability of pre-established atherosclerotic plaques by affecting lesion cellularity and inflammation, and fibrous cap integrity.

PS 3916 Function-Barrier changes in the lungs of Apoe^{-/-} mice following repeated exposure to flaming eucalyptus-manzanita smoke.

C. Yazbeck¹, F. Koeini¹, N. Micovic¹, M. J. Gollner², C. Bellini¹, and J. Oakes¹.

¹Northeastern University, Boston, MA; and ²University of California, Berkeley, CA.

Background and Purpose: Public and occupational health concerns regarding wild-fire smoke (WFS) inhalation have increased markedly due to the rising intensity and frequency of wildland fires. Wildland fires generate both flaming and smoldering smoke, however little is known about how flaming smoke affects lung function and barrier integrity. Flames generate smaller and more toxic particles than smoldering smoke, with significant lung toxicity potential (PMID: 29369516). WFS particles are hypothesized to impact extra-pulmonary organs by bypassing the lung barrier and translocating into the systemic circulation (PMID: 38662865). Here, we tested the consequences of flaming exposure on lung function and proposed a novel method for quantifying whole-lung permeability. **Methods:** Female Apoe^{-/-} mice (9 $\pm$ 1 weeks, N=20) were assigned to flaming WFS (50:50 eucalyptus/manzanita), filtered lab-air controls, or LPS- or PBS-treated controls for inflammation-driven comparisons. Flaming and air-control mice were exposed in a whole-body chamber for 2 hours daily over 7 days to smoke or lab air, respectively. LPS mice received a single intratracheal dose of 2 mg/kg b.w. LPS. Flaming parameters were 16 g fuel mass and 600 °C furnace temperature. After the 7th exposure day, or 2 days after LPS/PBS administration, lung function was assessed using derecruitability tests on the flexiVent (SCIREQ). Solution of the constant-phase model yielded coefficients of tissue elastance (H), tissue damping (G), and airway resistance (Rn). Barrier integrity was then evaluated using ventilator-induced lung injury (VILI) and ventilator-assisted aerosol delivery (VAAD) of 4 kDa FITC-dextran. For the VILI protocol, mice underwent 5 minutes of injurious ventilation (50 ml/kg tidal volume, 37.5 cmH₂O plateau pressure, zero PEEP, 50 breaths/min) to determine VILI onset, defined as the time when H doubled. For the VAAD approach, an Aerogen vibrating mesh nebulizer (2.5-4 μ m droplets) integrated with the flexiVent delivered 3.84 mg of FITC-dextran (32 mg/ml) under 120 RR, 2:1 I:E, and 20 ml/kg b.w. tidal volume. This method was validated in LPS mice, where one-hour post-nebulization, whole blood and bronchoalveolar lavage fluid (BALF) were collected. Concentration of FITC-dextran was measured in plasma, and mass in BALF (μ g) was calculated by multiplying the measured concentration by the fluid volume recovered. The permeability index (%) was defined as the ratio of fluorescence intensity plasma/BALF. **Results:** Flaming smoke contained 328 ppm CO and 4 mg/m³ PM. Flaming WFS-exposed mice showed significantly elevated H at intermediate PEEP levels (9, 6, 3 cmH₂O), similar to LPS mice, with no changes at 12 or 0 cmH₂O. Rn increased at all PEEP levels except zero, while G remained unchanged. These PEEP-dependent changes produced significantly lower hysteresivity ($\eta = G/H$) at all PEEP levels except ZEEP. VILI onset occurred earlier in flaming exposed mice than air controls. Nebulized Evans Blue dye showed a lung deposition pattern comparable to inhaled flaming smoke lungs under the VAAD configuration. The lungs of LPS-treated mice were more permeable than those of PBS-treated controls. This permeability assay will be leveraged in our smoke exposure studies to assess lung permeability following functional test. **Conclusions:** Repeated flaming WFS inhalation significantly impairs lung function and may underlie inflammatory responses associated with barrier compromise. Future work will incorporate smoldering WFS inhalation to delineate the differential impact of combustion mode on the lung function-structure relationship and barrier integrity. We advocate that tailored protective measures and health guidelines be implemented for individuals facing repeated smoke exposure.

J. Manzano, H. Park, M. Cheng, L. Sanchez, A. E. Valenzuela, M. C. Domanico, A. S. Wexler, K. J. Bein, P. J. Lein, and L. S. Van Winkle. University of California Davis, Davis, CA.

Background and Purpose: Traffic-related air pollution (TRAP) is a heterogeneous mixture of particulate matter (PM) and gaseous pollutants. TRAP is implicated in both respiratory and Alzheimer's disease (AD). However, it is unknown which components in TRAP drive adverse health effects and whether the respiratory and neurologic effects are linked. Here we addressed the hypothesis that TRAP triggers pulmonary inflammation, specifically, increased TGFβ. Increased pulmonary TGFβ can subsequently release TGFβ into the systemic circulation, which can impact the blood brain barrier and promote AD relevant phenotypes. We also examined the relative contribution of TRAP components on lung TGFβ levels. **Methods:** Male and female TgF344-AD rats, which express two human AD risk genes, were chronically exposed to ambient whole TRAP (containing both particles and gases), TRAP derived PM only or TRAP derived gases only collected from the emissions of light-duty vehicles (LDV) vs. light duty and heavy-duty vehicles (LDV+HDV). Age and sex matched controls housed at the same facility were exposed to filtered air (FA). Exposures began when animals were 1 month old with samples collected at 4, 9, 12, and 15 months (mos) of age. Bronchoalveolar lavage fluid (BALF) was collected to assess total protein leak and lung tissue was collected to measure protein levels of three TGFβ isoforms. **Results:** Protein leak in response to TRAP was minimal at 4 mos but a notable increase in total protein concentration in BALF supernatant was observed at 12 and 15 mos. At 12 mos, male rats exposed to PM + Gas (LDV + HDV) demonstrated a significant increase in BALF protein levels (p_{adj} 0.0116) and although 12 mos female rats exposed to PM (LDV + HDV) reached the highest mean BALF protein levels (>3000 µg/mL), this increase was not statistically significant compared to FA controls. At 15 mos, female BALF protein concentrations in all exposure groups diminished to levels comparable to FA controls but males continued to display elevated protein concentrations across all TRAP groups. TGFβ protein measurement in homogenized caudal lobes showed varying changes in TGFβ isoforms across timepoints, most prominently in males. While there were no clear or consistent changes across all timepoints, every PM containing TRAP exposure group had significantly increased ($p_{adj}<0.1$) pulmonary TGFβ-2 levels at 4 and 12 mos in males, but the same was not observed in females. Additionally, a few female TRAP groups had significantly reduced TGFβ-1 levels at 4 mos, but the same was not seen in males. All TRAP-induced changes in TGFβ-1 and 2 returned to near baseline (compared to FA) at 15 mos in females. **Conclusions:** Across all timepoints and TRAP exposures there appeared to be sex-dependent variability in TRAP-induced increases in BALF protein, indicating cellular injury in the lung, most notably in the male lung. There were progressive, sex-dependent increases in BALF protein concentrations over time. Changes in TGFβ protein, which play important roles in pulmonary fibrosis, were most prominently observed in the male lung. Together, these results suggest sex-dependent pulmonary vulnerability to chronic TRAP exposure, which merits further investigation into the sequence of pathologic events triggered by TRAP in the lung, the systemic circulation, and the brain. This study was supported by NIH grants RF1 AG074709, T32 HL007013, P30 ES023513, and T34GM136469.

PS 3918 Benzene-Induced Endothelial Activation: Mitigation by Heat Shock Proteins

S. A. McFall, N. S. Wickramasinghe, T. Malik, I. Zelko, and S. Srivastava. University of Louisville, Louisville, KY.

Background and Purpose: Benzene is a widespread environmental pollutant found at superfund sites and is abundant in petroleum products, tobacco smoke, and various household goods like cleaners, paints, and adhesives. It is a well-known human carcinogen with well-documented hematopoietic and immunotoxic effects. Epidemiological evidence also links benzene exposure to an increased risk of all-cause mortality, cardiovascular mortality, and stroke, though the biological mechanisms underlying these associations remain unclear. Endothelial activation plays a pivotal role in vascular inflammation and atherosclerosis, the underlying cause of myocardial ischemia and stroke. This study examines the impact of benzene exposure on endothelial cell activation and the underlying mechanisms. **Methods:** To understand the potential functional changes to the endothelium from benzene exposure, we used multiphoton-intravital microscopy (IVM). IVM allowed us to visualize real-time interactions between leukocytes and the endothelium in the mouse ear microvasculature. For all IVM experiments, Fluorescein-dextran (70 kDa; 1.5 µL/g in saline, intravenous) was used to label vasculature, and Rhodamine 6G (0.2% v/v in saline, intraperitoneal) to label leukocytes. For each mouse, two separate two-minute videos were taken of a blood vessel within the ear. For analysis, leukocyte dynamics (free-flowing, rolling, adhering) were quantified manually and the counts from both videos were averaged. First, male and female C57BL/6 mice (n=10/group) were exposed to benzene (1ppm, 6h/d 5d/wk, 4 weeks) or HEPA-filtered air and leukocyte rolling and adhesion was examined by IVM. *In vitro* we exposed human aortic endothelial cells (HAECs) to a benzene metabolite, t,t-muconaldehyde (MA; 10 µM) and assessed adhesion and transmigration of a leukocytic cell line (dTHP-1 cells). Our previous studies revealed that heat shock proteins, especially HSPA1B, protect against benzene-induced endothelial toxicity. To further assess the role of heat shock

proteins in benzene-induced endothelial activation, we exposed transgenic mice that selectively overexpress HSPA1B in the endothelium (EC-HSPA1B-TG) to either benzene (1ppm) or HEPA-filtered air and assessed leukocyte rolling and adhesion by IVM. **Results:** Chronic inhaled benzene exposure induced a significant increase in leukocyte rolling and adhesion, demonstrating a clear sex difference in response. While male mice showed increases in leukocyte rolling (16-fold, $p=0.0009$) and adhesion (11-fold, $p<0.0001$), female mice exhibited a significantly greater response (rolling: 20-fold, $p=0.001$; adhesion: 43-fold, $p<0.0001$). These sex differences were statistically significant for leukocyte rolling ($p=0.0029$) and adhesion ($p=0.0001$). *In vitro*, MA exposure enhanced leukocyte adhesion and transmigration and phosphorylation of eIF2α (reflecting endoplasmic reticulum (ER) stress and unfolded protein response). The endothelial-specific overexpression of HSPA1B reduced benzene-induced leukocyte rolling (5.4-fold decrease compared to WT, $p=0.0002$) and leukocyte adhesion (2-fold decrease compared to WT, $p=0.0026$). **Conclusions:** These findings suggest that benzene contributes to cardiovascular risk by promoting endothelial activation which could be prevented by endothelial cell specific overexpression of HSPA1B.

PS 3919 Inhaled Copper Nanoparticles Induce Pulmonary Inflammation and Blood-Brain Barrier Dysfunction in a Late-Onset Alzheimer's Disease Mouse Model

D. Lee¹, M. Pavlovic², M. Weis³, S. E. Beyer^{3,4}, S. Chatterjee^{3,4}, and J. Kim^{1,2}.

¹Department of Occupational and Environmental Health, College of Public Health, The University of Iowa, Iowa City, IA; ²Interdisciplinary Graduate Program in Human Toxicology, Graduate College, The University of Iowa, Iowa City, IA; ³Department of Neuroscience and Pharmacology, Carver College of Medicine, University of Iowa, Iowa City, IA; and ⁴Iowa Neuroscience Institute, University of Iowa, Iowa City, IA.

Background and Purpose: Inhalation of nanosized particles (<100 nm) is increasingly recognized as a contributor to neurotoxicity, yet the mechanistic link between pulmonary exposure and brain outcomes remains unclear. Recent findings indicate that systemic inflammation and blood-brain barrier (BBB) disruption may mediate the connection between lung injury and neural damage. Thus, this study investigated the pulmonary and neurotoxic effects of copper oxide nanoparticles (CuO NPs) in a late-onset Alzheimer's disease (LOAD2) mouse model carrying genetic risk factors such as *APOEε4*, *h-APP*, and *Trem2*^{R47H} mutations. We aimed to evaluate whether inhaled CuO NPs exacerbate systemic inflammation, impair BBB integrity, and contribute to neuroinflammatory signaling in brain regions associated with cognition. **Methods:** Wild-type and LOAD2 mice were exposed to CuO NP aerosols (3.5 mg/m³, 50 nm) using a dynamic whole-body inhalation exposure system (4 h/day, 5 days/week, for 4 weeks). Necropsies were performed 5 days post-exposure. Pulmonary responses were assessed by bronchoalveolar lavage fluid (BALF) analyses, including inflammatory cell counts, total protein, and lactate dehydrogenase (LDH) levels. Systemic responses were characterized by serum matrix metalloproteinase-9 (MMP-9) and S100B, a marker of BBB disruption. Tissue Cu accumulation was quantified using inductively coupled plasma-mass spectrometry (ICP-MS). Neuroinflammatory responses are currently being assessed in neocortical tissue at the protein and mRNA level by measuring cytokine levels, immune markers (CD68), and astrocytic activation markers (GFAP). **Results:** CuO NP exposure induced pronounced pulmonary inflammation, with elevated total and differential BALF macrophages, neutrophils, LDH activity, and total protein. These responses were observed in both wild type and LOAD2 mice, indicating a robust inflammatory response to CuO NP inhalation regardless of genotype. Systemically, CuO NP exposure elevated serum MMP-9 and S100B levels, consistent with tight-junction degradation and BBB compromise. S100B levels tended to be higher in LOAD2 mice, suggesting increased BBB susceptibility in the Alzheimer's disease genotype. ICP-MS analysis confirmed Cu accumulation in the lungs and brain, supporting hematogenous transport of NPs or dissolved Cu ions into the brain. Preliminary Western blot analysis of neocortical tissue revealed a trending increase in CD68 expression in CuO-exposed LOAD2 mice, suggesting potential microglial/macrophage activation. GFAP levels showed slight, non-significant elevation in LOAD2 mice, but the pattern was inconsistent across groups. Additional analyses are ongoing to define astrocytic responses and BBB-related changes. To further explore these findings, ongoing qPCR and RNA sequencing will further define the molecular pathways involved in CuO NP-induced neurotoxicity. **Conclusions:** Our data support the hypothesis that inhaled CuO NPs induce a cascade of pulmonary and systemic inflammatory responses that contribute to BBB leakage and neuroinflammation priming in a mouse model of Alzheimer's disease. Ongoing molecular analyses, including RNA sequencing, aim to elucidate pathway-specific mechanisms that link NP exposure to neurodegenerative vulnerability. These results provide mechanistic insight into the lung-brain axis in NP-induced neurotoxicity and underscores the importance of considering metal-based NPs as environmental risk factors of Alzheimer's disease progression.

M. Sullivan, and R. Woods. Cal/EPA, OEHHA, Sacramento, CA. Sponsor: M. Sun

Background and Purpose: California's Office of Environmental Health Hazard Assessment (OEHHA) conducts health risk assessments under the Air Toxics Hot Spots Program. Reference Exposure Levels (RELs) are airborne concentrations of a chemical that are not anticipated to result in adverse noncancer health effects for specified exposure durations in the general population and in sensitive subpopulations (e.g., children). RELs are based on the most sensitive and relevant noncancer health effects reported in the medical and toxicological literature. The Acute REL is intended to protect against infrequent 1-hour exposures; the 8-hour REL is for exposures that occur on a recurrent basis for a portion of each day; and the chronic value represents continuous exposure for a significant fraction of a lifetime. The California Air Resources Board then incorporates the RELs into the Hot Spots program to be used by stationary facilities and air districts in risk assessments. As such, RELs are a valuable tool for communities and regulators to use in evaluating the health impacts from air toxics exposures. OEHHA evaluated Trimethylbenzenes (TMBs), a group of volatile aromatic hydrocarbons (VOCs). TMBs exist as three isomeric forms: 1,2,3-, 1,2,4-, and 1,3,5-TMB. These VOCs are common components of gasoline, and emission sources include steel-making facilities, coal-fired plants, construction, cement, paving mixtures, asphalt, and metal coatings, amongst others. TMBs are found in printing inks, paint solvents, hydraulic fracturing fluids, and biogas. **Methods:** Searches were conducted in SCOPUS, PUBMED, and Google Scholar for relevant medical and toxicological literature, with an emphasis on human and animal inhalation toxicity studies. The most sensitive health effect was chosen to develop the RELs. Dose-response data from human and animal studies were used to develop acute, 8-hour, and chronic RELs using US EPA's Benchmark Dose Software. The resulting Benchmark Concentrations (BMCs) were adjusted for exposure duration. A Human Equivalent Concentration was calculated and Uncertainty Factors (UFs) were applied to the BMC in accordance with OEHHA's Technical Support Document methodology. **Results:** TMBs are readily absorbed via inhalation and accumulate in adipose tissue. Both acute and chronic exposures to TMBs in animal and human studies showed primarily respiratory and neurotoxic effects. Adverse effects on hematology, clinical chemistry, development, and several other organ systems were also seen. For all three REL values, neurotoxicity was the most sensitive endpoint. The Acute TMB REL is based on a neurobehavioral study in rats in which significant latencies were seen in a number of neurobehavioral tests following exposure to the 1,2,4-TMB isomer for up to 8 hours. The 8-hour and chronic RELs are based on a subchronic neurotoxicity study in rats in which exposure to 1,2,3- or 1,2,4-TMB for 3 months resulted in concentration-dependent disturbances in pain sensitivity and neuromuscular function. Inter- and intra-species UFs were applied and, for all TMB REL values, the intraspecies toxicodynamic component of the UF was increased to 10 from the default factor of 3 because TMBs are neurotoxicants, and likely to impact infants and children disproportionately. An additional subchronic to chronic UF was applied to the chronic and 8-hour REL values since the critical study was only 13 weeks in duration. This yielded an acute TMB REL of 2400 µg/m³ (490 ppb), an 8-hour TMB REL of 8 µg/m³ (2 ppb), and a chronic TMB REL of 4 µg/m³ (1 ppb). **Conclusions:** Because the three TMB isomers share multiple similarities regarding their chemical, toxicokinetic, and toxicological properties, it is expected that the REL values based on one isomer would be adequately health protective for the other isomers. US EPA has adopted a similar approach in the development of their Reference Concentrations for the TMB isomers (USEPA, 2012). Following approval by California's Scientific Review Panel on Toxic Air Contaminants in 2023, the TMB RELs were adopted by OEHHA for use in the Hot Spots Program to assess human health risks associated with emissions of TMBs state-wide. The TMB RELs will be used to identify facilities having localized impacts on nearby communities. If concentrations exceed certain exposure levels, then nearby residents will be informed of potential health risks, and strategies for reducing exposure to acceptable levels can be implemented.

PS 3921 Estrogen Signaling As a Determinant of Immune Vulnerability to Wildfire Smoke Exposure

K. E. Zychowski, M. Oh, E. Lim, S. Yazzie, E. Barr, E. Prossnitz, S. Leng, C. McVeigh, A. Bolt, and J. Gillette. University of New Mexico, Albuquerque, NM.

Background and Purpose: Wildfires are an escalating public health concern that contribute not only to acute respiratory injury but also to long-term impacts on cardiovascular, metabolic, cancer-related and immune-mediated disease. Wood smoke (WS), a major component of wildfire emissions, contains a complex mixture of particulate matter (PM), gases, and volatile organic compounds that can impair host defense and alter systemic immune regulation. Epidemiologic studies have reported associations between air pollution exposure and earlier menopause, as well as links between aging and increased immunological susceptibility following inhaled exposures. Despite these large-scale observations, there remains a significant gap in knowledge regarding immunotoxicological susceptibility during the menopausal transition and the mechanistic role of estradiol, post-WS exposure. **Methods:** In this study we subjected mice (n=10/group) to an acute wood smoke exposure paradigm (0.5mg/m³ 4h/d for 2d) or filtered air (FA, controls) in 1) sham vs. ovariectomized (OVX) mice 2) a mouse model of accelerated ovarian failure (AOF) and 3) wildtype (WT) vs. g-coupled protein estrogen receptor deficient (GPER-/-) mice. **Results:** Bone marrow immune cell profiling indicated significant increase (p<0.05) in CD11c+

dendritic cells and CD19+ B cells, and a decrease in Gr1+ neutrophils and CD11b+ monocyte/macrophage post WS-exposure in OVX mice, but not in Sham mice, as determined by a 2x2 factorial ANOVA. Single cell bone marrow transcriptomics demonstrated statistically significant differential expression between FA and WS in the OVX mice (p<0.05). A moderate AOF mouse model demonstrated diminished CD11b+ cells that was rescued with estradiol supplementation (0.2mg/kg for 60d). M-CSF differentiated macrophages from OVX mice demonstrated metabolic hypersensitivity, as shown by the Seahorse Mito Stress and glycolysis tests. However, this effect has not mediated by GPER, indicating some other estrogen receptor (ERα, ERβ), as a likely mechanistic target. **Conclusions:** Our exciting preliminary studies demonstrate that WS-induced immunotoxicity is dependent on estrogen signaling, highlighting the need to investigate endocrine-immune interactions in environmental susceptibility.

PS 3922 Traffic-related air pollution exposure across the lifespan accelerates age-related renal injury in rats

J. Haverfield¹, L. Aziz¹, M. Faquette¹, A. Bhusal², N. Nasim², A. E. Valenzuela², H. Ahabchane³, K. J. Wilkinson³, A. S. Wexler⁴, K. J. Bein^{4,5}, P. J. Lein^{2,4}, A. K. Ryan^{1,6,7}, and I. R. Gupta^{1,7,6}. ¹Research Institute of the McGill University Health Centre, Montreal, QC, Canada; ²Department of Molecular Biosciences, University of California, Davis, Davis, CA; ³Department of Chemistry, Université de Montréal, Montreal, QC, Canada; ⁴Air Quality Research Center, University of California, Davis, Davis, CA; ⁵Center for Health and the Environment, University of California, Davis, Davis, CA; ⁶Department of Human Genetics, McGill University, Montreal, QC, Canada; and ⁷Department of Pediatrics, McGill University, Montreal, QC, Canada.

Background and Purpose: Traffic-related air pollution (TRAP) comprises a complex mixture of exhaust and non-exhaust emissions, including gases, volatile organic compounds, and particulate matter enriched with metals. Epidemiological studies increasingly link TRAP exposure to heightened chronic kidney disease (CKD) risk, yet causal evidence remains limited because TRAP composition varies by location, time, and meteorological conditions, making it difficult to model true human exposures experimentally. To address this gap, we assessed real-world TRAP exposure by housing rats adjacent to a major freeway and comparing kidneys from animals exposed to either ambient TRAP or filtered air (FA). **Hypothesis:** Exposure to TRAP accelerates age-related renal injury that leads to CKD onset. **Aim:** To assess the effects of TRAP exposure across the lifespan on renal tubule morphology and CKD progression. **Methods:** Thirty-six transgenic Fischer 344 rats were transferred at 1 month of age to a vivarium situated beside a major freeway tunnel system in California. Ambient tunnel air (TRAP; n=18) was delivered unaltered and in real time through supply lines to the exposure chambers for 14 months. As a control, the same ambient air was routed through a series of emissions-control technologies to remove airborne pollutants before entering the chambers to provide clean filtered-air (FA; n=18). All rats were euthanized at 15 months of age, and the kidneys were dissected to assess renal injury and disease. The left kidney was fixed in 4% PFA, paraffin-embedded, sectioned, and stained using histological dyes and immunofluorescence. Whole-kidney brightfield and fluorescence images were acquired using the Zeiss AxioScan. The right kidney was snap-frozen for single-particle time-of-flight ICP-MS to quantify metallic nanoparticles in FA and TRAP kidneys. **Results:** Kidney weights did not differ significantly between TRAP- and FA-exposed animals (mean TRAP = 1.14 g; mean FA = 1.15 g, n = 18/group), including when normalised to body weight. Periodic acid-Schiff staining revealed abundant intratubular renal casts - a hallmark of tubular disease of the kidney - distributed throughout the renal cortex, medulla, and pelvis. Whole-kidney quantification showed a 2.5-fold increase in cast burden in TRAP kidneys (mean 711 per kidney) compared with FA controls (mean 286 per kidney) (n = 5/group). Immunofluorescent staining for kidney injury molecule-1 (KIM-1), a proximal tubule protein that is a biomarker of acute and chronic tubular injury, showed a marked increase in KIM-1-positive tubule cross-sections in TRAP kidneys (mean 104 per kidney) compared with FA kidneys (mean 19 per kidney), representing a 5.5-fold increase (n=3 kidney sections/group). Single-particle time-of-flight ICP-MS identified multiple metallic nanoparticles in TRAP-exposed filters, including Ti, Cr, Mn, Cu, Ag, Sn, Sb, Hf, Pb, and Bi (n=3). Among the elements detected in kidney tissue, Sn was the most enriched, with TRAP-exposed animals exhibiting a six-fold increase in Sn particles compared with FA controls (n=3/group). **Conclusions:** Lifetime TRAP exposure in rats increased the burden of intratubular renal casts, proteinaceous obstructive structures indicative of tubular injury, and markedly elevated KIM-1 expression, suggesting accelerated renal aging and heightened CKD risk. Nanoparticle profiling identified Sn as the most enriched metallic species in TRAP-exposed kidneys, indicating tissue accumulation and highlighting the need to determine the mechanistic contribution of Sn-containing particles to kidney injury and disease.

L. Goodwin¹, R. J. Richter¹, E. Scott¹, C. E. Furlong¹, A. Louie², R. Gupta², M. T. Kleinman³, J. A. Araujo³, and J. Marsillach¹. ¹University of Washington, Seattle, WA; ²University of California, Los Angeles, CA; and ³University of California, Irvine, CA.

Background and Purpose: Diesel exhaust (DE), an important source of particulate matter and other toxic compounds within traffic-related air pollution, generates reactive oxygen species (ROS), often leading to oxidative stress and inflammation in the body. The combination of particulate matter and a high-fat diet (HFD) has been linked to glucose intolerance, as well as an increase in inflammation and oxidative stress. Oxidative stress and inflammation can also lead to dysfunctional high-density lipoproteins (HDL), which can further increase oxidative stress and inflammation. The purpose of this research was to assess the impact of chronic DE exposure and a HFD on oxidative stress and inflammation in plasma, as well as HDL function in mice. An additional aim was to highlight how effects differ based on sex. **Methods:** Two different experimental groups of low-density lipoprotein receptor (*Ldlr*) knockout mice were used: chronic exposure mice (Group 1; male and female) and chronic exposure followed by diet recovery mice (Group 2; male only). Group 1 mice were exposed to filtered air (FA) or DE for 18 weeks, while fed either a high-fat diet (HFD) or Chow. Group 2 mice were exposed to FA or DE and fed HFD for 18 weeks, then fed Chow and exposed to DE or FA for 2 or 8 additional weeks. At the end of exposures, mice were sacrificed, and blood was collected via orbital bleeding and placed in heparinized tubes. Plasma was separated and kept at -80°C until needed for assays. Mouse paraoxonase-1 (Pon1) was measured in plasma using an enzymatic assay with diazoxon as a substrate, as a biomarker of oxidative stress, and serum amyloid A (SAA) was measured in plasma using a sandwich ELISA assay as a biomarker of inflammation. The SAA/Pon1 ratio was calculated and used to assess HDL function. **Results:** Group 1 DE HFD male mice had significantly higher SAA levels than DE HFD female mice. SAA levels in group 1 HFD male mice increased with both FA and DE compared to Chow. Group 1 DE HFD male mice had significantly higher SAA/Pon1 ratios compared to DE Chow male mice and DE HFD female mice. In Group 2 mice, the SAA/Pon1 ratios progressively declined with increasing weeks of diet recovery compared to the ratios observed in Group 1 DE HFD mice. The mice with 8 weeks of diet recovery showed the lowest SAA/Pon1 ratios, although levels remained higher in DE males than in FA males. **Conclusions:** Overall, exposure to DE and HFD in male mice leads to increased inflammation, decreased antioxidant capacity, and ultimately dysfunctional HDL, illustrated by the increased SAA/Pon1 ratios. Sex had a significant effect on SAA levels and SAA/Pon1 ratios in mice exposed to DE and fed HFD, suggesting male mice are more sensitive to the combination of DE and HFD compared to female mice. When HFD male mice exposed to DE for 18 weeks were switched to Chow diet for 8 weeks while exposed to DE, the SAA/Pon1 ratios decreased, indicating improved HDL functionality.

PS 3924 Genetic and Chemical Modulation of Heme Oxygenase-1 Regulates Ultrafine Particle-Induced Inflammation in Macrophages

A. Louie¹, R. Chuang¹, E. Y. Lin¹, S. Prabhu¹, A. Nair¹, A. Moroz¹, M. Sanchez¹, N. Fulton¹, E. Olivo Cauberghe¹, M. Badami², Y. Aghaei², C. Sioutas², and J. A. Araujo¹. ¹University of California, Los Angeles, Los Angeles, CA; and ²University of Southern California, Los Angeles, CA.

Background and Purpose: Ambient air pollution is a well-recognized, major risk factor for atherosclerosis, a chronic inflammatory disorder of the vasculature. Epidemiological, *in vivo*, and *in vitro* studies have supported a mechanism of inflammation and atherogenesis linked to the exposure of fine particles (or particulate matter (PM) with a diameter $\leq 2.5\mu\text{m}$). However, ultrafine particles (UFP; PM with a diameter $\leq 0.1\mu\text{m}$) are likely to pose a greater health risk due to their smaller size and greater adsorbed surface material, but the mechanisms are still unclear. It has been shown that upregulation of systemic Heme oxygenase-1 (HO-1) offers cytoprotection against vascular atherogenesis due to its important antioxidant and anti-inflammatory properties. With macrophages playing a central role in inflammation, atherogenesis, and PM clearance in the most distal regions of the lungs, it is pertinent to understand how PM, and more importantly, UFP, can affect inflammation. We hypothesize that UFP activate inflammatory processes via the upregulation of cytokines and the activation of the inflammasome in macrophages, all of which can be modulated by HO-1 expression. **Methods:** RAW 264.7 macrophages were seeded at 300,000 cells/well at passage 12 and grown overnight. Macrophages were pretreated with cobalt protoporphyrin (CoPPiX) (10 μM), tin protoporphyrin (SnPPiX) (10 μM), UFP (25 $\mu\text{g}/\text{mL}$) or a combination of chemical treatment and UFP for 24 hours. After the exposure duration, RNA was isolated from the cells and cDNA was synthesized. Bone marrow-derived macrophages (BMDMs) were harvested from the femurs of myeloid-specific Heme oxygenase-1 knockout mice (mHO-1-KO) and transgenic overexpressing Heme oxygenase-1 mice (mHO-1-Tg). For controls, BMDMs were harvested from their respective floxed counterparts. Briefly, marrow was extracted from the femurs of multiple mice and pooled (n=6-8) using complete RPMI media and frozen in 90% FBS and 10% DMSO until needed for experiments. BMDMs were cultured and differentiated in RPMI supplemented with M-CSF from L929 conditioned media. BMDMs were seeded at 500,000 cells/well and grown overnight. BMDMs were treated with UFP (25 $\mu\text{g}/\text{mL}$) for 24 hours. After the treatment duration,

RNA was isolated from the cells, and cDNA was synthesized. The expression of cytokines and inflammasome were assessed by quantitative PCR (Roche LightCycler 480) using Taqman probes on 384-well plates. **Results:** Our data show that exposure to UFP induced robust cytokine and inflammasome activation in RAW 264.7 macrophages (p<0.05). The data supports that chemical induction and inhibition of HO-1 modulates cytokine and inflammasome components expression in macrophages, as evidenced by the significant reduction or exacerbation in the expression of specific cytokines and NLRP3 (p<0.05). In BMDMs from control floxed mice, UFP treatment significantly increased cytokine expression. In BMDMs harvested from mHO-1-KO mice, there is an exacerbation of these respective cytokines (p<0.05) and NLRP3. On the contrary, BMDMs from mHO-1-Tg mice had a significant reduction in inflammatory cytokines (p<0.05) as well as decreased expression of NLRP3. **Conclusions:** These data warrant further investigation into the precise molecular mechanisms by which HO-1 exerts its regulatory effects. The observed modulatory capacity suggests that targeted manipulation of HO-1 expression levels could represent a viable therapeutic strategy for mitigating chronic inflammatory diseases, such as atherosclerosis, where environmental particle exposure contributes significantly to pathology.

PS 3925 CO₂ Mediated Regulation of Neutrophil NADPH Oxidase and Interaction with Reactive Nitrogen Species

D. Gupta, C. Guo, E. Abramova, H. Kipen, and A. Gow. Rutgers University, Piscataway, NJ.

Background and Purpose: Carbon dioxide (CO₂) can modulate inflammatory and redox signaling pathways. Previously it's been shown that *in vivo* exposure of mice and *in vitro* exposure of isolated human PMNs to elevated CO₂ levels (10%) stimulated reactive oxygen species (ROS) production, leading to microparticle release and activation of NLRP3 inflammasome. These findings suggest that CO₂ can modify neutrophil function through redox-dependent mechanisms. Literature shows that CO₂ reacts with peroxynitrite (ONOO⁻) to form caged radical nitrosoperoxycarbonate (ONOCO₂⁻), redirecting oxidative chemistry toward nitration rather than direct oxidation. Extending these concepts to human exposures we reported that 12 healthy participants exposed to 2,500 ppm CO₂ exhibited altered oxidative-burst kinetics in circulating PMNs compared with pre-exposure values, suggesting that environmentally relevant CO₂ can modulate innate immune activation. To determine whether CO₂ directly alters neutrophil function, we used differentiated HL60 (dHL60) cells to evaluate bicarbonate-dependent modulation of NADPH oxidase and its interaction with nitric oxide-derived species. We also specifically compared three NO donors—NOC-5, GSNO, and SIN-1, representing distinct redox species. SIN-1 releases both NO and superoxide, forming peroxynitrite, which in the presence of CO₂ favors nitration. GSNO, an S-nitrosothiol donor, causing transnitrosylation of protein thiols, can modulate NOX activity, while NOC-5 releases 2NO leading to nitrosative signaling. **Methods:** HL60 cells were differentiated for 5 days with 1 μM all-trans retinoic acid (RA). Seahorse XFe96 assays were performed with 40,000 cells /well. Sequential injections were as follows with final concentrations: 1) NaHCO₃ (0, 12.5, 25, 50, 100 mM, pH adjusted to 7.4), 2) Rotenone/Antimycin A (0.5 μM), 3) PMA (100 ng/mL) to activate NADPH oxidase, and 4) DPI (10 μM) to inhibit it. The Oxidative Burst (OB) assay was used to study NADPH oxidase activity by measuring real-time oxygen consumption rate (OCR) upon PMA stimulation, which directly reflects NOX2-dependent superoxide generation. Because glycolytic and mitochondrial parameters were unchanged across bicarbonate concentrations, consistent with human data, subsequent experiments focused on OB assays. To test the influence of nitric oxide-related and peroxynitrite signaling, cells were also exposed to NO donors (NOC-5 [150 μM], SIN-1 [1 mM], or GSNO [100 μM]) after Rotenone/Antimycin A and before PMA. **Results:** Increasing NaHCO₃ concentrations produced a dose-dependent reduction in PMA-stimulated oxygen consumption [3412.8 $\pm$ 1391.5 pmole (0 mM NaHCO₃) vs 2691.8 $\pm$ 1042.2 pmole (12.5 mM NaHCO₃), p = 0.046] and [AG1] 3373.7 $\pm$ 1391.5 pmole (0 mM NaHCO₃) vs 1634.1 $\pm$ 1133.5 pmole (25 mM NaHCO₃), p < 0.001] (n=5), indicating suppression of NADPH oxidase activity[AG2]. When SIN-1 (1 mM) was added, AUC (pmole) decreased at low bicarbonate (1924 at 0 mM NaHCO₃ vs 3569 without SIN-1) and at 12.5 mM NaHCO₃ (2197 vs 3473 without SIN-1), but the inhibitory effect plateaued at higher bicarbonate (25 mM = 1732 vs 1747 without SIN-1), suggesting that increasing NaHCO₃ concentration blunted SIN-1's effect. Across replicate runs, consistent dose-dependent inhibition patterns were observed with different NO donors. NOC-5 significantly reduced AUC values (pmole) (0 mM: 4889 $\rightarrow$ 1491; 12.5 mM: 3505 $\rightarrow$ 1672; 25 mM: 2711 $\rightarrow$ 460.6; 50 mM: 202.5 $\rightarrow$ 39.15), while GSNO didn't effect OB (0 mM: 4608 $\rightarrow$ 4025; 12.5 mM: 3348 $\rightarrow$ 3302; 25 mM: 2799 $\rightarrow$ 2594; 50 mM: 470.8 $\rightarrow$ 173.4). **Conclusions:** These data collectively indicate that while bicarbonate alone suppresses NADPH oxidase activity, RNS donors, especially NOC-5 reduces the NOX activity irrespective of bicarbonate and GSNO didn't change PMA induced OB or the effects of bicarbonate. SIN-1 reduces the PMA activity but with bicarbonate the NOX activity loss is restored. We propose that nitrosylation, nitrosation, and nitration are all means by which NOX activity can be regulated and that the presence of CO₂ can alter these reactions. In future studies we will examine how CO₂ and RNS cooperatively regulate NOX and contribute to systemic inflammatory and vascular changes associated with CO₂ exposure. Together, these results support a model in which CO₂ acts not as an inert gas but as a signaling molecule capable of altering neutrophil redox responses and immune activation.

E. Bonner, A. Costa, M. Miller, M. Celente, K. Hall, E. Farstad, and T. McMullin. CTEH, Golden, CO.

Background and Purpose: Ethylene oxide (EO) is a small, reactive gas widely used as a chemical intermediate and as a sterilizing agent for approximately half of all medical devices - many of which cannot be sterilized safely using alternative methods. In 2016, the U.S. Environmental Protection Agency (EPA) released an updated IRIS assessment that classified EO as carcinogenic to humans and derived new inhalation unit risk (IUR) estimates based on dose-response associations in a single sterilization-worker cohort. This revision increased EO potency by roughly 50-fold and introduced substantial regulatory and public health communication challenges, as elevated lifetime excess cancer risks were identified near EO-emitting facilities nationwide, including hospitals previously below reporting thresholds. Subsequent federal and state air monitoring campaigns revealed that EO is ubiquitous in ambient air at concentrations exceeding the 1-in-1-million excess cancer risk benchmark. Characterizing EO in background air is therefore essential to effectively evaluating, managing, and communicating public health risks from a specific EO source. The aim of this study was to compile and summarize federal and state air sampling data across the U.S. to support these data needs. **Methods:** We compiled publicly available US EO monitoring data from federal and state agencies and then conducted a descriptive analysis of the body of existing data, including trends by year, state, and monitoring location. **Results:** EO ambient air sampling data were sparse prior to 2018. Most measurements were first reported in 2018 following EPA's 2014 National Air Toxics Assessment, which incorporated the updated IUR. Between 2018 and 2024, EO monitoring data were available for 23 states and 85 monitoring locations. Monitoring density varied by state, with New York and Washington having the most stations, and years of available data differed across sites. Seven-year background EO concentrations across the 85 stations ranged from 0.013 ppb (10th percentile) to 0.515 ppb (98th percentile), with an overall average of 0.11 ppb. The highest single concentration (20 ppb) was measured in South Carolina in 2022; Virginia reported the highest average concentration. States with the lowest average and maximum levels included Florida, New York, Oregon, California, and Vermont. Overall, most average background concentrations fell between 0.038 and 0.512 ppb. Temporal trends were also investigated due to evolving laboratory detection methods. Colorado, for example, had the highest average EO concentrations in 2018 and lowest in 2024. **Conclusions:** EO is ubiquitous in ambient air across the U.S., and average concentrations are generally consistent across regions. Because current analytical methods cannot reliably detect EO below approximately 0.01 ppb, the concentration corresponding to a 100-in-1-million excess cancer risk, all detectable background levels exceed this regulatory benchmark. Exceedances of the 1- and 100-in-1-million excess cancer risk thresholds are therefore common, even in background air. As a result, quantifying EO in background environments is essential for site-specific risk assessments and for public health assessments associated with EO emissions.

PS 3927 CHEMR23 Signaling Protects Against Ozone-Induced Airspace Inflammation through RvE1 Signaling.

N. Suresh¹, A. Mehta¹, E. Schott¹, S. Varikuti¹, M. Yaeger¹, I. Cumming², G. Hutton¹, T. Ngatikaura¹, B. Kilburg-Basnyat³, R. M. Tighe², S. R. Shaikh⁴, H. B. Lovins¹, and K. M. Gowdy¹. ¹The Ohio State University Wexner Medical Center, Columbus, OH; ²Duke University Medical Center, Durham, NC; ³Arcus Biosciences, Hayward, CA; and ⁴The University of North Carolina at Chapel Hill, Chapel Hill, NC.

Background and Purpose: Ground-level ozone (O₃) is a criteria air pollutant known to trigger exacerbations of chronic respiratory diseases. Inhaled O₃ induces an acute pulmonary inflammatory response involving leukocyte recruitment, proinflammatory cytokine release, and proinflammatory lipid mediator production via n-6 polyunsaturated fatty acids (PUFAs). Specialized pro-resolving mediators (SPMs) are bioactive lipids that are produced during inflammation to promote resolution and restore tissue homeostasis, in part by binding to their corresponding G-protein coupled receptors. Most SPMs are derived from n-3 PUFAs, including Eicosapentaenoic Acid which can be metabolized into Resolvin E1 (RvE1). Prior research from our lab showed that O₃ exposure reduces the pulmonary expression of the RvE1 receptor CHEMR23. CHEMR23 is predominately expressed on macrophages, which play a role in initiating and resolving inflammation. Therefore, we hypothesize that CHEMR23 expression on pulmonary macrophages alters O₃-induced lung inflammation. **Methods:** Male C57BL/6J wild-type (WT) and CHEMR23-knockout (KO) mice were exposed to filtered air or 1 part per million O₃ for 3 hours. At 24 hours post-exposure, bronchoalveolar lavage fluid (BAL) and lung tissue were collected to assess injury and inflammation as well as immune cell quantification via flow cytometry. To evaluate macrophage specific functions of CHEMR23, bone marrow was collected from WT and KO mice and differentiated into bone marrow derived macrophages (BMDMs). BMDMs were treated with lipopolysaccharide (LPS, 100 ng/mL) or PBS followed by RvE1 (100 nM) or vehicle control. After a 4-hour incubation, cell supernatants and lysates were collected to quantify production of pro-inflammatory cytokines. **Results:** Following O₃ exposure, KO mice had increased airspace inflammation compared to WT mice with elevated airspace neutrophilia and proinflammatory cytokines. Furthermore, KO mice exhibited increases in pulmonary lymphocytes after O₃ exposure. RvE1 levels decreased post O₃ exposure in the airspace of WT mice which were further reduced

in KO mice. Using BMDMs collected from WT and KO mice, RvE1 treatment following LPS stimulation reduced cytokine expression in WT BMDMs. However, there was no change in LPS induction of cytokines in KO BMDMs following RvE1 treatment. **Conclusions:** Taken together, our results indicate that the absence of the CHEMR23 receptor augments O₃-induced airspace inflammation. LPS-induced inflammation was reduced with RvE1 treatment in WT BMDMs, but not in KO BMDMs, suggesting RvE1's anti-inflammatory treatment is mediated through CHEMR23 signaling. Future studies will analyze primary macrophages in the lung after O₃ exposure to determine if CHEMR23 signaling drives resolution responses.

PS 3928 Exploring the Role of Retinoids in Protecting the Lungs Against Inhaled Ozone

N. Ficken, K. Vayas, V. Sunil, A. J. Gow, D. L. Laskin, and I. Shmarakov. Rutgers University, Piscataway, NJ.

Background and Purpose: Ozone (O₃) is a criteria air pollutant and a powerful oxidant that can damage cell membranes in the lungs, leading to the activation of both proinflammatory and anti-inflammatory macrophages. The extent of lung inflammatory responses to O₃ exposure is defined by the alveolar microenvironment, specifically by the ability of macrophages residing in the alveolar-epithelial region to tolerate the direct cytotoxic actions of O₃ and to maintain effective intercellular signaling aimed at repairing injured tissue. Retinoids (vitamin A and its metabolites) are vital for maintaining adult lung health and function, especially during lung injury. These effects are predominantly mediated via the actions of all-trans-retinoic acid (ATRA), the most active retinoid metabolite, which serves as a transcriptional regulator of cell proliferation, differentiation, and intercellular signaling within the alveolar niche. The adult lungs accumulate retinoids due to the action of lecithin:retinol acyltransferase (Lrat), which catalyzes the esterification of dietary retinol (ROH) and allows for the accumulation of retinyl esters (RE). Locally stored REs have been shown to protect the lung against acute injury. These studies aimed to explore the role of retinoids in O₃ toxicity and their underlying mechanisms of action. **Methods:** Groups of male and female mice (10-12 wk, n=5-10/group) were exposed to ultrapure air or O₃ (0.8 ppm) for 3 h. To explore the actions of retinoids, groups of animals with different lung retinoid levels were employed, including: 1) *Lrat*^{-/-} mice (a genetic animal model deficient in tissue REs), 2) *Lrat*^{+/+} (wild type) mice (a control group kept on a chow diet with 15 IU/g of vitamin A) and 3) *Lrat*^{+/+} + VA mice (a high vitamin A group fed a chow diet with 200 IU/g of vitamin A for 6 wk prior to air or ozone exposure). Mice were euthanized 24, 48, and 72 h after exposure. Bronchoalveolar lavage (BAL) fluid, macrophages, plasma, and lung tissues were collected. Lung and plasma retinoids were analyzed using HPLC. Total RNAs were isolated from lung tissues and AMS, followed by cDNA synthesis using 1 µg of total RNA, and assessing gene expression by qRT-PCR. Expression levels of target genes were normalized to the reference gene 18S. Statistical differences between air- and O₃-treated groups, as well as between groups with different lung retinoid concentrations, were analyzed by ANOVA, p<0.05 was considered significant. **Results:** Exposure of wild-type mice to O₃ resulted in pulmonary inflammation, characterized by upregulation of lung proinflammatory genes (*Tnfa*, *Il-1β*, *Ptges*) as early as 48 h postexposure, followed by upregulated expression of reparative genes (*Tgfb*, *Col1a1*, *Acta2*) at 72 h postexposure. This was associated with a progressive decline in retinoid concentrations in lung tissue in both males and females as early as 24 h post-exposure. A significant elevation of canonical ATRA-responsive genes (*Rarg*, *Stra6*, *Cyp26b1*) was also noted at this time, suggesting activation of local lung retinoid mobilization required to assure upregulated ATRA-mediated signaling, a protective response to O₃. *Lrat*^{-/-} animals exhibited earlier (24 h post exposure) and significantly greater upregulation of proinflammatory gene expression, suggesting a more pronounced inflammatory response to O₃ by lungs lacking locally stored REs. Conversely, lung expression of proinflammatory genes in animals supplemented with dietary vitamin A prior to O₃ exposure was significantly lower when compared to wild-type and *Lrat*^{-/-} mice and was not different from that of air-treated animals, even 72 h post-exposure, suggesting that inflammation was mitigated in lungs with high RE stores. **Conclusions:** Lung retinoid metabolism and signaling are responsive to cellular damage induced by acute O₃ exposure. A lack of tissue retinoids contributes to an amplified inflammatory response. Dietary supplementation with vitamin A, resulting in higher lung retinoid concentrations, has a protective effect on the lungs against O₃ exposure. **Support:** NIH Grants ES005022, ES004738, HL171112.

PS 3929 Targeting All-trans-Retinoic Acid Signaling to Mitigate Ozone Respiratory Toxicity

I. Shmarakov, A. J. Gow, and D. L. Laskin. Rutgers University, Piscataway, NJ.

Background and Purpose: Environmental exposure to air pollutants is the leading cause of lung functional impairments and respiratory diseases worldwide. According to the WHO, more than 7 million premature deaths occur annually due to polluted air and air pollution-related illnesses. It is essential to identify effective and impactful strategies, including nutritional and pharmacological interventions, aimed at alleviating lung injuries resulting from environmental exposure to polluted air and preventing long-term lung pathologies. Retinoids (vitamin A and its metabolites) are essential for pre- and post-natal lung development and lung health. All-trans-retinoic

acid (ATRA), a transcriptionally active retinoid species, and its three distinct cognate nuclear hormone receptors, retinoic acid receptors (RAR α , - β , and - γ), mediate these processes by regulating lung cell proliferation, differentiation, and communication among lung macrophages, alveolar fibroblasts, epithelial, and endothelial cells. The physiological ramifications of ATRA-RAR signaling in the context of respiratory toxicology, as well as its cell-specific targeting to mitigate polluted air-borne lung injuries, have not been systematically explored. Our studies focus on understanding the mechanisms behind the protective actions of ATRA-RAR signaling in mitigating respiratory toxicity and associated lung disease resulting from exposure to air pollutants using ozone (O₃) as a criteria air pollutant. **Methods:** To test the hypotheses that stimulation of lung cell-specific ATRA-RAR signaling enhances lung resilience and function after exposure to O₃, mouse models of chronic and acute O₃ exposure are utilized, coupled with dietary (vitamin A-containing diets), pharmacological (RAR isoform-specific agonists and antagonists), and genetic (animal models lacking tissue retinoid stores or ablated RAR signaling) manipulations. Single-cell RNA-sequencing (scRNA-seq) is employed to assess lung cell-specific responses to O₃ exposure, followed by validation of transcriptional responses (qRT-PCR), protein expression (immunoblot and immunofluorescent staining), and retinoid concentrations (HPLC) in either whole lung tissue or primary lung cell populations (macrophages, fibroblasts, epithelial, and endothelial cells) isolated postexposure from animals with different vitamin A supplementation or altered ATRA-RAR signaling. **Results:** Exposure of mice to O₃ results in pulmonary inflammation, characterized by upregulation of lung proinflammatory genes (*Tnfa*, *Il-1 β* , *Ptges*) in transcriptionally diverse macrophages, followed by upregulation of reparative gene (*Tgfb β* , *Col1a1*, *Acta2*) expression by functionally heterogeneous activated lung fibroblast populations. This response is associated with a progressive decline in retinoid (retinol and retinyl esters) concentrations in lung tissue and a significant elevation of canonical ATRA-responsive genes driven by RAR α in lung structural cells and RAR γ in immune cells. Taken together, the data suggest activation of local lung retinoid mobilization for enhanced ATRA synthesis and upregulated cell-specific ATRA-RAR signaling, a protective response to O₃. Moreover, a lack of sufficient retinoid stores, as well as compromised RAR signaling, makes the lung highly susceptible to the damaging actions of O₃, resulting in enhanced lung inflammation and functional impairments. Dietary interventions employing vitamin A-supplemented diets or pharmacological manipulations involving RAR α agonists and RAR γ antagonists rescue the altered lung phenotype by reducing O₃-induced macrophage-associated inflammation and improving functional activities of lung epithelial and endothelial cells. **Conclusions:** Lung ATRA-RAR signaling is responsive to cellular damage induced by O₃ exposure in a cell-specific manner. Targeted stimulation of ATRA-RAR signaling with dietary supplementation with vitamin A, resulting in higher lung retinoid concentrations, has a protective effect on the lungs against O₃ exposure. Our studies can have a meaningful impact on public health by providing new mechanistic insights into how vitamin A can protect the lungs from O₃ and how individual nutritional interventions with vitamin A can minimize the risk of lung injury and optimize lung health during inhaled exposures. **Support:** NIH Grants ES005022, ES004738, HL171112.

PS 3930 The Interactions between Chromosomal and Gonadal Sex Affect Lung Function After Sub-Chronic Ozone Exposure

D. Rousselle, C. D. Ekpruke, and P. Silveyra. Indiana University, Bloomington, IN.

Background and Purpose: Epidemiological studies have shown that when exposed to ambient ozone, women typically have worse lung health outcomes such as higher mortality and decreased lung function compared to men. Animal models of acute ozone exposure have recapitulated sex differences in pulmonary responses; however, data remain conflictive. Previously, our lab found that hormone status modulates lung responses to acute ozone exposure. The contributions of sex hormones and the sex-specific responses to chronic or sub-chronic exposures remain understudied. To address this gap, we are using the Four-Core Genotype (FCG) mice, a mouse model where gonadal sex and chromosomal sex are independent of each other, to understand how same-sex and opposite-sex hormones alter the response to sub-chronic ozone. **Methods:** We exposed adult FCG mice to 1.5 ppm of ozone for 2 hours, twice a week, for 6 weeks (4-7 mice per experimental group). At 24 hours after the last exposure, mice were anesthetized, administered a paralytic, and attached to a rodent ventilator (flexiVent, Scireq). Baseline lung function data was recorded, including PV loops, inspiratory capacity, airway resistance, elastance, and compliance. Three-way ANOVAs with Tukey tests were used for statistical analyses with significance at p-value < 0.05. **Results:** Our preliminary results indicate that PV loops for the FCG mouse model varied after exposure to ozone depending on their combined chromosome and gonad composition. Mice with the XY sex-chromosome complement had no significant response to the ozone exposure, however mice with the XX sex-chromosome complement had changes to their PV loops. XX mice with testes had a reduction in volume for the given pressures, and XX mice with ovaries had an increase in volume for the given pressures. The XX mice with ovaries also showed a significant decrease in elastance (p < 0.0001), a significant increase in inspiratory capacity (p < 0.01), and a significant decrease in compliance (p < 0.001). **Conclusions:** After exposure to ozone, the increase in volumes for given pressures on the PV loop for the XX mice with ovaries suggests a shift towards emphysema, while the decrease in volumes for given pressures in the XX mice with testes suggests a shift towards fibrosis. Furthermore, the emphysema phenotype for the XX mice with ovaries is further evident by the significant increase in inspiratory capacity and decrease in elastance. In contrast, the XX mice with testes did not display the

typical increase in elastance expected of a fibrosis phenotype. In conclusion, our data show that the combination of gonads and hormones affect lung function after sub-chronic exposure to ozone. Future histological analysis will confirm these lung disease progressions in the response to ozone.

PS 3931 Effects of Sub-Chronic Ozone Exposure on Ovarian Follicular Development and Gene Expression in Adult Female Mice

A. Joyce, D. Rousselle, and P. Silveyra. Indiana University Bloomington, Bloomington, IN.

Background and Purpose: Ozone is a highly reactive gas known to trigger lung inflammation, oxidative stress, and other deleterious health effects when inhaled. Previous work in our lab has also shown that these systemic inflammatory responses may affect the hypothalamic-pituitary-gonadal (HPG) axis. The HPG axis is responsible for steroidogenesis for reproductive processes. These hormones contribute to the development and maturation of ovarian follicles, which are eventually released during ovulation. This study aimed to quantify changes in hormone production and follicle development following a sub-chronic ozone exposure in mice. Based on prior studies on acute exposures, we hypothesized that sub-chronic ozone exposure would result in stunted follicular development and altered hormone gene expression in the HPG axis. **Methods:** To test this hypothesis, we exposed adult female mice to 1.5 ppm ozone for 2 hours, twice a week for 6 weeks (n=5/group), or filtered air (control). At 24 hours after the last exposure, mice were euthanized, and blood, brains, and ovaries were collected. One ovary was used for histological analysis, where ovarian follicles were counted at varying stages of development. RNA was extracted from the other ovary, the pituitary gland, and the hypothalamus. Real-time qPCR with Taqman assays was used to determine the expression of gonadotropin-releasing hormone (GnRH) in the hypothalamus, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and GnRH receptor (GnRHR) in the pituitary gland, FSH receptor (FSHR), progesterone receptor (PGR), and LH receptor (LHCGR) in the ovaries, and 18S RNA as the endogenous control. Two-sample t-tests compared gene expression between ozone-exposed mice and controls in all tissues, with p-values < 0.05 considered significant. **Results:** Our preliminary results showed no significant difference in gene expression for any of the hormones or receptors measured. However, ozone-exposed mice showed a large increase in pituitary FSH expression, with a relative fold change 4 times higher than mice exposed to filtered air. The ozone group also showed significantly lower corpora lutea counts in ovarian histology (p<0.05), with means of 5.25 $\pm$ 0.24 in filtered air and 2.83 $\pm$ 0.07 in ozone. There were no significant changes in all other follicle stages. **Conclusions:** In conclusion, a lower corpus luteum count after sub-chronic ozone exposure suggests less frequent ovulation success. The potentially higher FSH expression could indicate the staggered peaking of FSH and LH to stimulate ovulation. Because LH and FSH together control the ovulation process, a relative difference in levels of the two may decrease ovulation success, which may contribute to the differential corpus lutea count. Future directions include increasing sample size to reduce variability, measuring hormones, and investigating intermediates induced by FSH prior to ovulation.

PS 3932 Ozone-Induced Lung Injury Increases Susceptibility to Lower Respiratory Infections by Elevating Airspace Iron Concentrations

E. Schott¹, S. J. Cochran¹, G. Hutton¹, M. J. Yaeger¹, M. I. McFadden¹, J. M. Baker², H. Lovins³, A. Lutton¹, J. Olesik¹, R. P. Dickson², A. Forero¹, R. M. Tighe⁴, M. E. Long¹, and K. M. Gowdy¹. ¹The Ohio State University, Columbus, OH; ²University of Michigan, Ann Arbor, MI; ³The University of Findlay, Findlay, OH; and ⁴Duke University, Durham, NC.

Background and Purpose: Epidemiological studies reported that increases in ambient air pollution associate with increased risk for hospitalization and/or mortality from lower respiratory tract infections. Acute elevations in ground level ozone (O₃), a criteria air pollutant produced by heat and sunlight reacting with volatile organic compounds and nitric oxides, increase hospitalization due to respiratory infections such as community acquired pneumonia. Despite this apparent susceptibility to infection, acute O₃ exposure stimulates the pulmonary immune response, and induces pulmonary inflammation through disruption of iron homeostasis. Prior research in our lab and others identified that acute O₃ exposure increases airspace iron and iron associated proteins. However, if this contributes to increased lung infection susceptibility is not fully understood. To uncover these specific mechanisms, we utilized a murine model of O₃-exposure followed by a pulmonary infection to test the hypothesis that O₃ increases susceptibility to pneumonia by promoting an airway microenvironment that favors pathogen growth. **Methods:** Male C57Bl/6J (WT) mice were exposed to filtered air (FA) or 1 ppm O₃ for 3h, and then 24h after exposure, mice were infected by oropharyngeal aspiration with 2000 colony forming units of the gram-negative bacteria *Klebsiella pneumoniae* (Kp). Mice were necropsied 24h post-infection and lung tissue and blood were obtained to quantify bacterial burden. Bronchoalveolar lavage fluid (BAL) was evaluated to define the pulmonary immune response. BAL protein levels were assessed to quantify lung injury, whereas lung inflammation was assessed by BAL leukocyte differentials and histopathology. Inductively coupled plasma-mass spectrometry (ICP-MS) was used to measure iron levels within the BAL and lung tissue was used for bulk RNA-sequencing. To

determine if factors within O₃-exposed lung directly promote bacterial pathogenesis, BAL from WT mice 24h post FA or 1 ppm O₃ exposure was incubated with *Kp*, and bacterial proliferation was assessed. Lastly, to understand how iron impacts bacterial growth following O₃ exposure, we utilized *Kp* mutants deficient in siderophore production, a key bacterial mechanism of iron acquisition, to assess bacterial proliferation and markers of lung injury and inflammation. **Results:** 24h following *Kp* infection, O₃-exposed mice, when compared to FA controls, had a significant increase in bacterial burden in lung tissue and blood. O₃-exposed *Kp*-infected mice also had a significant increase in airspace neutrophilia and total BAL protein. Transcriptional analysis of lung tissue by RNA-sequencing indicated that O₃-exposed mice infected with *Kp* had a significant increase in expression of genes related to immune pathways. Assessment of BAL iron concentration indicated airspace iron levels were significantly increased 24h following O₃-exposure when compared to FA. Based on the evidence of increased iron and increased infection risk and severity, we tested the direct potential relationship to airspace iron. First, we determined if cell free BAL increased *Kp* growth, observing an increase with co-incubation of *Kp* with BAL from O₃ exposed mice. To remove the potential for BAL proteins as causal factors, we heat inactivated the BAL. Consistent with the suggestion of iron as the driving reason for increased *Kp* growth, heat-inactivated BAL from O₃ exposed mice continued to increase *Kp* growth. Finally, we assess if this was a direct effect by using BAL from O₃ exposed mice with a *Kp* that lacks siderophores that would allow it to take up iron. In this setting, the pro-growth support of BAL from O₃ exposed mice was lost. **Conclusions:** Taken together, these data suggest that O₃-induced increases in airspace iron promote a microenvironment conducive to bacterial infection, ultimately increasing disease severity. Ongoing studies will identify how iron supplementation or depletion, through use of iron chelators, affects airspace *Kp* proliferation. Additionally, investigations as to how iron deposits in the lung following O₃ exposure to assess the mechanism or cell type responsible for elevations in airspace iron following O₃ exposure.

PS 3933 Prior Viral Lung Injury Enhances Lung Inflammation to Subsequent Ozone Exposure

C. Rankin¹, M. Albright², R. Nafikova³, A. Misharin³, and R. Tighe². ¹Nicholas School of the Environment, Integrated Toxicology and Environmental Health Program, Duke University, Durham, NC; ²Department of Medicine, Duke University Medical Center, Durham, NC; and ³Northwestern University Feinberg School of Medicine, Chicago, IL.

Background and Purpose: Exposure to ozone (O₃) increases the risk of significant cardiopulmonary events, in part due to increased and persistent lung inflammation. One question is if prior lung injury events sensitize the lung to enhanced or more persistent O₃-induced lung injury. In the present study, we define if O₃-induced lung injury is enhanced in mice that recover from prior influenza infection. **Methods:** We inoculated mice with 25 PFUs of H1N1 (WSN33) or heat-inactivated virus suspended in PBS via intratracheal administration and monitored weights for 21 days post-infection. At 21 days, when the mice had recovered from infection, they were exposed to either filtered air or O₃ (2 ppm x 3 hours) in a whole rodent exposure chamber. 24 hours post-exposure, mice were euthanized with ketamine/xylazine and bronchoalveolar lavage fluid (BALF) was collected to analyze for total protein, cell counts, and cell differentials. One-way ANOVA with Tukey's post-hoc analyses evaluated relationships among treatment conditions and endpoints. **Results:** Mice exposed to influenza lost on average 18% of total body weight before returning to their original starting weight over a three week period, suggesting adequate infection and recovery responses. Maximum weight loss was observed on day 11 with mice returning to starting weight by day 15. No mice experienced mortality as a sublethal infection model was desired. Influenza/ozone-exposed mice had higher total protein in their BALF than influenza/filtered air and heat-inactivated/ozone mice, suggesting enhanced lung injury. Additionally, influenza/ozone-exposed mice had more BALF macrophages than heat inactivated/ozone mice and more BALF neutrophils than influenza/filtered air and heat-inactivated/ozone mice, suggesting enhanced lung inflammation. **Conclusions:** Our data suggest that following recovery from a viral infection, mice have enhanced lung inflammation and injury to subsequent O₃ exposure. This is evidenced by increases in total protein and BALF macrophages and neutrophils. This suggests that prior injury responses may prime the lung to enhanced lung injury to subsequent air pollution exposure and could be a reason for persistent respiratory symptoms following infection. Future work will define how changes in immune cell composition following influenza infection could drive augmented O₃-induced lung injury.

PS 3934 Exaggerated defects in pulmonary mechanics following ozone exposure in mice lacking GCN2

J. R. Rodriguez, K. N. Vayas, E. V. Abramova, P. Zhou, T. G. Anthony, J. D. Laskin, A. J. Gow, and D. L. Laskin. Rutgers University, Piscataway, NJ.

Background and Purpose: Ozone is a criteria air pollutant known to cause injury, oxidative stress and inflammation in the lungs and to exacerbate chronic diseases such as asthma. This is associated with alterations in pulmonary function including airway hyperresponsiveness in both humans and rodents. We previously demonstrated increased airway resistance and decreased tissue elastance and lung volume

following acute ozone exposure in mice. Moreover, ozone causes a reduction in surfactant protein B (SP-B), a component of pulmonary surfactants, which are critical for proper lung functioning. Biochemical pathways underlying the effects of ozone are not fully understood. The integrated stress response (ISR) plays a key role in regulating anti-inflammatory and antioxidant responses. We discovered that ISR signaling through the activating kinase, GCN2, is important in protecting against ozone-induced lung injury and inflammation. Thus, loss of GCN2 exacerbates alveolar epithelial dysfunction leading to increased neutrophil accumulation in the lungs following ozone exposure. The effects of loss of GCN2 on pulmonary mechanics are unknown and were evaluated herein. We hypothesized that lack of GCN2 will lead to more pronounced lung dysfunction following acute ozone exposure. **Methods:** Male and female C57BL/6 wild-type (WT) and whole-body GCN2 knockout (GCN2^{-/-}) mice (11-14 wk) were exposed to filtered air or ozone (0.8 ppm) in a whole-body Plexiglass chamber for 3 hr. Mice were anesthetized 3 or 24 hr later and respiratory mechanics measured using a SCIREQ flexiVent small animal ventilator. A one-phase decay nonlinear regression line was fit to the real and imaginary values from forced oscillometry to analyze resistance and reactance respectively; Y0 and plateau values were compared to evaluate differences in the lower and upper respiratory tract. At 3 hr post-exposure, pressure-volume (PV) loops were generated and the area between inspiratory and expiratory curves calculated at positive end expiratory pressures (PEEP) of 1, 3, 6, and 9 cm H₂O. At 24 hr post-exposure, PV loops and PV loop area were generated at a PEEP of 3 cm H₂O; evaluation of airway resistance following methacholine challenge at 0, 6, 12, 48, 96 mg/mL was assessed. Lung expression of SP-B was analyzed by western blotting. **Results:** At 3 hr post ozone exposure, a significant decrease in PV loop area was noted in GCN2^{-/-} mice, but not WT mice at PEEPs 1 and 3 cm H₂O; this decrease persisted for at least 24 hr at PEEP 3 cm H₂O. Analysis of forced oscillometry revealed a frequency-dependent increase in airway resistance in GCN2^{-/-} mice compared to WT mice at PEEP 3 cm H₂O, 3 and 24 hr following ozone exposure, consistent with bronchoconstriction. Methacholine challenge at 24 hr resulted in a dose dependent increase in resistance in WT mice, with no difference between air and ozone exposures. GCN2^{-/-} mice were unresponsive to methacholine, a response independent of air or ozone exposure. No significant changes in expression of SP-B were observed following ozone exposure in either genotype. **Conclusions:** Loss of GCN2 leads to persistent functional alterations in the airways, but not in parenchymal tissue, as evidenced by differences in resistance at both 3 and 24 hr after exposure to ozone, with no change in reactance. This is supported by findings that ozone had no effect on expression of SP-B in GCN2^{-/-} mice and that air-exposed GCN2^{-/-} mice were unresponsive to methacholine. Alterations in airway function could also explain the significant reduction in PV loop area observed in GCN2^{-/-} mice following ozone exposure at lower PEEPs (1 and 3 cm H₂O). Moreover, because these effects are observed at 3 h post-exposure, it is likely that direct oxidative effects of ozone on the airways drive these changes. **Support:** NIH grants ES004738 and ES005022, and the Air Pollution Educational and Research Grant (APERG) Scholarship Program.

PS 3935 Prolonged Ozone Exposure Induces Sex-Specific Changes in the Gut Microbiota and Production of Short Chain Fatty Acids in Mice

C. R. Longoria¹, P. Zhou¹, V. Sunil¹, K. Vayas¹, J. D. Laskin¹, N. Burchat², H. Sampath², L. B. Joseph¹, S. C. Campbell², and D. L. Laskin¹. ¹Rutgers University, Piscataway, NJ; and ²Rutgers University, New Brunswick, NJ.

Background and Purpose: Prolonged exposure to ozone is known to induce pulmonary injury, oxidative stress and altered lung functioning; it has been linked to exacerbation of chronic respiratory diseases including asthma, bronchitis, and emphysema. Evidence suggests that the onset of these respiratory diseases is accompanied by changes in gastrointestinal health, the gut microbiota, and gut-derived metabolites such as short chain fatty acids (SCFAs). The effects of prolonged ozone exposure on the gut microbiota and cecal SCFAs are unknown and were assessed in the present studies. **Methods:** C57BL/6 mice (11 wk, male and female) were exposed to filtered air or 1.5 ppm ozone for 2h, 2x/wk for 6wk; mice were euthanized 24 hr after the final exposure. Fecal samples were collected from the distal colon for gut microbiota analysis. Genomic DNA was extracted using QIAamp PowerFecal Pro DNA kit and the V4 hypervariable region of the 16S rRNA gene was amplified using fusion primers, ligated to adapters, and then barcoded. Bacterial DNA sequencing was performed using the Ion GeneStudio S5, and amplicon sequence variants (ASVs) identified and matched. Alpha diversity (Shannon index, observed ASVs, and Faith's Phylogenetic Diversity (PD)) and relative abundance of bacteria were analyzed using QIIME2 and the phyloseq package in R. Statistical comparison was performed using a Kruskal Wallis test paired with Dunn's post hoc and p<0.05. SCFAs were assayed using gas chromatography-mass spectrometry from snap frozen cecal samples. Beta diversity (Bray-Curtis) was performed in the vegan R package and statistical comparisons of community dissimilarity between groups were analyzed using permutational multivariate analysis of variance paired with a Bonferroni post-hoc (p<0.05). Colon tissue mRNA expression of free fatty acid receptors (Ffar) 2 and 3, Olfr78, and Hcar2, which bind to and transport the SCFAs acetate, propionate, and butyrate, were analyzed using a two-way ANOVA paired with Tukey's posthoc and p<0.05. **Results:** Alpha diversity (gut microbiota differences within a community) identified a significant increase in observed ASVs within female, but not male, mice exposed to ozone when compared to air. No differences were observed in the Shannon Index, which examines species richness and diversity. Beta diversity (gut microbiota differences between communities) identified significant differences

between mice exposed to air compared to ozone in both sexes. At the phyla level, a significant increase in the relative abundance of Bacteroidota and a significant decrease in Bacillota and Proteobacteria was noted in both sexes. Following ozone exposure, there were significant decreases in the SCFA-producing genera *Alistipes* in female mice and *Faecalibaculum* in male mice compared to air-exposed mice. Additionally, an increased abundance of *Clostridia* UCG-014, a genus associated with inflammation, was observed in male mice exposed to ozone. Whereas decreases in acetate and propionate were evident in response to ozone in male and female mice, respectively, butyrate was increased in both sexes. Expression of *Ffar2* was significantly reduced in males, while *Hcar2* expression was significantly increased in female mice after ozone exposure. **Conclusions:** Prolonged ozone exposure alters bacterial communities in both male and female mice; notably, ozone causes a decrease in abundance of SCFA-producing bacteria and an increase in inflammatory gut microbes, responses that can influence cecal levels of acetate and propionate. Increases in butyrate likely reflect compensatory production following ozone exposure. mRNA expression of SCFA receptors is also altered by ozone in a sex-related manner, which suggests that there are distinct responses to ozone exposure in the colon of males and females.

PS 3936 Sex Differences in Airway Inflammation and Remodeling after Repeated Ozone Exposure in CC002 Mice

M. Ramar, A. D. Singh, G. L. Riley, III, L. Gao, C. Blesso, and L. C. Smith. University of Connecticut, Storrs, CT.

Background and Purpose: An increased frequency of extreme weather events, including wildfires and heat waves, enhances the formation of ozone and results in more consecutive ozone action days. This is a significant problem as ozone is a highly reactive and oxidizing gas that increases the development of new cases and worsens existing cases of non-allergic asthma. In this regard, studies using the genetically diverse Collaborative Cross strain CC002 have reported increased pathological hallmarks of non-allergic asthma, including airway eosinophilia and collagen deposition, after repeated exposure to ozone. Epidemiological studies report females exhibit increased severity and prevalence of non-allergic asthma relative to males, but whether this is influenced by ozone exposure is not known. We hypothesized that repeated exposure to ozone would result in increased eosinophilic inflammation and airway remodeling in female CC002 mice compared to males. **Methods:** Adult male and female CC002 mice were exposed to filtered air or ozone (0.8 ppm, 4 hr/day for 9 days) and euthanized 24 hr after the last exposure. Total protein content, IgM, and cytokine levels were analyzed in bronchoalveolar lavage (BAL) fluid by BCA, ELISA, and MILLIPLEX Multiplex assays, respectively. Eosinophils were enumerated in differentially stained BAL cytosins. Collagen content around small airways was quantified in Masson's Trichrome stained lung histological sections using QuPath image analysis software. mRNA expression was analyzed in lung tissue by qPCR. Data were analyzed by two-way ANOVA followed by Šidák's multiple comparisons test. **Results:** Repeated exposure to ozone significantly increased BAL levels of biomarkers of lung injury (total protein and IgM). No sex differences were observed, indicating that anatomical variation between males and females did not affect ozone deposition and degree of injury. Interestingly, female mice exhibited a significant increase in the number of eosinophils and levels of the eosinophil-derived cytokine, CXCL1, in BAL, and CXCL1 mRNA expression in lung tissue after repeated ozone exposure compared to males. This was associated with significantly enhanced collagen deposition around the small airways in ozone-exposed females relative to males. **Conclusions:** These results indicate that repeated exposure to ozone results in a more pronounced eosinophilic inflammation and airway remodeling response in female mice compared to males. We speculate that this is due to immune-potentiating actions of female gonadal steroid hormones, as the degree of lung injury was similar in males and females. Importantly, these sex differences mirror those observed in humans; thus, this model represents an ideal tool to investigate mechanisms underlying sex differences in non-allergic asthma.

PS 3937 Impact of Ozone Exposure Timing on Lung Injury and Inflammation in a Model of SurfactantProtein-C-Driven Inflammatory Exacerbations of Pulmonary Fibrosis

C. B. Montgomery¹, J. R. Cheminant², M. Buddy², and A. Venosa¹. ¹UC Davis, Davis, CA; and ²University of Utah, Salt Lake City, UT.

Background and Purpose: Pulmonary fibrosis (PF) is a form of interstitial lung disease characterized by progressive scarring of the alveolar compartment, leading to pathogenic loss of pulmonary function and mortality within 5 years of diagnosis. The fibrotic phenotype is often accelerated and exacerbated by acute inflammatory events. Although the initiating factors are often unknown, exposure to environmental stressors and air pollution are recognized contributors of this phenotype. Ozone (O₃) is a ubiquitous toxicant known to produce immediate but reversible epithelial damage, loss of alveolar function, airway hyperreactivity, and inflammatory cells infiltration and activation in healthy individuals. The effects in the susceptible or fibrosing lung are not fully established. We have previously described and developed a murine model of inflammatory exacerbations triggered by the induction of a PF-linked mutation in the Surfactant Protein C (*SP-C*^{T73T}) gene. We therefore set to investigate the

effects of O₃ exposure occurring at various times of an *SP-C*^{T73T}-induced exacerbations. **Methods:** Mutant *SP-C* induction is achieved through tamoxifen oral gavage (175 mg/kg, corn oil used as a control). O₃ exposure (800ppb, 3 hours) conducted on day 4 post tamoxifen gavage. A separate paradigm involved two O₃ exposures 48 hours apart from each other, prior to tamoxifen gavage. All experiments were terminated 7 days post tamoxifen. Bronchoalveolar lavage fluid was collected for cell counts, while perfused lungs were split for histological and histochemical analysis (right lobes) and flow cytometry (left lobe). **Results:** Histological evidence of septal injury and fibrosis induced by *SP-C* mutant induction were not significantly impacted by O₃, regardless of the timing of exposure. Mortality was significantly increased in the group receiving O₃ exposure following the initiation of an inflammatory exacerbation. Flow cytometric analysis showed that pre- or post-induction exposure does not have additive effects on myeloid and lymphoid cells relative abundance up to 7 days. This phenotype was characterized by increased neutrophilia and eosinophilia paired with drops in CD3⁺ lymphocytes and B cells. Histochemical analysis revealed changes in cellular proliferation (Ki-67) in the lungs of mice exposed to O₃ prior to an exacerbation. **Conclusions:** These results suggest that acute ozone exposure does not significantly alter the early trajectory of a fibrogenic exacerbation triggered by alveolar epithelial dysfunction in the *SP-C* mutant mouse. Further work will define any delayed effects and the impact of chronicity in this phenotype.

PS 3938 Alveolar Macrophage Temporal Transcriptional Plasticity in Response to Acute Ozone Exposure

I. Patil¹, L. C. Smith², A. J. Gow¹, J. D. Laskin¹, D. L. Laskin¹, and I. Shmarakov¹. ¹Rutgers University, Piscataway, NJ; and ²University of Connecticut, Storrs, CT.

Background and Purpose: Ozone (O₃) is a ubiquitous urban air pollutant. Inhaled O₃ causes protein and lipid oxidation, and the formation of aldehydes and free radicals in the alveoli, leading to lung damage and inflammation. Evidence suggests that macrophages contribute to the initiation and resolution of tissue injury induced by O₃. This activity is mediated by distinct subpopulations of these cells. Herein, the cell-specific temporal transcriptional responses of macrophages were assessed. We hypothesize that macrophage transcriptional plasticity orchestrates cellular responses to O₃ exposure. **Methods:** Female mice were exposed to air or ozone (0.8 ppm) for 3 h. To map the dynamics of lung macrophages and their transcriptional signatures in the intraalveolar compartment of the mouse lung after O₃ exposure, bronchoalveolar lavage (BAL) cells were profiled by single-cell RNA sequencing (scRNA-seq), capturing the alveolar injury (24 h) and reparative resolution (72 h) phases. Single-cell libraries, prepared using the Chromium Single Cell 3' Reagent Kits v3.1, were sequenced on a NovaSeq 6000 (Illumina) in a 2 x 100 bp configuration, and data processed using Cell Ranger v5.0.1 (10X Genomics). Filtered feature matrix outputs from Cell Ranger were used for all downstream analyses performed in R Software v4.4.0, using the Seurat v5.2.1 packages. **Results:** Unsupervised clustering of batch-corrected datasets, followed by the application of cell-specific gene markers, distributed BAL cells into fourteen clusters, including macrophages. Subsetting and reclustering of the macrophages identified five transcriptionally distinct subclusters. Differentially expressed gene (DEG) and gene set enrichment (GSEA) analyses allowed for the identification of the generated macrophage subclusters, including cluster 0 comprising tissue resident or main macrophages involved in surveying and surfactant turnover, cluster 1 macrophages with upregulated mitochondrial activity or stressed macrophages, cluster 2 and 3 highly proliferative or cycling macrophages in S phase and G2-M phase respectively, and cluster 4 recruited antigen-presenting or poised inflammatory macrophages. The macrophage cluster composition changed both qualitatively and quantitatively in response to O₃, with a significant increase in overall numbers and a shift in cluster percentage distribution over time. Twenty-four h post-exposure, proliferative clusters 2 and 3 were widely depleted, but returned to pre-exposure levels by 72 h. The percentage of clusters 0 and 1 cells gradually increased at 24 h and peaked at 72 h. Cluster 4 cells appeared only at 72 h. In pseudotime trajectory analysis, proliferative clusters 2 and 3 were positioned at the beginning of the pseudotime, giving rise to macrophages in cluster 0. Consequently, cluster 0 macrophages transition into the cluster 1 cells, positioning this cluster at the end of the pseudotime. Cluster 4 was not developmentally connected to other macrophage clusters, representing the unique recruited macrophage population that appeared in the alveolar compartment only 72 h after O₃. NicheNet analysis of cell-cell communications during O₃ post-exposure revealed that macrophage intracellular signaling can be triggered by intercellular interactions with other alveolar cells. Monocytes, dendritic, and epithelial cells were the sender cells expressing genes with the highest ligand activity, which could target gene candidates in macrophages, affecting their responsiveness to O₃. In line, pathway analysis using Hallmark, Reactome, and Gene Ontology (GO) databases identified temporal macrophage cluster-specific metabolic, cell trafficking, immune, and proliferative responses. **Conclusions:** Lung macrophages are a transcriptionally diverse cell population and an integral component of the alveolar microenvironment responding to O₃ in a temporal cell-specific manner. Both O₃ exposure and non-macrophage signaling within the alveolar niche result in cluster-specific responses in the macrophage transcriptome. Specific gene and pathway signatures of the identified macrophage clusters can serve as a tool for further temporal interrogation and molecular targeting of macrophage subpopulations to prevent O₃-induced toxicity and promote the resolution of lung injury. **Support:** NIH Grants ES005022, ES004738, ES032473, HL171112.

PS 3939 Interleukin-1 Receptor 2 Transcription in a Subset of Alveolar Macrophages During Acute Lung Injury induced by Ozone and Endotoxin

J. Radbel¹, A. Lemenze², P. Zhou³, E. Abramova⁴, K. Vayas⁴, J. D. Laskin³, A. J. Gow⁴, and D. L. Laskin⁴. ¹Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ; ²Rutgers New Jersey Medical School, Newark, NJ; ³Rutgers School of Public Health, Piscataway, NJ; and ⁴Ernest Mario School of Pharmacy, Piscataway, NJ.

Background and Purpose: Ozone exposure has been linked to the development of acute respiratory distress syndrome (ARDS) in patients with sepsis. In a murine model, we demonstrated that inhalation of ozone prior to intravenous administration of lipopolysaccharide (LPS) to model sepsis, induces neutrophilic inflammation and acute lung injury (ALI). Resident alveolar macrophages (AMs) play a key role in resolving inflammation associated with ARDS. However, the heterogeneity of AM responses is becoming more apparent. In these studies, we performed single-cell RNA sequencing to elucidate transcriptional changes in AM subpopulations that may contribute to resolution of inflammation during ozone-induced ALI. **Methods:** Male C57BL/6J mice were exposed to 0.8 ppm ozone or filtered air for 3 h in a whole-body chamber. After 24 h, mice received LPS (3 mg/kg, i.v.) or PBS control. Bronchoalveolar lavage cells were collected 24 h post-treatment from pooled samples (2-3 mice/group) across 3 replicate experiments. Cells were processed for single-cell RNA sequencing using the 10x Genomics Chromium platform and sequenced with Illumina technology. Cell clusters were identified using a nearest-neighbor approach and visualized via Uniform Manifold Approximation and Projection (UMAP). Significant differentially regulated genes were further assessed using Integrated Pathway Analysis (Qiagen). **Results:** Among 22 identified cell clusters, 12 were classified as resident AMs based on characteristic gene markers (*Mertk*, *Mrc1*, *Itgax*, *Adgre1*, *Siglec1*). Mice exposed to ozone + LPS showed a marked decrease in resident AM frequency compared to air + PBS, air + LPS, or ozone + PBS exposure groups (29.0% vs. 86.2%, 86.6%, and 91.7%, respectively). Re-clustering within resident AMs revealed 14 subpopulations; with subpopulation 3 abundance increased only in mice exposed to ozone + LPS. Within this expanded subpopulation, pseudo-bulk and IPA analyses revealed the interleukin-1 family signaling pathway as the most likely upregulated pathway unique to ozone + LPS exposure (z-score 5.4; p = 0.0004). While genes with both pro and anti-inflammatory function were increased within this pathway, the gene with the highest expression was *Il1r2* (log2fold change 10.3) which encodes IL1-R2, a dummy/decoy receptor for IL-1. This was increased by orders of magnitude relative to *Il1b* (encoding IL-1β; log2fold change 7.8), *Il1a* (encoding IL-1α; log2fold change 3.7) and *Il1rn* (encoding IL-1 receptor antagonist; log2fold change 4.8). **Conclusions:** Both *Il1r2* and *Il1rn* transcription act to counterbalance proinflammatory IL-1 signaling. We identified a distinct subset of resident AMs that proportionally increase after exposure to ozone + LPS and exhibit markedly increased *Il1r2* transcription relative to *Il1rn*. While IL-1 receptor antagonists are clinically employed to treat macrophage activation syndrome, IL-1R2 supplementation has never been evaluated therapeutically. The preferential upregulation of *Il1r2* in this AM subset suggests that this decoy receptor may play an even more critical role than IL-1 receptor antagonists in resolving acute lung injury (ALI) during sepsis. These findings highlight IL-1R2 as a promising candidate for development as a therapeutic strategy to mitigate ozone-induced ARDS.

PS 3940 Ozone Exposure Alters Alveolar Macrophage Efferocytosis Receptor Gene Expression in Mice

B. Gelfand-Titiyevskiy¹, P. Zhou¹, E. Abramova¹, J. D. Laskin², A. J. Gow¹, D. L. Laskin¹, and J. Radbel³. ¹Ernest Mario School of Pharmacy, Rutgers, The State University of New Jersey, Piscataway, NJ; ²Environmental and Occupational Health Sciences Institute, Rutgers, The State University of New Jersey, Piscataway, NJ; and ³Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ.

Background and Purpose: Neutrophils (PMNs) accumulate in the lungs following inhalation exposure to the oxidant air pollutant, ozone. These short-lived cells undergo apoptosis and are cleared from the lungs by resident alveolar macrophages (AMs) by a phagocytic process called efferocytosis. We previously reported that efferocytosis is impaired in AMs 48 hr after ozone exposure, leading to prolonged neutrophilia during sepsis. Efferocytosis requires recognition of apoptotic cells by macrophage receptors including MerTK, Axl, SR-AI/All, SR-BI, and CD36. Expression of these receptors is regulated by the transcription factor peroxisome proliferator activated receptor gamma (PPARγ). PPARγ signaling, which is downregulated following ozone exposure. However, the effects of ozone on genetic expression of efferocytosis receptors during the resolution of ozone-induced injury is not clearly defined, and this was assessed in the present studies. **Methods:** Male wild type C57BL/6J mice were exposed to air or ozone (0.8 ppm, 3 h) in a whole-body chamber. Mice were euthanized 48 h later, and lung cells collected by bronchoalveolar lavage (BAL) with gentle tissue massage. Cells were enriched for resident AMs by magnetic depletion of CD11b expressing cells and analyzed for expression of *Pparg* (encoding PPARγ), *Msr1* (encoding SR-AI/All), *Scarb1* (encoding SR-BI), *Cd36*, *Mertk*, and *Axl* using qPCR. Expression levels were normalized to the geometric mean of housekeeping genes *Actb*, *Gapdh*, or *18s*, and fold change values calculated using the $\Delta\Delta C_T$ method. Data were analyzed by a Kolgorov-Smirnov test. **Results:** Exposure to ozone resulted in a decrease in *Pparg* expression in AMs (fold change = 0.37) this was associated with decreased transcription of *Mertk* (0.60) and significantly decreased transcription of *Cd36* (0.61), with no change in *Scarb1* (1.31) or *Axl* (0.99)

expression. Conversely, *Msr1* transcription was significantly increased (3.83) following ozone exposure. **Conclusions:** These data suggest that decreased transcription of macrophage efferocytosis receptor genes contributes impairment in AM efferocytosis following exposure to ozone. SR-AI/All is known to promote efferocytosis by augmenting MerTK signaling in macrophages. Upregulation of SR-AI/All may represent a compensatory mechanism for decreased *Mertk* transcription. We further speculate that increases in SR-AI/All are insufficient to compensate for this impairment.

PS 3941 The role of CD163-mediated cell free hemoglobin clearance in ozone-induced pulmonary injury and inflammation

S. J. Cochran¹, B. Saunders¹, G. M. Hutton¹, E. Schott¹, K. Dunigan-Russell¹, A. Vose², A. Birukova², C. Rankin², M. Velayutham³, S. Hussain³, T. J. McMahon², R. M. Tighe², and K. M. Gowdy¹. ¹The Ohio State University, Columbus, OH; ²Duke University, Durham, NC; and ³West Virginia University, Morgantown, WV.

Background and Purpose: Inhalation of tropospheric ozone (O₃) induces pulmonary inflammation in part through the production of damage associated molecular patterns (DAMPs), which bind to pattern recognition receptors (PRRs) and activate pro-inflammatory pathways in innate immune cells. However, different members of the scavenging receptor (SR) class of PRRs can either augment inflammation or protect against inhaled oxidants. CD163 is a SR responsible for clearance of cytotoxic, cell free hemoglobin (CFH) that accumulates in the lungs following sterile lung injury. Additionally, CD163 internalization and CFH metabolism upregulate anti-inflammatory and antioxidant pathways. However, the relevance of CD163 in scavenging CFH and promoting anti-inflammatory responses in O₃-induced lung injury is not currently understood. We hypothesize that CD163-mediated CFH clearance is necessary for resolution of pulmonary inflammation caused by acute O₃ inhalation. **Methods:** Female, wild type (WT) and CD163^{tm1(KOMP)Vlcg} (CD163^{-/-}) knockout (KO) mice were exposed to either filtered air (FA) or 1 ppm O₃ for 3 hours, which models an environmentally relevant O₃ exposure hazardous to humans. A separate cohort of WT and KO mice were given a single oropharyngeal (o.p.) dose of CFH (1 mg/ml, 100 µg/mouse) or vehicle control. Mice were necropsied 12- and 24-hours following exposure to collect bronchoalveolar lavage (BAL) and lung tissue. Gene expression was measured by real-time polymerase chain reaction. Lung injury and permeability were measured by BAL total protein and albumin, respectively. Lung inflammation was measured by airspace cell differential. CFH clearance was measured by BAL concentration of scavenging proteins, hemopexin (Hx) and haptoglobin (Hp). Airspace oxidative stress was measured by BAL electron paramagnetic resonance (EPR). **Results:** CD163 expression was significantly increased in WT mice 12 hours after O₃ exposure, concomitant with lung neutrophilia, BAL Hp concentration, and oxidative stress. Additionally, markers of lung injury and inflammation were significantly augmented in CD163^{-/-} mice, 12 hours after O₃ exposure. At 24 hours, O₃ significantly increased BAL neutrophilia and oxidative stress in CD163^{-/-} mice compared to WT controls; however, there was no difference in markers of lung injury. Compared to vehicle controls, airspace total protein and immune cell numbers were significantly increased in both WT and CD163^{-/-} mice 24 hours after CFH administration, with no difference between WT and CD163^{-/-} mice. CD163^{-/-} mice exposed to CFH had significantly greater airspace neutrophilia compared to WT mice exposed to CFH. CFH exposure led to significantly increased BAL Hp in CD163^{-/-} mice compared to WT mice after 24 hours and significantly increased oxidative stress in CD163^{-/-} mice only. **Conclusions:** These findings indicate that pulmonary injury, inflammation, and oxidative stress are augmented in CD163^{-/-} mice exposed to O₃ or CFH. Additionally, these data suggest that CFH clearance is impaired in CD163^{-/-} mice, supporting a role for CFH scavenging by CD163 in resolution of O₃-induced pulmonary injury and inflammation. Further research will examine CD163 expression by different lung cell populations, the role of soluble CD163 (sCD163) in response to O₃ exposure, and translation to human studies.

PS 3942 Synergistic effects of ozone and heatwave exposure on lung inflammation in young mice: Evidence and Mechanism of Lung Stem Cells

X. Jian, X. Zhang, and F. Feng. Zhengzhou University, Zhengzhou, China. Sponsor: F. Feng, Environmental Mutagenesis and Genomics Society

Background and Purpose: Chronic respiratory diseases, the fourth leading cause of mortality globally, result a substantial public health burden. Concurrent extreme events are projected to increase with climate change, with ozone (O₃) and heatwaves (HW) extremes posing significant threats to respiratory health, particularly in children. Lung stem cells are crucial for maintaining homeostasis and regeneration of lung tissue. However, the mechanisms of lung stem cells in O₃ and HW-induced respiratory inflammatory diseases remain unclear. This study investigated the combined effects of O₃ and HW on lung inflammation, focusing on lung stem cell function in young mice, to inform adaptation strategies for concurrent events. **Methods:** C57BL/6 SPF male mice (4-6 weeks) were randomly assigned to four groups (n=10): control group (filtered air) and three treatment groups exposed to 36°C, 0.6 ppm O₃, and 0.6 ppm O₃+36°C for 21 consecutive days (3h/d). After exposure, lung function, pathological changes and inflammatory cytokines (TNF-α, IL-1β, CC16) were assessed. Club cells, key lung stem cells, are involved in the

maintenance of lung epithelium function and repair after injury. *Lkb1* (Liver Kinase B1) may affect the proliferation and differentiation of lung stem cells, so *Lkb1* expression in lung tissue and club cells was determined. To evaluate *Lkb1*'s effect on club cells, we used *CCSP^{CreER};Lkb1^{fl/fl}* mice (*Lkb1* was conditionally deleted in club cells) and *Lkb1^{fl/fl}* mice, measuring Ki67 (proliferation marker), Clca1 (goblet cell marker), and Foxj1 (ciliary cell marker) in club cells. Then we used an FACS-based method to separate club cells for transcriptomics analysis, with results validated by RT-qPCR. **Results:** Co-exposure to O₃ and HW significantly exacerbated lung inflammation, with a synergistic effect on lung function impairment and elevated inflammatory cytokines, while *Lkb1* expression was reduced in young mice. Lack of *Lkb1* in club cells significantly aggravated the lung inflammation and impaired club cells proliferation and differentiation, specifically suppressing ciliated cell generation while promoting goblet cell hyperplasia. Single-cell transcriptomic analysis revealed that the differentially expressed genes were significantly enriched in metabolic pathways, with lipid metabolism being the most prominently altered. Persistent dysregulation of key lipid metabolic genes was confirmed by qRT-PCR, including significant downregulation of *Bbox1* and upregulation of *Fbp1* and *Them5* ($P < 0.05$). **Conclusions:** Co-exposure to O₃ and HW synergistically aggravated lung inflammation by impairing club cell function in young mice, likely through *Lkb1*-driven lipid metabolic disruption.

PS 3943 Peripheral and Lung Cytokine Profiles Are Associated with Ozone-Induced Lung Inflammation in Humans

O. Kline¹, S. Cochran², I. Cumming¹, E. Schott², C. Rankin¹, T. Schappe¹, K. Kilpatrick¹, L. Lin¹, K. Gowdy², and R. Tighe¹. ¹Duke University, Durham, NC; and ²Ohio State University, Columbus, OH.

Background and Purpose: Ozone (O₃) is a criterion air pollutant that causes airway inflammation and epithelial injury. However, individual O₃-induced lung injury and inflammation responses are highly variable, and there is a need for less invasive measures, which correlate with pulmonary responses to assess variability. This study examined whether assessments of peripheral immune cell populations and circulating cytokine levels correlate with O₃-induced lung inflammation in humans. **Methods:** Healthy adults (18-45 years; n=16) underwent a crossover-challenge exposure to filtered air (FA) and O₃ (200 ppb for 2.25 h). Peripheral blood was collected immediately after exposure and at the time of bronchoscopy to obtain bronchoalveolar lavage fluid (BALF; approximately 20 hours post-exposure). Flow cytometry was used to quantify immune cell populations, and cytokines were measured in BALF and serum using Mesoscale Discovery V-PLEX Proinflammatory panels. Bayesian modeling (COMPASS) was applied to assess proportional changes in immune cells, while Kruskal-Wallis and Spearman correlation analyses evaluated relationships among cytokines and cell populations. **Results:** O₃ exposure did not significantly alter peripheral immune cell proportions at either post- or 24-hour post-exposure time points (all $p > 0.1$). Functionality scores derived from COMPASS modeling similarly showed no association with lung inflammation ($p > 0.1$). Alternatively, IL-6 and IL-10 BAL cytokine levels were significantly elevated in participants exhibiting BAL inflammation as defined by BAL neutrophils ($p = 0.012$) and ($p = 0.022$). For levels of peripheral cytokines and peripheral cell populations, correlations were observed based on the timepoint following exposure. Immediately following O₃ exposure, IL-1 β was positively correlated with CD8⁺ T cells ($p = 0.0033$). IL-4 was negatively correlated with PMNs ($p = 0.007$), and IL-12p70 was positively correlated with eosinophils ($p = 0.001$). Alternatively, at 20 hours post-exposure, IL-8 was positively correlated with other T cells ($p = 0.034$), IL-12p70 remained positively correlated with eosinophils ($p = 0.023$), and TNF- α was negatively correlated with neutrophils ($p = 0.022$). For peripheral cytokines and lung bronchoalveolar lavage cell populations, at 24 hours post-exposure, IL-4 was negatively correlated with PMNs ($p = 0.043$), and IL-8 was negatively correlated with CD8⁺ T cells ($p = 0.041$). **Conclusions:** While no consistent peripheral immune cell changes were detected following acute O₃ exposure, cytokine-cell correlations, particularly involving IL-6 and TNF- α associations indicate inflammatory immune responses following acute O₃ exposure. These findings suggest that cytokine profiles, rather than cell proportions, may serve as more sensitive biomarkers of O₃-induced lung inflammation and could help to define inter-individual variability in susceptibility to air pollutant exposures.

PS 3944 Diesel exhaust particle inhalation-induced exacerbation of murine lupus nephritis may be mitigated with probiotic supplementation.

K. Nguyen-Alley, N. Ramesh, and A. K. Lund. University of North Texas, Denton, TX.

Background and Purpose: Lupus nephritis (LN) is the most common clinical manifestation of systemic lupus erythematosus (SLE), a chronic autoimmune disease in which the immune system creates autoantibodies against nucleic acid-based autoantigens. Autoantibody-autoantigen immune complexes (ICs) form, travel through systemic circulation, and become trapped in the glomerulus and adjacent tubules of the nephron. LN is characterized by the accumulation of ICs in the nephron, which leads to persistent localized inflammation and damage to the glomerular filtration barrier, thus reducing kidney function. Traffic-generated air pollution exposure is known to exacerbate general kidney diseases and has been proposed to do the same in LN, given the increased incidence in urban areas. Thus, this study is focused on investigating whether inhalational exposure to vehicular air pollutants contributes to

more advanced LN pathophysiology. Conventional pharmacological treatments of SLE/LN often have adverse side effects and may not be effective due to the heterogeneity of disease activity between individuals. This has led to increased interest in identifying adjunct methods of disease management, such as the use of probiotics, due to their known immunomodulating properties. Thus, this study is also focused on investigating the effectiveness of probiotic supplementation in mitigating LN severity. **Methods:** To achieve both of these aims, 18-week-old female NZB/WF1 (Jackson Labs) LN-model mice were exposed to either 35 μ g of diesel exhaust particles (NIST SRM #2975; DEP, n=24) suspended in 30 μ l 0.9% sterile saline or sterile saline only (CON, n=24) via oropharyngeal aspiration and received either 0.3g (7.5 x 10⁸ CFU) Ecologic® Barrier 849 probiotic (PRO, n=24) or nutrient-matched placebo (PLC, n=24) daily in drinking water for 50 days. Deposition of IgG and complement 3 (C3) and expression of TNF- α were measured using immunofluorescent microscopy, and Masson's trichrome staining was utilized to measure collagen deposition in frozen kidney sections. The average kidney-to-body weight ratio was also assessed, and statistical analyses were performed using two-way ANOVA to determine significance. **Results:** Deposition of IgG and C3 was significantly increased in DEP PLC compared to CON groups, and Masson's trichrome showed increased collagen deposition in DEP groups. These alterations reflect greater accumulation of ICs with DEP exposure, leading to fibrosis in the glomerulus and adjacent tubules of the nephron. IgG deposition was significantly decreased in DEP PRO compared to all other experimental groups, and TNF- α expression and kidney:body weight ratio were significantly reduced in CON PRO compared to all other experimental groups. These alterations suggest that probiotic supplementation has mitigative effects on LN severity, both with and without DEP insult. **Conclusions:** These results indicate that inhalational exposure to diesel exhaust particles contributes to more advanced lupus nephritis and that probiotic supplementation may be beneficial as an adjunctive treatment. PS 3945 Sex Differences and Estrogen Dependent Cytokine Release in Human Small and Large Airway Epithelial Cells Exposed to Peat and Eucalyptus Wood Smoke Condensates

T. M. Reinartz¹, M. J. Rodriguez², Y. Kim³, K. Okuda⁴, and M. Rebuli⁵. ¹UNC-CH, Chapel Hill, NC; ²UNC School of Medicine, Chapel Hill, NC; ³Public Health and Integrated Toxicology Division, Center for Public Health and Environmental Assessment, U.S. EPA, RTP, NC; ⁴Marsico Lung Institute/Cystic Fibrosis Research Center, Chapel Hill, NC; and ⁵Center for Environmental Medicine, Asthma, and Lung Biology, Department of Pediatrics, Chapel Hill, NC.

Background and Purpose: Wildfires and biomass combustion are growing global health concerns due to the release of particulate matter (PM), which impairs respiratory function and contributes to cardiopulmonary disease. These risks are amplified by the increasing prevalence, severity, and geography of wildfires. Prior studies have shown that smoke chemistry can vary substantially by fuel type (e.g. eucalyptus (chaparral, southern California) and peat (peatland/coastal, midwestern and south-eastern US)) and studies from our lab and others have shown that by varying fuel type, respiratory immune responses can also be altered. However, there is limited research exploring these effects in primary respiratory epithelial cells from differing compartments of the respiratory tract. Beyond fuel type, sex-specific differences in airway disease pathogenesis also shape susceptibility and outcomes following wood smoke exposure. For example, in asthma and chronic obstructive pulmonary disease (COPD), females exhibit greater small airway inflammation, while males are more prone to alveolar destruction. The role of sex hormones in respiratory response to wood smoke exposure also remains understudied, although studies indicate that estrogen can modulate the respiratory immune system through estrogen receptors present on epithelial and immune cells in both small and large airways. Together, these factors suggest that interactions between wood fuel type, sex, and airway compartment influence immune responses to wood smoke exposure *in vitro*, though the mechanisms remain unclear. **Methods:** To investigate these factors, primary human small airway epithelial (SAE) and large airway epithelial (LAE) cells derived from male and female donors (n = 6M, 6F) were cultured at air-liquid interface for 4 weeks. To assess the role of estrogen in wood smoke induced inflammatory responses, a subset of cells were treated with 1 nM 17 β -estradiol (E2) throughout differentiation, equivalent to circulating levels in females of reproductive age. These cultures were then exposed to wood smoke condensates (WSCs) generated from peat and eucalyptus biomass at 25 μ g/cm² for 4 hours. Cytokine secretion was measured using the MSD V-Plex Human Cytokine multiplex ELISA. Significant values were determined in comparison to individual donor PBS-treated controls to account for inter-individual variability. **Results:** The data revealed several region-, fuel- and sex-dependent effects. IL-1 β was consistently up regulated across conditions, indicating a core inflammatory response to biomass smoke, while VEGF was selectively induced by peat, suggesting unique activation of airway remodeling pathways. TNF α was consistently elevated in males but increased in females only with peat, indicating sex- and fuel-specific pro-inflammatory signaling. Females had unique up regulation of IL-2, IL-6, and IL-13 for both peat and eucalyptus, consistent with a Th2-biased immune phenotype. IFN γ induction was found in female LAEs but suppressed by E2 treatment in SAEs. In males, E2 reversed cytokine responses in LAEs: peat shifted Eotaxin-3 and TARC from up- to downregulation, while eucalyptus shifted IL-4 and IL-12p40 from down- to upregulation. E2 exerted opposite effects on TARC by airway region in males, highlighting compartment-specific estrogen modulation. **Conclusions:** Together, these findings demonstrate that wood smoke elicits both

biomass fuel-conserved and sex-specific immune responses, with estrogen status and airway compartment serving as significant modulators. Peat and eucalyptus fuels also showed distinct cytokine profiles in some mediators measured, highlighting the role of fuel source in shaping inflammatory outcomes. This research provides insight into factors that may influence individual susceptibility to wood smoke exposure, such as local ecology, sex, level of circulating sex hormones and potentially provides targets for future research into treatments or preventative measures by sex or specific to location of exposure or smoke source.

PS 3946 Associations between PM_{2.5} and self-reported cognitive decline in the United States, 2015 to 2022: Evidence from the behavioral risk factor surveillance system (BRFSS)
